The target of word ordering is to generate a well-formed sentence given a bag of words. To capture word connections implicated in the sentence, an LSTM-based word ordering model with self-attention is proposed. Self-attention mechanism effectively decides which words in the word bag are more important in generating the next word. It improves the ability of our model to capture word connections. As illustrated in Figure 1, the proposed word ordering model consists of two layers:

Encoder Layer

Given a bag of words $w_1, w_2, ..., w_n$, we encode each word by a character-level BiLSTM ($c_{w_{1:n}}^{wo}$), which could reduce the parameters used in our model compared with word embeddings. For the input word of current time-step (w_i), a self-attention layer is utilized to align the word with its related words, producing its self-attended vector ($sa_{w_i}^{wo}$) as following:

$$s_j^i = \mathrm{v}^{\mathrm{T}}\mathrm{ReLU}(W^{sa}[c_{w_i}^{wo}; c_{w_j}^{wo}]) \quad (1)$$

$$a_t^i = \exp(s_t^i)/\Sigma_{j=1}^{n}\exp(s_j^i) \quad (2)$$

$$sa_{w_i}^{wo} = \Sigma_{j=1}^{n} a_j^i c_{w_j}^{wo} \quad (3)$$

The scores $s_{1:n}^i$ in self-attention explicitly represent the connections between words.

We then concatenate the character-level word embedding ($c_{w_i}^{wo}$) and its self-attended vector ($sa_{w_i}^{wo}$):

$$x_i^{wo} = [c_{w_i}^{wo}; sa_{w_i}^{wo}] \quad (4)$$

x_i^{wo} is fed into the decoder layer to generate the next word.

Decoder Layer

Given the current input vector (x_i^{wo}), which contains current word information and weighted information of related words, a forward LSTM is used to generate the next word. We initialize the forward LSTM with an average of the input word embeddings ($c_{w_{i:n}}^{wo}$). A virtual token $\langle$BOS$\rangle$ is added as the input of the first LSTM time-step:

$$\overrightarrow{h}_i^{wo} = \mathrm{LSTM}(x_i^{wo}, \overrightarrow{h}_{i-1}^{wo}) \quad (5)$$

At each time-step, the hidden state $\overrightarrow{h}_i^{wo}$ is utilized to predict the next word. Due to the output vocabulary is limited in the bag of words, we just compute scores for the given words ($w_{1:n}$):

$$so_j^i = \mathrm{v}^{\mathrm{T}}\mathrm{ReLU}(W^o[\overrightarrow{h}_i^{wo}; cd_{w_j}^{wo}]) + {\overrightarrow{h}_i^{wo}}^{\mathrm{T}} M wd_{w_j}^{wo} \quad (6)$$

To reduce the parameters, each output word is represented by a character-level BiLSTM embedding ($cd_{w_j}^{wo}$) and a low-dimensional word embedding[2] ($wd_{w_j}^{wo}$). M is a matrix projecting a low-dimensional embedding back up to the dimensionality of LSTM hidden states. The scores $so_{1:n}^i$ are then normalized with Softmax, and the word with max probability is chosen as the next token.

The word ordering model could be trained easily in an unsupervised manner. Given a large set of unlabeled sentences, we can just ignore the word

---

[2] Character-level representations lack the capacity to differentiate between words that have very different meanings but that are spelled similarly. Low-dimensional word embeddings are added to improve the ability.

order of sentence and train the model to generate the corresponding well-formed sentence in the training set. To be specific, we minimize the sum of negative log probabilities of the ground truth words on the unlabeled data set. Different from language model, the choice for each decoder step is limited in the bag of words. Moreover, self-attention can be introduced into the word ordering model since we have known the bag of words, which could capture the dependency connections between words. We also pre-train a backward word ordering model to generate sentences in reverse order. The forward and backward models share character-level BiLSTM embeddings, self-attention layer, and Softmax layer.

Different from previous word ordering models (Liu et al., 2015; Schmaltz et al., 2016), self-attention mechanism is introduced into our model to capture word connections. Moreover, our more important goal is to implicitly utilize large-scale unlabeled data to help dependency parsing.

3 Neural Graph-based Parsing Model

We implement an LSTM-based neural network model as our graph-based dependency parsing baseline, which is similar to (Kiperwasser and Goldberg, 2016; Wang and Chang, 2016). As shown in the Figure 2, it consists of three layers:

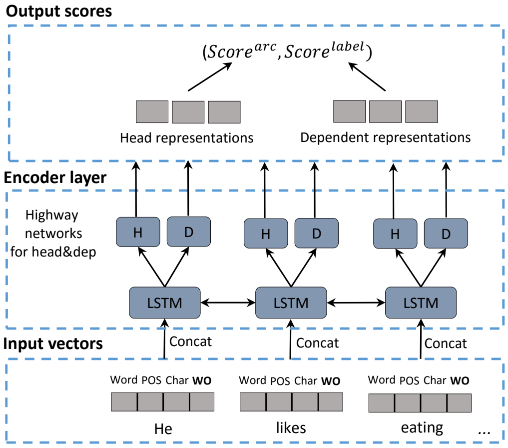

Figure 2: Overview of neural graph-based dependency parsing model. WO represents pre-trained vectors from word ordering model.

Input Layer

Given a n-words input sentence s with words $w_1, w_2, ..., w_n$ and its POS tags $p_1, p_2, ..., p_n$. The input layer creates a sequence of input vectors $x_{1:n}$ in which each x_i is a concatenation of its word embedding (e_{w_i}), POS tag embedding (e_{p_i}), character-level BiLSTM embedding (c_{w_i}), and word ordering model pre-trained vector (wo_{w_i}):

$$x_i = [e_{w_i}; e_{p_i}; c_{w_i}; wo_{w_i}] \tag{7}$$

To get the word ordering model pre-trained vector (wo_{w_i}), the sentence s is fed into the pre-trained word ordering model. Following Peters et al. (2018), we then combine the input vector ($x_i^{wo} = [c_{w_i}^{wo}; sa_{w_i}^{wo}]$) and L-layer BiLSTM vectors ($h_{i,j}^{wo} = [\overrightarrow{h}_{i,j}^{wo}; \overleftarrow{h}_{i,j}^{wo}] \mid j=1,2,...,L$) by a Softmax-normalized weight (W^{woc}) and a scalar parameter (γ):

$$wo_{w_i} = \gamma(W_0^{woc} x_i^{wo} + \Sigma_{j=1}^{L} W_j^{woc} h_{i,j}^{wo}) \tag{8}$$

The parameters of word ordering model are fixed during the training of parsing model. However, the weight and scalar parameters are tuned to better adapt to it. The combined output wo_{w_i} contains word connections from self-attention, word information from character-level embedding and contextual information from LSTM.

Encoder & Output Layer

To introduce more contextual information, we encode each input element by deep BiLSTMs:

$$v_i = \textbf{BiLSTM}(x_{1:n}, i) \tag{9}$$

Two different highway networks (Srivastava et al., 2015) are then used to encode head word representations ($v_{1:n}^{head}$) and dependent word representations ($v_{1:n}^{dep}$). For a head-dependent dependency pair (w_h, w_d), the dependency arc and label score are computed by two MLP networks:

$$i_{h,d} = [v_h^{head}; v_d^{dep}; v_h^{head} \odot v_d^{dep}] \tag{10}$$

$$s_{h,d}^{arc} = W_1^{arc}\mathrm{ReLU}(W_2^{arc} i_{h,d}) \tag{11}$$

$$s_{h,d}^{label} = W_1^{label}\mathrm{ReLU}(W_2^{label} i_{h,d}) \tag{12}$$

We use the Max-Margin criterion to train our parsing model, which is the same as (Kiperwasser and Goldberg, 2016; Wang and Chang, 2016).

4 Experiments

4.1 Datasets

We conduct experiments on the English Penn Treebank and the CoNLL 09 English dataset. For

Method	PTB UAS / LAS	CONLL 09 UAS / LAS
Bohnet2012	- / -	92.87 / 90.60

Table 1: Results on the English PTB dataset and CoNLL 09 English dataset. WO represents the pre-trained word ordering model. LM represents the pre-trained language model from Peters et al. (2018).

PTB dataset, we follow the standard splits. Using section 2-21 for training, section 22 as development set and 23 as test set. The treebank is converted to Stanford Basic Dependencies (Marneffe et al., 2006) by version 3.3.0[3] of the Stanford parser. The Stanford POS Tagger (Toutanova et al., 2003) is used for assigning POS tags. Following previous work, UAS (unlabeled attachment scores) and LAS (labeled attachment scores) are calculated by excluding punctuation. For the CoNLL 09 English dataset, we follow the standard practice and include all punctuation in the evaluation. We pre-train our word ordering model on the 1 billion word benchmark (Chelba et al., 2014).

4.2 Implementation Details

The graph-based dependency parsing model and word ordering model are optimized with Adam with an initial learning rate of $2e^{-3}$. The β_1 and β_2 used in Adam are 0.9 and 0.999 respectively.

The following hyper-parameters are used in all graph-based dependency parsing models: word embedding size = 300, POS tag embedding size = 32, character embedding size = 50, word-level LSTM hidden vector size = 200, word-level BiLSTM layer number = 3, character-level LSTM hidden vector size = 50, character-level BiLSTM layer number = 2, batch size = 32. We also apply dropout for the input and each layer with dropout rate of 0.3. We use pre-trained case-sensitive GloVe embeddings[4] to initialize word embeddings. These word embeddings are fine tuned with the graph-based dependency parsing model. The parameters of pre-trained word ordering model are fixed during the training of dependency parsing model. For deep BiLSTM, we concatenate the outputs of each layer as its final outputs.

For our word ordering model: input character-level LSTM hidden vector size = 512, input character-level BiLSTM layer number = 1, word-level LSTM hidden vector size = 1024, word-level LSTM layer number = 2, output character-level LSTM hidden vector size = 512, output character-level BiLSTM layer number = 1, output low-dimensional word embedding size = 64, batch size = 32, dropout for the input and each layer = 0.5.

4.3 Main Results & Ablation Study

Table 1 shows the performance of our model and previous work on two English benchmarks. Our model achieves promising results on both datasets. Two sets of experiments are provided to show the effectiveness of pre-trained word ordering model. Although our baseline system is similar to (Kiperwasser and Goldberg, 2016; Wang and Chang, 2016) but with subtle differences in architecture, the baseline could perform much better to our surprise and thus constitutes a very strong baseline. Compared with this baseline, introducing the pre-trained word ordering model achieves a significant improvement (almost 0.6% UAS gains for both datasets, $p < 0.001$). To further show the effectiveness of word ordering model, we also implement an even stronger baseline with pre-trained language model[5]. Compared with this much stronger baseline, incorporating pre-trained word ordering model still achieves a significant improvement (0.3% UAS gains for both datasets, $p < 0.01$). We attribute the improvement to the ability of word ordering model to capture word connections, which cannot be directly captured by language model. Moreover, by combining with a pre-trained language model, our model outperforms current SOTA model from 95.9% UAS to 96.35% UAS on the PTB dataset. The introduction

[5] We use the pre-trained language model provided by Peters et al. (2018), which can be downloaded at `http://allennlp.org/elmo`. The pre-trained language model vectors are added in the input layer, which are included in the same way as word ordering model. Peters et al. (2018) found the pre-trained language model works extremely well in six NLP tasks including QA, SRL, and others, we confirm its effectiveness in parsing task.

Model	UAS / LAS
Baseline+WO	**95.66 / 94.54**
-Self-attention vectors	95.38 / 94.27
Baseline+LM&WO	**96.35 / 95.25**
-Self-attention vectors	96.13 / 94.98

Table 2: Ablation tests of self-attention mechanism on the PTB dataset.

of POS tag features could contribute about 0.2% improvement in our experiments. The word ordering model could be more helpful without POS tag features and seem to compensate for the lack of POS tag features.

To show the importance of self-attention mechanism, we do ablation tests on the models with pre-trained word ordering model vectors. We remove self-attention vectors by replacing it with the character-level representations. As shown in table 2, self-attention further improves dependency parsing. Word connections modeled by self-attention are important for dependency parsing.

Figure 3 shows an example of word connections learned by the model, where we use the solid line to indicate the word connections learned by the word-ordering model and dashed line to the expected dependencies. We can see meaningful overlap could be observed in the example. The percentage of overlap between connections and dependency arcs is over 40% for the sentences less than 10 words. The differences between connections and dependency arcs are because that our word ordering model trained without any supervised dependency information. The connections are actually built to increase the likelihood.

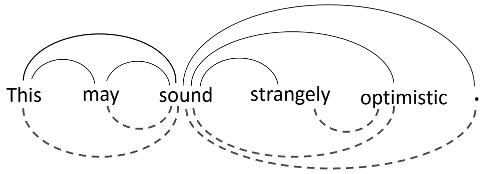

Figure 3: An example of self-attention. The solid line denotes the mostly attended word when generating the next word, dashed line denotes the correct dependency.

5 Conclusion

In this paper, we propose to implicitly capture word connections from large-scale unlabeled data by a word ordering model with self-attention. Experiments show these features are helpful for dependency parsing. Moreover, with the help of word ordering model and language model, our model achieves SOTA results on the PTB dataset. As for future work, we are testing on languages other than English.

Abstract

This paper presents a simple framework for characterizing morphological complexity and how it encodes syntactic information. In particular, we propose a new measure of morpho-syntactic complexity in terms of governor-dependent preferential attachment that explains parsing performance. Through experiments on dependency parsing with data from Universal Dependencies (UD), we show that representations derived from morphological attributes deliver important parsing performance improvements over standard word form embeddings when trained on the same datasets. We also show that the new morpho-syntactic complexity measure is predictive of the gains provided by using morphological attributes over plain forms on parsing scores, making it a tool to distinguish languages using morphology as a syntactic marker from others.

1 Introduction

While word embedding has proven a good solution to reduce data sparsity in parsing (Koo et al., 2008), treating word forms as atomic units is at odds with the fact that words have a potentially complex internal structure. Furthermore, it makes parameters estimation difficult for morphologically rich languages (MRL) in which the number of possible forms a word can take can be very large[1].

Recently, researchers have started to work on morphologically informed word embeddings (Cao and Rei, 2016; Botha and Blunsom, 2014), aiming at better capturing both lexical, syntactic and morphological information. But encoding lexicon and morphology in the same space makes it difficult to distinguish the role of each in syntactic tasks such as dependency parsing. Furthermore, morphologically rich languages for which we hope to see a real impact from those morphologically aware representations, might not all rely to the same extent on morphology for syntax encoding. Some might benefit mostly from reducing data sparsity while others, for which paradigm richness correlate with freer word order (Comrie, 1981), will also benefit from morphological information encoding.

This paper aims at characterizing the role of morphology as a syntax encoding device for various languages. Using simple word representations, we measure the impact of morphological information on dependency parsing and relate it to two measures of language morphological complexity: the basic form per lemma ratio and a new measure (*HPE*) defined in terms of head attachment preference encoded by its morphological attributes. We show that this new measure is predictive of parsing result differences observed when using different word representations and that it allows one to distinguish amongst morphologically rich languages, those that use morphology for syntactic purpose from those using morphology as a more semantic marker. To the best of our knowledge, this work is the first attempt at systematically measuring the syntactic content of morphology in a multi-lingual environment.

Section 2 presents the representation learning method and the dependency parsing model. It also defines two measures of morphological complexity. Section 3 describes the experimental setting and analyses parsing results in terms of the previously defined morphological complexity measures. Section 4 gives some conclusions and future work perspectives.

---

[1] A typical English noun has 2 forms while a Finnish one may have more than 30. This shows in data as English lemmas have 1.39 forms on average while Finnish ones have 2.19, as measured on UD data (Nivre et al., 2016).

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2864–2870
Brussels, Belgium, October 31 - November 4, 2018.

2 Framework

This section details: (i) our method for learning lexical and morphological representations, (ii) how these can be used for graph-based dependency parsing, and (iii) how to measure morphological complexity. Our representation learning and parsing techniques are purposely very simple in order to let us separate lexical and morphological information and weight the role of morphology in dependency parsing of MRL.

2.1 Word Representation

We construct separate vectorial representations for lemmas, forms and morphological attributes, either learned via dimension reduction of their own cooccurrence count matrices or represented as raw one-hot vectors.

Let $\mathcal{V}$ be a vocabulary (it can be lemmas or forms or morphological attributes (incl. values for POS, number, case, tense, mood...)) for a given language. Correspondingly, let $\mathcal{C}$ be the set of contexts defined over elements of $\mathcal{V}$. That is, lemmas appear in the context of other lemmas, forms in the context of forms, and attributes in the context of attributes. Then, given a corpus annotated with lemmas and morphological information, we can gather the cooccurrence counts in the matrix $\boldsymbol{M} \in \mathbb{N}^{|\mathcal{V}| \times |\mathcal{C}|}$, such that $\boldsymbol{M}_{ij}$ is the frequency of lemma (form or morphological attributes) $\mathcal{V}_i$ appearing in context $\mathcal{C}_j$ in the corpus. Here, we consider plain sequential contexts (i.e. surrounding bag of "words") of length 1, although we could extend them to more structured contexts (Bansal et al., 2014). Those cooccurrence matrices are then reweighted by unshifted Positive Point-wise Mutual Information (PPMI) and reduced via Singular Value Decomposition (SVD). For more information on word embedding via matrix factorization, please refer to (Levy et al., 2015).

Despite its apparent simplicity, this model is as expressive as more popular state of the art embedding techniques. Indeed, Goldberg and Levy (2014) have shown that the SkipGram objective with negative sampling of Mikolov's Word2vec (2013) can be framed as the factorization of a shifted PMI weighted cooccurrence matrix.

This matrix reduction procedure gives us vectors for lemmas, forms and morphological attributes, noted $\boldsymbol{R}$. Note that while a word has only one lemma and one form, it will often realize several morphological attributes. We tackle this issue by simply summing over all the attributes of a word (noted $Morph(w)$). If we note $\boldsymbol{r}_w$ the vectorial representation of word w we have:

$$\boldsymbol{r}_w = \sum_{a \in Morph(w)} \boldsymbol{R}_a.$$

Simple additive models have been shown to be very efficient for compositionally derived embeddings (Arora et al., 2017).

2.2 Dependency Parsing

We work with graph-based dependency parsing, which offers very competitive parsing models as recently re-emphasized by Dozat et al. (2017) in the CONLL 2017 shared-task on dependency parsing (Zeman et al., 2017).

Let $x = (w_1, w_2, ..., w_n)$ be a sentence, $\mathcal{T}_x$ be the set of all possible trees over it, $\hat{y}$ the tree that we predict for x, and $Score(\bullet, \bullet)$ a scoring function over sentence-tree pairs :

$$\hat{y} = \underset{t \in \mathcal{T}_x}{\text{argmax}}\ Score(x, t).$$

We use edge factorization to make the inference problem tractable. A tree score is thus the sum of its edges scores. We use a simple linear model:

$$Score(x, t) = \sum_{e \in t} \boldsymbol{\theta}^\top \cdot \boldsymbol{\phi}(x, e),$$

where $\boldsymbol{\phi}(x, e)$ is a feature vector representing edge e in sentence x, and $\boldsymbol{\theta} \in \mathbb{R}^m$ is a parameter vector to be learned.

The vector representation of an edge e_{ij} whose governor is the i-th word w_i and dependent is the j-th word w_j, is defined by the outer product of their respective representations in context. Let $\oplus$ note vector concatenation, $\otimes$ the outer product and $w_{k\pm1}$ be the word just before/after w_k, then: $\boldsymbol{v}_i = \boldsymbol{w}_{i-1} \oplus \boldsymbol{w}_i \oplus \boldsymbol{w}_{i+1}$, $\boldsymbol{v}_j = \boldsymbol{w}_{j-1} \oplus \boldsymbol{w}_j \oplus \boldsymbol{w}_{j+1}$ and

$$\boldsymbol{\phi}(x, e_{ij}) = \text{vec}(\boldsymbol{v}_i \otimes \boldsymbol{v}_j) \ \in \mathbb{R}^{9d^2}.$$

Recall that $\boldsymbol{w}_i$ of length $d \ll \mathcal{V}$ is a vector from $\boldsymbol{R}$.

We use the averaged Passive-Aggressive online algorithm for structured prediction (Crammer et al., 2006) for learning the model $\boldsymbol{\theta}$. Given a score for each edge, we use Eisner algorithm (Eisner, 1996) to retrieve the best projective spanning tree. Even though some languages display a fair amount of non-projective edges, on average Eisner algorithm scores higher than Chu-Liu-Edmonds algorithm (Chu and Liu, 1965) in our setting.

2.3 Measuring Morpho-Syntactic Complexity

Some languages use morphological cues to encode syntactic information while other encode more semantic information with them. For example, the Case feature (especially core cases) is of prime syntactic importance, for it encodes the type of relation words have with each other. On the contrary, the Possessor feature (in Hungarian for example) is more semantic in nature and need not impact sentence structure. This remark would support different treatment for each language. However, those languages tend to be treated equally in works dealing with MRL.

Form to Lemma Ratio A basic measure of morphological complexity is the form per lemma ratio, we note it F/L. It captures the tendency of words to inflect in a given language. Because some word classes tend not to inflect and not all forms are equally productive, we note F/iL the ratio of form per inflected lemma. Given a language l with a lemma vocabulary $\mathcal{V}^l$ and a form counting function $c : \mathcal{V}^l \to \mathbb{N}$ that returns the number of forms a lemma can take, we have:

$$F/L(l) = \frac{1}{|\mathcal{V}^l|} \sum_{w \in \mathcal{V}^l} c(w),$$

$$F/iL(l) = \frac{1}{|\mathcal{V}^l_i|} \sum_{w \in \mathcal{V}^l_i} c(w), \mathcal{V}^l_i = \{w \in \mathcal{V}^l | c(w) > 1\}$$

F/L and F/iL do not measure the informative content of morphology, but simply its productivity. Bentz et al. (2016) compared five different measures of morphological complexity amongst which word entropy and the micro-averaged version of F/L (they call it TTR) and showed that they all have high positive correlation given enough data.

Head POS Entropy In order to compare the morpho-syntactic complexity of different languages, we introduce a new measure called *Head Part-of-speech Entropy* or *HPE*. The *HPE* of a token t represents the amount of information t has about the part-of-speech of its governor. More formally, let $POS(Gov(t))$ be the set of parts-of-speech that t can depend on, and let $\pi_t(p)$ be the probability of t actually depending on part-of-speech p, then the *HPE* is defined as:

$$HPE(t) = \sum_{p \in POS(Gov(t))} -\pi_t(p) log_2(\pi_t(p)).$$

This is a measure of a token preferencial attachment to its head. A token with a low *HPE* tends to attach often to the same part-of-speech, while a token with a high *HPE* will attach to many different parts-of-speech. Thus a language with a low *HPE* will tend to encode a lot of syntactic information in the morphology, rather than in word order say.

For example, a noun can attach to another noun like a genitive, or to a verb as a subject or object, or even to an adjective in the case of transitive adjective. French nouns do not inflect for case, thus attachment to another noun or verb can only be infered from words relative positions. On the contrary, Gothic nouns do inflect for case, thus making verb or noun attachment clear directly from the morphological analysis.

We compute the *HPE* of a language as the averaged *HPE* of its attributes sets over a given corpus. Likewise, we use the empirical counts as a surrogate for c in F/L and F/iL.

3 Experiments

In order to test the hypothesis that morphological representations contain syntactic information crucial for dependency parsing of morphologically rich languages, but that this information is not equally distributed across MRL, we run experiments on data from the Universal Dependencies (Nivre et al., 2016) project.

Data Description For conciseness, we focused on eleven languages that display varying degrees of morphological complexity and belong to four different language families. Basque (eu) is an isolate and it is an ergative language. English (en), Gothic (got), Danish (da) and Swedish (sv) are Germanic languages, and French (fr) and Romanian (ro) are Romance languages (Indo-European). Finnish (fi), Estonian (et) and Hungarian (hu) are Finno-Ugric languages. Hebrew (he) is a Semitic language. Basic statistics are provided in Table 1.

Experimental Settings For the experiments we use the train/dev/test data provided by UD 2.0. Basic statistics about the data are reported in the appendix. Lemmas and forms are embedded in 150 dimensions, while Morphological attributes are embedded in 50 dimensions, because they are much less numerous (less than 100). All embeddings are induced on their language respective train set only using a context window of size 1 (i.e. the

Table 2: UAS scores for parsers using lemmas (Lem), word forms (Form) or morphological attributes (Morph) representations as features. For each type, we report results using one-hot representation (OH) and results using embeddings (Emb).

directly preceding and following words).

Parsers are trained for 10 iterations using either lemma, form or morphological representations, and we pick the best iteration on the basis of UAS on the development set.

While we used gold lemmas as provided in the corpora, we ran two experiments for morphological attributes, one with gold attributes and one with predicted attributes. Morphological attributes are predicted with a simple multinomial logistic regression per attribute (POS, Tense, Case, Gender...), where we add a special *undef* value (except for POS) to represent the lack of an attribute (e.g., nouns have no Tense in English). The models predict attribute values for the center word of trigrams represented by feature vectors encoding word prefixes and suffixes of length 1, 2 and 3, word length and capitalization. We used the logistic regression implemented in the Scikit-Learn (Pedregosa et al., 2011) library with the default settings. It can output an argmaxed decision or a softmaxed decision, thus we tried both as input to the parser. The argmaxed decision gives a vector of zeros and ones, while the softmaxed decision gives a continuous vector with each each attributes summing to one (the probability assigned to each possible value for Gender like Masculine, Feminine, Neuter and Undef must sum to one). Then those vectors are used unchanged for the one-hot representation or passed through an embedding matrix for the embedding representation.

Results For clarity, we focus on comparing results using form embeddings and gold morphological representations. They are given in Table 2. Because the analysis carries to the labeled case, we stick to unlabeled scores (UAS) for the analysis. A more complete table is provided in the appendix as well as a complete labeled accuracy score (LAS) table. Morphological complexity measures are also reported.

One-hot gold morphological attributes consistently outerperform form embeddings. This is expected since forms embedding were trained on much fewer data than usually considered necessary. However, improvements are not consistent across languages, ranging from 1.14 point for English to 15.20 points for Finnish. While those differences are not explained by morphological productivity alone (Figure 1a), a measure of preferential attachment gives a good account of them (Figure 1b). Those inconsistencies become even more striking, considering results using predicted attributes. We notice that despite a general drop of performance of 5-12 points, predicted attributes

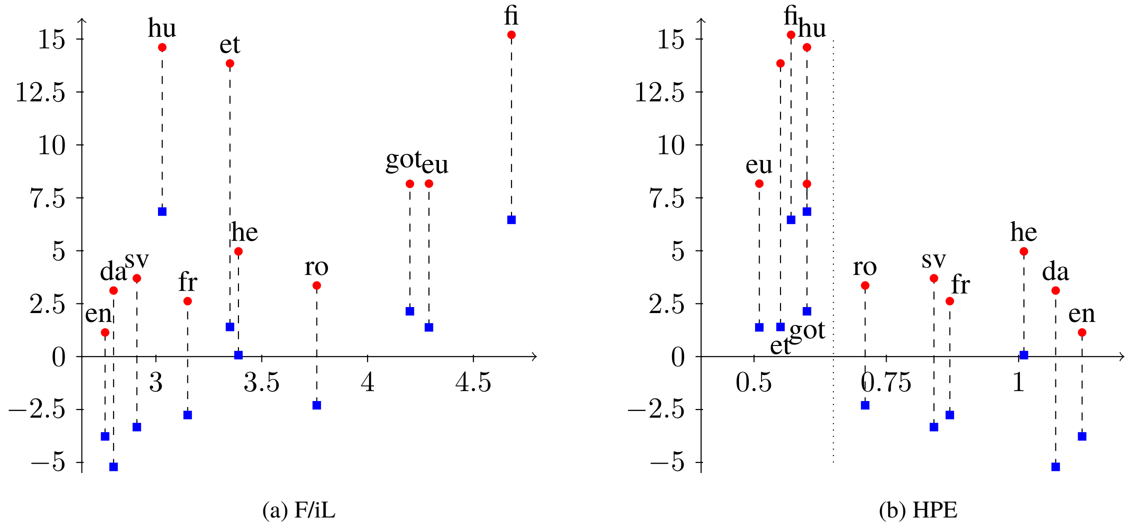

Figure 1: Accuracy differences (y-axis) between parsers using form embeddings and parsers using one-hot attributes, with respect to morphological complexity (x-axis). Red dots represent the gold attributes scores and blue squares the predicted attributes scores.

still perform significantly better than form embeddings for those morphologically rich languages that have an *HPE* lower than 0.65 as depicted on Figure 1b.

Figures 1a and 1b plot the differences in parsing scores. For each language, the red dot corresponds to the score difference between using form embeddings and gold attributes one-hot representations, and the blue square corresponds to the score difference between using the same form embeddings and predicted attributes softmax representations (the complete scores are given in the appendix). Figure 1a plots those differences with regard to the form per inflected lemma ratio (F/iL) and Figure 1b plots those differences with regard to the head POS entropy (*HPE*).

Both Figures show trends. Score differences seem to increase with F/iL and decrease with *HPE*. But while the F/iL plot suffers outliers (Hungarian, Estonian and Romanian), the *HPE* plot shows a clear boundary between languages benefiting fully from morphological information (even predicted) and those benefiting primarily from reducing data sparsity. While Hebrew seems to be an outlier, it might be due to its annotation style, where attached prepositions, articles and possessive markers are treated as independent words rather than morphological inflection as other languages do, thus artificially increasing the parsing accuracy with a lot of trivial dependencies.

This shows that indeed, *HPE* is a good measure of the syntactic informativeness of a language morphology, and that it can help deciding between encoding morphological information or just reducing data sparsity. Furthermore, it seems to be link to the distinction that Kibort and Corbett (2010) do between morphosyntax and morphosemantic.

4 Conclusion

We have contributed a new measure of morpho-syntactic complexity (*HPE*) that helps distinguishing languages that use morphology for syntactic purpose from languages that use morphology to encode more semantic information. We showed that this measure correlates much more with differences in parsing results using morphological representations than the simple form per lemma ratio. It could thus be used to help designing language specific word representations.

It is worth mentioning that we focused here on dependent marked head selection. It would be interesting to have a similar measure for head-marking situations with dependencies marked on the governor. We leave it for future work.

Abstract

Neural sequence-to-sequence models have proven very effective for machine translation, but at the expense of model interpretability. To shed more light into the role played by linguistic structure in the process of neural machine translation, we perform a fine-grained analysis of how various source-side morphological features are captured at different levels of the NMT encoder while varying the target language. Differently from previous work, we find no correlation between the accuracy of source morphology encoding and translation quality. We do find that morphological features are only captured in context and only to the extent that they are directly transferable to the target words.

1 Introduction

The advent of Neural Machine Translation (NMT) (Sutskever et al., 2014; Bahdanau et al., 2014) has led to remarkable improvements in machine translation quality (Bentivogli et al., 2016) but has also produced models that are much less interpretable. In particular, the role played by linguistic features in the process of understanding the source text and rendering it in the target language remains hard to gauge. Acquiring this knowledge is important to inform future research in NMT, especially regarding the usefulness of injecting linguistic information into the NMT model, e.g. by using supervised annotation (Sennrich and Haddow, 2016).

Hill et al. (2014) gave a first answer to this question, reporting high accuracies by source-side NMT word embeddings on the well-known analogy task by Mikolov et al. (2013) which also includes a number of derivational and inflectional transformations in the morphologically poor English language. More recent work (Shi et al., 2016) has shown that source *sentence* representations produced by NMT encoders contain a great deal of syntactic information. Belinkov et al. (2017a) focused on the *word* level and examined to what extent part-of-speech and morphological information can be extracted from various NMT word representations. The latter study found that source-side morphology is captured slightly better by the first recurrent layer than by the word embedding and the final recurrent layer. Another, somewhat surprising finding was that source-side morphology is learned better when translating into an 'easier' target language than into a related one, even if the 'easier' language is morphologically poor.

In this paper, we also focus on source-side morphology but perform a finer-grained analysis of how morphological features are captured by different components of the NMT encoder while varying the target language. We argue that predicting generic morphological tags where all features are mixed, as done by Belinkov et al. (2017a), can only give us a limited insight into the linguistic competence of the model. Hence, we predict morphological features independently from one another and ask the following questions:

- Are different morphological features captured by the NMT encoder to substantially different extents and, if yes, why?
- Are morphological features captured as a word type property (i.e. at the word embedding level) or are they mostly computed in context (i.e. at the recurrent state level)?
- How does source-target language relatedness affect the morphological competence of the NMT encoder?

More specifically, we look at whether the NMT encoder only learns those morphological features that can be directly transferred to the target words

Figure 1: Two example French sentences translated to Italian, German, and English. Number (top) is usually carried over to the three target languages, while gender (bottom) is less predictable. Colored fonts mark agreement with the noun in boldface.

(such as *number*) or whether it also learns features that are not directly transferable but can still be useful to correctly parse and infer the meaning of a sentence (such as *gender*). See example in Fig. 1.

We focus on French and similarly to previous work (Shi et al., 2016; Belinkov et al., 2017a) we use the continuous word representations produced by a trained NMT system to build and evaluate a number of linguistic feature classifiers. Classifier accuracy represents the extent to which a given feature is captured by the NMT encoder.

2 Methods

We train NMT systems on the following language pairs: French-Italian (FR_{IT}), French-German (FR_{DE}), and French-English (FR_{EN}). We chose these language pairs for their different levels of language relatedness and morphological feature correspondence. Grammatical gender is especially interesting as it is marked in French, Italian and German, but not in English (except for a few pronouns). The gender of Italian nouns often corresponds to that of French because of their common language ancestor, whereas German gender is mostly unrelated from French gender (see example in Fig. 1).

The continuous word representations produced by the three NMT systems while encoding a corpus of French sentences are used to build and evaluate several specialized classifiers: one per morphological feature. If a classifier significantly outperforms the majority baseline, we conclude that the corresponding feature is captured by the NMT encoder. While this methodology is similar to that of previous work (Köhn, 2015; Belinkov et al., 2017a,b; Dalvi et al., 2017) we make sure that our results are not affected by overfitting by eliminating any vocabulary overlap between the classifier's training and test sets. We find this step crucial to ensure that the redundancy in this type of data does not lead to over-optimistic conclusions. We now provide more details on the experimental setup.

Parallel corpora. For a fair comparison among target languages, we extract the intersection of the Europarl corpus (Koehn, 2005) in our three language pairs so that the source side data is identical for all NMT systems. Sentences longer than 50 tokens are ignored. This data is then split into an NMT training, validation, and test set of 1.3M, 2.5K, and 2.5K sentence pairs respectively.

NMT model. The NMT architecture is an attentional encoder-decoder model similar to (Luong et al., 2015) and uses a long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) as the recurrent cell. The models have 3 stacked LSTM layers and are trained for 15 epochs. Embedding and hidden state sizes are set to 1000. Source and target vocabularies are limited to the 30,000 most frequent words on each side of the training data.[1] The NMT models achieve a test BLEU score of **32.6**, **25.4** and **39.4** for French-Italian, French-German and French-English respectively.

Continuous word representations. Given a source sentence, the NMT system first encodes it into a sequence of word embeddings (context-independent representations), and then into a sequence of recurrent states (context-dependent representations). As we are mostly interested in the impact of context on word representations, we compare the word embeddings against the final layer of the stacked LSTMs (corresponding to layers 0 and 3 in Belinkov et al. (2017a)'s terms) while disregarding the intermediate layers.

Morphological classification. The continuous word representations are used to train a logistic regression classifier[2] for each morphological feature: *gender* and *number* for noun and adjectives; *tense* for verbs (with labels: present, fu-

---

[1] Subword/character-level representations are not included in this study since we are interested in the models' ability to learn morphology from word usage, rather than word form.

[2] We use linear classifiers since their accuracies can be interpreted as a measure of supervised clustering accuracy, which gives a better insight on the structure of the vector space (Köhn, 2015). Results with a simple multi-layer perceptron were consistent with the findings by the linear classifier, with slightly better performance overall.

ture, imperfect, or simple past). Word labels are taken from the *Lefff* French morphological lexicon (Sagot, 2010)[3]. To ensure a fair comparison between context-independent and context-dependent embedding classification, words that are ambiguous with respect to a given feature are excluded from the respective classifier's training and test data.

Classifiers' training/test data. The classifiers are trained on a 50K-sentence subset of the NMT training data and tested on the NMT test sets (2.5K). For each experiment, we extract *one vector per token* from the NMT encoder. While this is the only possible setup for context-dependent representations, it leads to a problematic training/test overlap in the word embedding experiment because all occurrences of the same word are associated to exactly the same vector. We find that, due to this overlap, a dummy binary feature assigned to a random half of the vocabulary can be predicted from the word embeddings with very high accuracy (86% for a linear, 98% for a non-linear classifier) leading to over-optimistic conclusions on the linguistic regularities of these representations. To avoid this, we split the vocabulary in two parts of 15K types: the first is used to filter the training samples and the second to filter the test samples. We repeat each experiment five times using five different random vocabulary splits and report mean accuracies. This process is applied to all experiments (including those on hidden states) to allow for a fair comparison of the results.

3 Results and Discussion

This section presents our results along three dimensions: context-dependency of the word representations (§3.1), different morphological features (§3.2), and target language impact (§3.3). Unless explicitly stated, all discussed results are statistically significant (computed using a t-test for a one-tailed hypothesis and independent means).

3.1 Word embeddings *vs* recurrent states

One of our goals was to discover whether morphological features are captured as a word type property or in context. Fig. 2 shows the extent to which the NMT encoder captures different features at the word level (word embeddings) compared to the recurrent state level (LSTM state), averaged over all target languages. We can see that each feature is clearly captured at the recurrent state level, confirming that source-side morphology is indeed successfully exploited by NMT models. However, at the word embedding level, accuracies are comparable to the majority class baseline (these differences are not significant), which implies that the source-side lexicon of our NMT systems does not encode morphology in a systematic way. This might be partly explained by the fact that learning morphological features at the word level is difficult due to data sparsity – indeed the rarest French words in our dataset are observed only 10 times in the training data. However, additional experiments showed that our finding is consistent across different word frequency bins: that is, even the embeddings of frequent words do not encode morphological features better than the majority baseline.

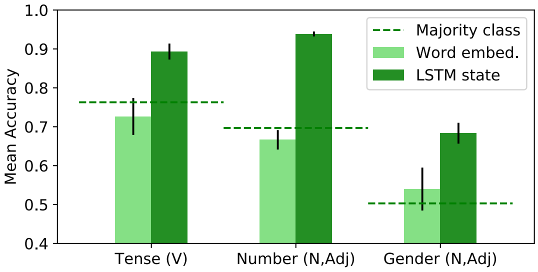

Figure 2: Classifier accuracy for different morphological features, averaged over target languages.

This result is surprising, considering that our morphological features are usually easy to infer from the immediate context of French words (see examples in Fig.1) and that morphology was shown to be well captured by monolingual word embeddings in various European languages including French (Köhn, 2015). By contrast, our NMT encoders choose not to store morphology at the word type level, perhaps in order to allocate more capacity to semantic information.

3.2 Different morphological features

Secondly, we asked whether the NMT encoder captured different morphological features to different extents. For this question, we disregard the word embedding results because none of the features are significantly captured at this level.

Fig. 2 shows that the mean accuracy of *number* is the highest, followed by *tense* and then by *gender*. However, it should be noted that the majority baselines for number and tense are much higher than the one for gender. In both absolute and rela-

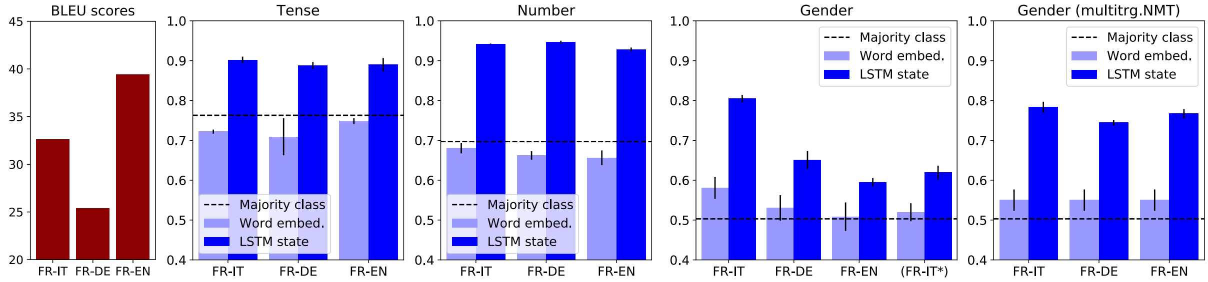

Figure 3: Translation quality (left) and classifier accuracy for each morphological feature in the three different language pairs. IT* denotes a modified Italian language where gender marking is removed.

tive terms, the best performing feature is number. This can be explained by the fact that number remains most often unchanged through translation, and is marked in all target languages – albeit to different extents. On the other hand, tense is determined by the semantics but also by language-specific usage, while gender has little semantic value and is mostly assigned to nouns arbitrarily.

The fact that the results of different morphological features are so variable confirms the setup of examining each feature independently.

3.3 Source-target language relatedness

Fig. 3 shows the impact of the target language on the encoded morphology accuracy. We again focus our analysis on the LSTM state level since embedding level results are mostly near the baseline.

Differently from Belinkov et al. (2017a) we do not find that source-side morphology is captured better when translating into the 'easiest' language, which in our case is English, both in terms of morphological complexity and BLEU performance. We note that their findings were based on very small, possibly not significant differences, and on the prediction of all morphological features simultaneously. By contrast, our fine-grained analysis reveals that the impact of target language is significant and even major on only one feature, namely *gender*, where it agrees with our linguistic intuition. Indeed this feature differs from the others because it varies largely among languages and, when present, is semantically determined only to a very limited extent. FR_{IT}, where source gender is a good predictor of target gender, shows the highest accuracy; FR_{EN}, where target gender is not marked, shows the lowest; FR_{DE}, where source gender is often confounding for target gender, lies in-between.

Is language relatedness the main explaining variable? To find that out, we experiment with a modified Italian target language without gender marking, i.e. all gender-marked words are replaced by their masculine form (FR_{IT*}). This language pair achieves a slightly higher BLEU score than FR_{IT} (33.2 *vs* 32.6), which can be attributed to the smaller target vocabulary. However its source gender accuracy is much worse (see Fig. 3), which indicates that the high performance of the FR_{IT} encoder is mostly due to the ubiquitous gender marking in the target language, rather than to language relatedness. All this suggests that source morphological features contribute to sentence understanding to some degree, but the incentive to learn them mostly depends on how directly they can be transferred to the target sentence.

Finally, we look at what happens when a single NMT system is trained in a multitarget fashion on our three language pairs. Following the setup of Johnson et al. (2017), we prepend a *to-target-language* tag $\{2it, 2de, 2en\}$ to the source side of each sentence pair and mix all language pairs in the NMT training data. Results are presented for gender in Fig. 3 (right).[4] Note that, while word embeddings are identical for the three language pairs, recurrent states change according to the language tag. In this setup the target language impact is less visible and gender accuracy at the LSTM state level is overall much higher than that of the mono-target systems (0.77 *vs* 0.68 on average) whereas BLEU scores are slightly lower (-0.9% on average). While this is only an initial exploration of multilingual NMT systems, our results suggest that this kind of multi-task objective pushes the model to learn linguistic features in a more consistent way (Bjerva, 2017; Enguehard et al., 2017).

---

[4] Multitarget results for tense and number did not differ significantly from the corresponding monotarget results.

4 Conclusion

We have confirmed previous findings that morphological features are significantly captured by word-level NMT encoders. However, the features are not captured at the word type level but only at the recurrent state level where word representations are context-dependent. Secondly, there is a visible difference in the extent to which different morphological features are learned: Semantic categories like number and verb tense are well captured in all language pairs, whereas grammatical gender with its only agreement-triggering function, is dramatically affected by the target language. Source-side gender is encoded well only when it is a good predictor of target gender and when target-side marking is extensive, i.e. when translating from French to Italian.

Our findings indicate that the importance of linguistic structure for the neural translation process is very variable and language-dependent. They also suggest that the NMT encoder is rather 'lazy' when it comes to learning grammatical features of the source words, unless these are directly transferable to their target equivalents.

Acknowledgments

This research was partly funded by the Netherlands Organization for Scientific Research (NWO) under project number 639.021.646. Part of the work was carried out on the DAS computing system (Bal et al., 2016) while the authors were affiliated at the Informatics Institute of the University of Amsterdam. Imitation Learning for Neural Morphological String Transduction

Peter Makarov **Simon Clematide**

University of Zurich, Switzerland
makarov@cl.uzh.ch simon.clematide@cl.uzh.ch

Abstract

We employ imitation learning to train a neural transition-based string transducer for morphological tasks such as inflection generation and lemmatization. Previous approaches to training this type of model either rely on an external character aligner for the production of gold action sequences, which results in a suboptimal model due to the unwarranted dependence on a single gold action sequence despite spurious ambiguity, or require warm starting with an MLE model. Our approach only requires a simple expert policy, eliminating the need for a character aligner or warm start. It also addresses familiar MLE training biases and leads to strong and state-of-the-art performance on several benchmarks.

1 Introduction

Recently, morphological tasks such as inflection generation and lemmatization (Figure 1) have been successfully tackled with neural transition-based models over edit actions (Aharoni and Goldberg, 2017; Robertson and Goldwater, 2018; Makarov and Clematide, 2018; Cotterell et al., 2017b). The model, introduced in Aharoni and Goldberg (2017), uses familiar inductive biases about morphological string transduction such as conditioning on a single input character and monotonic character-to-character alignment. Due to this, the model achieves lower time complexity (compared to soft-attentional seq2seq models) and strong performance on several datasets.

하다 {V, Past, Formal Polite, Interrogative, Honorific} ▷ 하셨습니까

하셨습니까 ▷ 하다

Figure 1: Morphological tasks with examples in Korean: inflection generation (top) and lemmatization (bottom). (McCune-Reischauer: 하다=hada, 하셨습니까=hasyŏssŭmnikka).

Aharoni and Goldberg train the model by maximizing the conditional log-likelihood (MLE) of gold edit actions derived by an independent character-pair aligner. The MLE training procedure is therefore a pipeline, and the aligner is completely uninformed of the end task. This results in error propagation and the unwarranted dependence of the transducer on a single gold action sequence—in contrast to weighted finite-state transducers (WFST) that take into account all permitted action sequences. Although these problems—as well as the exposure bias and the loss-metric mismatch arising from this MLE training (Wiseman and Rush, 2016)—can be addressed by reinforcement learning-style methods (Ranzato et al., 2016; Bahdanau et al., 2017; Shen et al., 2016, RL), for an effective performance, all these approaches require warm-start initialization with an MLE-pretrained model. Another shortcoming of the RL-style methods is delayed punishment: For many NLP problems, including morphological string transduction, one can pinpoint actions that adversely affect the global score. For example, it is easy to tell if inserting some character c at step t would render the entire output incorrect. Assigning individual blame to single actions directly—as opposed to scoring the entire sequence via a sequence-level objective—simplifies the learning problem.

Faced with problems similar to those arising in transition-based dependency parsing with static oracles (Goldberg and Nivre, 2012), we train this model in the imitation learning (IL) framework (Daumé III et al., 2009; Ross et al., 2011; Chang et al., 2015), using a simple expert policy. Our approach eliminates both all dependency on an external character aligner and the need for MLE pre-training. By making use of exploration of past

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2877–2882
Brussels, Belgium, October 31 - November 4, 2018.

and future actions and having a global objective, it addresses the MLE training biases, while providing relevant action-level training signal. The approach leads to strong and state-of-the-art results on a number of morphological datasets, outperforming models trained with minimum risk training (MRT).

2 Model Description

We use a variant of the seq2seq state-transition system by Aharoni and Goldberg (2017). The model transduces the input string into the output string by performing single-character edits (insertions, deletions). The encoder RNN computes context-enriched representations of input characters, which are pushed onto the buffer at the beginning of transduction. The decoder RNN keeps track of the history of edits. Transitions—edits—are scored based on the output of the decoder state and can write a character or pop the representation of a character from the top of the buffer. We choose the model variant of Makarov and Clematide (2018), who add the copy edit, which results in strong performance gains in low-resource settings.

Let $\mathbf{x} = x_1 \dots x_n$, $x_i \in \Sigma_x$ be an input sequence, $\mathbf{y} = y_1 \dots y_p$, $y_j \in \Sigma_y$ an output sequence, and $\mathbf{a} = a_1 \dots a_m$, $a_t \in \Sigma_a$ an action sequence. Let $\{f_h\}_{h=1}^{H}$ be the set of all features. The morpho-syntactic description of a transduction is then an n-hot vector $\mathbf{e} \in \{0,1\}^H$.

The model employs a bidirectional long short-term memory (LSTM) encoder (Graves and Schmidhuber, 2005) to produce representations for each character of the input $\mathbf{x}$:

$$\mathbf{h}_1, \dots, \mathbf{h}_n = \text{BiLSTM}(E(x_1), \dots, E(x_n)), \quad (1)$$

where E returns the embedding for x_i. We push $\mathbf{h}_1, \dots, \mathbf{h}_n$ in reversed order onto the buffer. The transduction begins with the full buffer and the empty decoder state.

Transitions are scored based on the output of the LSTM decoder state (Hochreiter and Schmidhuber, 1997):

$$\mathbf{s}_t = \text{LSTM}(\mathbf{c}_{t-1}, [A(a_{t-1})\ ;\ \mathbf{h}_i]), \quad (2)$$

where $\mathbf{c}_{t-1}$ is the previous decoder state, $A(a_{t-1})$ is the embedding of the previous edit action, and $\mathbf{h}_i$ is the input character representation at the top of the buffer. If features are part of the input in the task, then the input to the decoder also contains the representation of morpho-syntactic description $\mathbf{e}$, $[F(f_1)\,; \dots ; F(f_H)]$, which is a concatenation of the embedded features and a designated embedding $F(0)$ is used instead of $F(f_h)$ if $e_h = 0$.

The probabilities of transitions are computed with a softmax classifier:

$$P(a_t = k \mid \mathbf{a}_{<t}, \mathbf{x}, \Theta) = \text{softmax}_k(\mathbf{W} \cdot \mathbf{s}_t + \mathbf{b}) \quad (3)$$

Model parameters Θ include $\mathbf{W}$, $\mathbf{b}$, the embeddings, and the parameters of the LSTMs.

The alphabet of edit actions Σ_a contains INSERT(c) for each $c \in \Sigma_y$, DELETE, and COPY. An INSERT(c) action outputs c; DELETE pops $\mathbf{h}_i$ from the top of the buffer; COPY pops $\mathbf{h}_i$ from the top of the buffer and outputs x_i. The system exhibits spurious ambiguity: Multiple action sequences lead to the same output string.

2.1 MLE Training

Aharoni and Goldberg train their model by minimizing the negative conditional log-likelihood of the data $D = \{(\mathbf{x}^{(l)}, \mathbf{a}^{(l)})\}_{l=1}^{N}$:

$$\mathcal{L}(D, \Theta) = -\sum_{l=1}^{N} \sum_{t=1}^{m} \log P(a_t^{(l)} \mid \mathbf{a}_{<t}^{(l)}, \mathbf{x}^{(l)}, \Theta), \quad (4)$$

where gold action sequences $\mathbf{a}^{(l)}$ are deterministically computed from a character-pair alignment of the input and output sequences $(\mathbf{x}^{(l)}, \mathbf{y}^{(l)})$. The character-pair aligner is trained separately to optimize the likelihood of the actual training data $T = \{(\mathbf{x}^{(l)}, \mathbf{y}^{(l)})\}_{l=1}^{N}$. For the details, we refer the reader to Aharoni and Goldberg (2017).

3 IL Training

One problem with the MLE approach is that the aligner is trained in a disconnect from the end task. As a result, alignment errors lead to the learning of a suboptimal transducer. Switching to a different aligner can dramatically improve performance (Makarov and Clematide, 2018). More fundamentally, in the face of the vast spurious ambiguity, the transducer is forced to adhere to a single gold action sequence whereas typically, legitimate and equally likely alternative edit sequences exist. This uncertainty is not accessible to the transducer, but could be profitably leveraged by it.

We address this problem within the IL framework and train the model to imitate an expert policy (dynamic oracle), which is a map—on the training data—from configurations to sets of optimal actions. Actions are optimal if they lead to the lowest sequence-level loss, under the assumption that all future actions are also optimal (Daumé III et al., 2009). In the *roll-in* stage, we run the model on a training sample and follow actions either returned by the expert policy (as in teacher forcing) or sampled from the model (which itself is a stochastic policy). In this way, we obtain a sequence of configurations summarized as decoder outputs $\mathbf{s}_1, \ldots, \mathbf{s}_m$. In the *roll-out* stage, we compute the sequence-level loss for every valid action a in each configuration $\mathbf{s}_t$. To this end, we execute a and then either query the expert to obtain the loss for the optimal action sequence following a or run the model for the rest of the input and evaluate the loss of the resulting action sequence. Finally, the sequence-level losses obtained in this way for all actions a enter the action-level loss for configuration $\mathbf{s}_t$ that we minimize with respect to Θ.

Sequence-level loss We define the loss in terms of the *Levenshtein distance* (Levenshtein, 1966) between the prediction and the target and the *edit cost* of the action sequence. Given input $\mathbf{x}^{(l)}$ with target $\mathbf{y}^{(l)}$, the loss from producing an action sequence $\mathbf{a}$ is:

$$\ell(\mathbf{a}, \mathbf{x}^{(l)}, \mathbf{y}^{(l)}) = \beta\, \text{distance}(\mathbf{y}, \mathbf{y}^{(l)}) + \text{cost}(\mathbf{a}), \quad (5)$$

where $\mathbf{y}$ is computed from $\mathbf{a}$ and $\mathbf{x}^{(l)}$ and $\beta \geq 1$ is some penalty for unit distance.[1] The first term represents the task objective. The second term enforces that the task objective is reached with a minimum number of edits.

The second term is crucial as it takes over the role of the character aligner. Initially, we also experimented with only Levenshtein distance as loss, similar to previous work on character-level problems (Leblond et al., 2018; Bahdanau et al., 2017). However, models did not learn much, which we attribute to sparse training signal as all action sequences producing the same $\mathbf{y}$ would incur the same sequence-level loss, including intuitively very wasteful ones, e.g. first deleting all of $\mathbf{x}^{(l)}$ and then inserting of all of $\mathbf{y}^{(l)}$.

Expert The expert policy keeps track of the prefix of the target $\mathbf{y}^{(l)}$ in the predicted sequence $\mathbf{y}_{<t}$ and returns actions that lead to the completion of the suffix of $\mathbf{y}^{(l)}$ using an action sequence with the lowest edit cost. The resulting prediction $\mathbf{y}$ attains the minimum edit distance from $\mathbf{y}^{(l)}$. For example, if $\mathbf{x}^{(l)} = walk$ and $\mathbf{y}^{(l)} = walked$, the top of the buffer is $\mathbf{h}_3$ representing $x_3 = l$, and $\mathbf{y}_{<3} = wad$ due to a sampling error from a roll-in with the model, the expert returns $\{\text{COPY}\}$.

Action-level loss Given sequence-level losses, we compute the regret for each action a:

$$r_t(a) = \ell(\mathbf{a}, \mathbf{x}^{(l)}, \mathbf{y}^{(l)}) - \min_{a' \in A(\mathbf{s}_t)} \ell(\mathbf{a}', \mathbf{x}^{(l)}, \mathbf{y}^{(l)}), \quad (6)$$

where $\mathbf{a}$ (or $\mathbf{a}'$) is the action sequence resulting from taking a (or a') at $\mathbf{s}_t$ and $A(\mathbf{s}_t)$ is the set of valid actions. Thus, $r_t(a)$, which quantifies how much we suffer from taking action a relative to the optimal action under the current policy, constitutes the direct blame of a in the sequence-level loss.

Classic IL employs cost-sensitive classification, with regrets making up costs (Daumé III et al., 2009; Chang et al., 2015). Our initial experiments with cost-sensitive classification resulted in rather inefficient training and not very effective models. Instead, we choose to minimize the negative marginal log-likelihood of all optimal actions (Riezler et al., 2000; Goldberg, 2013; Ballesteros et al., 2016). Given the training data $T = \{(\mathbf{x}^{(l)}, \mathbf{y}^{(l)})\}_{l=1}^{N}$, the action-level loss is:

$$\mathcal{L}(T, \Theta) = -\sum_{l=1}^{N} \sum_{t=1}^{m} \log \sum_{a \in A_t} P(a \,|\, \mathbf{a}_{<t}, \mathbf{x}^{(l)}, \Theta), \quad (7)$$

where $A_t = \{a \in A(\mathbf{s}_t) : r_t(a) = 0\}$, the set of optimal actions under the current policy. Depending on the roll-in schedule, the next edit a_{t+1} is sampled either uniformly at random from A_t or from the distribution of valid edits. To include all the computed regrets into the loss, we also experiment with the cost-augmented version of this objective (Gimpel and Smith, 2010), where regrets function as costs.

The downside of IL is that roll-outs are costly. We avoid computing most of the roll-outs by checking if an action increases the edit distance from $\mathbf{y}^{(l)}$. If it does, we heuristically assign this action a regret of β. We use this heuristic in both expert and model roll-outs.

4 Experiments

We demonstrate the effectiveness of our approach on three tasks: inflection generation (using the typologically diverse SIGMORPHON 2016 and SIGMORPHON 2017 datasets of Cotterell et al. (2016, 2017a)), reinflection (the small-sized German CELEX dataset of Dreyer et al. (2008)), and

---

[1] We use unit costs to compute edit cost and distance.

Experimental results. Soft-attention seq2seq models: MED=Kann and Schütze (2016) (cited from Aharoni and Goldberg (2017)), SOFT=Aharoni and Goldberg (2017), LEM=Bergmanis and Goldwater (2018). WFSTs: LAT=Dreyer et al. (2008), NWFST=Rastogi et al. (2016). Transition-based models: HA=Aharoni and Goldberg (2017), SGM17TOP=Makarov et al. (2017), and from Makarov and Clematide (2018): HA*=reimplementation of HA, CA=model in §2, and HA*-MRT, CA-MRT (risk=normalized edit distance). We report exact-match accuracies for ensembles of 5 models (SIGM. 2016 and 2017) and single-model averages over 5 folds (CELEX) and 10 folds (lemmatization).

lemmatization (the standard subset of the Wicentowski (2002) dataset).

We use character and feature embeddings of size 100 and 20, respectively, and one-layer LSTMs with hidden-state size 200. Following Aharoni and Goldberg, for every character $c \in \Sigma_x \cap \Sigma_y$, we let $A(\text{INSERT}(c)) := E(c)$, i.e. the same embedding represents both c and the insertion of c. We optimize with ADADELTA (Zeiler, 2012), use early stopping and batches of size 1. We set the penalty for unit distance $\beta = 5$ and roll in with an inverse-sigmoid decay schedule as in Bengio et al. (2015). CA-D models are trained with expert roll-outs only (as is often the case in dynamic-oracle parsing). CA-R and CA-RM models mix expert and learned roll-outs with probability 0.5 as in Chang et al. (2015). CA-RM models optimize softmax-margin.

For comparison, we also train models with MRT (CA-MRT-A) as in Shen et al. (2016), using a global objective similar to our sequence-level loss (Eq. 5). We use batches of at most 20 unique samples per training example. The risk is a convex combination of normalized Levenshtein distance and the action sequence cost, which we min-max scale, within a batch, to the [0, 1] interval.

We decode all our models using beam search with beam width 4.

Our approach performs best on most languages of the SIGMORPHON 2016 data (Table 1) and both limited-resource settings of SIGMORPHON 2017 (Table 4). It achieves marginal improvement over an MRT model on the reinflection task (Table 2) with consistent gains on the 2PKE$\mapsto$z transformation (Dreyer et al., 2008), that involves infixation. Using mixed roll-outs (CA-R, CA-RM) improves performance on the SIGMORPHON 2017 inflection data (Table 4), otherwise the results are close to CA-D. We also note strong gains over CA-MRT-A trained with a similar global loss (Table 4). Generally, improvements are most pronounced in inflection generation, the only task where the model could profit from adjusting alignment to available feature information (cf. Table 3).

[3] Personal communication.

We take a closer look at the results in the SIGMORPHON 2017 medium data-size setting (1,000 training examples per language). CA-RM makes the largest performance gains on languages with complex morphological phenomena (Semitic and Uralic languages, Navajo) and an above average number of unique morpho-syntactic descriptions. Khaling and Basque, outliers with 367 and 740 unique morpho-syntactic descriptions in the training data, are among the top five languages with the largest gains. The lowest gains and rare losses are made for Romance and Germanic languages and languages with many unique morpho-syntactic descriptions but regular morphologies (Quechua, Urdu/Hindi).

5 Related work

Traditionally, morphological string transduction has been approached with discriminative weighted finite-state transducers (Rastogi et al., 2016; Cotterell et al., 2014; Dreyer et al., 2008; Eisner, 2002). Yu et al. (2016) and Graves (2012) tackle the modeling of unbounded dependencies in the output, while preserving latent monotonic hard character alignment. Faruqui et al. (2016); Kann and Schütze (2016) successfully apply seq2seq modeling to the task. Aharoni and Goldberg (2017) introduce a neural version of the transition-based model over edits. Makarov and Clematide (2018) show gains from using the copy edit and address the MLE training biases with MRT.

The limitations of teacher forcing have recently been the focus of intense research (Edunov et al., 2017; Wiseman and Rush, 2016; Shen et al., 2016), including the adaptation of RL methods (Ranzato et al., 2016; Bahdanau et al., 2017). Most of these approaches require warm start with an MLE model and themselves introduce discrepancies between training with sampling and search-based decoding. Such biases do not arise from IL, which has recently been proposed for seq2seq models (Leblond et al., 2018). Our approach, related to Leblond et al. (2018), additionally addresses the problem of spurious ambiguity, which is not present in seq2seq models.

6 Conclusion

We show that training to imitate a simple expert policy results in an effective neural transition-based model for morphological string transduction. The fully end-to-end approach addresses various shortcomings of previous training regimes (the need for an external character aligner, warm-start initialization, and MLE training biases), and leads to strong empirical results. We make our code and predictions publicly available.[4]

Acknowledgments

We thank Mathias Müller for help with the manuscript, Toms Bergmanis for sharing with us the results of his system, and the reviewers for interesting and helpful comments. We also thank the anonymous COLING reviewer who suggested that we should look at spurious ambiguity. Abstract

The Paradigm Cell Filling Problem in morphology asks to complete word inflection tables from partial ones. We implement novel neural models for this task, evaluating them on 18 data sets in 8 languages, showing performance that is comparable with previous work with far less training data. We also publish a new dataset for this task and code implementing the system described in this paper.[1]

1 Introduction

An important learning question in morphology—both for NLP and models of language acquisition—is the so-called Paradigm Cell Filling Problem (PCFP). So dubbed by Ackerman et al. (2009), this problem asks how it is that speakers of a language can reliably produce inflectional forms of most lexemes without ever witnessing those forms before. For example, a Finnish noun or adjective can be inflected in 2,263 ways if one includes case forms, number, and clitics (Karlsson, 2008). However, it is unlikely that a Finnish speaker would have heard all forms for even a single, highly frequent lexical item. It is also unlikely that all 2,263 forms are found in the aggregate of all the witnessed inflected forms over different lexemes and speakers must be able to assess the felicity of, and possibly produce such inflectional combinations they have never witnessed for any noun or adjective. Figure 1 illustrates the PCFP.

This paper investigates PCFP in three different settings: (1) when we know $n > 1$ randomly selected forms in each of a number of inflection tables, (2) when we know a set of frequent word forms in each table (this most closely resembles an L1 language learning setting), and finally (3) when we know exactly $n = 1$ word form from each table.

We treat settings (1) and (2) as traditional morphological reinflection tasks (Cotterell et al., 2016) as explained in Section 2. In contrast, setting (3) is substantially more challenging because it cannot be handled using a traditional reinflection approach. To overcome this problem, we utilize an adaptive dropout mechanism which will be discussed in Section 2. This allows us to train the reinflection system in a manner reminiscent of denoising autoencoders (Vincent et al., 2008).

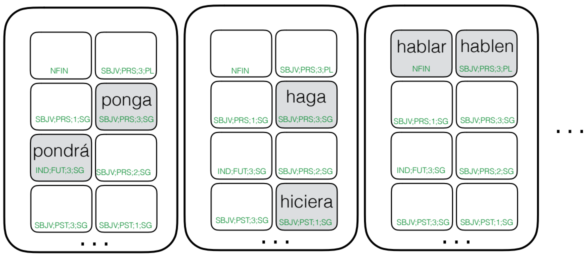

Figure 1: Illustration of the PCFP using a fraction of Spanish verb tables: given such partially filled paradigms, the task is to fill in all the missing forms.

Related Work Neural models have recently been shown to be highly competitive in many different tasks of learning supervised morphological inflection (Faruqui et al., 2016; Kann and Schütze, 2016; Makarov et al., 2017; Aharoni and Goldberg, 2017) and derivation (Cotterell et al., 2017b). Most current architectures are based on encoder-decoder models (Sutskever et al., 2014), and usually contain an attention component (Bahdanau et al., 2015).

The SIGMORPHON (Cotterell et al., 2016) and CoNLL-SIGMORPHON (Cotterell et al., 2017a, 2018) shared tasks in recent years have explored morphological inflection but not explicitly the PCFP. In the 2017 task, participants were given full paradigms—i.e. a listing of all forms—of

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2883–2889
Brussels, Belgium, October 31 - November 4, 2018.

lexemes during training after which they were given incomplete paradigms which had to be completed at test time. This is a slightly unrealistic setting in an L1-style learning scenario (Blevins and Blevins, 2009) where arguably very few full paradigms are ever witnessed and where generalization has to proceed on a number of very gappy paradigms. Of course, such gaps form a distribution where frequently used lexemes have fewer gaps than infrequent ones, which we will attempt to model in this work.

Silfverberg et al. (2018) evaluate an extension to a linguistically informed symbolic paradigm model based on stem extraction from the longest common subsequence (LCS) shared among related forms (Ahlberg et al., 2014, 2015). While the original LCS paradigm extraction method was intended to learn from complete inflection tables (Hulden, 2014), Silfverberg et al. (2018) present modifications to allow learning from incomplete paradigms as well, and apply it to the PCFP. Comparing against their results, shows that our neural model consistently outperforms such a subsequence-based learning model.

Kann et al. (2017) report results on so-called multi-source reinflection in which several input forms are used to generate one output form. This task is related to the PCFP; however, Kann et al. (2017) use full inflection tables for training. Moreover, their approach is applicable for PCFP only when 3 or more forms are given in the input tables. Since this mostly excludes our experimental settings, we do not compare to their system. Malouf (2016, 2017) documents an experiment with a generator LSTM in completing inflection tables in up to seven languages with either 10% or 40% of table entries missing. Our work differs from this in that Malouf gives as input a two-hot encoding of both the lexeme and the desired slot during training and testing for which an inflection table is to be completed, which means the system cannot complete paradigms which it has not seen examples of in the training data. By contrast, our system has no notion of lexeme and we simply work from the symbol strings which are collections of inflected forms of a lexeme given in the test data which may in principle be completely disjoint from training data lexemes. We use the Malouf system as a baseline to compare against.

2 Encoder-Decoder Models for PCFP

We explore two different models for paradigm filling. The first model is applicable when $n > 1$ forms are given in each inflection table. When exactly one ($n = 1$) form is given, we use another model.

Case n>1 When more than one form is given in training tables, PCFP can be treated as a morphological reinflection task (Cotterell et al., 2016), where the aim is to translate inflected word forms and their tags into target word forms. For example, a model would translate **tried+PAST** into the present participle (**PRES,PCPLE**) form **trying**. We adopt a common approach employed by Kann and Schütze (2016) and many others: we build a model which translates an input word form, its tag and a target tag, for example **tried+PAST+PRES,PCPLE**, into the target word form **trying**.

Our model closely follows the formulation of the encoder-decoder LSTM model for morphological reinflection proposed by Kann and Schütze (2016). We use a 1-layer bidirectional LSTM encoder for encoding the input word form into a sequence of state vectors and a 1-layer LSTM decoder with an attention mechanism over encoder states for generating the output word form.

We form training pairs by using the given forms in each table, i.e. take the cross-product of the given forms and learn to reinflect each given form in a table to another given form in the same table as demonstrated in Figure 2.[2] During test time, we predict forms for missing slots based on each of the given forms in the table and take a majority vote of the results.[3]

Case n=1 When only one form is given in each inflection table, we cannot train the model as a traditional reinflection model. The best we can do is to train a model to reinflect forms into the same form **walked+PAST+PAST** ↦ **walked** and then try to apply this model for reinflection to fill in missing forms **walked+PAST+PRES,PCPLE** ↦ **walking**. According to preliminary experiments, this however leads to massive over-fitting and the model simply learns to only copy input forms.

---

[2] Note that the CoNLL-SIGMORPHON data provides a 'citation form' that identifies each table; we do not use this form and the model has no knowledge of it.

[3] When only two forms are given in the partial inflection table, we randomly choose one of the resulting output forms since the vote is always tied.

Figure 2: Partial inflection table for the Latvian noun **augana** 'growth'. From a partial inflection table with two given forms, we get two training examples. With n given forms in a table, we hence produce $n(n-1)$ training examples.

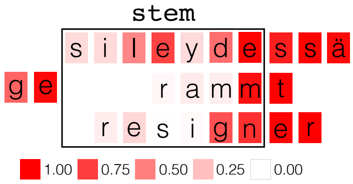

Figure 3: Language model confidences for a Finnish noun (singular inessive of **sileys** 'smoothness'), a German past participle (of **rammen** 'to ram') and a French verb (infinitive form of **resigner** 'to resign'). The figure demonstrates that confidence is higher in the inflectional affixes than in the stem in general. It is also high at the stem-affix boundary.

The idea for our approach in case $n = 1$ is to first learn to segment word forms into a stem and an affix, for example **walk+ed**. We then hide the affix in the input form and learn to inflect. In other words, we map the word form **walked** into **walk$$** and then learn a mapping **walk$$+PAST** $\mapsto$ **walked**. This model suffers less from overfitting and we can use it to find missing forms in partial inflection tables.

Since we do not have access to segmented training data, we cannot directly train a segmentation model. Instead, we use the forms in the training data to train an LSTM language model conditioned on morphological tags. We then use the language model for identifying which characters belong to stems and which characters belong to affixes.

As shown in Figure 3, the language model in general gives higher confidence for predictions of characters in the affix than in the word stem. Nevertheless, it only gives a probabilistic segmentation into a stem and affix(es). Therefore, we do not perform a deterministic segmentation. Instead we use the language model to guide a character dropout mechanism in our word inflection model. When the language model is very confident, as in the case of affix characters, we frequently drop characters. In contrast, when the language model is less confident, as in the case of stem characters, we typically keep the character. Apart from this adaptive dropout applied during training, our inflection system in case $n = 1$ is exactly the same as in case $n > 1$.

Table 1: We reproduce experiments in Malouf (2017) using our own implementation of the model. In contrast to Malouf (2017), who used cross-validation, we train one system for each language. Therefore, we only report standard deviation for the results in Column 2.

More precisely, given an input word form, which is a sequence of characters $x = x_1, ..., x_T$, the LSTM language model emits a probability $p(x_{t+1}, \mathbf{h_t}, \mathrm{E}_{x_t}, \mathrm{E}_y)$ for the next character x_{t+1} based on the entire previous input sequence $x_1, ..., x_t$. Here $\mathbf{h_t}$ is the hidden state vector of the language model at position t, E a joint tag and character embedding and y the morphological tag of the input word form. The embedding vector E_y is in fact a sum of sub-tag embeddings. For example, $\mathrm{E}_{\mathrm{PAST+PCPLE}}$ denotes $\mathrm{E}_{\mathrm{PAST}} + \mathrm{E}_{\mathrm{PCPLE}}$. This allows us to handle combinations of sub-tags which we have not seen in the training data. Guided by the language model, we replace input characters x_{t+1} during training of the reinflection system with a dropout character $ with probability equal to language model confidence $p(x_{t+1}, \mathbf{h_t}, \mathrm{E}_{x_t}, \mathrm{E}_y)$.[4]

Baseline Model As a baseline model, we use the neural system presented by Malouf (2016, 2017) for solving PCFP. It is an LSTM generator which is conditioned on the table number of the partial inflection tables and the morphological tag index. The model is trained to generate training word forms in inflection tables. During testing, it can then generate missing forms by conditioning on morphological tags for the missing forms.

In order to assure fair comparison, we perform the paradigm completion experiment described in Malouf (2017), where 90% of the word forms in the data set is used for training and the remaining 10% for testing. [5] As the results in Table 1 show,

---

[4] In practice, we pad input forms with end-of-sequence characters in order to be able to drop x_1 if needed.

[5] We perform the the experiments on the original data sets,

our results very closely replicate those reported by Malouf (2017).

Implementation details We use 1-layer bidirectional LSTM encoders, decoders and generators with embeddings and hidden states of size 100. We train the language model for case $n > 1$ for 20 epochs and all other models for 60 epochs without batching. We train 10 models for every language and part-of-speech and apply majority voting to get the final output forms. All models were implemented using DyNet (Neubig et al., 2017).

3 Data

We use UniMorph morphological paradigm data in our experiments (Kirov et al., 2018). Unimorph data sets are crowd-sourced collections of morphological inflection tables based on Wiktionary. We conduct experiments on noun and verb paradigms from eight languages.[6] Not all languages have 1,000 noun and verb tables. Hence, our selection is not complete as seen in Table 3.

We conduct experiments on two different sets of tables: (1) we randomly sample 1,000 tables for each language and part-of-speech, and (2) we select Unimorph tables including some of the 10,000 most common word forms according to Wikipedia frequency. The Wikipedia word frequencies are based on plain Wikipedia text dumps from the Polyglot project (Al-Rfou et al., 2013). Georgian and Latin did not have a Polyglot Wikipedia so we excluded those. Moreover, we excluded Latvian verbs because there was very little overlap between the most frequent Wikipedia word forms and Unimorph table entries (< 200 forms occurred in both). Details for both types of data sets are given in Tables 3 and 2.

	# Tables	Table Size
Finnish Nouns	1,335	27.3
Finnish Verbs	513	38.9

Table 4: Overall results for filling in missing forms when the 10,000 most frequent forms are given in the inflection tables. We give the 0.99 confidence intervals as given by a one-sided t-test. Figures where one system significantly outperforms the other one are in boldface.

4 Experiments and Results

We perform two experiments. In the first one, we take the set of 1,000 randomly sampled inflection tables for each language and part-of-speech and then randomly select n=1, 2 or 3 training forms from each table. We then train a reinflection system on these forms and use the resulting system to predict the missing forms. We report accuracy on correctly predicted missing forms and on reconstructing the entire paradigm correctly. In our second experiment, we consider Unimorph tables which contain entries from a list of 10,000 most common word tokens compiled using a Wikipedia dump of the language as explained above. We take the forms in the top-10,000 list as given and train a model which is used to reconstruct the remaining forms in each table. We train an identical model as in the case $n > 1$ on tables with more than one given form. As in the first task, we evaluate with regard to accuracy for reconstructed forms and full tables. Results are presented in Tables 4 and 5, and Figure 4.

5 Discussion and Conclusions

Table 4 shows results for completing tables for common lexemes. Our system significantly out-

Table 5: Accuracy for filling in missing forms when n=1,2 or 3 forms are given in the inflection table (accuracy for complete paradigms in parentheses). We give the 0.99 confidence intervals as given by a one-sided t-test. Figures where one system significantly outperforms the other one are in boldface.

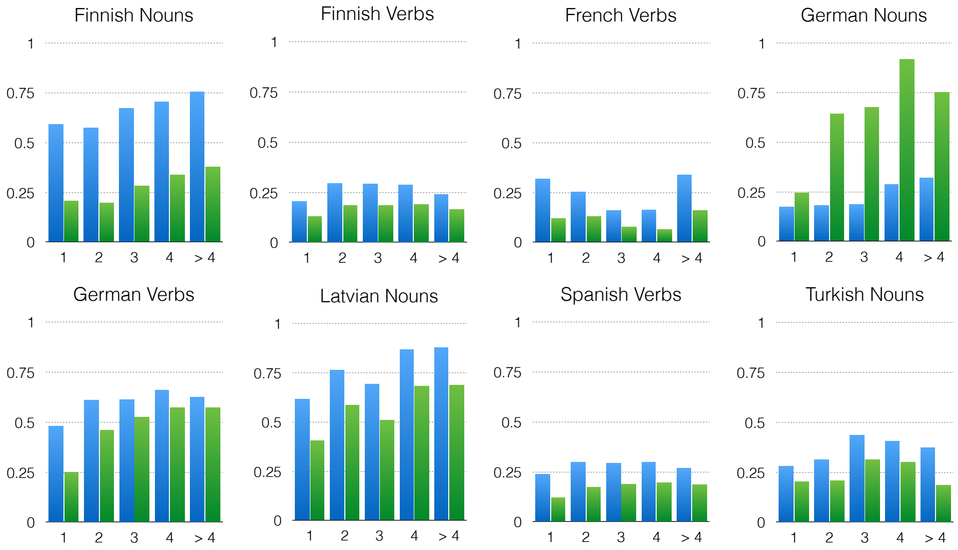

Figure 4: Detailed results for filling in missing forms when the 10,000 most frequent forms are given in the inflection tables. The blue bars (on the left) denote accuracy for our system and green bars (on the right) accuracy for the baseline system. The graphs show accuracy separately for tables where 1, 2, 3, 4, and $>$ 4 forms are given.

performs the baseline on all other datasets apart from German nouns. We believe that the reason for the German outlier is the high degree of syncretism in German noun tables. To see why syncretism is harmful, consider the German noun **Gräben**. Its paradigm consists of eight forms but four of those are identical: **Gräben**. Only this form is observed among the top 10,000 forms in the German Wikipedia. Following Section 2, this gives rise to 12 training examples where both the input and output form are **Gräben**. This strongly biases the system to copying input forms into the output. However, this will never give the correct output because, by design, missing forms cannot be **Gräben**.[7] This can be seen as a problem with our datasets rather than the model itself. Consequently, an important future work in addressing the PCFP from an acquisition perspective is to create realistic and accurate data sets that model learner exposure both in word types and frequencies to enable assessment of the true difficulty of the PCFP.

There is a notable transition from witnessing one form in each inflection table to witnessing two forms. With only two forms given, we already approach accuracies reported in earlier work (Malouf, 2016, 2017) that used almost complete tables to train—only 10% of the forms were missing. Additionally, our encoder-decoder model strongly outperforms that generator model designed for the same task with the same amount of training data on nearly all of our datasets.

Abstract

Deep neural networks (DNNs) are vulnerable to adversarial examples, perturbations to correctly classified examples which can cause the model to misclassify. In the image domain, these perturbations are often virtually indistinguishable to human perception, causing humans and state-of-the-art models to disagree. However, in the natural language domain, small perturbations are clearly perceptible, and the replacement of a single word can drastically alter the semantics of the document. Given these challenges, we use a black-box population-based optimization algorithm to generate semantically and syntactically similar adversarial examples that fool well-trained sentiment analysis and textual entailment models with success rates of 97% and 70%, respectively. We additionally demonstrate that 92.3% of the successful sentiment analysis adversarial examples are classified to their original label by 20 human annotators, and that the examples are perceptibly quite similar. Finally, we discuss an attempt to use adversarial training as a defense, but fail to yield improvement, demonstrating the strength and diversity of our adversarial examples. We hope our findings encourage researchers to pursue improving the robustness of DNNs in the natural language domain.

1 Introduction

Recent research has found that deep neural networks (DNNs) are vulnerable to *adversarial examples* (Goodfellow et al., 2015; Szegedy et al., 2014). The existence of adversarial examples has been shown in image classification (Szegedy et al., 2014) and speech recognition (Carlini and Wagner, 2018). In this work, we demonstrate that adversarial examples can be constructed in the context of natural language. Using a black-box population-based optimization algorithm, we successfully generate both semantically and syntactically similar adversarial examples against models trained on both the IMDB (Maas et al., 2011) sentiment analysis task and the Stanford Natural Language Inference (SNLI) (Bowman et al., 2015) textual entailment task. In addition, we validate that the examples are both correctly classified by human evaluators and similar to the original via a human study. Finally, we attempt to defend against said adversarial attack using adversarial training, but fail to yield any robustness, demonstrating the strength and diversity of the generated adversarial examples.

Our results show that by minimizing the semantic and syntactic dissimilarity, an attacker can perturb examples such that humans correctly classify, but high-performing models misclassify. We are open-sourcing our attack[1] to encourage research in training DNNs robust to adversarial attacks in the natural language domain.

2 Natural Language Adversarial Examples

Adversarial examples have been explored primarily in the image recognition domain. Examples have been generated through solving an optimization problem, attempting to induce misclassification while minimizing the perceptual distortion (Szegedy et al., 2014; Carlini and Wagner, 2017; Chen et al., 2018; Sharma and Chen, 2018). Due to the computational cost of such approaches, fast methods were introduced which, either in one-step or iteratively, shift all pixels simultaneously until a distortion constraint is reached (Goodfellow et al., 2015; Kurakin et al., 2017; Madry et al., 2018). Nearly all popular methods are gradient-based.

Brussels, Belgium, October 31 - November 4, 2018.

Such methods, however, rely on the fact that adding small perturbations to many pixels in the image will not have a noticeable effect on a human viewer. This approach obviously does not transfer to the natural language domain, as all changes are perceptible. Furthermore, unlike continuous image pixel values, words in a sentence are discrete tokens. Therefore, it is not possible to compute the gradient of the network loss function with respect to the input words. A straightforward workaround is to project input sentences into a continuous space (e.g. word embeddings) and consider this as the model input. However, this approach also fails because it still assumes that replacing *every* word with words nearby in the embedding space will not be noticeable. Replacing words without accounting for syntactic coherence will certainly lead to improperly constructed sentences which will look odd to the reader.

Relative to the image domain, little work has been pursued for generating natural language adversarial examples. Given the difficulty in generating semantics-preserving perturbations, distracting sentences have been added to the input document in order to induce misclassification (Jia and Liang, 2017). In our work, we attempt to generate semantically and syntactically similar adversarial examples, via word replacements, resolving the aforementioned issues. Minimizing the number of word replacements necessary to induce misclassification has been studied in previous work (Papernot et al., 2016), however without consideration given to semantics or syntactics, yielding incoherent generated examples. In recent work, there have been a few attempts at generating adversarial examples for language tasks by using back-translation (Iyyer et al., 2018), exploiting machine-generated rules (Ribeiro et al., 2018), and searching in underlying semantic space (Zhao et al., 2018). In addition, while preparing our submission, we became aware of recent work which target a similar contribution (Kuleshov et al., 2018; Ebrahimi et al., 2018). We treat these contributions as parallel work.

3 Attack Design

3.1 Threat model

We assume the attacker has black-box access to the target model; the attacker is not aware of the model architecture, parameters, or training data, and is only capable of querying the target model with supplied inputs and obtaining the output predictions and their confidence scores. This setting has been extensively studied in the image domain (Papernot et al., 2017; Chen et al., 2017a; Alzantot et al., 2018), but has yet to be explored in the context of natural language.

3.2 Algorithm

To avoid the limitations of gradient-based attack methods, we design an algorithm for constructing adversarial examples with the following goals in mind. We aim to minimize the number of modified words between the original and adversarial examples, but only perform modifications which retain semantic similarity with the original and syntactic coherence. To achieve these goals, instead of relying on gradient-based optimization, we developed an attack algorithm that exploits population-based gradient-free optimization via genetic algorithms.

An added benefit of using gradient-free optimization is enabling use in the black-box case; gradient-reliant algorithms are inapplicable in this case, as they are dependent on the model being differentiable and the internals being accessible (Papernot et al., 2016; Ebrahimi et al., 2018).

Genetic algorithms are inspired by the process of natural selection, iteratively evolving a population of candidate solutions towards better solutions. The population of each iteration is a called a *generation*. In each generation, the quality of population members is evaluated using a *fitness* function. “Fitter” solutions are more likely to be selected for breeding the next generation. The next generation is generated through a combination of *crossover* and *mutation*. Crossover is the process of taking more than one parent solution and producing a child solution from them; it is analogous to reproduction and biological crossover. Mutation is done in order to increase the diversity of population members and provide better exploration of the search space. Genetic algorithms are known to perform well in solving combinatorial optimization problems (Anderson and Ferris, 1994; Mühlenbein, 1989), and due to employing a population of candidate solutions, these algorithms can find successful adversarial examples with fewer modifications.

`Perturb` Subroutine: In order to explain our algorithm, we first introduce the subroutine `Perturb`. This subroutine accepts an input sentence $\mathbf{x}_{cur}$ which can be either a modified sentence or the same as $\mathbf{x}_{orig}$. It randomly selects a word w

in the sentence $\mathbf{x}_{cur}$ and then selects a suitable replacement word that has similar semantic meaning, fits within the surrounding context, and increases the $target$ label prediction score.

In order to select the best replacement word, `Perturb` applies the following steps:

- Computes the N nearest neighbors of the selected word according to the distance in the GloVe embedding space (Pennington et al., 2014). We used euclidean distance, as we did not see noticeable improvement using cosine. We filter out candidates with distance to the selected word greater than δ. We use the counter-fitting method presented in (Mrkšić et al., 2016) to post-process the adversary's GloVe vectors to ensure that the nearest neighbors are synonyms. The resulting embedding is independent of the embeddings used by victim models.
- Second, we use the Google 1 billion words language model (Chelba et al., 2013) to filter out words that do not fit within the context surrounding the word w in $\mathbf{x}_{cur}$. We do so by ranking the candidate words based on their language model scores when fit within the replacement context, and keeping only the top K words with the highest scores.
- From the remaining set of words, we pick the one that will maximize the target label prediction probability when it replaces the word w in $\mathbf{x}_{cur}$.
- Finally, the selected word is inserted in place of w, and `Perturb` returns the resulting sentence.

The selection of which word to replace in the input sentence is done by random sampling with probabilities proportional to the number of neighbors each word has within Euclidean distance δ in the counter-fitted embedding space, encouraging the solution set to be large enough for the algorithm to make appropriate modifications. We exclude common articles and prepositions (e.g. a, to) from being selected for replacement.

Optimization Procedure: The optimization algorithm can be seen in Algorithm 1. The algorithm starts by creating the initial generation $\mathcal{P}^0$ of size S by calling the `Perturb` subroutine S times to create a set of distinct modifications to the original sentence. Then, the fitness of each population member in the current generation is computed as the target label prediction probability, found by querying the victim model function f. If a population member's predicted label is equal to the target label, the optimization is complete. Otherwise, pairs of population members from the current generation are randomly sampled with probability proportional to their fitness values. A new *child* sentence is then synthesized from a pair of parent sentences by independently sampling from the two using a uniform distribution. Finally, the `Perturb` subroutine is applied to the resulting children.

Algorithm 1 Finding adversarial examples

```
for $i = 1, ..., S$ in population do
    $\mathcal{P}_i^0 \leftarrow \texttt{Perturb}(\mathbf{x}_{orig}, target)$
for $g = 1, 2...G$ generations do
    for $i = 1, ..., S$ in population do
        $F_i^{g-1} = f(\mathcal{P}_i^{g-1})_{target}$
    $\mathbf{x}_{adv} = \mathcal{P}^{g-1}_{\arg\max_j F_j^{g-1}}$
    if $\arg\max_c f(\mathbf{x}_{adv})_c == t$ then
        return $\mathbf{x}_{adv}$ $\triangleright$ {Found successful attack}
    else
        $\mathcal{P}_1^g = \{\mathbf{x}_{adv}\}$
        $p = Normalize(F^{g-1})$
        for $i = 2, ..., S$ in population do
            Sample $parent_1$ from $\mathcal{P}^{g-1}$ with probs $p$
            Sample $parent_2$ from $\mathcal{P}^{g-1}$ with probs $p$
            $child = Crossover(parent_1, parent_2)$
            $child_{mut} = \texttt{Perturb}(child, target)$
            $\mathcal{P}_i^g = \{child_{mut}\}$
```

4 Experiments

To evaluate our attack method, we trained models for the sentiment analysis and textual entailment classification tasks. For both models, each word in the input sentence is first projected into a fixed 300-dimensional vector space using GloVe (Pennington et al., 2014). Each of the models used are based on popular open-source benchmarks, and can be found in the following repositories[2][3]. Model descriptions are given below.

Sentiment Analysis: We trained a sentiment analysis model using the IMDB dataset of movie reviews (Maas et al., 2011). The IMDB dataset consists of 25,000 training examples and 25,000 test examples. The LSTM model is composed of 128 units, and the outputs across all time steps are

Original Text Prediction = **Negative**. (Confidence = 78.0%)
*This movie had **terrible** acting, **terrible** plot, and **terrible** choice of actors. (Leslie Nielsen ...come on!!!) the one part I **considered** slightly funny was the battling FBI/CIA agents, but because the audience was mainly **kids** they didn't understand that theme.*

Adversarial Text Prediction = **Positive**. (Confidence = 59.8%)
*This movie had **horrific** acting, **horrific** plot, and **horrifying** choice of actors. (Leslie Nielsen ...come on!!!) the one part I **regarded** slightly funny was the battling FBI/CIA agents, but because the audience was mainly **youngsters** they didn't understand that theme.*

Table 1: Example of attack results for the sentiment analysis task. Modified words are highlighted in green and red for the original and adversarial texts, respectively.

Original Text Prediction: **Entailment** (Confidence = 86%)
Premise: *A runner wearing purple strives for the finish line.* **Hypothesis:** *A **runner** wants to head for the finish line.*

Adversarial Text Prediction: **Contradiction** (Confidence = 43%)
Premise: *A runner wearing purple strives for the finish line.* **Hypothesis:** *A **racer** wants to head for the finish line.*

Table 2: Example of attack results for the textual entailment task. Modified words are highlighted in green and red for the original and adversarial texts, respectively.

	Sentiment Analysis		Textual Entailment	
	% success	% modified	% success	% modified
`Perturb` baseline	52%	19%	–	–
Genetic attack	97%	14.7%	70%	23%

Table 3: Comparison between the attack success rate and mean percentage of modifications required by the genetic attack and perturb baseline for the two tasks.

averaged and fed to the output layer. The test accuracy of the model is 90%, which is relatively close to the state-of-the-art results on this dataset.

Textual Entailment: We trained a textual entailment model using the Stanford Natural Language Inference (SNLI) corpus (Bowman et al., 2015). The model passes the input through a ReLU "translation" layer (Bowman et al., 2015), which encodes the premise and hypothesis sentences by performing a summation over the word embeddings, concatenates the two sentence embeddings, and finally passes the output through 3 600-dimensional ReLU layers before feeding it to a 3-way softmax. The model predicts whether the premise sentence entails, contradicts or is neutral to the hypothesis sentence. The test accuracy of the model is 83% which is also relatively close to the state-of-the-art (Chen et al., 2017b).

4.1 Attack Evaluation Results

We randomly sampled 1000, and 500 *correctly classified* examples from the test sets of the two tasks to evaluate our algorithm. Correctly classified examples were chosen to limit the accuracy levels of the victim models from confounding our results. For the sentiment analysis task, the attacker aims to divert the prediction result from positive to negative, and vice versa. For the textual entailment task, the attacker is only allowed to modify the hypothesis, and aims to divert the prediction result from 'entailment' to 'contradiction', and vice versa. We limit the attacker to maximum $G = 20$ iterations, and fix the hyperparameter values to $S = 60$, $N = 8$, $K = 4$, and $\delta = 0.5$. We also fixed the maximum percentage of allowed changes to the document to be 20% and 25% for the two tasks, respectively. If increased, the success rate would increase but the mean quality would decrease. If the attack does not succeed within the iterations limit or exceeds the specified threshold, it is counted as a failure.

Sample outputs produced by our attack are shown in Tables 1 and 2. Additional outputs can be found in the supplementary material. Table 3 shows the attack success rate and mean percentage of modified words on each task. We compare to the `Perturb` baseline, which greedily applies the `Perturb` subroutine, to validate the use of population-based optimization. As can be seen from our results, we are able to achieve high success rate with a limited number of modifications on both tasks. In addition, the genetic algorithm significantly outperformed the `Perturb` baseline in both success rate and percentage of words modified, demonstrating the additional benefit yielded by using population-based optimization. Testing using a single TitanX GPU, for sentiment analysis and textual entailment, we measured average runtimes on success to be 43.5 and 5 seconds per example, respectively. The high success rate and reasonable runtimes demonstrate the practicality of our approach, even when scaling to long sentences, such as those found in the IMDB dataset.

Speaking of which, our success rate on textual entailment is lower due to the large disparity in sentence length. On average, hypothesis sentences in the SNLI corpus are 9 words long, which is very short compared to IMDB (229 words, limited to 100 for experiments). With sentences that short, applying successful perturbations becomes much harder, however we were still able to achieve a success rate of 70%. For the same reason, we didn't apply the `Perturb` baseline on the textual entailment task, as the `Perturb` baseline fails to achieve any success under the limits of the maximum allowed changes constraint.

4.2 User study

We performed a user study on the sentiment analysis task with 20 volunteers to evaluate how perceptible our adversarial perturbations are. Note that the number of participating volunteers is significantly larger than used in previous studies (Jia and Liang, 2017; Ebrahimi et al., 2018). The user study was composed of two parts. First, we presented 100 adversarial examples to the participants and asked them to label the sentiment of the text (i.e., positive or negative.) 92.3% of the responses matched the original text sentiment, indicating that our modification did not significantly affect human judgment on the text sentiment. Second, we prepared 100 questions, each question includes the original example and the corresponding adversarial example in a pair. Participants were asked to judge the similarity of each pair on a scale from 1 (very similar) to 4 (very different). The average rating is 2.23 ± 0.25, which shows the perceived difference is also small.

4.3 Adversarial Training

The results demonstrated in section 4.1 raise the following question: How can we defend against these attacks? We performed a preliminary experiment to see if adversarial training (Madry et al., 2018), the only effective defense in the image domain, can be used to lower the attack success rate. We generated 1000 adversarial examples on the cleanly trained sentiment analysis model using the IMDB training set, appended them to the existing training set, and used the updated dataset to adversarially train a model from scratch. We found that adversarial training provided no additional robustness benefit in our experiments using the test set, despite the fact that the model achieves near 100% accuracy classifying adversarial examples included in the training set. These results demonstrate the diversity in the perturbations generated by our attack algorithm, and illustrates the difficulty in defending against adversarial attacks. We hope these results inspire further work in increasing the robustness of natural language models.

5 Conclusion

We demonstrate that despite the difficulties in generating imperceptible adversarial examples in the natural language domain, semantically and syntactically similar adversarial examples can be crafted using a black-box population-based optimization algorithm, yielding success on both the sentiment analysis and textual entailment tasks. Our human study validated that the generated examples were indeed adversarial and perceptibly quite similar. We hope our work encourages researchers to pursue improving the robustness of DNNs in the natural language domain.

Abstract

Multi-head attention is appealing for the ability to jointly attend to information from different representation subspaces at different positions. In this work, we introduce a disagreement regularization to explicitly encourage the diversity among multiple attention heads. Specifically, we propose three types of disagreement regularization, which respectively encourage the subspace, the attended positions, and the output representation associated with each attention head to be different from other heads. Experimental results on widely-used WMT14 English⇒German and WMT17 Chinese⇒English translation tasks demonstrate the effectiveness and universality of the proposed approach.

1 Introduction

Attention model is now a standard component of the deep learning networks, contributing to impressive results in neural machine translation (Bahdanau et al., 2015; Luong et al., 2015), image captioning (Xu et al., 2015), speech recognition (Chorowski et al., 2015), among many other applications. Recently, Vaswani et al. (2017) introduced a multi-head attention mechanism to capture different context with multiple individual attention functions.

One strong point of multi-head attention is the ability to jointly attend to information from *different* representation subspaces at *different* positions. However, there is no mechanism to guarantee that different attention heads indeed capture distinct features. In response to this problem, we introduce a disagreement regularization term to explicitly encourage the diversity among multiple attention heads. The disagreement regularization serves as an auxiliary objective to guide the training of the related attention component.

Specifically, we propose three types of disagreement regularization, which are applied to the three key components that refer to the calculation of feature vector using multi-head attention. Two regularization terms are respectively to maximize cosine distances of the input subspaces and output representations, while the last one is to disperse the positions attended by multiple heads with element-wise multiplication of the corresponding attention matrices. The three regularization terms can be either used individually or in combination.

We validate our approach on top of advanced TRANSFORMER model (Vaswani et al., 2017) for both English⇒German and Chinese⇒English translation tasks. Experimental results show that our approach consistently improves translation performance across language pairs. One encouraging finding is that TRANSFORMER-BASE with disagreement regularization achieves comparable performance with TRANSFORMER-BIG, while the training speed is nearly twice faster.

2 Background: Multi-Head Attention

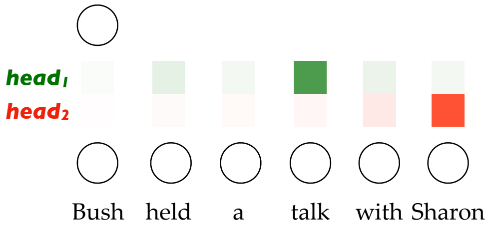

Figure 1: Illustration of the multi-head attention, which jointly attends to different representation subspaces (colored boxes) at different positions (darker color denotes higher attention probability).

Attention mechanism aims at modeling the strength of relevance between representation pairs,

Brussels, Belgium, October 31 - November 4, 2018.

such that a representation is allowed to build a direct relation with another representation. Instead of performing a single attention function, Vaswani et al. (2017) found it is beneficial to capture different context with multiple individual attention functions. Figure 1 shows an example of a two-head attention model. For the query word "Bush", green and red head pay attention to different positions of "talk" and "Sharon" respectively.

Attention function softly maps a sequence of query $Q = \{Q_1, \dots, Q_N\}$ and a set of key-value pairs $\{K, V\} = \{(K_1, V_1), \dots, (K_M, V_M)\}$ to outputs. More specifically, multi-head attention model first transforms Q, K, and V into H subspaces, with different, learnable linear projections, namely:

$$Q^h, K^h, V^h = QW_h^Q, KW_h^K, VW_h^V,$$

where $\{Q^h, K^h, V^h\}$ are respective the query, key, and value representations of the h-th head. $\{W_h^Q, W_h^K, W_h^V\} \in \mathbb{R}^{d \times d_k}$ denote parameter matrices, d and d_k represent the dimensionality of the model and its subspace. Furthermore, H attention functions are applied in parallel to produce the output states $\{O^1, \dots, O^H\}$, among them:

$$O^h = A^h V^h \;\; with \;\; A^h = softmax(\frac{Q^h {K^h}^T}{\sqrt{d_k}}).$$

Here A^h is the attention distribution produced by the h-th attention head. Finally, the output states are concatenated to produce the final state.

3 Approach

Multi-head attention allows the model to jointly attend to information from *different* representation subspaces at *different* positions. To further guarantee the diversity, we enlarge the distances among multiple attention heads with disagreement regularization (Section 3.1). Specifically, we propose three types of disagreement regularization to encourage each head vector O^i to be different from other heads (Section 3.2).

3.1 Framework

In this work, we take the machine translation tasks as application. Given a source sentence $\mathbf{x}$ and its translation $\mathbf{y}$, a neural machine translation model is trained to maximize the conditional translation probability over a parallel training corpus.

We introduce an auxiliary regularization term in order to encourage the diversity among multiple attention heads. Formally, the training objective is revised as:

$$J(\theta) = \arg\max_{\theta} \{ \underbrace{L(\mathbf{y}|\mathbf{x};\theta)}_{likelihood} + \lambda * \underbrace{D(\mathbf{a}|\mathbf{x},\mathbf{y};\theta)}_{disagreement} \},$$

where $\mathbf{a}$ is the referred attention matrices, λ is a hyper-parameter and is empirically set to 1.0 in this paper. The auxiliary regularization term $D(\cdot)$ guides the related attention component to capture different features from the corresponding projected subspaces.

Note that the introduced regularization term works like $L1$ and $L2$ terms, which do not introduce any new parameters and only influence the training of the standard model parameters.

3.2 Disagreement Regularization

Three types of regularization term, which are applied to three parts of the original multi-head attention, are introduced in this section.

Disagreement on Subspaces (Sub.) This disagreement is designed to maximize the cosine distance between the projected values. Specifically, we first calculate the cosine similarity $\cos(\cdot)$ between the vector pair V^i and V^j in different value subspaces, through the dot product of the normalized vectors[1], which measures the cosine of the angle between V^i and V^j. Thus, the cosine distance is defined as negative similarity, i.e, $-\cos(\cdot)$. Our training objective is to enlarge the average cosine distance among all head pairs. The regularization term is formally expressed as:

$$D_{subpace} = -\frac{1}{H^2} \sum_{i=1}^{H} \sum_{j=1}^{H} \frac{V^i \cdot V^j}{\|V^i\| \|V^j\|}. \qquad (1)$$

Disagreement on Attended Positions (Pos.) Another strategy is to disperse the attended positions predicted by multiple heads. Inspired by the agreement regularization (Liang et al., 2006; Cheng et al., 2016) which encourages multiple alignments to be similar, in this work, we deploy a variant of the original term by introducing an alignment disagreement regularization. Formally, we employ the sum of element-wise multiplication of corresponding matrix cells[2], to measure the

---

[1] We did not employ the Euler Distance between vectors since we do not care the absolute value in each vector.

[2] We also used the squared element-wise subtraction of two matrices in our preliminary experiments, and found it underperforms its multiplication counterpart, which is consistent with the results in (Cheng et al., 2016).

similarity between two matrices A^i and A^j of two heads:

$$D_{position} = -\frac{1}{H^2}\sum_{i=1}^{H}\sum_{j=1}^{H}|A^i \odot A^j|. \quad (2)$$

Disagreement on Outputs (Out.) This disagreement directly applies regularization on the outputs of each attention head, by maximizing the difference among them. Similar to the *subspace* strategy, we employ negative cosine similarity to measure the distance:

$$D_{output} = -\frac{1}{H^2}\sum_{i=1}^{H}\sum_{j=1}^{H}\frac{O^i \cdot O^j}{\|O^i\|\|O^j\|}. \quad (3)$$

4 Related Work

The regularization on attended positions is inspired by agreement learning in prior works, which encourages alignments or hidden variables of multiple models to be similar. Liang et al. (2006) first assigned agreement terms for jointly training word alignment in phrase-based statistic machine translation (Koehn et al., 2003). The idea was further extended into other natural language processing tasks such as grammar induction (Liang et al., 2008). Levinboim et al. (2015) extended the agreement for general bidirectional sequence alignment models with model inevitability regularization. Cheng et al. (2016) further explored the agreement on modeling the source-target and target-source alignments in neural machine translation model. In contrast to the mentioned approaches which assigned agreement terms into loss function, we deploy an alignment disagreement regularization by maximizing the distance among multiple attention heads.

As standard multi-head attention model lacks effective control on the influence of different attention heads, Ahmed et al. (2017) used a weighted mechanism to combine them rather than simple concatenation. As an alternative approach to multi-head attention, Shen et al. (2018a) and Shen et al. (2018b) extended the single relevance score to multi-dimensional attention weights, demonstrating the effectiveness of modeling multiple features for attention networks. Our approach is complementary to theirs: our model encourages the diversity among multiple heads, while theirs enhance the power of each head.

5 Experiments

5.1 Setup

To compare with the results reported by previous work (Gehring et al., 2017; Vaswani et al., 2017; Hassan et al., 2018), we conduct experiments on both WMT2017 Chinese⇒English (Zh⇒En) and WMT2014 English⇒German (En⇒De) translation tasks. The Zh⇒En corpus consists of 20M sentence pairs, and the En⇒De corpus consists of 4M sentence pairs. We follow previous work to select the validation and test sets. Byte-pair encoding (BPE) is employed to alleviate the Out-of-Vocabulary problem (Sennrich et al., 2016) with 32K merge operations for both language pairs. We use the case-sensitive 4-gram NIST BLEU score (Papineni et al., 2002) as evaluation metric, and *sign-test* (Collins et al., 2005) for statistical significance test.

We evaluate the proposed approaches on the advanced TRANSFORMER model (Vaswani et al., 2017), and implement on top of an open-source toolkit – THUMT (Zhang et al., 2017). We follow Vaswani et al. (2017) to set the configurations and have reproduced their reported results on the En⇒De task. All the evaluations are conducted on the test sets. We have tested both *Base* and *Big* models, which differ at hidden size (512 vs. 1024) and number of attention heads (8 vs. 16). We study model variations with *Base* model on the Zh⇒En task (Section 5.2 and 5.3), and evaluate overall performance with *Big* model on both Zh⇒En and En⇒De tasks (Section 5.4).

5.2 Effect of Regularization Terms

In this section, we evaluate the impact of different regularization terms on the Zh⇒En task us-

ing TRANSFORMER-BASE. For simplicity and efficiency, here we only apply regularizations on the encoder side. As shown in Table 1, all the models with the proposed disagreement regularizations (Rows 2-4) consistently outperform the vanilla TRANSFORMER (Row 1). Among them, the *Output* term performs best which is +0.65 BLEU score better than the baseline model, the *Position* term is less effective than the other two. In terms of training speed, we do not observe obvious decrease, which in turn demonstrates the advantage of our disagreement regularizations.

However, the combinations of different disagreement regularizations fail to further improve translation performance (Rows 5-7). One possible reason is that different regularization terms have overlapped guidance, and thus combining them does not introduce too much new information while makes training more difficult.

5.3 Effect on Different Attention Networks

The TRANSFORMER consists of three attention networks, including encoder self-attention, decoder self-attention, and encoder-decoder attention. In this experiment, we investigate how each attention network benefits from the disagreement regularization. As seen from Table 2, all models consistently improve upon the baseline model. When applying disagreement regularization to all three attention networks, we achieve the best performance, which is +0.72 BLEU score better than the baseline model. The training speed decreases by 12%, which is acceptable considering the performance improvement.

5.4 Main Results

Finally, we validate the proposed disagreement regularization on both WMT17 Chinese-to-English and WMT14 English-to-German translation tasks. Specifically, we adopt the *Output* disagreement regularization, which is applied to all three attention networks. The results are concluded in Table 3. We can see that our implementation of TRANSFORMER outperforms all existing NMT systems, and matches the results of TRANSFORMER reported in previous works. Incorporating disagreement regularization consistently improves translation performance for both base and big TRANSFORMER models across language pairs, demonstrating the effectiveness of the proposed approach. It is encouraging to see that TRANSFORMER-BASE with disagreement regu-

larization achieves comparable performance with TRANSFORMER-BIG, while the training speed is nearly twice faster.

5.5 Quantitative Analysis of Regularization

In this section, we empirically investigate how the regularization terms affect the multi-head attention. To this end, we compare the disagreement scores on subspaces ("Sub."), attended positions ("Pos."), and outputs ("Out."). Since the scores are negative values, we list $\exp(D)$ for readability, which has a maximum value of 1.0. Table 4 lists the results of encoder-side multi-head attention on the Zh⇒En validation set. As seen, the disagreement score on the individual component indeed increases with the corresponding regularization term. For example, the disagreement of outputs increases to almost 1.0 by using the *Output* regularization, which means that the output vectors are almost perpendicular to each other as we measure the cosine distance as the disagreement.

One interesting finding is that attending to different positions may not be the essential strength of multi-head attention on the translation task. As seen, the disagreement score on the attended positions for the standard multi-head attention is only 0.007, which indicates that almost all the heads attend to the same positions. Table 5 shows the disagreement scores on attended positions across encoder layers. Except for the 1^{st} layer that attends to the input word embeddings, the disagreement scores on other layers (i.e. ranging from the 2^{nd} to 6^{th} layer) are very low, which confirms out above hypothesis.

Concerning the regularization terms, except that on position, the other two regularization terms (i.e. "Sub." and "Out.") do not increase the disagreement score on the attended positions. This can explain why positional regularization term does not work well with the other two terms, as shown in Table 1. This is also consistent with the finding in (Tu et al., 2016), which indicates that neural networks can model linguistic information in their own way. In contrast to attended positions, it seems that the multi-head attention prefer to encoding the differences among multiple heads in the learned representations.

6 Conclusion

In this work, we propose several disagreement regularizations to augment the multi-head attention model, which encourage the diversity among attention heads so that different head can learn distinct features. Experimental results across language pairs validate the effectiveness of the proposed approaches.

The models also suggest a wide range of potential advantages and extensions, from being able to improve the performance of multi-head attention in other tasks such as reading comprehension and language inference, to being able to combine with other techniques (Shaw et al., 2018; Shen et al., 2018a; Dou et al., 2018; Yang et al., 2018) to further improve performance.

`zlipton@cmu.edu`

Abstract

Several recent papers investigate Active Learning (AL) for mitigating the data-dependence of deep learning for natural language processing. However, the applicability of AL to real-world problems remains an open question. While in supervised learning, practitioners can try many different methods, evaluating each against a validation set before selecting a model, AL affords no such luxury. Over the course of one AL run, an agent annotates its dataset exhausting its labeling budget. Thus, given a new task, an active learner has no opportunity to compare models and acquisition functions. This paper provides a large-scale empirical study of deep active learning, addressing multiple tasks and, for each, multiple datasets, multiple models, and a full suite of acquisition functions. We find that across all settings, *Bayesian active learning by disagreement*, using uncertainty estimates provided either by Dropout or Bayes-by-Backprop significantly improves over i.i.d. baselines and usually outperforms classic uncertainty sampling.

1 Introduction

While over the past several years, deep learning has pushed the state of the art on numerous tasks, its extreme data-dependence presents a formidable obstacle under restricted annotation budgets. Active Learning (AL) presents one promising approach to reduce deep learning's data requirements (Cohn et al., 1996). Strategically selecting points to annotate over alternating rounds of labeling and learning, an active learner is hoped to outperform budget-matched i.i.d. labeling. Typical *acquisition functions* select examples for which the current predictor is most uncertain. However, how precisely to quantify uncertainty, especially for neural networks, remains an open question.

Classical approaches interpret either the entropy or the negative argmax of the predictive (e.g. softmax) distribution as the model's uncertainty, yielding the *maximum entropy* and *least confidence* heuristics, respectively. These approaches account for aleatoric but not epistemic uncertainty (Kendall and Gal, 2017). Several recent Bayesian formulations of deep learning provide alternative techniques for extracting uncertainty estimates from deep networks, including a *dropout*-based approach (Gal and Ghahramani, 2016b), previously employed in Deep Active Learning (DAL) for image classification (Gal et al., 2017) and named entity recognition (Shen et al., 2018), and Bayes-by-Backprop (Blundell et al., 2015). To our knowledge, our paper is the first to apply Bayes-by-Backprop in the context of DAL.

While the results in recent papers hint at DAL's potential, its suitability in practice has yet to be proven. That's because papers often address just a single task, just a single model, and sometimes just one or two datasets. However, it's not enough to look back retrospectively after a final round of experiments and declare that one acquisition function outperforms an i.i.d. baseline. To apply DAL in practice, we must be confident that the technique will work correctly—*the first time*—on a dataset that we have never seen before. Otherwise, we might exhaust the annotation budget while performing worse than an i.i.d. baseline. Once we've exhausted our resources for labeling, there's no going back. Moreover, many DAL papers suffer from implicit target leaks. The architectures and hyper-parameters are often tuned using the full dataset, before concealing the labels and *simulating* AL.

In this paper, we present a large-scale study[1], comparing various acquisition functions across multiple tasks: Sentiment Classification (SC),

Named Entity Recognition (NER), and Semantic Role Labeling (SRL). For each task we consider, with multiple datasets, multiple models, and multiple acquisition functions. Moreover, in all experiments, we set hyper-parameters on warm-start data, allowing for a more honest assessment. This paper does not seek to champion any one approach but instead to ask, *is there any single method that we can reliably expect to work out-of-the-box on a new problem?*

To our surprise, we find that BALD (Houlsby et al., 2011), which measures uncertainty by the frequency over multiple Monte Carlo draws from a stochastic model with which the drawn models disagree with the plurality, proved effective across all combinations of task, dataset, and model. Moreover both variants of the approach, drawing samples according to the dropout method (Gal et al., 2017) and from a Bayes-by-Backprop network (Blundell et al., 2015), performed similarly well across most tasks, datasets, and models.

Related Work Only a few papers have addressed DAL for NLP, notably Shen et al. (2018) for NER and Zhang et al. (2017) who address text classification, proposing to select examples according to the expected magnitude of updates to word embeddings. In this paper, we do not consider the latter heuristic because we address sequence tagging tasks, where the difficulty of marginalizing over all possible labels blows up exponentially with sequence length. While both previous papers do conduct experiments on multiple datasets (2 and 3, respectively) they each consider just one task and just one model.

Gal et al. (2017) apply the dropout-based uncertainty estimates due to (Gal and Ghahramani, 2016a) together with the BALD framework due to (Houlsby et al., 2011) for image classification with convolutional neural networks. They obtain significant improvement over classic uncertainty-based acquisition functions on the MNIST dataset and for diagnosing skin cancer from lesion images (ISIC2016 task). Our work builds on theirs, both by offering a large-scale evaluation of BALD for NLP tasks and models, and by exploring BALD with another method for estimating uncertainty: the uncertainty of the weights as modeled by a Bayes-by-Backprop network.

2 Bayesian Deep Learning

While space constraints preclude an extensive discussion of the various Bayesian formulations of neural nets, we briefly summarize the methods compared in this paper, pointing out various design decisions that are important for reproducing our results.

Monte Carlo Dropout According to (Gal and Ghahramani, 2016b), the dropout regularization techniques for neural networks can be interpreted as a Bayesian approximation to Gaussian processes (Rasmussen, 2004). Here, unlike standard uses of dropout, we apply it at prediction time. Uncertainty estimates are produced by comparing the output of a trained neural network using T different stochastic passes through the neural network. The extension to CNNs is straightforward. To apply dropout to RNNs, we follow the approach due to (Gal and Ghahramani, 2016c), who extended their variational analysis to RNNs, arguing that dropout ought to be applied to the recurrent layers (and not just the synchronous connections, per previous standard practice (Zaremba et al., 2014)) by applying identical dropout masks at each sequence step.

Bayes by Backprop In this approach due to Blundell et al. (2015), instead of maintaining a point estimate for each weight, we maintain a probability distribution over the weights. A standard L-layer MLP model $P(y|x, w)$ is parametrized by weights $w = \{W_l, b_l\}_{l=1}^{L} \in \mathbb{R}^d$. Then, $\hat{y} = \phi(W_L \cdot ... \cdot +\phi(W_1 \cdot x + b_1) + .. + b_L)$ where ϕ is an activation function such as tanh or ReLU. Bayes-by-Backprop represents imposes a prior over the weights, $p(w)$ and seeks to learn the posterior distribution $p(w|D)$ given training data $D = \{x^i, y^i\}_{i=1}^{N}$. To deal with intractability, Bayes-by-Backprop approximates $p(w|D)$ by a variational distribution $q(w|\theta)$, typically choosing q to be a Gaussian with diagonal covariance and each weight sampled from $\mathcal{N}(\mu_i, \sigma_i^2)$. To enforce non-negativity, the σ_i are further parametrized via the *softplus* function $\sigma_i = log(1 + exp(\rho_i))$ giving variational parameters $\theta = \{\mu_i, \rho_i\}_{i=1}^{d}$.

Our objective in optimizing the variational parameters is to minimize the KL divergence between $q(\theta)$ and $p(w|D)$. Some simplification of the objective gives $\mathcal{L}(D, \theta) = \sum_{j=1}^{N} \left[\log q(w^j|\theta) - \log p(w^j) - \log p(D|w^j)\right]$, where w^j denotes the j-th Monte Carlo sample drawn from $q(w|\theta)$ (we use $N = 1$). In Bayes-by-Backprop, the parameters are optimized by stochastic gradient descent, using the re-parameterization trick popularized by Kingma and Welling (2014). Extending Bayes-by-Backprop to CNNs and RNNs is straightforward with the latter requiring minor adjustments for truncated back-propagation through time (Fortunato et al., 2017). Uncertainty estimates calculated via Bayes-by-Backprop have been shown to be useful for efficient exploration in reinforcement learning (Lipton et al., 2018).

3 Experimental Setup

3.1 Acquisition functions

In this work, we consider only uncertainty-based acquisition. In particular, we consider least confidence (LC) for classification and maximum length-normalized log probability (MNLP) for sequence labeling tasks (Shen et al., 2018). LC chooses that example with for which the prediction has lowest predicted probability. MNLP extends this to sequences, selecting by log probability normalized by length, removing the bias for the model to preferentially select longer sequences.

BALD We briefly articulate the details of the Bayesian Active Learning by Disagreement (BALD) approach due to Houlsby et al. (2011), upon which both our Bayesian approaches are based. We denote Monte Carlo Dropout Disagreement by DO-BALD and its Bayes-by-Backprop counterpart as BB-BALD. BALD originally selects samples that maximise the information gained about the model parameters. This boils down to choosing data points which each stochastic forward pass through the model would have the highest probability assigned to a different class (Gal et al., 2017). Our measure of uncertainty is the fraction of models, across MC samples from the network, that that disagree with most popular choice. This can be mathematically represented as

$$\arg\max_j \left(1 - \frac{count(mode(\tilde{y}_j^{(1)}, ..., \tilde{y}_j^{(T)}))}{T}\right)$$

Here $\tilde{y}_j^{(t)}$ represents the prediction (argmax) applied to the tth forward pass on jth sample $\tilde{y}_j^{(t)} = \texttt{argmax}(\hat{y}_j^{(t)})$. We resolve ties by choosing the least confident predictions as determined by the mean probability assigned to the consensus class. For sequences, we look at agreement on the entire sequence tag, noting that this may exhibit a bias to preferentially sample longer sentences. Because we measure the budget at each round in words (not sentences), while this constitutes a bias, it does not constitute an unfair advantage. Moreover, we note that all AL necessarily consists of biased sampling.

3.2 Training details

The active learning process begins with a random acquisition of 2% *warmstart* samples from the dataset. We train an initial model on this data. Then based on this model's uncertainty estimates, we apply our chosen acquisition function to sample an additional 2% of examples and train a new model based on this data In each round, we train from scratch to avoid badly overfitting the data collected in earlier rounds per observations by Hu et al. (2018). We continue with alternating rounds of labeling and training until we have annotated 50% of the dataset. For classification tasks, the we measure the budget in sentences while for sequence labeling, we measure the budget by the number of words because the annotator must provide one tag per word.

In each iteration, we train each model to convergence, decided based on early stopping with a patience of 1 epoch, or 25 epochs (whichever comes earlier). For datasets with fixed validation sets such as Conll 2003, instead of using the entire validation set for early stopping, we use the percentage of validation data equivalent to that in our current training pool. Our motivation here is to keep the simulation realistic. Essentially, we assume that given a large annotation budget, one will collect both a larger training set and a larger validation set. As a motivating example, it seems unreasonable that a practitioner might have only 500 training examples but 10,000 examples available for early stopping. Our reported results are averaged over 3 runs with different warmstart samples.

3.3 Sentence Classification

We use two datasets for simulation: one question classification dataset TrecQA (Roth et al., 2002) and one sentiment analysis dataset (Pang and Lee, 2005) and two architectures for training: CNNs and BiLSTMs. For implementation of the CNNs on both these datasets, we follow the setup of Kim (2014) and for BiLSTMs, we use a single layer model with 300 hidden units for both datasets. We

Dataset: CoNLL 2005 SRL, Model= BiLSTM_CRF
Dataset: CoNLL 2012 SRL, Model= BiLSTM_CRF

Figure 3: Performance of different acquisition functions on SRL task for two datasets

use 300-dimensional glove embeddings (Pennington et al., 2014) pretrained on 6B tokens for all 4 settings, a dropout rate of 0.5, and the Adam optimizer (Kinga and Adam, 2015) with initial learning rate 1e-3. We use a batch size set to be either 50 or the number required for at least 10 updates whichever is lower. This is done to ensure that when the training pool is small, the batch size is not too large and models get sufficient number of updates in an epoch. We also train a Unigram + Bigram + Linear SVM model with LC acquisition as a shallow AL baseline.

3.4 Named Entity Recognition

Again, we use two datasets: CoNLL 2003 (Tjong Kim Sang and De Meulder, 2003) and OntoNotes 5.0. The two architectures used for training are CNN-BiLSTM-CRF (CNN for character-level encoding, BiLSTM for word-level encoding, and CRF for decoding) (Ma and Hovy, 2016) and CNN-CNN-LSTM (CNN for character-level encoding, CNN for word-level encoding, and LSTM for decoding) (Shen et al., 2018). We follow the exact experimental settings of these papers except that batch size is 16 for CoNLL and 80 for OntoNotes (minimum 10 updates heuristic is followed here too).

We note that our NER models consist of multiple modular components, and that we only train a subset of those units in a Bayesian fashion. In both DO-BALD and BB-BALD, we apply dropout/stochastic weights on the word-level layers, but not on the character-level encoders or decoding layers. For example, with DO-BALD, we apply recurrent dropout in the BiLSTM word-level component of CNN-BiLSTM-CRF and we apply normal dropout in the word-level (middle) CNN layer of the CNN-CNN-LSTM. For NER, as a shallow AL baseline, we have a linear chain CRF model with MNLP acquisition.

3.5 Semantic Role Labeling

We consider two datasets: CoNLL 2005 (Carreras and Màrquez, 2005) and CoNLL 2012, focusing only on an LSTM-based model this time. Our model resembles He et al. (2017), but instead of using contained A* decoding, we use a CRF decoder, noting that while this causes a 2% drop in performance (at 100% annotation), our goal is to compare acquisition functions, not achieve record-setting performance. We follow the experimental setup of the paper but use a higher dropout rate of 0.25, adjusting the batch size according to the minimum update heuristic.

3.6 Results

We plot the performance for various annotation budgets for all combinations of dataset, model, and acquisition function, for the SC, NER, and SRL tasks in Figures 1, 2, and 3, respectively. In all cases, the active learning methods perform better than random i.i.d. baseline. We note that across the board, DAL methods show significant improvement over shallow baselines. The Bayesian acquisition functions, DO-BALD and BB-BALD consistently outperform classic uncertainly sampling, although in a few cases including the setting considered by Shen et al. (2018), the improvement is only marginal. This finding underscores the importance of examining proposed AL methods on a broad set of representative tasks and with a broad set of representative models.

In general, we find that the advantages of DAL can be substantial. For example, on NER tasks, we achieve roughly 98-99% of the full-dataset performance while labeling only 20% of the samples for both CNN-BiLSTM-CRF and CNN-CNN-LSTM models. By comparison, the i.i.d. baseline requires 50% of the data to achieve comparable F score. While the reduction in the percentage of data required is not as dramatic in the classification datasets (possibly owing to their comparatively small size), the relative improvement over i.i.d. baselines remains significant.

4 Conclusion

This paper set out to investigate the practical utility of DAL for NLP. Our study consisted of over 40 experiments, each repeated for 3 times to average results and consisting of roughly 25 rounds of retraining, adding up to 3000 training runs to completion. Our goal was not to champion any one approach, but to ask if there was any consistent story at all: *can active learning be applied on a new dataset with an arbitrarily architecture, without peeking at the labels to perform hyperparameter tuning?* To our surprise, we found that across many tasks, both classic uncertainty sampling and Bayesian approaches outperform i.i.d. baselines and that DO-BALD and BB-BALD consistently perform best.

Abstract

In natural language processing, a lot of the tasks are successfully solved with recurrent neural networks, but such models have a huge number of parameters. The majority of these parameters are often concentrated in the embedding layer, which size grows proportionally to the vocabulary length. We propose a Bayesian sparsification technique for RNNs which allows compressing the RNN dozens or hundreds of times without time-consuming hyperparameters tuning. We also generalize the model for vocabulary sparsification to filter out unnecessary words and compress the RNN even further. We show that the choice of the kept words is interpretable.

1 Introduction

Recurrent neural networks (RNNs) are among the most powerful models for natural language processing, speech recognition, question-answering systems (Chan et al., 2016; Ha et al., 2017; Wu et al., 2016; Ren et al., 2015). For complex tasks such as machine translation (Wu et al., 2016) modern RNN architectures incorporate a huge number of parameters. To use these models on portable devices with limited memory the model compression is desired.

There are a lot of RNNs compression methods based on specific weight matrix representations (Tjandra et al., 2017; Le et al., 2015) or sparsification (Narang et al., 2017; Wen et al., 2018). In this paper we focus on RNNs compression via sparsification. One way to sparsify RNN is pruning where the weights with a small absolute value are eliminated from the model. Such methods are heuristic and require time-consuming hyperparameters tuning. There is another group of sparsification techniques based on Bayesian approach. Molchanov et al. (2017) describe a model called SparseVD in which parameters controlling sparsity are tuned automatically during neural network training. However, this technique was not previously investigated for RNNs. In this paper, we apply Sparse VD to RNNs taking into account the specifics of recurrent network structure (Section 3.2). More precisely, we use the insight about using the same sample of weights for all timesteps in the sequence (Gal and Ghahramani, 2016; Fortunato et al., 2017). This modification makes local reparametrization trick (Kingma et al., 2015; Molchanov et al., 2017) not applicable and changes SparseVD training procedure.

In natural language processing tasks the majority of weights in RNNs are often concentrated in the first layer that is connected to the vocabulary, for example in embedding layer. However, for some tasks the most of the words are unnecessary for accurate predictions. In our model we introduce multiplicative weights for the words to perform vocabulary sparsification (Section 3.3). These multiplicative weights are zeroing out during training causing filtering corresponding unnecessary words out of the model. It allows to boost RNN sparsification level even further.

To sum up, our contributions are as follows: (i) we adapt SparseVD to RNNs explaining the specifics of the resulting model and (ii) we generalize this model by introducing multiplicative weights for words to purposefully sparsify the vocabulary. Our results show that Sparse Variational Dropout leads to a very high level of sparsity in recurrent models without a significant quality drop. Models with additional vocabulary sparsification boost compression rate on text classification tasks but do not help that much on language modeling tasks. In classification tasks the vocabulary is compressed dozens of times, and the choice of words is interpretable.

2 Related work

Reducing RNN size is an important and rapidly developing area of research. There are three research directions: approximation of weight matries (Tjandra et al., 2017; Le et al., 2015), reducing the precision of the weights (Hubara et al., 2016) and sparsification of the weight matrices (Narang et al., 2017; Wen et al., 2018). We focus on the last one. The most popular approach here is pruning: the weights of the RNN are cut off on some threshold. Narang et al. (2017) choose threshold using several hyperparameters that control the frequency, the rate and the duration of the weights eliminating. Wen et al. (2018) propose to prune the weights in LSTM by groups corresponding to each neuron, this allows to accelerate forward pass through the network.

Another group of sparsification methods relies on Bayesian neural networks (Molchanov et al., 2017; Neklyudov et al., 2017; Louizos et al., 2017). In Bayesian NNs the weights are treated as random variables, and our desire about sparse weights is expressed in a prior distribution over them. During training, the prior distribution is transformed into the posterior distribution over the weights, used to make predictions on testing phase. Neklyudov et al. (2017) and Louizos et al. (2017) also introduce group Bayesian sparsification techniques that allow to eliminate neurons from the model.

The main advantage of the Bayesian sparsification techniques is that they have a small number of hyperparameters compared to pruning-based methods. Also, they lead to a higher sparsity level (Molchanov et al., 2017; Neklyudov et al., 2017; Louizos et al., 2017).

There are several works on Bayesian recurrent neural networks (Gal and Ghahramani, 2016; Fortunato et al., 2017), but these methods are hard to extend to achieve sparsification. We apply sparse variational dropout to RNNs taking into account its recurrent specifics, including some insights highlighted by Gal and Ghahramani (2016), Fortunato et al. (2017).

3 Proposed method

3.1 Notations

In the rest of the paper $x = [x_0, \dots, x_T]$ is an input sequence, y is a true output and $\hat{y}$ is an output predicted by the RNN (y and $\hat{y}$ may be single vectors, sequences, etc.), X, Y denotes a training set $\{(x^1, y^1), \dots, (x^N, y^N)\}$. All weights of the RNN except biases are denoted by ω, while a single weight (an element of any weight matrix) is denoted by w_{ij}. Note that we detach biases and denote them by B because we do not sparsify them.

For definiteness, we will illustrate our model on an example architecture for the language modeling task, where $y = [x_1, \dots, x_T]$:

$$\begin{aligned}
&\text{embedding} : \tilde{x}_t = w^e_{x_t};\\
&\text{recurrent} : h_{t+1} = \sigma(W^h h_t + W^x \tilde{x}_{t+1} + b^r);\\
&\text{fully-connected} : \hat{y}_t = \text{softmax}(W^d h_t + b^d).
\end{aligned}$$

In this example $\omega = \{W^e, W^x, W^h, W^d\}$, $B = \{b^r, b^d\}$. However, the model may be directly applied to any recurrent architecture.

3.2 Sparse variational dropout for RNNs

Following Kingma et al. (2015), Molchanov et al. (2017), we put a fully-factorized log-uniform prior over the weights:

$$p(\omega) = \prod_{w_{ij} \in \omega} p(w_{ij}), \quad p(w_{ij}) \propto \frac{1}{|w_{ij}|}$$

and approximate the posterior with a fully factorized normal distribution:

$$q(w|\theta, \sigma) = \prod_{w_{ij} \in \omega} \mathcal{N}\big(w_{ij}|\theta_{ij}, \sigma^2_{ij}\big).$$

The task of posterior approximation $\min_{\theta,\sigma,B} KL(q(\omega|\theta,\sigma)||p(\omega|X,Y,B))$ is equivalent to variational lower bound optimization (Molchanov et al., 2017):

$$-\sum_{i=1}^{N} \int q(\omega|\theta,\sigma) \log p(y^i|x^i_0, \dots, x^i_T, \omega, B) d\omega + \\ + \sum_{w_{ij} \in \omega} KL(q(w_{ij}|\theta_{ij}, \sigma_{ij})||p(w_{ij})) \to \min_{\theta,\sigma,B}. \tag{1}$$

Here the first term, a task-specific loss, is approximated with one sample from $q(\omega|\theta,\sigma)$. The second term is a regularizer that moves posterior closer to prior and induces sparsity. This regularizer can be very closely approximated analytically (Molchanov et al., 2017):

$$KL(q(w_{ij}|\theta_{ij}, \sigma_{ij})||p(w_{ij})) \approx k\left(\frac{\sigma^2_{ij}}{\theta^2_{ij}}\right), \tag{2}$$

$$k(\alpha) \approx 0.64\sigma(1.87 + 1.49\log\alpha) - \frac{1}{2}\log\Bigl(1 + \frac{1}{\alpha}\Bigr).$$

To make integral estimation unbiased, sampling from the posterior is performed with the use of reparametrization trick (Kingma and Welling, 2014):

$$w_{ij} = \theta_{ij} + \sigma_{ij}\epsilon_{ij}, \quad \epsilon_{ij} \sim \mathcal{N}(\epsilon_{ij}|0, 1) \qquad (3)$$

The important difference of RNNs compared to feed-forward networks consists in sharing the same weight variable between different timesteps. Thus, we should use the same sample of weights for each timestep t while computing the likelihood $p(y^i|x_0^i, \ldots, x_T^i, \omega, B)$ (Gal and Ghahramani, 2016; Fortunato et al., 2017).

Kingma et al. (2015), Molchanov et al. (2017) also use local reparametrization trick (LRT) that is sampling preactivation instead of individual weights. For example,

$$(W^x x_t)_i = \sum_j \theta_{ij}^x x_{tj} + \epsilon_i \sum_j (\sigma_{ij}^x)^2 x_{tj}^2.$$

Tied weight sampling makes LRT not applicable to weight matrices that are used in more than one timestep in the RNN.

For the hidden-to-hidden matrix W^h the linear combination $(W^h h_t)$ is not normally distributed because h_t depends on W^h from the previous timestep. As a result, the rule about the sum of independent normal distributions with constant coefficients is not applicable. In practice, network with LRT on hidden-to-hidden weights cannot be trained properly.

For the input-to-hidden matrix W^x the linear combination $(W^x x_t)$ is normally distributed. However, sampling the same W^x for all timesteps and sampling the same noise ϵ_i for preactivations for all timesteps are not equivalent. The same sample of W^x corresponds to different samples of noise ϵ_i at different timesteps because of the different x_t. Hence theoretically LRT is not applicable here. In practice, networks with LRT on input-to-hidden weights may give the same results and in some experiments, they even converge a little bit faster.

Since the training procedure is effective only with 2D noise tensor, we propose to sample the noise on the weights per mini-batch, not per individual object.

To sum up, the training procedure is as follows. To perform forward pass for a mini-batch, we firstly sample all weights ω following (3) and then apply RNN as usual. Then the gradients of (1) are computed w.r.t $\theta, \log\sigma, B$.

During the testing stage, we use the mean weights θ (Molchanov et al., 2017). Regularizer (2) causes the majority of θ components approach 0, and the weights are sparsified. More precisely, we eliminate weights with low signal-to-noise ratio $\frac{\theta_{ij}^2}{\sigma_{ij}^2} < \tau$ (Molchanov et al., 2017).

3.3 Multiplicative weights for vocabulary sparsification

One of the advantages of Bayesian sparsification is an easy generalization for the sparsification of any groups of the weights that doesn't complicate the training procedure (Louizos et al., 2017). To do so, one should introduce shared multiplicative weight per each group, and elimination of this multiplicative weight will mean the elimination of the corresponding group. In our work we utilize this approach to achieve vocabulary sparsification.

Precisely, we introduce multiplicative probabilistic weights $z \in \mathbb{R}^V$ for words in the vocabulary (here V is the size of the vocabulary). The forward pass with z looks as follows:

1. sample vector z^i from the current approximation of the posterior for each input sequence x^i from the mini-batch;
2. multiply each one-hot encoded token x_t^i from the sequence x^i by z^i (here both x_t^i and z^i are V-dimensional);
3. continue the forward pass as usual.

We work with z in the same way as with other weights W: we use a log-uniform prior and approximate the posterior with a fully-factorized normal distribution with trainable mean and variance. However, since z is a one-dimensional vector, we can sample it individually for each object in a mini-batch to reduce the variance of the gradients. After training, we prune elements of z with a low signal-to-noise ratio and subsequently, we do not use the corresponding words from the vocabulary and drop columns of weights from the embedding or input-to-hidden weight matrices.

4 Experiments

We perform experiments with LSTM architecture on two types of problems: text classification and language modeling. Three models are compared here: baseline model without any regularization, SparseVD model and SparseVD model with multiplicative weights for vocabulary sparsification (SparseVD-Voc).

To measure the sparsity level of our models we calculate the compression rate of individual weights as follows: $|w|/|w \neq 0|$. The sparsification of weights may lead not only to the compression but also to the acceleration of RNNs through group sparsity. Hence, we report the number of remaining neurons in all layers: input (vocabulary), embedding and recurrent. To compute this number for vocabulary layer in SparseVD-Voc we use introduced variables z_v. For all other layers in SparseVD and SparseVD-Voc, we drop a neuron if all weights connected to this neuron are eliminated.

We optimize our networks using Adam (Kingma and Ba, 2015). Baseline networks overfit for all our tasks, therefore, we present results for them with early stopping. For all weights that we sparsify, we initialize $\log \sigma$ with -3. We eliminate weights with signal-to-noise ratio less then $\tau = 0.05$. More details about experiment setup are presented in Appendix A.

4.1 Text Classification

We evaluated our approach on two standard datasets for text classification: IMDb dataset (Maas et al., 2011) for binary classification and AGNews dataset (Zhang et al., 2015) for four-class classification. We set aside 15% and 5% of training data for validation purposes respectively. For both datasets, we use the vocabulary of 20,000 most frequent words.

We use networks with one embedding layer of 300 units, one LSTM layer of 128 / 512 hidden units for IMDb / AGNews, and finally, a fully connected layer applied to the last output of the LSTM. Embedding layer is initialized with word2vec (Mikolov et al., 2013) / GloVe (Pennington et al., 2014) and SparseVD and SparseVD-Voc models are trained for 800 / 150 epochs on IMDb / AGNews.

The results are shown in Table 1. SparseVD leads to a very high compression rate without a significant quality drop. SparseVD-Voc boosts the compression rate even further while still preserving the accuracy. Such high compression rates are achieved mostly because of the sparsification of the vocabulary: to classify texts we need to read only some important words from them. The remaining words in our models are mostly interpretable for the task (see Appendix B for the list of remaining words for IMBb). Figure 1 shows the only kept embedding component for remaining words on IMDb. This component reflects the sentiment score of the words.

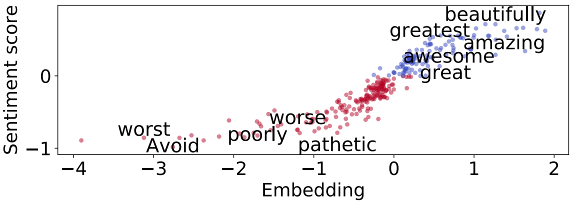

Figure 1: IMDB: remained embedding component vs sentiment score ((#pos. - #neg.) / #all texts with the word).

4.2 Language Modeling

We evaluate our models on the task of character-level and word-level language modeling on the Penn Treebank corpus (Marcus et al., 1993) according to the train/valid/test partition of Mikolov et al. (2011). The dataset has a vocabulary of 50 characters or 10,000 words.

To solve character / word-level tasks we use networks with one LSTM layer of 1000 / 256 hidden units and fully-connected layer with softmax activation to predict next character or word. We train SparseVD and SparseVD-Voc models for 250 / 150 epochs on character-level / word-level tasks.

The results are shown in Table 2. To obtain these results we employ LRT on the last fully-connected layer. In our experiments with language modeling LRT on the last layer accelerate the training without harming the final result. Here we do not get such extreme compression rates as in the previous experiment but still, we are able to compress the models several times while achieving better quality w.r.t. the baseline because of the regularization effect of SparseVD. Vocabulary is not sparsified in the character-level task because there are only 50 characters and all of them matter. In the word-level task more than a half of the words are dropped. However, since in language modeling almost all words are important, the sparsification of the vocabulary makes the task more difficult to the network and leads to the drop in quality and the overall compression (network needs more difficult dynamic in the recurrent layer).

Task	Method	Accuracy %	Compression	Vocabulary	Neurons $\tilde{x}$ - h
	Original	84.1	1x	20000	$300-128$

Abstract

Graphemes of most languages encode pronunciation, though some are more explicit than others. Languages like Spanish have a straightforward mapping between its graphemes and phonemes, while this mapping is more convoluted for languages like English. Spoken languages such as Cantonese present even more challenges in pronunciation modeling: (1) they do not have a standard written form, (2) the closest graphemic origins are logographic Han characters, of which only a subset of these logographic characters implicitly encodes pronunciation. In this work, we propose a multimodal approach to predict the pronunciation of Cantonese logographic characters, using neural networks with a geometric representation of logographs and pronunciation of cognates in historically related languages. The proposed framework improves performance by 18.1% and 25.0% respective to unimodal and multimodal baselines.

1 Introduction

In phonographic languages, there is a direct correspondence between graphemes and phonemes (Defrancis, 1996), though this correspondence is not always one-to-one. For example, in English, the word *table* corresponds to the pronunciation [“teɪ.bl], in which each alphabetic character corresponds to one phoneme, and the character *e* is mapped to silence. However, in logographic languages, the correspondence between graphemes and phonemes is more ambiguous (Defrancis, 1996), as only some sub-units in a grapheme are indicative of its phonemes. Korean[1], Vietnamese[2] and Chinese languages (e.g. Cantonese) are examples of logographic languages, all belonging to the Han logographic family. Similar to pronunciation modeling in phonographic languages, in which words are broken down into characters and modeling is done at the character level, pronunciation modeling in logographic languages requires decomposing logographs into sub-units and extracting only sub-units carrying pronunciation hints. As the correspondence of Han logograph to phoneme is intricately complex with many sub-rules or exceptions (Hashimoto, 1978), it is challenging to computationally model these correspondences using white box approaches (e.g. graphical model). Instead, we exploit neural networks, as they (1) can flexibly model the implicit similarity of grapheme-phoneme relationships across languages with Han origin, (2) can automatically learn the most relevant knowledge representation with minimal feature engineering (LeCun et al., 2015), such as extracting pronunciation hints from logographic representations.

Due to historical contact, there is much lexical overlap across Han logographic languages, as they borrowed words from one another (Rokuro, 1969; Miyake, 1997; Loveday, 1996; Sohn, 2001; Alves, 1999). As a result, cognates in different languages are written using identical graphemes but pronounced differently. For example, [she] in Mandarin and [sip] in Cantonese are cognates; their pronunciations are different yet they are written using the same logograph (懾), which represents “admire”. Though Han logographic languages are mutually unintelligible (Tang and Van Heuven, 2009; Handel, 2015), the correspondence of Han logographic graphemes to phonemes across languages is often similar in systematic ways (Cai et al., 2011; Frellesvig and Whitman, 2008; Miyake, 1997). The shared characteristics in pronunciation of cognates could be leveraged in deciphering the pronunciation of Han logographs. In this work, we proposed a neural pronuncia-

tion model that exploits both embeddings of logographs and cognates' phonemes. The proposed model significantly improves pronunciation prediction of logographs in Cantonese.

2 Related Work

The basic units in writing (graphemes) of Han logographic languages are logographs. A word contains one or more logographs and a logograph consists of one or more radicals. The pronunciation of a logograph corresponds to a syllable which has three phonemes: onset, nucleus and coda.

Grapheme-to-phoneme (G2P) approaches such as (Xu et al., 2004; Chen et al., 2016) predicted a Han logograph's pronunciation from its local context in a phrase. This was similar to predicting a Latin word's pronunciation from its surrounding words, essentially treated individual logographs as the basic units of the model and did not delve further into the logographic sub-units (the radicals).

While we are unaware of any work that derives features for pronunciation prediction from logographs, there are recent work in deriving representation of logographs for various semantic tasks. Some methods (Shi et al., 2015; Ke and Hagiwara, 2017; Nguyen et al., 2017; Zhuang et al., 2017) decomposed logographs into subunits using expert-defined rules and then extracted the relevant semantic features. Other methods use convolutional neural network to extract features from the images of logographs (Dai and Cai, 2017; Liu et al., 2017; Toyama et al., 2017). Other works combined multiple level of information for feature extraction, using both logograph and sub-units obtained from logograph decomposition (Dong et al., 2016; Han et al., 2017; Peng et al., 2017; Yu et al., 2017; Yin et al., 2016).

In this work, we explicitly looked at the relationship between a logograph's constituent radicals and its pronunciation. Among Han logographs, 81% of frequently used logographs are semantic-phonetic compounds (Li and Kang, 1993) which consist of radicals that might contain phonetic or semantic hints (Hsiao and Shillcock, 2006). The pronunciation of a logograph could conceivably be predicted from the phonetic radicals. Furthermore, the relative position of radicals in the logograph might also offer clues about it pronunciation. Table 1 shows an example of such intricate relationships between a logograph's pronunciation and its constituent radicals. All Han logographs in the table have a common phonetic radical (in red), which offers an inkling of the pronunciation of these logographs. For instance, logographs that have the phonetic radical on the left (剖 and 部) share a similar pronunciation in Korean (in blue) while logographs that have the phonetic radical on the right (陪, 賠, and 蓓) share a similar pronunciation in Mandarin, Cantonese and Vietnamese. Note that for each logograph, their pronunciations across the different languages share similarities: when the phonetic radical is on the left, the nucleus ends in a back vowel like *u* or *o*, whereas when the phonetic radical is on the right, the nucleus ends in a front vowel like *i*.

Position of 音					
Logograph	剖	部	陪	賠	蓓
Mandarin	pou	bu	**pei**	**pei**	bei
Cantonese	fau	bou	**pui**	**pui**	bui
Korean	**pwu**	**pwu**	**pay**	**pay**	**pay**
Vietnamese	phau	bo	**boi**	**boi**	bui

Table 1: The position of radicals affects pronunciations. All logographs share a common radical in red. Similar pronunciations for 剖 and 部 are bolded in blue. Similar pronunciations for 陪, 賠, and 蓓 are bolded in green. The pronunciation of a logograph in Mandarin, Cantonese, Korean and Vietnamese are represented by Pinyin, Jyutping, Yale, and Vietnamese alphabet symbols respectively.

The example in Table 1 explains the motivation for our proposed approach to predict a logograph's pronunciation by modelling both the constituent radicals and their geometric positions. Furthermore, the proposed approach can generalize to unseen logographs if the co-occurrence patterns of their constituent radicals have been learnt.

3 Model

We first describe a geometric decomposition of logographs and then different neural pronunciation models for logographs. Finally, we present a multimodal neural model that incorporates both logographic input and the cognates' phonemes in predicting pronunciation of logographs.

Representation of Han logographs

The majority of logographs (characters) in Han logographic language family comprise of a radical that indicates its nominal semantic category and a phonetic radical that gives an inkling of the pronunciation (Defrancis, 1996). Thus, patterns of co-occurrence of radicals across logographs might

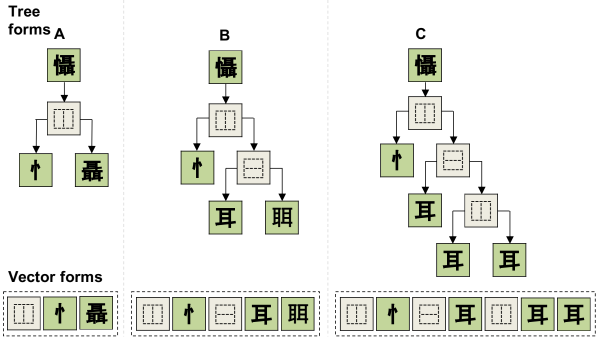

*Figure 1: Geometric representation of the logograph "admire". **A**, **B** and **C** are equivalent decomposition of the same logograph but with different levels of granularity. The geometric representation comprises of both the radicals and geometric operators, which can be used to reconstruct the original logograph.*

be exploited to find the phonetic radicals, which in turn can suggest the corresponding pronunciation of a logograph. Using this intuition, we model the pronunciation of logographs at the radical level.

We investigated two representations of radicals in a logograph. In the first approach, a logograph is represented as a bag of its unordered constituent radicals (BoR), encoded as a vector of radical counts. The second approach is to use a decomposition of radicals in the logograph that retains the original geometric organization of the radicals. The geometric decomposition (GeoD) approach preserves important cues about the word's pronunciation in the relative position of the radicals. For example, differentiating the left radical from the right radical in a left-right semantic-phonetic compound allows more effective extraction of pronunciation hints. In addition, radicals that should be interpreted together are closer spatially in the GeoD representation, making the knowledge representation easier to learn. Note that the GeoD representation is lossless as the original logograph can be reconstructed perfectly (details in Appendix A). Figure 1 shows the geometric decomposition of the Han logograph "admire" at three levels of granularity.

Neural pronunciation prediction models

Figure 2 and Figure 3 show two neural pronunciation prediction models of logographs. In Figure 2, each logograph is treated as an ordered "bag of radicals" (BoR). For example, assume the vocabulary of radicals in the whole dataset is [忄, 氵, 耳, 灬], the word 懾 ("admire" - see Figure 1) is represented by a vector of counts $[1, 0, 3, 0]$, corresponding to one radical 忄 and three radicals 耳. The BoR is input to a multilayer perceptron (MLP) with three layers of size 750, 500, 250. L2 regularization of 1e-4 is applied to the hidden layers. The three dropout layers have dropout probabilities of 0.5, 0.5, and 0.2, respectively. As the output variables are categorical, cross-entropy loss was used.

We investigated two structures for predicting output phonemes (i.e. onset, nucleus, coda). In the first structure, output phonemes were predicted independently using the last hidden layer. The second structure made a sequential prediction (1) the coda was first predicted using the last hidden layer (2) the nucleus was predicted using both the final hidden layer and the predicted coda, and (3) the onset was predicted using the last hidden layer together with the predicted coda and nucleus. The second structure was motivated by a stronger dependency between the nuclues and coda. For example, the nucleus and coda are often grouped together as a single unit (rime/final) in the syllabic structure of most languages (Kessler and Treiman, 2002). In our experiments, the sequential structure yielded lower error rates so it is used in all neural network models.

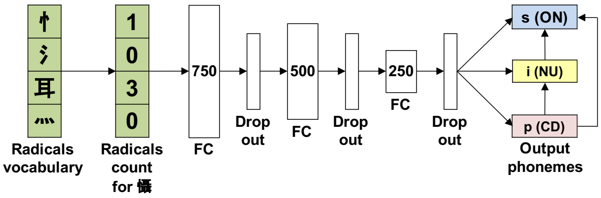

Figure 2: Pronunciation model of logographs using multilayer perceptron (MLP). FC: Fully connected.

In Figure 3, each logograph is represented by its geometric decomposition (GeoD). For example, the logograph 懾 is represented by a sequence of radicals and geometric operators shown in Figure 1C. The neural prediction model consists of two LSTM layers with 256 memory cells each. Input and recurrent dropout (Gal and Ghahramani, 2016) of 0.2 and 0.5 are applied to the LSTM layers to prevent overfitting.

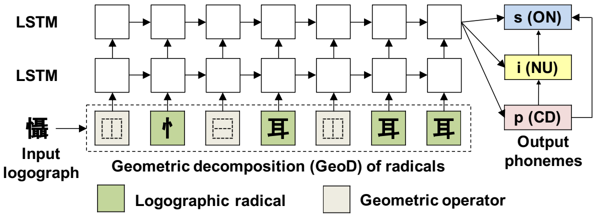

Figure 3: Neural pronunciation model with geometric decomposition of logographs.

Multimodal neural pronunciation model of logographs

In this section, we want to model the pronunciations of a logograph in the target language Cantonese using multimodal information from both the logograph and phonemes of the cognates, as shown in Figure 4. Given a vocabulary of phonemes in the source languages related to Cantonese (Mandarin, Korean, Vietnamese), the cognates' phonemes are encoded as an indicator vector, with an element equals 1 if the corresponding phoneme in the vocabulary appears in a cognate's pronunciation, and 0 otherwise.

The geometric decomposition (GeoD) of the logograph is fed to two LSTM layers. The output at the last time step is concatenated together with the multilingual phonemic vector and used as input for a multi-layer perceptron (MLP). The MLP and LSTM setups are the same as those in Figure 2 and Figure 3 respectively. Deep supervision (Szegedy et al., 2015) was applied by using the output of the LSTM to make auxiliary prediction of the output phonemes. Note that the auxiliary prediction should be identical to the main prediction. While predicting the same target, the main prediction used both cognate phonemes and the logograph while the auxiliary prediction used only the logograph. This was to ensure features extracted from the logographs are useful for pronunciation prediction and are complementary to the features extracted from the multilingual phonemes.

4 Experiments

We investigate whether Cantonese phonemes could be predicted using Han logographs and the cognates' phonemes from Mandarin, Korean, and Vietnamese. The prediction output are Cantonese onsets, nuclei and codas. The experimental design is motivated by the nature of Han-logographic languages. A Chinese logograph (character) is phonologically equivalent to a syllable in English while the constituent radicals are analogous to alphabet letters (with far less phonetic information). While in most languages, a syllable's pronunciation is influenced by neighboring syllables, most Han-logographic languages are monosyllabic and a logograph's pronunciation is rarely affected by neighboring logographs. Therefore, pronunciation prediction at the logograph (character) level for Han logographs is more appropriate. We use string error rate (SER) and token error rate (TER) as evaluation metrics. A wrongly predicted phoneme (onset, nucleus or coda) is counted as one token error. A syllable containing token error(s) is counted as one string error. All the neural networks were trained using Adam (Kingma and Ba, 2014).

Data

The dataset is extracted from the UniHan database,[3] which is a pronunciation database of logographs from Han logographic languages and maintained by the Unicode consortium. For each entry in the dataset, a logograph corresponds to phonemes in Cantonese, Mandarin, Korean and Vietnamese, represented by Jyutping,[4] Pinyin,[5] Yale,[6] and Vietnamese alphabet symbols respectively.[7] We randomly partition the dataset into two sets, with 80% for training and the other 20% for testing. Overall, there are 16,011 entries in the training set and 4,002 entries in the test set. 1000 entries of the training set are used as the development set for hyper-parameters fine-tuning.

In the test set, only 16% of logographs have pronunciations in all non-target languages, while 6% of logographs have no non-target language pronunciation. The availability of pronunciations in non-target languages differs from logograph to logograph. For example, some logographs have Mandarin and Korean pronunciations, while others only have Mandarin pronunciations.

Predicting pronunciation using logograph input

We compared the neural networks against a decision tree baseline. The decision tree baseline was implemented using scikit-learn (Pedregosa et al., 2011). The input of the decision tree (DT) model is the BoR representation of the logograph, while the input of neural networks can be either BoR or GeoD. The MLP network in Figure 2 uses BoR, while the LSTM in Figure 3 uses GeoD as input. All models output phonemes in Cantonese.

From Table 2, the neural network (MLP) outperforms decision tree when using BoR input. Both the SER and TER of the MLP model are lower than those of the decision tree. The LSTM model using GeoD leads to the lowest SER and TER, suggesting the benefits of relative positional

information of radicals in predicting pronunciation. The trends of onset, nucleus and coda error rates are similar to those of TER and SER. However, as the gap of of error rate between MLP (BoR) and LSTM (GeoD) for TER and SER are quite small, using BoR instead of GeoD can be a good computation-accuracy trade-off.

Method	SER	TER	On.	Nu.	Cd.
DT (BoR)	63.8	39.8	50.7	45.7	22.9
MLP (BoR)	59.2	33.6	44.5	38.6	17.8
LSTM (GeoD)	**58.4**	**32.6**	**43.3**	**37.4**	**17.1**

Table 2: Prediction error rates of Cantonese phonemes by decision tree (DT), MLP and LSTM using only logographic input. Best results are in bold.

Predicting pronunciation using multimodal input

The input of the models are logographs and cognate phonemes from Mandarin, Korean and Vietnamese. Table 3 shows that the proposed multimodal neural network exploits multimodal and geometric information effectively. The relative improvement reaches 18.2% and 33.3% for SER and TER respectively. The last rows in Table 2 and Table 3 show that by combining Korean, Mandarin and Vietnamese phonemes input with GeoD, the prediction performance improves by 54.1% relative in TER and by 65.5% relative in SER. Moreover, using solely logograph input resulted in higher onset error (43.3%) than nucleus error (37.4%) while using both logographs and multilingual phonemes improves the onset error (23.5%) to be lower than nucleus error (24.6%). This suggests that logographs and phonemes of cognates provide complementary information about the pronunciation of a logograph, which in this case, most notably at the onset position. While logographs usually carry hints about phonemes at the nucleus and coda position but not at the onset position, multilingual phonemes input might carry hints about pronunciation at all three positions.

Method	SER	TER	On.	Nu.	Cd.
DT (BoR, ph)	44.0	24.8	29.8	29.9	14.7
MLP (BoR, ph)	38.5	19.6	23.4	24.8	10.5
LSTM (GeoD, ph)	**37.2**	**18.6**	**22.6**	**23.4**	**9.8**

Table 3: Prediction error rates of Cantonese phonemes by multimodal models; BoR: Bag of Radicals; GeoD: Geometric Decomposition; ph:phonemes. Best results are in bold.

5 Discussion

We have empirically shown that the systematic yet tenuous correspondence between pronunciations of cognates in Han logographic languages can be exploited for pronunciation modeling using neural networks. Moreover, combining logograph with cognate pronunciations further improves pronunciation prediction. These results could be potentially applied to speech processing tasks such as speech synthesis, where the construction of pronunciation dictionaries are expert labor-intensive, especially for under-resourced spoken languages.

For future work, recursive neural network (Tai et al., 2015) can be used as it is better suited for the hierarchical logographic decomposition. Besides, incorporating more detailed relationship between radicals (e.g. (Zhuang et al., 2017)) can help improve the model. The proposed approaches can also be applied to other languages such as Min Nan or Hakka, which are spoken languages that are even less well-documented than Cantonese.

Abstract

Chinese pinyin input method engine (IME) converts pinyin into character so that Chinese characters can be conveniently inputted into computer through common keyboard. IMEs work relying on its core component, pinyin-to-character conversion (P2C). Usually Chinese IMEs simply predict a list of character sequences for user choice only according to user pinyin input at each turn. However, Chinese inputting is a multi-turn online procedure, which can be supposed to be exploited for further user experience promoting. This paper thus for the first time introduces a sequence-to-sequence model with gated-attention mechanism for the core task in IMEs. The proposed neural P2C model is learned by encoding previous input utterance as extra context to enable our IME capable of predicting character sequence with incomplete pinyin input. Our model is evaluated in different benchmark datasets showing great user experience improvement compared to traditional models, which demonstrates the first engineering practice of building Chinese aided IME.

1 Introduction

Pinyin is the official romanization representation for Chinese and the P2C converting the inputted pinyin sequence to Chinese character sequence is the most basic module of all pinyin based IMEs.

Most of the previous research (Chen, 2003; Zhang et al., 2006; Lin and Zhang, 2008; Chen and Lee, 2000; Jiang et al., 2007; Cai et al., 2017a) for IME focused on the matching correspondence between pinyin syllables and Chinese characters. (Huang et al., 2018; Yang et al., 2012; Jia and Zhao, 2014; Chen et al., 2015) regarded the P2C as a translation between two languages and solved it in statistical or neural machine translation framework. The fundamental difference between (Chen et al., 2015) work and ours is that our work is a fully end-to-end neural IME model with extra attention enhancement, while the former still works on traditional IME only with converted neural network language model enhancement. (Zhang et al., 2017) introduced an online algorithm to construct appropriate dictionary for P2C. All the above mentioned work, however, still rely on a complete input pattern, and IME users have to input very long pinyin sequence to guarantee the accuracy of P2C module as longer pinyin sequence may receive less decoding ambiguity.

The Chinese IME is supposed to let user input Chinese characters with least inputting cost, i.e., keystroking, which indicates extra content predication from incomplete inputting will be extremely welcomed by all IME users. (Huang et al., 2015) partially realized such an extra predication using a maximum suffix matching postprocessing in vocabulary after SMT based P2C to predict longer words than the inputted pinyin.

To facilitate the most convenience for such an IME, in terms of a sequence to sequence model as neural machine translation (NMT) between pinyin sequence and character sequence, we propose a P2C model with the entire previous inputted utterance confirmed by IME users being used as a part of the source input. When learning the type of the previous utterance varies from the previous sentence in the same article to the previous turn of utterance in a conversation, the resulting IME will make amazing predication far more than what the pinyin IME users actually input.

In this paper, we adopt the attention-based NMT

framework in (Luong et al., 2015) for the P2C task. In contrast to related work that simply extended the source side with different sized context window to improve of translation quality (Tiedemann and Scherrer, 2017), we add the entire input utterance according to IME user choice at previous time (referred to the *context* hereafter). Hence the resulting IME may effectively improve P2C quality with the help of extra information offered by context and support incomplete pinyin input but predict complete, extra, and corrected character output. The evaluation and analysis will be performed on two Chinese datasets, include a Chinese open domain conversations dataset for verifying the effectiveness of the proposed method.

2 Model

As illustrated in Figure **1**, the core of our P2C is based the attention-based neural machine translation model that converts at word level. Still, we formulize P2C as a translation between pinyin and character sequences as shown in a traditional model in Figure 1(a). However, there comes a key difference from any previous work that our source language side includes two types of inputs, the current source pinyin sequence (noted as P) as usual, and the extended context, i.e., target character sequence inputted by IME user last time (noted as C). As IME works dynamically, every time IME makes a predication according to a source pinyin input, user has to indicate the 'right answer' to output target character sequence for P2C model learning. This online work mode of IMEs can be fully exploited by our model whose work flow is shown in Figure 1(b).

As introduced a hybrid source side input, our model has to handle document-wide translation by considering discourse relationship between two consecutive sentences. The most straightforward modeling is to simply concatenate two types of source inputs with a special token 'BC' as separator. Such a model is in Figure 1(c). However, the significant drawback of the model is that there are a slew of unnecessary words in the extended context (previous utterance) playing a noisy role in the source side representation.

To alleviate the noise issue introduced by the extra part in the source side, inspired by the work of (Dhingra et al., 2016; Pang et al., 2016; Zhang et al., 2018c,a,b; Cai et al., 2017b), our model adopts a gated-attention (GA) mechanism that performs multiple hops over the pinyin with the extended context as shown in Figure 1(d). In order to ensure the correlation between each other, we build a parallel bilingual training corpus and use it to train the pinyin embeddings and the Chinese embeddings at once. We use two Bidirectional gated recurrent unit (BiGRU) (Cho et al., 2014) to get contextual representations of the source pinyin and context respectively, $H_p = \mathrm{BiGRU}(P), H_c = \mathrm{BiGRU}(C)$, where the representation of each word is formed by concatenating the forward and backward hidden states.

For each pinyin p_i in H_p, the GA module forms a word-specific representation of the context $c_i \in H_c$ using soft attention, and then adopts element-wise product to multiply the context representation with the pinyin representation. $\alpha_i = softmax(H_c^{\mathrm{T}} p_i), \beta_i = C\alpha_i, x_i = p_i \odot \beta_i$, where $\odot$ is multiplication operator.

The pinyin representation $\tilde{H}_p = x_1, x_2, ..., x_k$

is augmented by context representation and then sent into the encoder-decoder framework. The encoder is a bi-directional long short-term memory (LSTM) network (Hochreiter and Schmidhuber, 1997). The vectorized inputs are fed to forward and backward LSTMs to obtain the internal representation of two directions. The output for each input is the concatenation of the two vectors from both directions. Our decoder based on the global attentional models proposed by (Luong et al., 2015) to consider the hidden states of the encoder when deriving the context vector. The probability is conditioned on a distinct context vector for each target word. The context vector is computed as a weighted sum of previous hidden states. The probability of each candidate word as being the recommended one is predicted using a softmax layer over the inner-product between source embeddings and candidate target characters.

This work belongs to one of the first line which fully introduces end-to-end deep learning solution to the IME implementation following a series of our previous work (Zhu et al., 2018; Wu and Zhao, 2018; Zhang and Zhao, 2018; Bai and Zhao, 2018; Cai et al., 2018; He et al., 2018; Qin et al., 2018; Li et al., 2018; Jia et al., 2013).

3 Experiment

3.1 Definition of Incomplete Input for IME

The completeness in IME is actually uneasily well-defined as it is a relative concept for inputting procedure. Note that not until user types the return key *enter*, user will not (usually) really make the input choice. Meanwhile, even though the entire/complete input can be strictly defined by the time when user types *enter*, user still can make decision at any time and such incompleteness cannot be well evaluated by all the current IME metrics. As the incomplete from is hard to simulate and it is diverse in types, we have to partially evaluate it in the following two ways[1],

The incomplete pinyin as abbreviation pinyin To compare with previous work directly, we followed (Huang et al., 2015) and focused on the abbreviated pinyin (the consonant letter only) to perform evaluation (i.e., tian_qi to t_q).

Take incomplete user input as the incomplete As IME works as an interactive system, it will always give prediction only if users keep typing. If user's input does not end with typing *enter*, we can regard the current input pinyin sequence is an incomplete one.

3.2 Datasets and Settings

	PD		DC	
	Train	Test	Train	Test
# Sentence	5.0M	2.0K	1.0M	2.0K
$L < 10$ %	88.7	89.5	43.0	54.0
$L < 50$ %	11.3	10.5	47.0	42.0
$L > 50$ %	0.0	0.0	4.0	2.0
Relativity %	18.0	21.1	65.8	53.4

Table 1: Data statistics for the sentence number and sentence length (L) of two corpora.

Our model is evaluated on two datasets, namely the People's Daily (PD) corpus and Douban conversation (DC) corpus. The former is extracted from the People's Daily from 1992 to 1998 that has word segmentation annotations by Peking University. The DC corpus is created by (Wu et al., 2017) from Chinese open domain conversations. One sentence of the DC corpus contains one complete utterance in a continuous dialogue situation. The statistics of two datasets is shown in Table 1. The relativity refers to total proportion of sentences that associate with contextual history at word level. For example, there are 65.8% of sentences of DC corpus have words appearing in the context. With character text available, the needed parallel corpus between pinyin and character texts is automatically created following the approach proposed by (Yang et al., 2012).

Our model was implemented using the PyTorch[2] library, here is the hyperparameters we used: (a) the RNNs used are deep LSTM models, 3 layers, 500 cells, (c) 13 epoch training with plain SGD and a simple learning rate schedule - start with a learning rate of 1.0; after 9 epochs, halve the learning rate every epoch, (d) mini-batches are of size 64 and shuffled, (e) dropout is 0.3. Word embeddings are pre-trained by word2vec (Mikolov et al., 2013) toolkit on the adopted corpus and unseen words are assigned unique random vectors. (f) the gated attention layers size is 3, the hidden units number of BiGRU is 100.

Two metrics are used: Maximum Input Unit (MIU) accuracy (Zhang et al., 2017) and KeyStroke Score (KySS) (Jia and Zhao, 2013).

IME: shang'hai
1. 上海 (Shanghai) 2. 北京 (Beijing) 3. 南京(Nanjing)

(a)

Context: 给十岁的小女孩买什么礼物？(what gift is bought for the little girl?)
Input: e luo si tao wa ye man hao de
Gold: 俄罗斯套娃也蛮好的。(Russian doll is fine.)
IME: e'luo'si'tao'wa'ye'man hao de
1. 黑色 (Black) 2. 香水 (Perfume) 3. 京东 (Joybuy.com) 4.额(brow)

(b)

Figure 2: Examples of the candidates list given by the proposed IMEs.

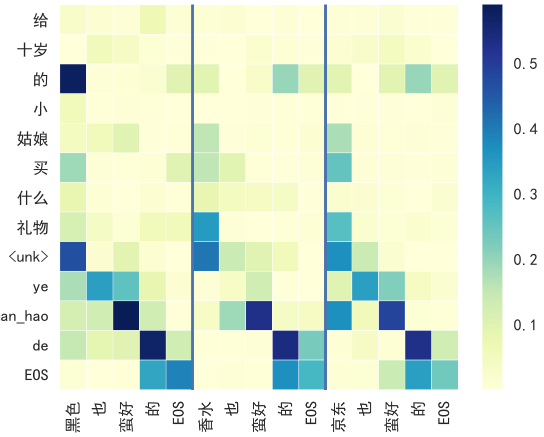

Figure 3: Attention visualization. Deeper color mean larger value.

The former measures the conversion accuracy of MIU, whose definition is the longest uninterrupted Chinese character sequence during inputting. As the P2C conversion aims to output a rank list of the corresponding character sequences candidates, the Top-K MIU accuracy means the possibility of hitting the target in the first K predicted items. The KySS quantifies user experience by using keystroke count. For an ideal IME with complete input, we have KySS $= 1$. An IME with higher KySS is supposed to perform better.

3.3 Model Definition

We considered the following baselines: (a) Google IME: the only commercial Chinese IME providing a debuggable API in the market now; (b) OMWA: online model for word acquisition proposed by (Zhang et al., 2017); (c) CoCat: an SMT based input method proposed by (Huang et al., 2015) that supports incomplete pinyin inputs.

Three models with incomplete or complete inputs will be evaluated: (a) Basic P2C, the basic P2C based on attention-NMT model; (b) Basic C2C, the basic C to C model based on Seq2Seq model; (b) Simple C+ P2C, the simple concatenated P2C conversion model that concatenate context to pinyin representation; (c) Gated C+ P2C, our gated attention based context-enhanced pinyin-to-character model. Pinyin in model * has been actually set to abbreviation form when we say it goes to (Huang et al., 2015) incomplete definition.

3.4 Result and Analysis

Effect of Gated Attention Mechanism Table 3 shows the Effect of gated attention mechanism. We compared models with Gated C+ P2C and Simple C+ P2C. The MIU accuracy of the P2C model has over 10% improvement when changing the operate pattern of the extra information proves the effect of GA mechanism. The Gated C+ P2C achieves the best in DC corpus, suggesting that the gated-attention works extremely well for handling long and diverse context.

Effect of P2C modules with Different Input Forms Table 2 shows the evaluation results of P2C modules with different input forms. It should

	DC				PD			
	Top-1	Top-5	Top-10	KySS	Top-1	Top-5	Top-10	KySS
Google IME	62.13	72.17	74.72	0.6731	70.93	80.32	**82.23**	0.7535
CoCat	59.15	71.85	76.78	0.7651	61.42	73.08	78.33	0.7933
OMWA	57.14	72.32	80.21	0.7389	64.42	72.91	77.93	0.7115
basic P2C	71.31	89.12	90.17	0.8845	70.5	79.8	80.1	0.8301
Simple C+ P2C	61.28	71.88	73.74	0.7963	60.87	71.23	75.33	0.7883
Gated C+ P2C	**73.89**	**90.14**	**91.22**	**0.8935**	**70.98**	**80.79**	81.37	**0.8407**

Table 3: Comparison with previous state-of-the-art models.

not surprise that straightforward concatenation strategy for source inputs performs poorly when the input pinyin is incomplete in DC corpus, due to obvious noise in too long context. The relatively small gap between the results of CoCat⋆ and CoCat indicate that statistical learning model may be helpful in obtaining some useful patterns from limited input. When the input statement contains adequacy information, the MIU accuracy of Gated C+ P2C system achieves more than 20% improvement in both corpora. However, we find that the KySS scores are much more close even with different pinyin integrity, which indicates that user experience in terms of KySS are more hard improved.

Instance Analysis We input a dialogue in wonder to how much of the contextual information is used when P2C module find the input pinyin is unknown. Figure 2 demonstrates the effect of the gated attention mechanism on candidates offering and unknown word replacement. As shown in Figure 2(a), we find that our IME suggests a more suitable candidates to the user when user is obviously not consistent with what the model has learned previously, which shows our model exceeds the Simple C+ P2C learning for maximally matching the inputted pinyin, but become capable of effectively resisting user pinyin input noise, and turns to learn potential language knowledge in previous input history[3].

As the ability predict user input from incomplete pinyin cannot be covered by any current IME performance metrics, thus the reported results yielded by our model actually underestimate our model performance to some extent. We illustrate the empirical discoveries of Figure 2(b) to demonstrate the extra effect of our P2C system on such situation, which indicates that the gated-attention pattern has taken great advantage of contextual information when given an unknown word. Or, namely, our model enables the incomplete input prediction though has to let it outside the current IME performance measurement. We display the attention visualization of Figure 2(b) in Figure 3 for better reference to explain the effect extended context plays on the generation of target characters.

Main Result Our model is compared to other models in Table 3. So far, (Huang et al., 2015) and (Zhang et al., 2017) reported the state-of-the-art results among statistical models. We list the top-5 accuracy contrast to all baselines with top-10 results, and the comparison indicates the noticeable advancement of our P2C model. To our surprise, the top-5 result on PD of our best Gated C+ P2C system approaches the top-10 accuracy of Google IME. On DC corpus, our Gated C+ P2C model with the best setting achieves 90.14% accuracy, surpassing all the baselines. The comparison shows our gated-attention system outperforms all state-of-the-art baselines with better user experience.

4 Conclusion

For the first time, this work makes an attempt to introduce additional context in neural pinyin-to-character converter for pinyin-based Chinese IME as to our best knowledge. We propose a gated-attention enhanced model for digging significant context information to improve conversion quality. More importantly, the resulting IME supports incomplete user pinyin input but returns complete, extra and even corrected character outputs, which brings about a story-telling mode change for all existing IMEs.

---

[3] Note as we evaluate our model only on two available corpora, but not the real world case from true user inputting history, which makes the instance situation limit to the domain feature of the given corpora.

Abstract

Recurrent neural network language models (RNNLMs) are the current standard-bearer for statistical language modeling. However, RNNLMs only estimate probabilities for complete sequences of text, whereas some applications require context-independent phrase probabilities instead. In this paper, we study how to compute an RNNLM's *marginal* probability: the probability that the model assigns to a short sequence of text when the preceding context is not known. We introduce a simple method of altering the RNNLM training to make the model more accurate at marginal estimation. Our experiments demonstrate that the technique is effective compared to baselines including the traditional RNNLM probability and an importance sampling approach. Finally, we show how we can use the marginal estimation to improve an RNNLM by training the marginals to match n-gram probabilities from a larger corpus.

1 Introduction

Recurrent neural networks (RNNs) are the state-of-the-art architecture for statistical language modeling (Jozefowicz et al., 2016; Melis et al., 2018), the task of assigning a probability distribution to a sequence of words. The relative likelihoods of the sequences are useful in applications such as speech recognition, machine translation, automated conversation, and summarization (Mikolov et al., 2010; Bahdanau et al., 2014; See et al., 2017; Wen et al., 2017). Typically, RNN language models (RNNLMs) are trained on complete sequences (e.g., a sentence or an utterance), or long sequences (e.g. several documents), and used in the same fashion in applications or testing. A question arises when we want to compute the probability of a short sequence without the preceding context. For instance, we may wish to query for how likely the RNNLM is to generate a particular phase aggregated over *all contexts*. We refer to this context-independent probability of a short phrase as a *marginal probability*, or marginal.

These marginal probabilities are useful in three board categories of applications. First, they allow us to inspect the behavior of a given RNNLM. We could check, for example, whether an RNNLM-based generator might ever output a given offensive phrase. Second, the marginals could be used in phrase-based information extraction, such as extracting cities by finding high-probability x's in the phrase "cities such as x" (Soderland et al., 2004; Bhagavatula et al., 2014). Finally, we can use the phrase probabilities to train an RNNLM itself, e.g. updating the RNNLM according to n-gram statistics instead of running text (Chelba et al., 2017; Noraset et al., 2018). In our experiments, we show an example of the last application.

Estimating marginals from an RNNLM is challenging. Unlike an n-gram language model (Chen and Goodman, 1996), an RNNLM does not explicitly store marginal probabilities as its parameters. Instead, previous words are recurrently combined with the RNN's hidden state to produce a new state, which is used to compute a probability distribution of the next word (Elman, 1990; Mikolov et al., 2010). When the preceding context is absent, however, the starting state is also missing. In order to compute the marginal probability, in principle we must marginalize over all possible previous contexts or all continuous-vector states. Both options pose a severe computational challenge.

In this paper, we study how to efficiently approximate marginal probabilities from an RNNLM, without generating a large amount of text. Given an RNNLM and a phrase, our goal is

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2930–2935
Brussels, Belgium, October 31 - November 4, 2018.

to estimate how frequently the phrase will occur in text generated by the RNNLM. We present two approaches that can be used to estimate the marginal probabilities: sampling for the starting state, and using a single starting state with altered RNNLM training. We show empirically that we can use a zero vector as a starting state of an RNNLM to compute accurate marginal estimates, but we must randomly reset the RNNLM state to zero during training and add a unigram likelihood term to the RNNLM training objective. Finally, we demonstrate that we can use marginal estimation to incorporate n-gram statistics from a larger corpus to improve the perplexity of an RNNLM trained on a similar, but smaller corpus.

2 Marginal Estimation

The goal of marginal estimation is to determine the likelihood of a short phrase where the preceding context is not known; we refer to this likelihood as a *marginal probability*. In other words, the marginal probability of a query refers to how likely a language model will generate a query regardless of context.

2.1 Problem settings

An RNNLM (Mikolov et al., 2010) defines a probability distribution over words conditioned on previous words as the following:

$$\begin{aligned} P(w_{1:T}) &= \prod_{t=1}^{T} P(w_t | w_{1:t-1}) \\ P(w_t | w_{1:t-1}) &= P(w_t | h_t) \propto \exp(\theta_o^{(w)} h_t) \\ h_t &= g(h_{t-1}, w_{t-1}) \end{aligned}$$

where $w_{1:t-1}$ is a sequence of previous words, θ_o^w denotes the output weights of a word w, and $g(\cdot)$ is a recurrent function such as an LSTM (Hochreiter and Schmidhuber, 1997) or GRU unit (Cho et al., 2014).

An initial state, h_1 is needed to start the recurrent function $g(h_1, w_1)$, and also defines the probability distribution of the first word $P(w_1|h_1)$. In the standard language model setting, we compute h_1 using a start-of-sentence symbol for w_0 ("`<s>`"), and a special starting state h_0 (usually set to be a vector of zeros $\vec{0}$). This initialization approach works fine for long sequences, because it is only utilized once and its effect is quickly swamped by the recurrent steps of the network. However, it is not effective for estimating marginal probabilities of a short phrase. For example, if we naively apply the standard approach to compute the probability of the phrase "`of the`", we would obtain:

$$\begin{aligned} P(\texttt{of the}) = &P(\texttt{of} | h_1 = g(\vec{0}, \texttt{<s>})) \times \\ &P(\texttt{the} | h_2 = g(h_1, \texttt{the})) \end{aligned}$$

The initial setting of the network results in low likelihoods of the first few tokens in the evaluation. For instance, the probability $P(\texttt{of the})$ computed in the above fashion will likely be a bad underestimate, because "`of the`" does not usually start a sentence.

We would like to compute the likelihood of standalone phrases, where rather than assuming the starting state we instead marginalize out the preceding context. Let the RNN's state prior to our query sequence be $z \in \mathbb{R}^d$, a vector-valued random variable representing the RNN initial state, and let $w_{1:T}$ be a short sequence of text. The marginal probability is defined as:

$$P(w_{1:T}) = \int P(w_{1:T}|z) P(z) dz \qquad (1)$$

The integral form of the marginal probability is intractable and requires an unknown density estimator of the state, $P(z)$.

2.2 Trace-based approaches

The integral form of the marginal probability in Eq 1 can be approximated by sampling for z. In this approach, we assume that there is a source of samples which asymptotically approaches the true distribution of the RNN states as the number of samples grows. In this work, we use a collection of RNN states generated in an evaluation, called a *trace*.

Given a corpus of text, a trace of an RNNLM is the corresponding list of RNN states, $H^{(tr)} = (h_1^{(tr)}, h_2^{(tr)}, ..., h_M^{(tr)})$, produced when evaluating the corpus. We can estimate the marginal probability by sampling the initial state z from H as follows:

$$P(w_{1:T}) = \mathbb{E}_{z \sim H^{(tr)}} \left[P(w_1|z) \prod_{t=2}^{T} p(w_t|h_t) \right] \quad (2)$$

where $h_2 = g(z_\psi, w_1)$ and $h_t = g(h_{t-1}, w_{t-1})$ for $t > 2$ (i.e. the following states are the deterministic output of the RNN function). Given a large trace this may produce accurate estimates, but it is intractably expensive and also wasteful, since in general there are very few states in the trace that yield a high likelihood for a sequence.

To reduce the number of times we run the model on the query, we use importance sampling over the trace. We train an encoder to output for a given n-gram query a state "near" the starting state(s) of the query, $z_\chi = q_\chi(w_{1:T})$. We define a sampling weight for a state in the trace, $h^{(tr)}$, proportional to the dot product of the state and the output of the encoder, z_χ , as the following:

$$P(h^{(tr)}|w_{1:T}) = \frac{exp(z_\chi h^{(tr)})}{\sum\limits_{h'^{(tr)}\in H^{(tr)}} exp(z_\chi h'^{(tr)})}$$

This distribution is biased to toward states that are likely to precede the query $w_{1:T}$. We can estimate the marginal probability as the following:

$$P(w_{1:T}) = \mathop{\mathbb{E}}_{z\sim P(h^{(tr)}|w_{1:T})}\left[\frac{P(z)}{P(z|w_{1:T})}P(w_1|z)\prod_{t=2}^{T} p(w_t|h_t)\right]$$

Here the choice of the prior $P(z)$ is a uniform distribution over the states in the trace. The encoder, $q_\chi(w_{1:T})$, is a trained RNN with its input reversed, and z_χ is the final output state of q_χ. To train the encoder, we randomly draw sub-strings $w_{i:i+n}$ of random length from the text used to produce the trace, and minimize the mean-squared difference between z_χ and $h_i^{(tr)}$.

2.3 Fixed-point approaches

While the trace-based approaches work on an existing (already trained) RNNLM, they might take several samples to accurately estimate the marginal probability. We would like to have a single point as the starting state, named z_ψ. We can either train this vector or simply set it to a zero vector. Then the marginal probability in Eq 1 can be estimated with a single run i.e. $p(z_\psi) = 1.0$ and $p(z) = 0.0$ if $z \neq z_\psi$. The computation is reduced to:

$$P(w_{1:T}) = P(w_1|z_\psi)\prod_{t=2}^{T} P(w_t|h_t) \qquad (3)$$

where $h_2 = g(z_\psi, w_1)$ and the rest of the state process is as usual, $h_t = g(h_{t-1}, w_{t-1})$. In this paper, we set z_ψ to be a zero vector, and call this method *Zero*.

As we previously discussed, our fixed-point state, z_ψ, is not a suitable starting state of all n-grams for any given RNNLM, so we need to train an RNNLM to adapt to this state. To achieve this, we use a slight modification of the RNN's truncated back-propagation through time training algorithm. We randomly *reset* the states to z_ψ when computing a new state during the training of the RNNLM (a similar reset was used for a different purpose—regularization—in Melis et al. (2018)). This implies that z_ψ is trained to maximize the likelihood of different subsequent texts of different lengths, and thus is an approximately good starting point for any sequence. Specifically, a new state is computed during the training as follows:

$$h_t = rz_\psi + (1-r)g(h_{t-1}, w_{t-1})$$

where $r \sim Bern(\rho)$ and ρ is a hyper-parameter for the probability of resetting a state. Larger ρ means more training with z_ψ, but it could disrupt the long-term dependency information captured in the state. We keep ρ relatively small at 0.05.

In addition to the *state reset*, we introduce a *unigram* regularization to improve the accuracy of the marginal estimation. From Eq 3, z_ψ is used to predict the probability distribution of the first token, which should be the unigram distribution. To get this desired behavior, we employ regularization to maximize the likelihood of each token in the training data *independently* (as if reset every step). We call this a unigram regularizer:

$$\mathcal{L}_U = -\sum_{t=1}^{T} \text{log}P(w_t|z_\psi)$$

and we add it to the training objective: $\mathcal{L}_{text} = -\sum_{t=1}^{T} \text{log}P(w_t|h_t)$. Thus, the overall training loss is: $\mathcal{L} = \mathcal{L}_{text} + \mathcal{L}_U$.

3 Experiments and Results

3.1 Experimental Settings

We experiment with a standard medium-size LSTM language model (Zaremba et al., 2014) over 2 datasets: Penn Treebank (PTB) (Mikolov et al., 2010) and WikiText-2 (WT-2) (Merity et al., 2017). We use weight tying (Inan et al., 2017) and train all models with Adam (Kingma and Ba, 2014) for 40 epochs with learning rate starting from 0.003 and decaying every epoch at the rate of 0.85. We use a batch size of 64 and truncated backpropagation with 35 time steps, and

	PTB		WT-2	
	$E(\cdot)$	PPL	$E(\cdot)$	PPL
Zero	3.828	90.18	4.432	104.08

Table 1: The average error of different marginal estimation approaches and the testing perplexity. The RNNLM trained with *state-reset (R)* and *unigram (U)* regularization has the lowest error when using a zero starting state to estimate the marginals.

employ variational dropout (Gal and Ghahramani, 2016). The final parameter set is chosen as the one minimizing validation loss. For the query model $q_X(w_{1:T})$ used in importance sampling, we use the same settings for the model and the training procedure as the above.

3.2 Marginal Estimation

In this subsection, we evaluate the accuracy of each approach at estimating marginal probabilities. Given a model and a phrase, we first obtain a target marginal probability, $P_{text}(w_{1:T})$, from a frequency of the phrase occurring in a text generated by the model. Then, we use each approach to estimate the marginal probability of the phrase, $P_{est}(w_{1:T})$. To measure the performance, we compute the absolute value of the log ratio (lower is better) between the target marginal probability and the estimated marginal probability (P_{est}):

$$E(w_{1:T}) = \left|\log(P_{text}(w_{1:T})/P_{est}(w_{1:T}))\right| \quad (4)$$

This evaluation measure gives equal importance to every n-gram regardless of its frequency.

In the following experiments, we generate approximately 2 million and 4 million tokens for PTB and WT-2 models respectively. The probability of phrases occurring in the generated text serves as our target marginal. We form a test set consisting of all n-grams in the generated text for $n \leq 5$ words, excluding n-grams with frequency less than 20 to reduce noise from the generation. For the trace-based estimations, we average the marginal probabilities from 100 samples.

Table 1 shows the average discrepancy between marginal probabilities estimated by generated-text statistics and the methods discussed in Section 2 (Eq 4). From the table, the RNNLM trained with the *state-reset* and the *unigram* regularization (*Zero*$^{(RU)}$) performs better than both zero-start and trace-based approaches on the traditional model. The importance sampling method (*Trace-IW*) has the second lowest error and performs better than random sampling (*Trace-Rand*). Ablation analysis shows that both *state-reset* and the *unigram* regularization contribute to the accuracy. Note that the trace-based methods use the same model as *Zero*.

	1	2	3	4	5
Zero	1.02	4.18	6.15	8.78	10.8
Zero$^{(RU)}$	**0.38**	**0.72**	0.95	1.54	2.10
Trace-IW	0.70	0.81	**0.92**	**1.22**	**1.48**
n-grams	10.7	20.7	10.5	3.7	1.5

Table 2: The error aggregate by n-gram lengths. This shows the same trend as in Table 1, but *Trace-IW* performs better for longer n-grams.

To show how performance varies depending on the query, we present results aggregated by n-gram lengths. Table 2 shows the errors of the WT-2 dataset. When the n-gram length is greater than 2, *Trace-IW* has better accuracy. This makes sense because the encoder has more evidence to use when inferring the likely start state.

3.3 Training with marginal probabilities

We now turn to an application of the marginal estimation. One way that we can apply our marginal estimation techniques is to train an RNNLM with n-gram probabilities in addition to running text. This is helpful when we want to efficiently incorporate data from a much larger corpus without training the RNNLM on it directly (Chelba et al., 2017; Noraset et al., 2018). In this work, we frame the problem as a regression and use a loss equal to the squared difference of log probabilities:

$$\mathcal{L}_N = \frac{\alpha}{2K}\sum_{k}^{K}(\log P_{text}(x_{1:T}^{(k)}) - \log P_{est}(x_{1:T}^{(k)}))^2$$

where α is a hyper-parameter and set to 0.1. Following the result in Table 1, we use the *Zero* method to estimate $P_{est}(x_{1:T}^{(k)})$ as in Eq 3, and add $\mathcal{L}_N$ to the training losses that use the running text corpus.

To evaluate the approach, we follow the Noraset et al. (2018) experiment in which bi-gram statistics from the training text of WT-103 are used to

Loss	PPL
$\mathcal{L}_{text}^{(2)}\ (Zero)$	104.08
$\mathcal{L}_{text}^{(2)} + \mathcal{L}_{U}^{(2)}\ (Zero^{(U)})$	102.56
$\mathcal{L}_{text}^{(2)} + \mathcal{L}_{U}^{(2)} + \mathcal{L}_{N}^{(103)}$	**93.95**

Table 3: Test perplexities of RNNLMs trained on different loss functions. Using n-gram probabilities from a larger corpus (WT-103) improves perplexities.

improve an RNNLM trained using WT-2. In our experiment, we use n-grams up to $n = 5$ with frequency greater than 50. We ignore n-gram containing `<unk>`, because the vocabulary sets are different. Table 3 shows the result. Since we do not use the same setting as in the original work, we cannot directly compare to that work – they use different optimization settings, more expensive n-gram loss, and Kneser-Ney bi-gram language model. However, we see that the proposed n-gram loss is beneficial when combined with the unigram loss. Importantly, unlike the approach in Noraset et al. (2018), our approach requires no sampling which makes it several times faster.

In addition, we present our preliminary result comparing training with the marginal probability of n-grams to training with the complete data. Given a limited budget of optimization steps, we ask whether training on n-grams is more valuable than training on the full corpus. To keep the results compatible, we use the vocabulary set of WikiText-2 and convert all OOV tokens in the training data of WikiText-103 to the "`<unk>`" token. Figure 1 shows the loss (average negative log-likelihood) of the validation data as the number of optimization steps increases.

We can see that training with the marginals does not perform as well as training with WikiText-103 training data, but outperforms the model trained only with WikiText-2 training data. This might be due to our choice of n-grams and optimization settings such as a number of n-grams per batch, weight of the n-gram loss, and the learning rate decay rate. We leave exploring these hyperparameters as an item of future work.

4 Conclusion

We investigated how to estimate marginal probabilities of n-grams from an RNNLM, when the preceding context is absent. We presented a simple method to train an RNNLM in which we occasionally reset the RNN's state and also maximize

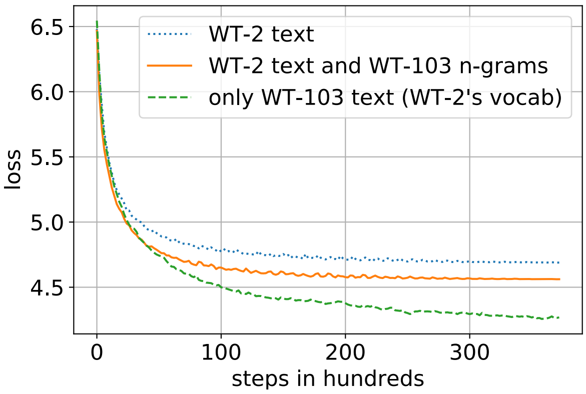

Figure 1: Loss in negative log-likelihood over steps in training. The loss computed using the valid data from WikiText-2 corpus. Training with n-grams from a larger corpus is helpful, but not as well as training with the running text from a larger corpus itself.

unigram likelihood along with the traditional objective. Our experiments showed that an RNNLM trained with our method outperformed other baselines on the marginal estimation task. Finally, we showed how to improve RNNLM perplexity by efficiently using additional n-gram probabilities from a larger corpus.

For future work, we would like to evaluate our approaches in more applications. For example, we can use the marginal statistics for information extraction, or to detect and remove abnormal phrases in text generation. In addition, we would like to continue improving the marginal estimation by experimenting with recent density estimation techniques such as NADE (Uria et al., 2016).

How to represent a word and predict it, too: Improving tied architectures for language modelling

Kristina Gulordava **Laura Aina** **Gemma Boleda**
Universitat Pompeu Fabra
Barcelona, Spain
{firstname.lastname}@upf.edu

Abstract

Recent state-of-the-art neural language models share the representations of words given by the input and output mappings. We propose a simple modification to these architectures that decouples the hidden state from the word embedding prediction. Our architecture leads to comparable or better results compared to previous tied models and models without tying, with a much smaller number of parameters. We also extend our proposal to word2vec models, showing that tying is appropriate for general word prediction tasks.

1 Introduction

In neural models, reusing representations of the same type of data (e.g., sentences or words) in different parts of the architecture can be a powerful way to aid learning: it reduces parameters, enabling more compact models and faster learning. Recurrent neural network (RNN) language models (Mikolov et al., 2010; Sundermeyer et al., 2012; Zaremba et al., 2014) have two word mappings: From the input word onto its embedding representation, and from the internal representation of the network (the hidden layer) to the weights for the prediction of the next word. In standard models, these representations are different. Recently, Inan et al. (2017) and Press and Wolf (2017) proposed to instead use a single word representation, *tying* the input and output mappings. Intuitively, both are representations of the same type of data (words), and information learnt when observing a word as input can be reused when predicting this word as output. Tied language models obtained better perplexity and better word similarity scores of embedding matrices while reducing the number of parameters. The models that achieve the latest state-of-the art results incorporate this technique (see, e.g., Merity et al., 2018).

However, note that, by tying the output mapping to the input mapping, the hidden layer of the network is optimised to match the representation of the predicted word. We suggest that this introduces a constraint that conflicts with the function of the hidden layer in language models to represent the previous context and transmit information to the next timestep. In this paper, we propose a minimal modification to tied LM architectures to address this issue: we add a linear transformation between the hidden layer and the word embedding prediction, partially decoupling the two. This has an important advantage. Standard tied architectures require the hidden layer to have the same dimensionality as the word embeddings. We lift this constraint in our architecture: by separating the hidden layer and the word mapping, we can choose a large hidden layer dimensionality while keeping the embedding dimensionality and, consequently, the size of the embedding matrix small.

In a set of experiments on LM, we show that our tied models achieve results similar to or better than models with standard or no tying, with much smaller embedding sizes and a reduction of 30-60% in the overall number of parameters. Notably, the word embeddings obtained with the modified model have a higher quality than double-sized embeddings obtained with standard tied models, as measured on word similarity.

We further extend this idea to word representation learning models (in particular, word2vec), which have a similar architecture and objective function to language models. For instance, the standard skipgram model (Mikolov et al., 2013) has two mappings, one for the context words and one for the target word. While tying these two matrices directly constraints learning too strongly, an additional linear mapping adds the sufficient capacity to learn embeddings of the same quality as the standard model using only half the parameters.

2 Tied LM architectures

2.1 Previous work

Equations (1) through (4) define a standard RNN language model (Mikolov et al., 2010):

$$\mathbf{\hat{x}_t} = \mathbf{x_t} E \tag{1}$$

$$\mathbf{h_t} = LSTM(\mathbf{\hat{x}_t}, \mathbf{h_{t-1}}) \tag{2}$$

$$\mathbf{o} = \mathbf{h_t} W^T \tag{3}$$

$$\mathbf{p} = softmax(\mathbf{o}), \tag{4}$$

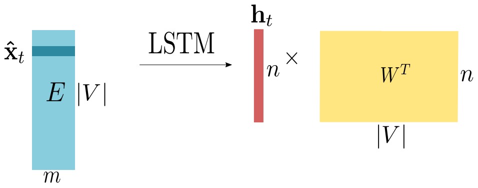
where $\mathbf{x_t}$ is the one-hot encoding of the input word at time t, $\mathbf{\hat{x}_t}$ is its embedded representation and E is the embedding matrix (input mapping). We follow the majority of previous work in adopting an LSTM (Hochreiter and Schmidhuber, 1997) as the recurrent unit, as it was shown to outperform other recurrent architectures for LM (Jozefowicz et al., 2015). The hidden vector $\mathbf{h_t}$ is used as input to the LSTM for the next time step and also as input to a linear transformation W (output mapping) which produces the output weights. These weights are normalised into probability scores using the softmax function.

The tied models proposed by Inan et al. (2017) and Press and Wolf (2017) set W to be equal to E (Figure 1b). Note that since E is of size $|V| \times m$, where m is the embedding size, and W is of size $|V| \times n$, where n is the hidden state size, the hidden and embedding dimensions must be equal, that is, $m = n$.

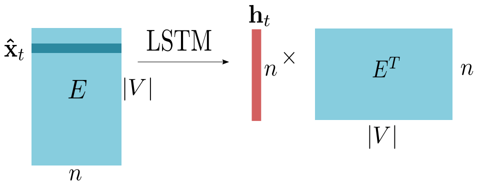
Press and Wolf (2017) observe that the output matrix W represents an embedding matrix since two similar words with indices i and j are learnt to receive similar probabilities given a context and hence the rows W_i and W_j should also be similar. Indeed, they show that on some word similarity evaluation tasks the output matrix W outperforms significantly the input matrix E. Tying E and W makes the model share the representations for the input and output vocabularies.

Inan et al. (2017) suggest a theoretical motivation for the tying technique and derive it as an instance of a more general approach of augmenting the cross-entropy loss. They show that a loss that takes into account not only the target word (i.e., $\log p_i$ for cross-entropy) but the scores for all words in the vocabulary according to their similarity to the target (computed as dot-product of embeddings in E) improves performance on LM.

(a) Non-tied model



(b) Tied model



(c) Tied+L model

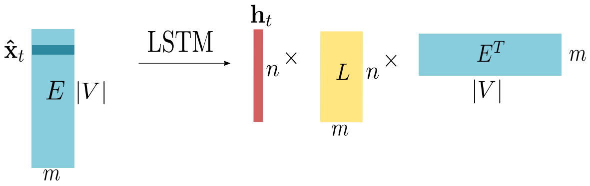


Figure 1: Effect of the three architectures on mapping sizes. Note that the actual difference between vocabulary size $|V|$ and n, m is of 2 to 3 orders of magnitude.

One important practical advantage of tying input and output matrices is the reduction in number of parameters with respect to a standard model with the same hidden and embedding dimensions, since instead of two matrices E and W of size $|V| \times m$ we have only one matrix of size $|V| \times m$.

2.2 Proposed modification

One potential problem with the tied model, where $E = W$, is that the hidden state $\mathbf{h_t}$ is optimised to be close to the embedding of the target word. To see this, consider that $o_j = \mathbf{e_j} \cdot \mathbf{h_t}, \forall j$. The cross-entropy objective is to maximise $\log p_i$ for the target word with index i and consequently to minimise $\log p_j \forall j \neq i$. Hence, $o_i = \mathbf{e_i} \cdot \mathbf{h_t}$ will be increased by the gradient descent update and $\mathbf{h_t}$ will be aligned closer with $\mathbf{e_i}$ (for each dimension k of the two vectors, $h_{tk} \cdot e_{ik}$ will be increased). This association between $\mathbf{h_t}$ and word embedding space could prevent efficient retention of LSTM history in $\mathbf{h_t}$, which is used as input for the following time step.

To address this issue, we propose a simple modification to the standard tied model, replacing the output transformation (3) as follows:

$$\begin{aligned}\hat{\mathbf{h}}_{\mathbf{t}} &= \mathbf{h}_{\mathbf{t}} L \\ \mathbf{o} &= \hat{\mathbf{h}}_{\mathbf{t}} E^T.\end{aligned} \tag{5}$$

L is an additional linear transformation that decouples the hidden state $\mathbf{h}_{\mathbf{t}}$, which is passed to the next time step and represents the previous, possibly long-term, linguistic context, from $\hat{\mathbf{h}}_{\mathbf{t}}$, which is instead optimised to match the embedding of the output word.

As Figure 1 illustrates, an important advantage of the additional transformation L is that a model can have different dimensions for the hidden vector (n) and the embedding vectors (m). The embedding matrix is the largest part of the model when the vocabulary is large ($|V| \gg n$). Reducing the size of the embedding m leads to a significant reduction in the number of parameters, proportional to $|V|$, and the acceleration of softmax computation. On the other hand, the size of the additional matrix L is only $n \times m$ and contributes very little to the overall size of the model. We test empirically how reducing the embedding size affects the performance of language models by varying hidden and embedding sizes in our experiments and evaluating embedding matrices on word similarity tasks.

Standardly used LM models often have two layers of LSTM cells. Thus, the issue we identifed might be mitigated in practice, since the hidden state of the first layer is not directly affected by tying the output and input transformation matrices. Moreover, an LSTM cell carries over information both through the hidden state and a memory state; the latter is affected by tying only indirectly (see Hochreiter and Schmidhuber (1997) for details on LSTM architectures). However, our experiments show that, in practice, two-layer LSTM LMs are still affected by tying despite these caveats.

2.3 Extending the tied technique to word2vec

The tied technique, as formulated above, can be in principle applied to any model which has the same general objective of LM: predicting a target word given context words. The CBOW word2vec model for word representation learning (Mikolov et al., 2013) is the primary candidate for testing the applicability of the tied technique beyond LM, since we can see it as substituting the LSTM function (2) with a simple sum of context word embeddings $\mathbf{h} = \sum_i \hat{\mathbf{x}}_{\mathbf{i}}$ (where x_i are words in the context window, e.g., of size 5). Similarly then, the equations in (5) describe the tied version of CBOW model. The linear step here provides the capacity to learn a transformation from the sum of embeddings to the predicted embedding $\hat{\mathbf{h}}$. Without such transformation, the tying model would assume that the sum function is always a good approximation of the output embedding.

The skipgram word2vec model (Mikolov et al., 2013) employs a variant of the LM objective: It is trained to predict context words given a word, instead of the opposite. As in CBOW and neural language models, words are both inputs and targets, making the use of tying an option also for this architecture. Press and Wolf (2017) apply direct tying to this architecture and report that the quality of the obtained embeddings is below the quality of non-tied skipgram embeddings. Unlike CBOW or LSTM, the input-to-hidden state function of the skipgram model is identity, reducing the tying model objective to $\hat{\mathbf{x}}_{\mathbf{i}} = \hat{\mathbf{x}}_{\mathbf{j}}$ for every pair of input-output words i, j. It is thus not surprising that enforcing the tying constraint leads to poor empirical results. We test whether adding an additional linear transformation improves performance of the tied technique also for a skipgram model.

3 Experiments and results

3.1 Evaluation data

We use two corpora for the evaluation of language models. First, we employ a medium-sized corpus of approximately 100M tokens with a relatively large vocabulary, 50K words, created from a Wikipedia dump (henceforth, Wiki).[1] To allow comparison with previous work, we also evaluate on the Penn Treebank (PTB), which is small but has been used as a benchmark for LM since Mikolov et al. (2011). The PTB has approximately 1M tokens and is preprocessed to have 10K vocabulary words; we use the standard train-validation-test split.

Furthermore, to evaluate the quality of the embeddings induced by the language models, as well as for the word representation experiments in Section 3.4, we use three standard word similarity datasets: SimLex-999 (Hill et al., 2015; SimLex), MEN (Bruni et al., 2014), and RareWords (Luong et al., 2013; RW). The performance on these datasets is evaluated in terms of Spearman corre-

lation between the cosine similarity of word pairs and human judgments.[2]

3.2 Training setup

As our base language models, we adopt the ones proposed in Zaremba et al. (2014). We use 2-layer LSTMs with dropout applied to the input embedding, to the output of the first LSTM layer and to the output of the second layer. We used the PyTorch implementation[3] and modified it to include the additional linear layer for our tied models. We report the best model after the hyperparameter search for dropout and learning rate (see the details in Appendix A).

3.3 Language modelling results

We present the LM results for the standard non-tied model, the tied model as in Inan et al. (2017) and Press and Wolf (2017), and our tied model with an additional linear transformation (*tied+L*) in Tables 1 (PTB) and 2 (Wiki).

Table 1 confirms that tying generally brings gains with respect to not tying. This is also true for the cases when the hidden and embedding sizes are different (e.g. 400/200 and 600/400), where our tied+L model outperforms the non-tied model by 5 to 6.4 points having around 40% less parameters. Furthermore, our decoupled model slightly but consistently improves results with respect to standard tying, confirming our intuition that the coupling of the hidden state to the embedding representation is a limiting constraint. Smaller tied+L models perform well compared to larger tied models. In particular, the tied+L model with 600/400 units has perplexity of 76.0, compared to 76.1 of the tied 600/600 model, with 55% the number of parametres. Note that our results are comparable to previously reported perplexity values on PTB for similar models. Our best results of 75.5 test perplexity is only 1.2 points behind the large tied model with 1500 units reported in Press and Wolf (2017) and is only 1.6 points behind the medium tied model with 650 units and variational dropout (Gal and Ghahramani, 2016) reported in Inan et al. (2017).

On the Wiki corpus with larger vocabulary (Table 2), we find that tied models achieve slightly lower perplexity than non-tied models with half the number of parameters, and our proposed tied+L model achieves lower perplexity than the tied model. The most relevant result of the present experiment, however, is that the tied+L model with 300 embedding units is actually better than the tied model with 600 units (38.5 vs 39.7 points; the tied+L model has 20M parameters compared to 36M of the tied model) – that is, a smaller model outperforms a larger model. Thus, our decoupling mechanism not only allows models to have better perplexity, but also more compact word embeddings, which are of a higher quality also as measured on word similarity: .42/.61/.68 for the tied+L embeddings of size 300, compared to .39/.55/.64 for the tied embeddings of size 600.

3.4 Experiments on word2vec models

Table 3 presents the evaluation of word2vec models on the three word similarity datasets. We ran the experiments only on the Wiki corpus due to its higher coverage (50K vocabulary), and used embeddings of size 300.

Our results on CBOW show that the tied+L architecture obtains comparable results to the non-

---

Table 3: Results (ρ) for word2vec models.

tied architecture with almost half the parameters (15.1M vs 30M). This confirms that tying with an additional linear transformation is appropriate not only for language models but for word learning models more generally.

The skipgram algorithm shows a small degradation of performance for the tied+L architecture with respect to the non-tied one; note that, as explained in Section 2.3, tying makes the most sense for CBOW. However, the fact that standard tying obtains much worse results (similarly to the results of Press and Wolf, 2017) shows that the linear mapping substantially relaxes the tying constraint.

4 Conclusions

Overall, our simple modification to tied language modelling architectures generalises previous work by allowing tying without imposing constraints on the number of hidden and embedding dimensions. This leads to flexible architectures with a more efficient use of both hidden states and embeddings. For word representation learning models, having an additional linear transformation reduces the number of parameters while maintaining learning capacity. In general, reducing model size without harming performance is a desirable feature in practice, for example in the case of language models running on mobile devices, and it is also desirable on theoretical grounds, since it is a better use of the learning capacity of neural networks.

The Importance of Generation Order in Language Modeling

Abstract

Neural language models are a critical component of state-of-the-art systems for machine translation, summarization, audio transcription, and other tasks. These language models are almost universally autoregressive in nature, generating sentences one token at a time from left to right. This paper studies the influence of token generation order on model quality via a novel *two-pass language model* that produces partially-filled sentence "templates" and then fills in missing tokens. We compare various strategies for structuring these two passes and observe a surprisingly large variation in model quality. We find the most effective strategy generates *function* words in the first pass followed by *content* words in the second. We believe these experimental results justify a more extensive investigation of generation order for neural language models.

1 Introduction

Neural networks have been extremely successful statistical models of text in language modeling and machine translation. Despite differences in model architectures, state of the art neural nets generate sequences from left to right (Vaswani et al., 2017; Jozefowicz et al., 2016; Wu et al., 2016). Although in some sense humans produce and consume language from left to right as well, there are many other intuitively appealing ways to generate text. For instance, language is slow enough on a neurological time scale for multiple passes of generation that incorporate feedback to occur. Linguistic intuition might suggest that we should first generate some abstract representation of what we want to say and then serialize it, a process that seems more universally appropriate given the existence of languages with freer word order such as Czech and Polish.

There has been interest in moving beyond the left-to-right generation order by developing alternative multi-stage strategies such as syntax-aware neural language models (Bowman et al., 2016) and latent variable models of text (Wood et al., 2011). Before embarking on a long-term research program to find better generation strategies that improve modern neural networks, one needs evidence that the generation strategy can make a large difference. This paper presents one way of isolating the generation strategy from the general neural network design problem. Our key technical contribution involves developing a flexible and *tractable* architecture that incorporates different generation orders, while enabling *exact* computation of the log-probabilities of a sentence. Our experiments demonstrate that even when using a few simple two-pass generation orders, the differences between good and bad orderings are substantial.

We consider ways of reordering the tokens within a sequence based on their identities. The best ordering we tried generates function words first and content words last, which cuts against the idea of committing to the general topic of a sentence first and only then deciding exactly how to phrase it. We offer some possible explanations in Section 3, and we conclude that our experimental results justify a more extensive investigation of the generation order for language and translation models.

2 Two-pass Language Models

We develop a family of *two-pass language models* that depend on a partitioning of the vocabulary into a set of *first-pass* and *second-pass* tokens to generate sentences. We perform a preprocessing step on each sequence $\mathbf{y}$, creating two new sequences $\mathbf{y}^{(1)}$ and $\mathbf{y}^{(2)}$. The sequence $\mathbf{y}^{(1)}$, which we call the *template*, has the same length as $\mathbf{y}$, and consists of the first-pass tokens from $\mathbf{y}$ together with a special *placeholder* token wherever

Table 1: Some example sentences from the dataset and their corresponding templates. The placeholder token is indicated by “__”.

$\mathbf{y}$ had a second-pass token. The sequence $\mathbf{y}^{(2)}$ has length equal to the number of these placeholders, and consists of the second-pass tokens from $\mathbf{y}$ in order.

We use a neural language model p_1 to generate $\mathbf{y}^{(1)}$, and then a conditional translation model p_2 to generate $\mathbf{y}^{(2)}$ given $\mathbf{y}^{(1)}$. Note that, since the division of the vocabulary into first- and second-pass tokens is decided in advance, there is a one-to-one correspondence between sequences $\mathbf{y}$ and pairs $(\mathbf{y}^{(1)}, \mathbf{y}^{(2)})$. The total probability of $\mathbf{y}$ is then

$$p(\mathbf{y}) \;=\; p_1(\mathbf{y}^{(1)})\, p_2(\mathbf{y}^{(2)} \mid \mathbf{y}^{(1)})\,. \qquad (1)$$

Two-pass language models present a unique opportunity to study the importance of generation order because, since the template is a deterministic function of $\mathbf{y}$, the probability of $\mathbf{y}$ can be computed exactly. This is in contrast to a language model using a *latent* generation order, which requires a prohibitive marginalization over permutations to compute the exact probabilities. Given the tractable nature of the model, exact learning based on log-likelihood is possible, and we can compare different vocabulary partitioning strategies both against each other and against a single-pass language model.

Our implementation consists of two copies of the Transformer model from Vaswani et al. (2017). The first copy just generates the template, so it has no encoder. The second copy is a sequence-to-sequence model that translates the template into the complete sentence. There are three places in this model where word embeddings appear — the first-phase decoder, the second-phase encoder, and the second-phase decoder — and all three sets of parameters are shared. The output layer also shares the embedding parameters.[1]

For the second pass, we include the entire target sentence, not just the second-pass tokens, on the output side. In this way, when generating a token, the decoder is allowed to examine all tokens to the left of its position. However, only the second-pass tokens count toward the loss, since in the other positions the correct token is already known. Our loss function is then the sum of all of these numbers (from both copies) divided by the length of the original sentence, which is the log-perplexity that our model assigns to the sentence.

We tried five different ways of splitting the vocabulary:

Common First and Rare First: The vocabulary was sorted by frequency and then a cutoff was chosen, splitting the vocabulary into “common” and “rare” tokens. The location of the cutoff[2] was chosen so that the number of common tokens and the number of rare tokens in the average sentence were approximately the same. In “common first”

---

[1] This behavior is enabled in the publicly available implementation of Transformer using the hyperparameter called `shared_embedding_and_softmax_weights`.

[2] In our experiments on LM1B, this is at index 78.

we place the common tokens in the first pass, and in "rare first" we start with the rare tokens.

Function First and Content First: We parsed about 1% of LM1B's training set using Parsey McParseface (Andor et al., 2016) and assigned each token in the vocabulary to the grammatical role it was assigned most frequently by the parser. We used this data to divide the vocabulary into "function" words and "content" words; punctuation, adpositions, conjunctions, determiners, pronouns, particles, modal verbs, "wh-adverbs" (Penn part-of-speech tag `WRB`), and conjugations of "be" were chosen to be function words. In "function first" we place the function words in the first phase and in "content first" we start with the content words.

Odd First: As a control, we also used a linguistically meaningless split where tokens at an odd index in the frequency-sorted vocabulary list were assigned to the first pass and tokens with an even index were assigned to the second pass.

A few sentences from the dataset are shown in Table 1 together with their templates. Note that the common and function tokens are very similar; the main differences are the "unknown" token, conjugations of "have," and some prepositions.

3 Experimental Results and Discussion

We ran experiments with several different ways of splitting the vocabulary into first-pass and second-pass tokens. We trained all of these models on the One Billion Word Language Modeling benchmark (LM1B) dataset (Chelba et al., 2013). One sixth of the training data was used as a validation set. We used a vocabulary of size 65,536 consisting of whole words (rather than word pieces) converted to lower-case.

We compared the two-pass generation strategies to a baseline version of Transformer without an encoder, which was trained to unconditionally predict the target sentences in the ordinary way. Because the two-pass models contain slightly more trainable parameters than this baseline, we also compare to an "enhanced baseline" in which the size of Transformer's hidden space was increased to make the number of parameters match the two-pass models.

Both the two-pass models and the baselines used the hyperparameters referred to as `base` in the publicly available implementation of Transformer,[3] which has a hidden size of 512, a filter size of 2048, and 8 attention heads, except that the enhanced baseline used a hidden size of 704. We used a batch size of 4096. All models were trained using ADAM (Kingma and Ba, 2014), with $\beta_1 = 0.85$, $\beta_2 = 0.997$, and $\epsilon = 10^{-6}$. The learning rate was tuned by hand separately for each experiment and the experiments that produced the best results on the validation set are reported. Dropout was disabled after some initial experimentation found it to be detrimental to the final validation loss.

Table 2 shows the results for all the two-pass generation strategies we tried as well as the baselines, sorted from worst to best on the validation set. Strikingly, the linguistically meaningless odd first generation strategy that splits words arbitrarily between the two phases is far worse than the baseline, showing that the two-pass setup on its own provides no inherent advantage over a single phase. The common first and closely related function first strategies perform the best of all the two-pass strategies, whereas the rare first and closely related content first strategies are much worse. Since the control, rare first, and content first orderings are all worse than the baseline, the gains seen by the other two orderings cannot be explained by the increase in the number of trainable parameters alone.

The enhanced version of the baseline achieved slightly better perplexity than the best of the two-pass models we trained. Given that state-of-the-art results with Transformer require models larger than the ones we trained, we should expect growing the embedding and hidden size to produce large benefits. However, the two-pass model we proposed in this work is primarily a tool to understand the importance of sequence generation order and was not designed to be parameter efficient. Thus, as these results indicate, increasing the embedding size in Transformer is a more effective use of trainable parameters than having extra copies of the other model parameters for the second pass (recall that the embeddings are shared across both passes).

One potential explanation for why the function first split performed the best is that, in order to generate a sentence, it is easier to first decide something about its syntactic structure. If this is the primary explanation for the observed results, then common first's success can be attributed to how many function words are also common. However, an alternative explanation might

Table 2: The perplexities achieved by the best version of each of our models.

simply be that it is preferable to delay committing to a rare token for as long as possible as all subsequent decisions will then be conditioning on a low-probability event. This is particularly problematic in language modeling where datasets are too small to cover the space of all utterances. We lack sufficient evidence to decide between these hypotheses and believe further investigation is necessary.

Ultimately, our results show that content-dependent generation orders can have a surprisingly large effect on model quality. Moreover, the gaps between different generation strategies can be quite large.

4 Related Work

For tasks conditioning on sequences and sets, it is well known that order significantly affects model quality in applications such as machine translation (Sutskever et al., 2014), program synthesis (Vinyals et al., 2016), and text classification (Yogatama et al., 2016). Experimentally, Khandelwal et al. (2018) show that recurrent neural networks have a memory that degrades with time. Techniques such as attention (Bahdanau et al., 2014) can be seen as augmenting that memory.

Text generation via neural networks, as in language models and machine translation, proceeds almost universally left-to-right (Jozefowicz et al., 2016; Sutskever et al., 2014). This is in stark contrast to phrase-based machine translation systems (Charniak et al., 2003) which traditionally split token translation and "editing" (typically via reordering) into separate stages. This line of work is carried forward in Post-Editing Models (Junczys-Dowmunt and Grundkiewicz, 2016), Deliberation Networks (Xia et al., 2017), and Review Network (Yang et al., 2016) which produce a "draft" decoding that is further edited. As any valid sequence may be used in a draft, calculating perplexity in these models is unfortunately intractable, and model quality can only be evaluated via external tasks.

In addition to surface-form intermediate representation, syntax-based representations have a rich history in text modeling. Chelba and Jelinek (1998); Yamada and Knight (2001); Graham and Genabith (2010); Shen et al. (2018) integrate parse structures, explicitly designed or automatically learned, into the decoding process.

Similar to the second phase of this work's proposed model, (Fedus et al., 2018) directly tackles the problem of filling in the blank, akin to the second stage of our proposed model. The Multi-Scale version of PixelRNN in (Van Oord et al., 2016) was also an inspiration for the two-pass setup we used here.

5 Conclusion and Future Work

To investigate the question of generation order in language modeling, we proposed a model that generates a sentence in two passes, first generating tokens from left to right while skipping over some positions and then filling in the positions that it skipped. We found that the decision of which tokens to place in the first pass had a strong effect.

Given the success of our function word first generation procedure, we could imagine taking this idea beyond splitting the vocabulary. One could run a parser on each sentence and use the resulting tree to decide on the generation order. Such a scheme might shed light on which aspect of this split was most helpful. Finally, filling in a template with missing words is a task that might be interesting in its own right. One might want to provide partial information about the target sentence as part of scripting flexible responses for a dialogue agent, question answering system, or other system that mixes a hand-designed grammar with learned responses.

Abstract

Neural Machine Translation (NMT) can be improved by including document-level contextual information. For this purpose, we propose a hierarchical attention model to capture the context in a structured and dynamic manner. The model is integrated in the original NMT architecture as another level of abstraction, conditioning on the NMT model's own previous hidden states. Experiments show that hierarchical attention significantly improves the BLEU score over a strong NMT baseline with the state-of-the-art in context-aware methods, and that both the encoder and decoder benefit from context in complementary ways.

1 Introduction

Neural machine translation (NMT) (Bahdanau et al., 2015; Wu et al., 2016; Vaswani et al., 2017) trains an encoder-decoder network on sentence pairs to maximize the likelihood of predicting a target-language sentence given the corresponding source-language sentence, without considering the document context. By ignoring discourse connections between sentences and other valuable contextual information, this simplification potentially degrades the coherence and cohesion of a translated document (Hardmeier, 2012; Meyer and Webber, 2013; Sim Smith, 2017). Recent studies (Tiedemann and Scherrer, 2017; Jean et al., 2017; Wang et al., 2017; Tu et al., 2018) have demonstrated that adding contextual information to the NMT model improves the general translation performance, and more importantly, improves the coherence and cohesion of the translated text (Bawden et al., 2018; Lapshinova-Koltunski and Hardmeier, 2017). Most of these methods use an additional encoder (Jean et al., 2017; Wang et al., 2017) to extract contextual information from previous source-side sentences. However, this requires additional parameters and it does not exploit the representations already learned by the NMT encoder. More recently, Tu et al. (2018) have shown that a cache-based memory network performs better than the above encoder-based methods. The cache-based memory keeps past context as a set of words, where each cell corresponds to one unique word keeping the hidden representations learned by the NMT while translating it. However, in this method, the word representations are stored irrespective of the sentences where they occur, and those vector representations are disconnected from the original NMT network.

We propose to use a hierarchical attention network (HAN) (Yang et al., 2016) to model the contextual information in a structured manner using word-level and sentence-level abstractions. In contrast to the hierarchical recurrent neural network (HRNN) used by (Wang et al., 2017), here the attention allows dynamic access to the context by selectively focusing on different sentences and words for each predicted word. In addition, we integrate two HANs in the NMT model to account for target and source context. The HAN encoder helps in the disambiguation of source-word representations, while the HAN decoder improves the target-side lexical cohesion and coherence. The integration is done by (i) re-using the hidden representations from both the encoder and decoder of previous sentence translations and (ii) providing input to both the encoder and decoder for the current translation. This integration method enables it to jointly optimize for multiple-sentences. Furthermore, we extend the original HAN with a multi-head attention (Vaswani et al., 2017) to capture different types of discourse phenomena.

Our main contributions are the following: (i) We propose a HAN framework for translation to capture context and inter-sentence connections in a structured and dynamic manner. (ii) We integrate the HAN in a very competitive NMT ar-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2947–2954
Brussels, Belgium, October 31 - November 4, 2018.

chitecture (Vaswani et al., 2017) and show significant improvement over two strong baselines on multiple data sets. (iii) We perform an ablation study of the contribution of each HAN configuration, showing that contextual information obtained from source and target sides are complementary.

2 The Proposed Approach

The goal of NMT is to maximize the likelihood of a set of sentences in a target language represented as sequences of words $\mathbf{y} = (y_1, ..., y_t)$ given a set of input sentences in a source language $\mathbf{x} = (x_1, ..., x_m)$ as:

$$\max_{\Theta} \frac{1}{N} \sum_{n=1}^{N} log(P_{\Theta}(\mathbf{y^n}|\mathbf{x^n})) \tag{1}$$

so, the translation of a document $\mathbf{D}$ is made by translating each of its sentences independently. In this study, we introduce dependencies on the previous sentences from the source and target sides:

$$\max_{\Theta} \frac{1}{N} \sum_{n=1}^{N} log(P_{\Theta}(\mathbf{y^n}|\mathbf{x^n}, \mathbf{D_{x^n}}, \mathbf{D_{y^n}})) \tag{2}$$

where $\mathbf{D_{x^n}} = (\mathbf{x^{n-k}}, ..., \mathbf{x^{n-1}})$ and $\mathbf{D_{y^n}} = (\mathbf{y^{n-k}}, ..., \mathbf{y^{n-1}})$ denote the previous k sentences from source and target sides respectively. The contexts $\mathbf{D_{x^n}}$ and $\mathbf{D_{y^n}}$ are modeled with HANs.

2.1 Hierarchical Attention Network

The proposed HAN has two levels of abstraction. The word-level abstraction summarizes information from each previous sentence j into a vector s^j as:

$$q_w = f_w(h_t) \tag{3}$$

$$s^j = \underset{i}{\text{MultiHead}}(q_w, h_i^j) \tag{4}$$

where h denotes a hidden state of the NMT network. In particular, h_t is the last hidden state of the word to be encoded, or decoded at time step t, and h_i^j is the last hidden state of the i-th word of the j-th sentence of the context. The function f_w is a linear transformation to obtain the *query* q_w. We used the MultiHead attention function proposed by (Vaswani et al., 2017) to capture different types of relations among words. It matches the *query* against each of the hidden representations h_i^j (used as *value* and *key* for the attention).

The sentence-level abstraction summarizes the contextual information required at time t in d_t as:

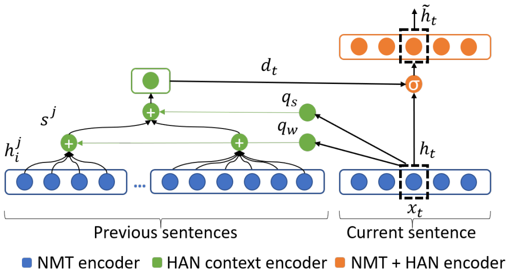

Figure 1: Integration of HAN during encoding at time step t, $\tilde{h}_t$ is the context-aware hidden state of the word x_t. Similar architecture is used during decoding.

$$q_s = f_s(h_t) \tag{5}$$

$$d_t = \text{FFN}(\underset{j}{\text{MultiHead}}(q_s, s^j)) \tag{6}$$

where f_s is a linear transformation, q_s is the query for the attention function, FFN is a position-wise feed-forward layer (Vaswani et al., 2017). Each layer is followed by a normalization layer (Lei Ba et al., 2016).

2.2 Context Gating

We use a gate (Tu et al., 2018, 2017) to regulate the information at sentence-level h_t and the contextual information at document-level d_t. The intuition is that different words require different amount of context for translation:

$$\lambda_t = \sigma(W_h h_t + W_d d_t) \tag{7}$$

$$\tilde{h}_t = \lambda_t h_t + (1 - \lambda_t) d_t \tag{8}$$

where W_h, W_p are parameter matrices, and $\tilde{h}_t$ is the final hidden representation for a word x_t or y_t.

2.3 Integrated Model

The context can be used during encoding or decoding a word, and it can be taken from previously encoded source sentences, previously decoded target sentences, or from previous alignment vectors (i.e. context vectors (Bahdanau et al., 2015)). The different configurations will define the input *query* and *values* of the attention function. In this work we experiment with five of them: one at encoding time, three at decoding time, and one combining both. At encoding time the *query* is a function of the hidden state h_{x_t} of the current word to be encoded x_t, and the *values* are the encoded states of previous sentences $h_{x_i}^j$ (HAN encoder). At decoding time, the *query* is a function of the hidden state h_{y_t} of the current word to be decoded y_t, and the *values* can be (a) the encoded states of previous sentences $h_{x_i}^j$ (HAN decoder *source*),

(b) the decoded states of previous sentences $h^j_{y_i}$ (HAN decoder), and (c) the alignment vectors c^j_i (HAN decoder *alignment*). Finally, we combine complementary target-source sides of the context by joining HAN encoder and HAN decoder. Figure 1 shows the integration of the HAN encoder with the NMT model; a similar architecture is applied to the decoder. The output $\tilde{h}_t$ is used by the NMT model as replacement of h_t during the final classification layer.

3 Experimental Setup

3.1 Datasets and Evaluation Metrics

We carry out experiments with Chinese-to-English (Zh-En) and Spanish-to-English (Es-En) sets on three different domains: talks, subtitles, and news.

TED Talks is part of the IWSLT 2014 and 2015 (Cettolo et al., 2012, 2015) evaluation campaigns[1]. We use *dev2010* for development; and *tst2010-2012* (Es-En), *tst2010-2013* (Zh-En) for testing. The Zh-En subtitles corpus is a compilation of TV subtitles designed for research on context (Wang et al., 2018). In contrast to the other sets, it has three references to compare. The Es-En corpus is a subset of OpenSubtitles2018 (Lison and Tiedemann, 2016)[2]. We randomly select two episodes for development and testing each. Finally, we use the Es-En News-Commentaries11[3] corpus which has document-level delimitation. We evaluate on WMT sets (Bojar et al., 2013): *newstest2008* for development, and *newstest2009-2013* for testing. A similar corpus for Zh-En is too small to be comparable. Table 2 shows the corpus statistics.

For evaluation, we use BLEU score (Papineni et al., 2002) (*multi-blue*) on *tokenized* text, and we measure significance with the paired bootstrap resampling method proposed by Koehn (2004) (implementations by Koehn et al. (2007)).

3.2 Model Configuration and Training

As baselines, we use a NMT transformer, and a context-aware NMT transformer with cache memory which we implemented for comparison following the best model described by Tu et al. (2018), with memory size of 25 words. We used the OpenNMT (Klein et al., 2017) implementation of the transformer network. The configuration is the same as the model called "base model" in the original paper (Vaswani et al., 2017). The encoder and decoder are composed of 6 hidden layers each. All hidden states have dimension of 512, dropout of 0.1, and 8 heads for the multi-head attention. The target and source vocabulary size is 30K. The optimization and regularization methods were the same as proposed by Vaswani et al. (2017). Inspired by Tu et al. (2018) we trained the models in two stages. First we optimize the parameters for the NMT without the HAN, then we proceed to optimize the parameters of the whole network. We use $k = 3$ previous sentences, which gave the best performance on the development set.

4 Experimental Results

4.1 Translation Performance

Table 1 shows the BLEU scores for different models. The baseline NMT transformer already has better performance than previously published results on these datasets, and we replicate previous previous improvements from the cache method over the this stronger baseline. All of our proposed HAN models perform at least as well as the cache method. The best scores are obtained by the combined encoder and decoder HAN model, which is significantly better than the cache method on all datasets without compromising training speed (2.3K vs 2.6K tok/sec). An important portion of the improvement comes from the HAN encoder, which can be attributed to the fact that the source-side always contains correct information, while the target-side may contain erroneous predictions at testing time. But combining HAN decoder with HAN encoder further improves translation performance, showing that they contribute complementary information. The three ways of incorporating information into the decoder all perform similarly.

Table 3 shows the performance of our best HAN model with a varying number k of previous sentences in the test-set. We can see that the best performance for TED talks and news is archived with 3, while for subtitles it is similar between 3 and 7.

4.2 Accuracy of Pronoun/Noun Translations

We evaluate coreference and anaphora using the reference-based metric: accuracy of pronoun translation (Miculicich Werlen and Popescu-Belis, 2017b), which can be extended for nouns. The list of evaluated pronouns is predefined in the metric, while the list of nouns was extracted using NLTK POS tagging (Bird, 2006). The upper part

Test	5.5K	4.7K	1.2K	1.0K	13.5K

Table 2: Dataset statistics in # sentence pairs.

of Table 4 shows the results. For nouns, the joint HAN achieves the best accuracy with a significant improvement compared to other models, showing that target and source contextual information are complementary. Similarity for pronouns, the joint model has the best result for TED talks and news. However, HAN encoder alone is better in the case of subtitles. Here HAN decoder produces mistakes by repeating past translated personal pronouns. Subtitles is a challenging corpus for personal pronoun disambiguation because it usually involves dialogue between multiple speakers.

4.3 Cohesion and Coherence Evaluation

We use the metric proposed by Wong and Kit (2012) to evaluate lexical cohesion. It is defined as the ratio between the number of repeated and lexically similar content words over the total number of content words in a target document. The lexical similarity is obtained using WordNet. Table 4 (bottom-left) displays the average ratio per tested document. In some cases, HAN decoder achieves the best score because it produces a larger quantity of repetitions than other models. However, as previously demonstrated in 4.2, repetitions do not always make the translation better. Although HAN boosts lexical cohesion, the scores are still far from the human reference, so there is room for improvement in this aspect.

For coherence, we use a metric based on Latent Semantic Analysis (LSA) (Foltz et al., 1998). LSA is used to obtain sentence representations, then cosine similarity is calculated from one sentence to the next, and the results are averaged to get a document score. We employed the pre-trained LSA model *Wiki-6* from (Stefanescu et al., 2014). Table 4 (bottom-right) shows the average coherence score of documents. The joint HAN model consistently obtains the best coherence score, but close to other HAN models. Most of the improvement comes from the HAN decoder.

	TED Talks		**Subtitles**		**News**
k	Zh–En	Es–En	Zh–En	Es–En	Es–En
1	17.70	37.20	29.35	36.20	22.46
3	**17.79**	**37.24**	29.67	**36.23**	**22.76**
5	17.49	37.11	**29.69**	36.22	22.54
7	17.00	37.22	29.64	36.21	22.64

Table 3: Performance for variable context sizes k with the HAN encoder + HAN decoder.

4.4 Qualitative Analysis

Table 5 shows an example where HAN helped to generate the correct translation. The first box shows the current sentence with the analyzed word in bold; and the second, the past context at source and target. For the context visualization we use the toolkit provided by Pappas and Popescu-Belis (2017). Red corresponds to sentences, and blue to words. The intensity of color is proportional to the weight. We see that HAN correctly translates the ambiguous Spanish pronoun "*su*" into the English "*his*". The HAN decoder highlighted a previous mention of "*his*", and the HAN encoder highlighted the antecedent "*Nathaniel*". This shows that HAN can capture interpretable inter-sentence connections. More samples with different attention heads are shown in the Appendix **??**.

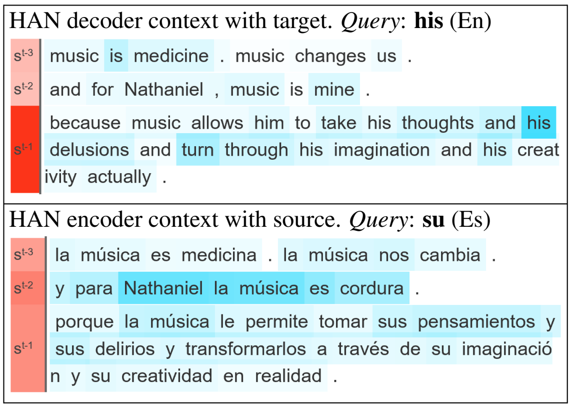
HAN:	and this is an escape from **his** $< unk >$ state .

Context from Previous Sentences



HAN decoder context with target. *Query*: **his** (En)

s^{t-3} music is medicine . music changes us .

s^{t-2} and for Nathaniel , music is mine .

s^{t-1} because music allows him to take his thoughts and his delusions and turn through his imagination and his creativity actually .

HAN encoder context with source. *Query*: **su** (Es)

s^{t-3} la música es medicina . la música nos cambia .

s^{t-2} y para Nathaniel la música es cordura .

s^{t-1} porque la música le permite tomar sus pensamientos y sus delirios y transformarlos a través de su imaginación y su creatividad en realidad .

Table 5: Example of pronoun disambiguation using HAN (TED Talks Es-En).

mann, 2010; Gong et al., 2011). However, most of the work explicitly models discourse phenomena (Sim Smith, 2017) such as lexical cohesion (Meyer and Popescu-Belis, 2012; Xiong et al., 2013; Loáiciga and Grisot, 2016; Pu et al., 2017; Mascarell, 2017), coherence (Born et al., 2017), and coreference (Rios Gonzales and Tuggener, 2017; Miculicich Werlen and Popescu-Belis, 2017a). Hardmeier et al. (2013) introduced the document-level SMT paradigm.

Sentence-level NMT Initial studies on NMT enhanced the sentence-level context by using memory networks (Wang et al., 2016), self-attention (Miculicich Werlen et al., 2018; Zhang et al., 2016), and latent variables (Yang et al., 2017).

Document-level NMT Tiedemann and Scherrer (2017) use the concatenation of multiple sentences as NMT's input/output, Jean et al. (2017) add a context encoder for the previous source sentence, Wang et al. (2017) includes a HRNN to summarize source-side context, and Tu et al. (2018) use a dynamic cache memory to store representations of previously translated words. Recently, Bawden et al. (2018) proposed test-sets for evaluating discourse in NMT, Voita et al. (2018) shows that context-aware NMT improves the of anaphoric pronouns, and Maruf and Haffari (2018) proposed a document-level NMT using memory-networks.

6 Conclusion

We proposed a hierarchical multi-head HAN NMT model[5] to capture inter-sentence connections. We integrated context from source and target sides by directly connecting representations from previous sentence translations into the current sentence translation. The model significantly outperforms two competitive baselines, and the ablation study shows that target and source context is complementary. It also improves lexical cohesion and coherence, and the translation of nouns and pronouns. The qualitative analysis shows that the model is able to identify important previous sentences and words for the correct prediction. In future work, we plan to explicitly model discourse connections with the help of annotated data, which may further improve translation quality.

Abstract

Due to the benefits of model compactness, multilingual translation (including many-to-one, many-to-many and one-to-many) based on a universal encoder-decoder architecture attracts more and more attention. However, previous studies show that one-to-many translation based on this framework cannot perform on par with the individually trained models. In this work, we introduce three strategies to improve one-to-many multilingual translation by balancing the shared and unique features. Within the architecture of one decoder for all target languages, we first exploit the use of unique initial states for different target languages. Then, we employ language-dependent positional embeddings. Finally and especially, we propose to divide the hidden cells of the decoder into shared and language-dependent ones. The extensive experiments demonstrate that our proposed methods can obtain remarkable improvements over the strong baselines. Moreover, our strategies can achieve comparable or even better performance than the individually trained translation models.

1 Introduction

Encoder-decoder based neural machine translation (NMT) has achieved the new state-of-the-art due to powerful end-to-end modeling (Sutskever et al., 2014; Bahdanau et al., 2015; Wu et al., 2016; Hassan et al., 2018). Under this end-to-end framework, many researchers attempt to improve the translation quality between two languages by exploiting monolingual data (Sennrich et al., 2016; Zhang and Zong, 2016), taking advantage of both NMT and statistical machine translation (Wang et al., 2017a; Tang et al., 2016; Zhao et al., 2018; Zhou et al., 2017) and so on.

Another research direction about how to perform multilingual translation within this encoder-decoder architecture has recently drawn more and more attention (Zoph and Knight, 2016; Dong et al., 2015; Luong et al., 2016; Johnson et al., 2017; Firat et al., 2016b).

In multilingual translation scenarios, one can employ multi-task learning framework to perform many-to-one or one-to-many translation using multiple encoders or multiple decoders (Luong et al., 2016; Dong et al., 2015). Firat et al. (2016a) and Lu et al. (2018) further propose to share a universal attention mechanism for many-to-many translations. In these methods, encoder or decoder is language dependent and network parameters increase linearly with the number of languages.

Johnson et al. (2017) and Ha et al. (2016) present an appealing approach in which a universal encoder-decoder framework is designed for many-to-one, many-to-many and one-to-many multilingual translation tasks. The network model is compact and the model size does not grow as the number of languages increases. However, Johnson et al. (2017) observe that only the many-to-one paradigm can achieve better translation results than the individually trained models. For the other two paradigms, there are various degrees of quality degradation. In this work, we focus on one-to-many multilingual translation under the universal encoder-decoder framework and attempt to boost its performance while maintaining the model compactness.

To this end, we propose three strategies which exploit the unique features of each target language and keep as many parameters shared as possible. First, we design two special labels at the tail of encoder and the head of decoder to mark the target language and guide the generation of different target languages. Then, we introduce language-dependent positional embeddings into the bottom

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2955–2960
Brussels, Belgium, October 31 - November 4, 2018.

layer of the decoder network and correspondingly the structural difference between target languages can be well captured. Finally and especially, we propose a new parameter-sharing mechanism in which we divide the hidden units of each decoder layer into shared and language-dependent ones.

We verify the effectiveness of our proposed methods on two one-to-many tasks: Chinese-to-English/Japanese translation and English-to-German/French translation. The experimental results demonstrate that the three strategies can significantly outperform the baseline multilingual models and they can achieve comparable or even better performance than the individually trained translation models.

Specifically, our contributions in this paper are two-fold:

- The proposed three strategies can take advantage of unique features of each target language while sharing the network parameters as many as possible.
- The extensive experiments on multiple translation tasks show that the three proposed strategies improve the translation quality. Moreover, the effects of the strategies are complementary and the combined one can perform on par with or better than the individually optimized translation models.

2 Background

Our proposed approach can be applied to any encoder-decoder architecture. Considering the excellent translation performance of Transformer network (Vaswani et al., 2017), we implement our method entirely based on it in this work. Transformer consists of stacked encoder and decoder layers. The encoder maps an input sequence $\mathbf{x} = (x_1, x_2, \cdots, x_n)$ to a sequence of continuous representations $\mathbf{z} = (z_1, z_2, \cdots, z_n)$ whose size varies with respect to the source sentence length. The decoder generates an output sequence $\mathbf{y} = (y_1, y_2, \cdots, y_m)$ from the continuous representations $\mathbf{z}$. Since the Transformer network contains no recurrence, positional embeddings are used in model to make use of sequence order. The encoder and decoder are trained to maximize the conditional probability of target sequence given a source sequence:

$$L(\theta) = \sum_{t=1}^{N} \log P(y_t | y_{<t}, x; \theta) \qquad (1)$$

For the sake of brevity, we refer the reader to Vaswani et al. (2017) for more details regarding the architecture.

3 Method Description

In this section, we introduce our general strategies for extending the transformer network to one-to-many translation task. We decompose the probability of the target sequences into the products of per token probabilities in all translation forms:

$$L(\theta) = \sum_{t=1}^{M} \sum_{l=1}^{N_l} \log(P(y_t^l | x, y_{<t}^l; \theta)) \qquad (2)$$

where M is number of target languages, and $P(y_t^l | x, y_{<t}^l; \theta)$ denotes the translation probability of t-th word of the l-th target language. Note that the translation process for all target languages uses the same parameter set θ.

Our methods mainly concentrate on improving one-to-many multilingual translation by designing new decoder structure under the universal encoder-decoder framework. The idea is to exploit the shared and unique features of different target languages, and we respectively propose three strategies including special label initialization, language-dependent positional embedding and a new parameter-sharing mechanism.

3.1 Special Label Initialization

In the universal encoder-decoder network for one-to-many multilingual translation (Johnson et al., 2017), a special token (e.g. **en2fr**) is added at the end of the source sentence to indicate the translation direction. Although it is an effective mechanism, we find that the initial states of the decoder are very important to guide the generation process for different target languages. In order to enhance the model, we utilize another special language-dependent label at the beginning of the decoder and we regard it as the first generated token of the target language (e.g. **2fr**).

3.2 Language-dependent Positional Embedding

Positional embeddings give the model the sense of which part of the sequence is currently being dealt with. Intuitively, different target languages should have different positional embeddings to distinguish the structural difference between multiple target languages. Therefore, we design language-dependent positional embeddings in the universal

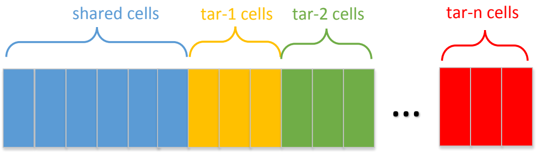

Figure 1: The hidden units of decoder network. Blue part represents the shared units, and yellow, green and red parts denote different language-dependent units respectively.

encoder-decoder multilingual translation. For the fixed embedding method (Vaswani et al., 2017), $sine(x)$ and $cosine(x)$ functions are used to generate positional embeddings. In this case, we introduce trigonometric functions with different orders or offsets on the decoder to distinguish different target languages. For the dynamic embedding method (Gehring et al., 2017), we equip the target inputs by embedding the absolute position of different languages separately.

3.3 Shared and Language-dependent Hidden Units per Layer

In the universal encoder-decoder multilingual translation, the hidden layers of the decoder are responsible for generating different target language sentences. As a result, the hidden layers should embody some language-dependent information.

In this work, we propose to divide the hidden units of each decoder layer into shared units and language-dependent ones. On the one hand, shared units can learn the commonality of languages and enable one-to-many translation to share the network parameters as many as possible. On the other hand, language-dependent units are capable of capturing the characteristic of each specific language.

Figure 1 gives a brief description of our proposed strategy. For instance, in training step for one target language (**tar-1**), we tune the shared units and the language-dependent units of **tar-1**, and mask out other parts. In decoding step, we only use the shared and language-dependent hidden units of target language **tar-1** to predict translation results.

4 Experiments Settings

In this section, we test the proposed methods on two one-to-many translation tasks, including (i) Chinese→English/Japanese in general domain, and (ii) English→French/German in WMT14 task.

Chinese→English/Japanese For this translation task, the training sets of Chinese-to-English (briefly, Zh→En) and Chinese-to-Japanese (briefly, Zh→Ja) both contain about 10 million parallel corpora. We evaluate our methods on NIST03-06 (MT03-06) for Zh→En translation and 400 sentences extracted from our general corpus for Zh→Ja translation.

English→French/German The training set consists of about 4.5 million bilingual sentence pairs in WMT14 English-German (briefly, En→De) task and about 36 million sentence pairs in WMT14 English-French (briefly, En→Fr) task[1]. We use the combination of *newstest2012* and *newstest2013* as our validation set, and we use *newstest2014* as our test set on En→De and En→Fr tasks.

We adopt the tensor2tensor[2] library for training and evaluating our basic Transformer translation model. We use wordpiece method (Wu et al., 2016; Schuster and Nakajima, 2012) to encode source side sentences and the combination of target side sentences. The vocabulary size is 37,000 for both sides. We train our models using configuration *transformer_big* adopted by Vaswani et al. (2017), which contains a 6-layer encoder and a 6-layer decoder with 1024-dimensional hidden representations. During training, each mini-batch on one GPU contains a set of sentence pairs with roughly 3,072 source and 3,072 target tokens. We use Adam optimizer (Kingma and Ba, 2014) with β_1=0.9, β_2=0.98, and ϵ=10^{-9}. For our model, we train for 400,000 steps on one machine with 8 NVIDIA Tesla M40 GPUs.

5 Results and Analysis

We show the results of one-to-many translation experiments using our proposed strategies. The translation performance is evaluated by case-insensitive BLEU4 for Zh→En translation, character-level BLEU5 for Zh→Ja translation, and case-sensitive BLEU4 (Papineni et al., 2002) for En→De/Fr translation task.

5.1 Our Strategies vs. Baseline

Table 1 reports the main translation results of Zh→En/Ja and En→De/Fr translation tasks. We conduct universal one-to-many translation using

O2M + ①	43.91	44.01	45.12	44.14	44.30	42.54	26.78	41.56
O2M + ① + ② (Dyn)	44.24	44.45	45.43	44.51	44.66	42.77	26.98	41.78
O2M + ① + ② (Fixed)	44.13	44.57	45.22	44.68	44.65	42.70	26.90	41.75
O2M + ① + ③	44.78	45.23	45.78	45.22	45.25	42.97	27.11	**41.98**
O2M + ① + ② (Dyn)+ ③	**44.85**	**45.51**	**45.91**	**45.38**	**45.41**	**43.03**	27.23	41.92

Table 1: Translation performance of our methods on Zh→En/Ja and En→De/Fr tasks. Indiv means translation model of individual pair. O2M is the our baseline system. ① , ② and ③ denote our proposed three strategies of special label initialization, language-dependent positional embedding and the new parameter-sharing mechanism separately. ② (Dyn) and ② (Fixed) represent the two ways of language-dependent positional embedding method. For shared and language-dependent method, we set one-half of hidden units as shared units, and for another half, we use a quarter hidden units to denote two output languages respectively.

Johnson et al. (2017) method on Transformer framework as our baseline system (briefly, O2M method). From the first two lines, we can see that the O2M method cannot perform on par with the individually trained systems in most cases.

We mentioned before that our goal is to improve the universal one-to-many multilingual translation framework while maintaining the parameter sharing property. We can observe from the table that all our proposed strategies (last part in Table 1) improve the translation performance compared to the baseline (O2M). Specifically, the combined use of three strategies performs best and it can achieve the improvements up to 1.96 BLEU points (45.51 vs. 43.55 on Zh→En MT04). As for language-dependent positional embedding, we find that both fixed and dynamic styles perform similarly.

Our ultimate goal is to make the universal one-to-many framework as good as or better than the individually trained systems. Table 1 demonstrates some encouraging results. It is shown in the table that the universal one-to-many architecture enhanced with our strategies can outperform the individually trained models on three out of four language translations (Zh→En, Zh→Ja, En→Fr). The results verify the effectiveness of our proposed methods.

5.2 Comparison of Shared Unit Size

For the new parameter-sharing mechanism, it is an open question to decide how many hidden units should be shared and how many ones should be language dependent. To figure out this question, we further conduct an experiment to investigate different settings. For example, we keep a quarter of the hidden units of each decoder layer as shared and make the left three quarters evenly distributed to different target languages.

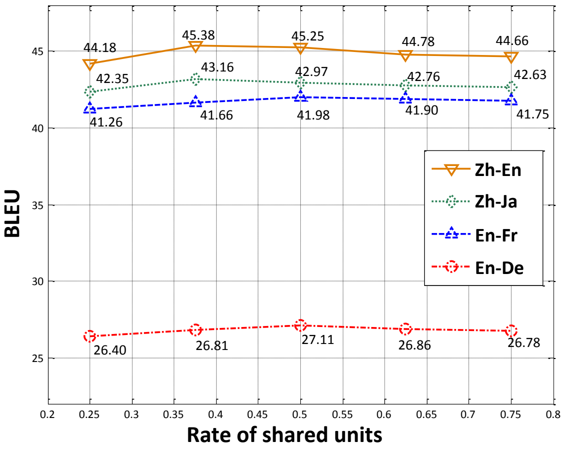

Figure 2: The comparison of different shared units.

Figure 2 reports the results. We can observe different trends for different language pairs. On the En→De/Fr translation task, the performance is best when we share one-half of the hidden units. In contrast, it obtains the best results when we share only 37.5% of hidden units on Zh→En/Ja translation. It indicates that similar languages (De/Fr) can share more hidden units and languages with a great difference (En/Ja) may share less hidden units.

6 Related Work

In this work, we explore the balancing problem of shared and unique parameters, and attempt to incorporate the language-dependent presentation features to distinguish different target languages under the scenario of one-to-many multilingual translation.

Multilingual translation has been extensively studied in Dong et al. (2015), Firat et al. (2016a), Luong et al. (2016) and Johnson et al. (2017). Owing to excellent translation performance and ease of use, many researchers (Blackwood et al., 2018; Lakew et al., 2018) have conduct translation of multiple languages based on the framework of Johnson et al. (2017) and Ha et al. (2016). As for low-resource translation scenario (Zoph et al., 2016; Chen et al., 2017; Wang et al., 2017b), similar to above method, Gu et al. (2018) enable sharing of lexical and sentence representation across multiple languages especially for low-resource multilingual NMT. Different from previous methods, our work mainly focuses on improving the one-to-many multilingual translation framework while sharing as many parameters as possible.

7 Conclusion

In this paper, we have proposed three effective strategies to improve the universal one-to-many multilingual translation, including special label initialization, language-dependent positional embedding and a new parameter-sharing mechanism. The empirical experiments on four language pairs demonstrate that our strategies can obtain significant improvement over the strong baseline, and can achieve comparable or even better results than the individually trained models.

For future work, we plan to extend our strategies on many-to-many multilingual translation scenarios, and explore other effective strategies to balance parameter sharing.

Abstract

We introduce a novel multi-source technique for incorporating source syntax into neural machine translation using linearized parses. This is achieved by employing separate encoders for the sequential and parsed versions of the same source sentence; the resulting representations are then combined using a hierarchical attention mechanism. The proposed model improves over both seq2seq and parsed baselines by over 1 BLEU on the WMT17 English→German task. Further analysis shows that our multi-source syntactic model is able to translate successfully without any parsed input, unlike standard parsed methods. In addition, performance does not deteriorate as much on long sentences as for the baselines.

1 Introduction

Neural machine translation (NMT) typically makes use of a recurrent neural network (RNN) -based encoder and decoder, along with an attention mechanism (Bahdanau et al., 2015; Cho et al., 2014; Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014). However, it has been shown that RNNs require some supervision to learn syntax (Bentivogli et al., 2016; Linzen et al., 2016; Shi et al., 2016). Therefore, explicitly incorporating syntactic information into NMT has the potential to improve performance. This is particularly true for source syntax, which can improve the model's representation of the source language.

Recently, there have been a number of proposals for using linearized representations of parses within standard NMT (Aharoni and Goldberg, 2017; Li et al., 2017; Nadejde et al., 2017). Linearized parses are advantageous because they can inject syntactic information into the models without significant changes to the architecture. However, using linearized parses in a sequence-to-sequence (seq2seq) framework creates some challenges, particularly when using source parses. First, the parsed sequences are significantly longer than standard sentences, since they contain node labels as well as words. Second, these systems often fail when the source sentence is not parsed. This can be a problem for inference, since the external parser may fail on an input sentence at test time. We propose a method for incorporating linearized source parses into NMT that addresses these challenges by taking both the sequential source sentence and its linearized parse simultaneously as input in a multi-source framework. Thus, the model is able to use the syntactic information encoded in the parse while falling back to the sequential sentence when necessary. Our proposed model improves over both standard and parsed NMT baselines.

2 Related Work

2.1 Seq2seq Neural Parsing

Using linearized parse trees within sequential frameworks was first done in the context of neural parsing. Vinyals et al. (2015) parsed using an attentional seq2seq model; they used linearized, unlexicalized parse trees on the target side and sentences on the source side. In addition, as in this work, they used an external parser to create synthetic parsed training data, resulting in improved parsing performance. Choe and Charniak (2016) adopted a similar strategy, using linearized parses in an RNN language modeling framework.

2.2 NMT with Source Syntax

Among the first proposals for using source syntax in NMT was that of Luong et al. (2016), who introduced a multi-task system in which the source data was parsed and translated using a shared encoder and two decoders. More radical changes to

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2961–2966
Brussels, Belgium, October 31 - November 4, 2018.

the standard NMT paradigm have also been proposed. Eriguchi et al. (2016) introduced tree-to-sequence NMT; this model took parse trees as input using a tree-LSTM (Tai et al., 2015) encoder. Bastings et al. (2017) used a graph convolutional encoder in order to take labeled dependency parses of the source sentences into account. Hashimoto and Tsuruoka (2017) added a latent graph parser to the encoder, allowing it to learn soft dependency parses while simultaneously learning to translate.

2.3 Linearized Parse Trees in NMT

The idea of incorporating linearized parses into seq2seq has been adapted to NMT as a means of injecting syntax. Aharoni and Goldberg (2017) first did this by parsing the target side of the training data and training the system to generate parsed translations of the source input; this is the inverse of our parse2seq baseline. Similarly, Nadejde et al. (2017) interleaved CCG supertags with words on the target side, finding that this improved translation despite requiring longer sequences.

Most similar to our multi-source model is the parallel RNN model proposed by Li et al. (2017). Like multi-source, the parallel RNN used two encoders, one for words and the other for syntax. However, they combined these representations at the word level, whereas we combine them on the sentence level. Their mixed RNN model is also similar to our parse2seq baseline, although the mixed RNN decoder attended only to words. As the mixed RNN model outperformed the parallel RNN model, we do not attempt to compare our model to parallel RNN. These models are similar to ours in that they incorporate linearized parses into NMT; here, we utilize a multi-source framework.

2.4 Multi-Source NMT

Multi-source methods in neural machine translation were first introduced by Zoph and Knight (2016) for multilingual translation. They used one encoder per source language, and combined the resulting sentence representations before feeding them into the decoder. Firat et al. (2016) expanded on this by creating a multilingual NMT system with multiple encoders and decoders. Libovický and Helcl (2017) applied multi-source NMT to multimodal translation and automatic post-editing and explored different strategies for combining attention over the two sources. In this paper, we apply the multi-source framework to a novel task, syntactic neural machine translation.

3 NMT with Linearized Source Parses

We propose a multi-source method for incorporating source syntax into NMT. This method makes use of linearized source parses; we describe these parses in section 3.1. Throughout this paper, we refer to standard sentences that do not contain any explicit syntactic information as *sequential*; see Table 1 for an example.

3.1 Linearized Source Parses

We use an off-the-shelf parser, in this case Stanford CoreNLP (Manning et al., 2014), to create binary constituency parses. These parses are linearized as shown in Table 1. We tokenize the opening parentheses with the node label (so each node label begins with a parenthesis) but keep the closing parentheses separate from the words they follow. For our task, the parser failed on one training sentence of 5.9 million, which we discarded, and succeeded on all test sentences. It took roughly 16 hours to parse the 5.9 million training sentences.

Following Sennrich et al. (2016b), our networks operate at the subword level using byte pair encoding (BPE) with a shared vocabulary on the source and target sides. However, the parser operates at the word level. Therefore, we parse then break into subwords, so a leaf may have multiple tokens without internal structure.

The proposed method is tested using both *lexicalized* and *unlexicalized* parses. In *unlexicalized* parses, we remove the words, keeping only the node labels and the parentheses. In *lexicalized* parses, the words are included. Table 1 shows an example of the three source sentence formats: sequential, lexicalized parse, and unlexicalized parse. Note that the lexicalized parse is significantly longer than the other versions.

3.2 Multi-Source

We propose a multi-source framework for injecting linearized source parses into NMT. This model consists of two identical RNN encoders with no shared parameters, as well as a standard RNN decoder. For each target sentence, two versions of the source sentence are used: the sequential (standard) version and the linearized parse (lexicalized or unlexicalized). Each of these is encoded simul-

	Example Sentence
sequential	history is a great teacher .
lexicalized parse	(ROOT (S (NP (NN history)) (VP (VBZ is) (NP (DT a) (JJ great) (NN teacher))) (. .)))
unlexicalized parse	(ROOT (S (NP (NN)) (VP (VBZ) (NP (DT) (JJ) (NN))) (. .)))
target sentence	die Geschichte ist ein großartiger Lehrmeister .

Table 1: Example source training sentence with sequential, lexicalized parse, and unlexicalized parse versions. We include the corresponding target sentence for reference.

taneously using the encoders; the encodings are then combined and used as input to the decoder. We combine the source encodings using the hierarchical attention combination proposed by Libovický and Helcl (2017). This consists of a separate attention mechanism for each encoder; these are then combined using an additional attention mechanism over the two separate context vectors. This multi-source method is thus able to combine the advantages of both standard RNN-based encodings and syntactic encodings.

4 Experimental Setup

4.1 Data

We base our experiments on the WMT17 (Bojar et al., 2017) English (EN) → German (DE) news translation task. All 5.9 million parallel training sentences are used, but no monolingual data. Validation is done on newstest2015, while newstest2016 and newstest2017 are used for testing.

We train a shared BPE vocabulary with 60k merge operations on the parallel training data. For the parsed data, we break words into subwords after applying the Stanford parser. We tokenize and truecase the data using the Moses tokenizer and truecaser (Koehn et al., 2007).

4.2 Implementation

The models are implemented in Neural Monkey (Helcl and Libovický, 2017). They are trained using Adam (Kingma and Ba, 2015) and have minibatch size 40, RNN size 512, and dropout probability 0.2 (Gal and Ghahramani, 2016). We train to convergence on the validation set, using BLEU (Papineni et al., 2002) as the metric.

For sequential inputs and outputs, the maximum sentence length is 50 subwords. For parsed inputs, we increase maximum sentence length to 150 subwords to account for the increased length due to the parsing labels; we still use a maximum output length of 50 subwords for these systems.

	System	**2016**	**2017**
baseline	seq2seq	25.0	20.8
	parse2seq	25.4	20.9
proposed	multi-source lex	**26.5**	**21.9**
	multi-source unlex	26.4	21.7

Table 2: BLEU scores on newstest2016 and newstest2017 datasets for the baselines, unlexicalized (unlex), and lexicalized (lex) systems.

4.3 Baselines

Seq2seq

The proposed models are compared against two baselines. The first, referred to here as *seq2seq*, is the standard RNN-based neural machine translation system with attention (Bahdanau et al., 2015). This baseline does not use the parsed data.

Parse2seq

The second baseline we consider is a slight modification of the mixed RNN model proposed by Li et al. (2017). This uses an identical architecture to the seq2seq baseline (except for a longer maximum sentence length in the encoder). Instead of using sequential data on the source side, the linearized parses are used. We allow the system to attend equally to words and node labels on the source side, rather than restricting the attention to words. We refer to this baseline as *parse2seq*.

5 Results

Table 2 shows the performance on EN→DE translation for each of the proposed systems and the baselines, as approximated by BLEU score.

The multi-source systems improve strongly over both baselines, with improvements of up to 1.5 BLEU over the seq2seq baseline and up to 1.1 BLEU over the parse2seq baseline. In addition, the lexicalized multi-source systems yields slightly higher BLEU scores than the unlexicalized multi-source systems; this is surprising because the lexicalized systems have significantly longer sequences than the unlexicalized ones. Finally, it is interesting to compare the seq2seq and parse2seq baselines. Parse2seq outperforms

System	Source Data	2016	2017
parse2seq	seq	0.6	0.5
multi-source lex	seq + seq	23.6	20.0
	seq + null	23.1	19.3
multi-source unlex	seq + seq	**23.7**	19.9
	seq + null	23.6	**20.9**

Table 3: BLEU scores on newstest2016 and newstest2017 when no parsed data is used during inference.

seq2seq by only a small amount compared to multi-source; thus, while adding syntax to NMT can be helpful, some ways of doing so are more effective than others.

6 Analysis

6.1 Inference Without Parsed Sentences

The parse2seq and multi-source systems require parsed source data at inference time. However, the parser may fail on an input sentence. Therefore, we examine how well these systems do when given only unparsed source sentences at test time.

Table 3 displays the results of these experiments. For the parse2seq baseline, we use only sequential (*seq*) data as input. For the lexicalized and unlexicalized multi-source systems, two options are considered: *seq* + *seq* uses identical sequential data as input to both encoders, while *seq* + *null* uses null input for the parsed encoder, where every source sentence is “( )”.

The parse2seq system fails when given only sequential source data. On the other hand, both multi-source systems perform reasonably well without parsed data, although the BLEU scores are worse than multi-source with parsed data.

6.2 BLEU by Sentence Length

For models that use source-side linearized parses (multi-source and parse2seq), the source sequences are significantly longer than for the seq2seq baseline. Since NMT already performs relatively poorly on long sentences (Bahdanau et al., 2015), adding linearized source parses may exacerbate this issue. To detect whether this occurs, we calculate BLEU by sentence length.

We bucket the sentences in newstest2017 by source sentence length. We then compute BLEU scores for each bucket for the seq2seq and parse2seq baselines and the lexicalized multi-source system. The results are in Figure 1.

In line with previous work on NMT on long sentences (Bahdanau et al., 2015; Li et al., 2017), we see a significant deterioration in BLEU for longer sentences for all systems. In particular, although the parse2seq model outperformed the seq2seq model overall, it does worse than seq2seq for sentences containing more than 30 words. This indicates that parse2seq performance does indeed suffer due to its long sequences. On the other hand, the multi-source system outperforms the seq2seq baseline for all sentence lengths and does particularly well for sentences with over 50 words. This may be because the multi-source system has both sequential and parsed input, so it can rely more on sequential input for very long sentences.

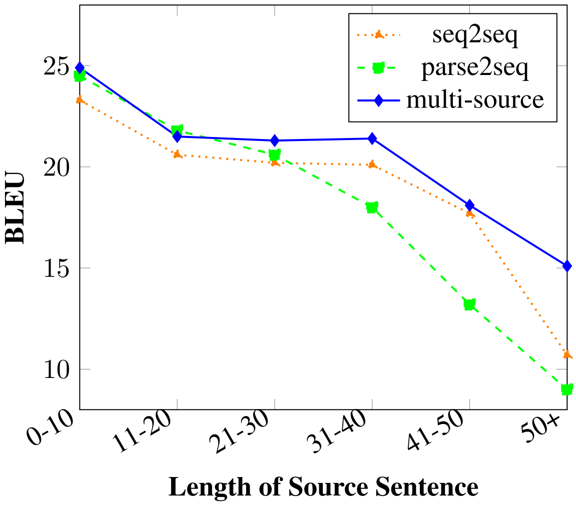

Figure 1: BLEU by sentence length on newstest2017 for baselines and lexicalized multi-source.

7 Conclusion

In this paper, we presented a multi-source method for effectively incorporating linearized parses of the source data into neural machine translation. This method, in which the parsed and sequential versions of the sentence were both taken as input during training and inference, resulted in gains of up to 1.5 BLEU on EN→DE translation. In addition, unlike parse2seq, the multi-source model translated reasonably well even when the source sentence was not parsed.

In the future, we will explore adding back-translated (Sennrich et al., 2016a) or copied (Currey et al., 2017) target data to our multi-source system. The multi-source model does not require all training data to be parsed; thus, monolingual data can be used even if the parser is unreliable for the synthetic or copied source sentences.

Abstract

Corpus-based approaches to machine translation rely on the availability of clean parallel corpora. Such resources are scarce, and because of the automatic processes involved in their preparation, they are often noisy. This paper describes an unsupervised method for detecting translation divergences in parallel sentences. We rely on a neural network that computes cross-lingual sentence similarity scores, which are then used to effectively filter out divergent translations. Furthermore, similarity scores predicted by the network are used to identify and fix some partial divergences, yielding additional parallel segments. We evaluate these methods for English-French and English-German machine translation tasks, and show that using filtered/corrected corpora actually improves MT performance.

1 Introduction

Parallel sentence pairs are the only necessary resource to build Machine Translation (MT) systems. In the case of neural MT, a large neural network is trained through maximising a proxy of translation performance on a parallel corpus. Therefore, the quality of MT engines is heavily dependent on the amount but also the quality of available parallel sentences.[1]

Parallel texts are unfortunately, scarce resources: There are relatively few language pairs for which parallel corpora of large sizes exist, and even for those pairs, available corpora only concern few restricted domains. To alleviate the lack of parallel data, several approaches have been developed over the years. They range from methods using non-parallel, or comparable data (Zhao and Vogel, 2002; Fung and Cheung, 2004; Munteanu and Marcu, 2005; Grégoire and Langlais, 2018; Grover and Mitra, 2017; Schwenk, 2018) to techniques that produce synthetic parallel data from monolingual corpora (Sennrich et al., 2016a; Chinea-Rios et al., 2017), using automated alignment/translation engines that are prone to the introduction of noise in the resulting parallel sentences. Mismatches in parallel sentences extracted from translated texts are also reported (Tiedemann, 2011; Xu and Yvon, 2016). This problem is mostly ignored in MT, where parallel sentences are considered to convey the exact same meaning; yet it seems particularly important for neural MT engines (Chen et al., 2016).

Table 1 gives some examples of English-French parallel sentences that are not completely semantically equivalent, extracted from the OpenSubtitles corpus (Lison and Tiedemann, 2016).

Multiples types of translation divergences are found in parallel corpora: Additional segments are included on either side of the parallel sentences (first and second rows) most likely due to errors in sentence segmentation; Some translations may be completely uncorrelated (third row); Inaccurate translations also exist (fourth row). Note that divergent translations can be due various reasons (Li et al., 2014), the study of which is beyond the

---

[1] Recent work on neural MT (Lample et al., 2018; Artetxe et al., 2018) completely dispenses with parallel data, using unsupervised methods to obtain performance improvements over word-by-word statistical MT. These systems however lag far behind supervised systems, as considered in this work.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2967–2973
Brussels, Belgium, October 31 - November 4, 2018.

scope of this paper.

In this work, we present an unsupervised method for building cross-lingual sentence embeddings based on modelling word similarity, relying on a neural architecture (see § 3) that is able to identify several types of common cross-lingual divergences. The resulting embeddings are then used to measure semantic equivalence between sentences. To evaluate our method, we show in § 4 that translation accuracy can be improved after filtering out divergent sentence pairs in an English-to-French and an English-to-German translation tasks. We also show that in some cases, divergent sentences can be fixed by removing divergent segments, further increasing translation quality. All the code used in this paper is freely available.[2]

2 Related Work

Attempts to measure the impact of translation divergences in MT have focused on the introduction of noise in sentence alignments (Goutte et al., 2012), showing that statistical MT is highly robust to noise, and that performance only degrades seriously at very high noise levels. In contrast, neural MTs seem to be more sensitive to noise (Chen et al., 2016), as they tend to assign high probabilities to rare events (Hassan et al., 2018).

Efforts devoted to characterising the degree of semantic equivalence between two snippets of texts in the same or different languages are presented (Agirre et al., 2016). In (Mueller and Thyagarajan, 2016), a monolingual sentence similarity network is proposed, making use of a simple LSTM layer to compute sentence representations. The authors show that a simple SVM classifier exploiting such sentence representations achieves state-of-the-art results in a textual entailment task. With the same objective, the system of He and Lin (2016) uses multiple convolutional layers and models pairwise word interactions.

Our work is inspired by Carpuat et al. (2017), who train a SVM-based cross-lingual divergence detector using word alignments and sentence length features. Their work shows that an NMT system trained only on non-divergent sentences yields slightly better translation scores, while requiring less training time. A follow-up study by the same authors (Vyas et al., 2018) achieves even better results, using the neural architecture of He and Lin (2016). Our work differs from theirs as we make use of a network with a different, arguably simpler, topology. We model sentence similarity by means of optimising a loss function based on word alignments. Furthermore, the network predicts word similarity scores that we further use to correct divergent sentences.

3 Neural Divergence Classifier

The architecture of our network is inspired by the work on word alignment of Legrand et al. (2016), using however contextual, rather than fixed, word embeddings (see Figure 1).

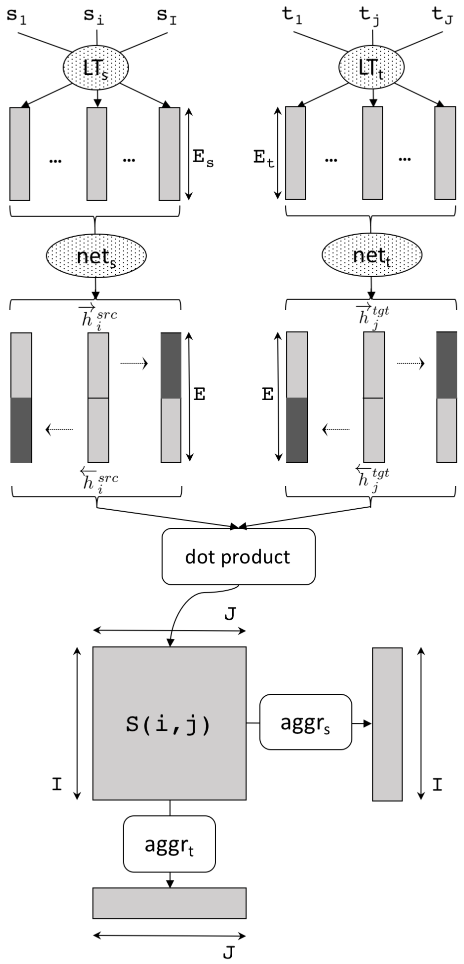

Figure 1: Illustration of the model.

It computes the similarity of any source-target sentence pair (s, t), where $s = (s_1, ..., s_I)$ and $t = (t_1, ..., t_J)$. The model is composed of 2 bi-directional LSTM subnetworks, net_s and net_t, which respectively encode source and target sentences. Since both net_s and net_t take the same form, we only describe the former network: it outputs forward and backward hidden states, $\overrightarrow{h}_i^{src}$ and $\overleftarrow{h}_i^{src}$, which are then concate-

---

[2] https://github.com/jmcrego/similarity

nated into a vector encoding the i^{th} source word as $h_i^{src} = [\overrightarrow{h}_i^{src}; \overleftarrow{h}_i^{src}]$. In addition, the last forward/backward hidden states (in dark grey on Figure 1) are also concatenated to represent whole sentences $h_{src} = [\overrightarrow{h}_I^{src}; \overleftarrow{h}_1^{src}]$. The similarity between sentence pairs can then be obtained using eg. the cosine similarity:

$$sim(h_{src}, h_{tgt}) = \frac{h_{src} \cdot h_{tgt}}{||h_{src}|| * ||h_{tgt}||} \tag{1}$$

Our model is trained to maximize word alignment scores between words in both sentences, using aggregation functions that summarise the alignment scores for each source/target word. Similar to (Legrand et al., 2016), alignment scores $S(i,j)$ are given by the dot-product $S(i,j) = h_i^{src} \cdot h_j^{tgt}$, further aggregated as follows:

$$\begin{aligned} aggr_s(i, S) &= \frac{1}{r}\, log \left(\sum_{j=1}^{J} e^{r * S(i,j)} \right) \\ aggr_t(j, S) &= \frac{1}{r}\, log \left(\sum_{i=1}^{I} e^{r * S(i,j)} \right) \end{aligned} \tag{2}$$

The training loss function is then defined as:

$$\begin{aligned} &\mathcal{L}(src, tgt) = \\ &\quad \sum_{i=1}^{I} log(1 + e^{aggr_s(i,S) * sign_i}) \ + \\ &\quad + \sum_{j=1}^{J} log(1 + e^{aggr_t(j,S) * sign_j}) \end{aligned} \tag{3}$$

3.1 Training with Negative Examples

Training is performed by minimizing Eq. (3), for which annotated examples of source (sign_i) and target (sign_j) words are needed. As positive examples, we use paired sentences of a parallel corpus; all words in such sentences are labelled as parallel ($\forall i, j, \text{sign}_i = \text{sign}_j = -1$). We consider three types of negative instances: the basic case uses random unpaired sentences; in this case, all words are labelled as divergent ($\forall i, j, \text{sign}_i = \text{sign}_j = +1.$). Since negative pairs may be very easy to classify and we want our network to detect less obvious divergences, we further create more difficult negative examples as follows.

We first replace random sequences of words in source or target by a sequence of words with the same part-of-speeches.[3] Words that are not replaced are deemed parallel ($\text{sign}_i = -1$) while those replaced are annotated as $\text{sign}_i = +1$. Words aligned to some replaced words are also assigned the divergent label ($\text{sign}_i = +1$). For instance, given the original sentence pair:

src: `What do you feel ?`
tgt: `Que ressentez-vous ?` ,

we may replace '`you feel`', with part-of-speech tags '`PRP VB`', by another sequence with same tags (i.e. '`we want`'), yielding a new negative instance (divergent words are in bold):

src:	`What`	`do`	**we**	**want**	`?`
$\mathcal{Y}^{src}$:	`-1`	`-1`	**+1**	**+1**	`-1`
tgt:	`Que`	**ressentez-vous**			`?`
$\mathcal{Y}^{tgt}$:	`-1`	**+1**			`-1`

Note that we need word alignments to identify as divergent the sequence '`ressentez-vous`', which was aligned to '`you feel`' in the original sentence. Finally, motivated by sentence segmentation errors observed in many corpora, we also build negative examples by inserting a sentence at the beginning (or end) of the source (or target) sentence. Words in the original sentence pair are annotated $\text{sign}_i = -1$, while the new words inserted are considered divergent ($\text{sign}_i = +1$). Given the same sentence pair as above, a negative example is created by inserting the sentence '`Not .`' at the end of the original source:

src:	`What`	`do`	`you`	`want`	`?`	**Not**	**.**
$\mathcal{Y}^{src}$:	`-1`	`-1`	`-1`	`-1`	`-1`	**+1**	**+1**
tgt:	`Que`	`ressentez-vous`			`?`		
$\mathcal{Y}^{tgt}$:	`-1`	`-1`			`-1`		

To finally avoid the generation of easy negative sentence pairs having a large difference in sentence length, we restrict negative examples to have a length ratio < 2.0 (3.0 for shortest sentences).

3.2 Divergence Correction

Our training corpora contains many divergent sentences that follow a common pattern, consisting of adding some extra leading/trailing words. Accordingly, we implemented a simple algorithm that discards sequences of leading/trailing words on both

---

[3] The rationale is to try to keep the generated sentences as grammatical as possible; Otherwise, the network could learn to flag non-grammatical sentences as non-parallel.

sides. To find optimal source (u, v) and target (x, y) indices that enclose parallel segments within the original sentence, we compute:

$$\underset{u,v,x,y}{\arg\max}\left\{ \sum_{u \le I \le v} \max_{x \le j \le y} \{S(i,j)\} \right\}$$

The $\mathcal{N}$-best sequences (s_u^v, t_x^y) are considered as likely corrections, in which we use the one having the highest similarity score to replace the original (s_1^I, t_1^J). Note that short sentences are not considered and we enforce $v - u > \tau$ and $y - x > \tau$. Figure 2 (left) displays an example of an alignment matrix $S(i, j)$. An acceptable correction is: *Que ressentez-vous ? ⇔ What do you feel ?*. corresponding to $u = 1$, $v = 5$, $x = 1$ and $y = 3$.

4 Experiments

4.1 Corpora

We filter out divergences from the English-French OpenSubtitles corpus (Lison and Tiedemann, 2016), which consists of a collection of movie and TV subtitles. We also use the very noisy English-German Paracrawl[4] corpus. Both corpora present many potential divergences. To evaluate English-French translation performance, we use the En-Fr Microsoft Spoken Language Translation corpus, created from actual Skype conversations (Federmann and Lewis, 2016). English-German performance is evaluated on the publicly available Newstest-2017 (Bojar et al., 2017), corresponding to news stories selected from online sources.

In order to better assess the quality of our classifier when facing different word divergences, we also collected from the original OpenSubtitles corpus 500 sentences containing different types of examples: 200 paired sentences; 100 unpaired sentences; 100 sentences with replace examples; and 100 sentences with insert examples (see § 3.1). All data is preprocessed with `OpenNMT`[5], performing minimal tokenisation. After tokenisation, each out-of-vocabulary word is mapped to a special UNK token, assuming a vocabulary containing the $50,000$ more frequent words.

4.2 Neural Divergence

Word embeddings of $E_s = E_t = 256$ cells are initialised using `fastText`,[6] further aligned by means of `MUSE`[7] following the unsupervised method of Lample et al. (2018). Both bi-LSTMs use 256-dimensional hidden representations ($E = 512$). Network optimization is done using SGD with gradient clipping (Pascanu et al., 2013). For each epoch, we randomly select 1 million sentence pairs that we place in batches of 32 examples. We run 10 epochs and start decaying at each epoch by 0.8 when the loss on validation set increases. Divergence is computed as in equation (1) and setting $r = 1.0$; For divergence correction, we use $\mathcal{N} = 20$ and $\tau = 3$. The same number of examples are always generated for each type of example (`Paired`, `Unpaired`, `Replace` and `Insert`). Alignments needed for `Replace` and `Insert` methods are performed using `fast_align`[8].

4.3 Neural Translation

In addition to the basic tokenisation detailed above, we perform Byte-Pair Encoding (Sennrich et al., 2016b) with 30000 merge operations learned by joining both language sides. Neural systems are based on the open-source project `OpenNMT`; using a Transformer model similar to the model of Vaswani et al. (2017): both encoder and decoder have 6 layers; Multi-head attention is performed over 8 head; the hidden layer size is 512; and the inner layer of feed forward network is of size 2048. Word embeddings have 512 cells. We set the dropout probability to 0.1 and the batch size to 3072. The optimiser is Lazy Adam with $\beta_1 = 0.9$, $\beta_2 = 0.98$, $\epsilon = 10^{-9}$, $warmup\_steps = 4000$. Training stops after 30 epochs.

5 Results

We first evaluate the ability of our divergence classifier to predict different types of divergences at the level of words. We use the test set manually annotated for that purpose and train our model on the OpenSubtitles corpus. A word is considered divergent when associated to a negative aggregation score (see Equation (2)). Accuracies obtained for various combinations of negative examples, where we see that non-divergent words in parallel and unpaired sentences (columns `P` and `U`) are easy to spot, as long as the model has seen these types of examples in training. However, the accuracy drops dramatically when the model is not trained with unpaired sentences (rows `PR`, `PI` and `PRI`). Regarding columns `R` and `I`, accuracies are lower

[7] https://github.com/facebookresearch/MUSE

[8] https://github.com/clab/fast_align

since these sentences contain a mix of divergent and non-divergent words.

	Accuracy	Test examples				
		`P`	`U`	`R`	`I`	`PURI`
Train examples	`PU`	**0.996**	**0.994**	0.671	0.673	0.874
	`PR`	**0.995**	0.033	**0.951**	0.689	0.746
	`PI`	**0.998**	0.071	0.697	**0.725**	0.705
	`PUR`	**0.994**	**0.989**	**0.919**	0.710	0.932
	`PUI`	**0.995**	**0.996**	0.662	**0.769**	0.887
	`PRI`	**0.991**	0.161	**0.924**	**0.719**	0.768
	`PURI`	**0.995**	**0.980**	**0.916**	**0.788**	**0.942**

Table 2: Word divergence accuracies according to different type of examples used in train/test.

Models that were trained with the matching examples (`R` and `I`) obtain the highest accuracies (in bold letters). Column `PURI` gives results for the complete test set, mixing all type of examples. As expected, the best accuracy is also obtained when training on all types of examples.

Figure 2 illustrates the output of our network when trained using `PU` examples (right) and `PURI` examples (left). The former (right) fails to predict some divergences, most likely because its training set does not contain sentences mixing divergent and non-divergent words. Furthermore, the network trained with `PURI` examples correctly assigns a lower similarity score to this pair, as both sentences do not convey the exact same meaning.

	Que	ressentez-vous	?		
	+6.8	+6.4	+5.1		
What	+6.0	+2.1	-0.5	+6.0	What
do	+5.5	+4.1	+1.3	+5.7	do
you	+5.2	+5.2	+2.3	+5.9	you
feel	+4.1	+5.9	+3.1	+6.1	feel
?	-0.6	+1.3	+4.9	+4.9	?
Not	-3.4	-2.5	-0.2	-0.1	Not
.	-3.1	-2.9	-0.3	-0.2	.

+0.1201

	Que	ressentez-vous	?		
	+3.9	+3.9	+4.4		
What	+3.2	+0.9	-1.1	+3.3	What
do	+2.5	+2.4	+0.8	+3.2	do
you	+2.1	+2.8	+1.9	+3.4	you
feel	+1.0	+3.0	+2.7	+3.6	feel
?	-1.2	+0.2	+3.1	+3.1	?
Not	-1.7	-0.5	+3.1	+3.1	Not
.	-2.0	-1.4	+2.7	+2.7	.

+0.2036

Figure 2: Sentence pair with similarity scores produced by our model when trained with `PU` examples (right) and over `PURI` examples (left). Aggregation scores (Eq. (2)) are shown next to words. Matrices contain alignment scores. Sentence similarities (Eq. (1)) are below matrices.

Finally, BLEU scores obtained with varying training data configurations are in Table 3: The entire[9] data sets (`all`); The most similar pairs after optimizing Eq. (3) (`sim`); After applying the correction algorithm of § 3.2 (`sim+fix`). Columns Ref and Fix indicate the number of original and corrected sentences (in millions) used in training.

Data	**Ref (M)**	**Fix (M)**	**Test (BLEU)**
OpenSubtitles English-French			
`all`	27.2	-	42.18
`sim`	15.5	-	43.12 (+0.94)
`sim`	18.0	-	43.19 (+1.01)
`sim+fix`	15.5	2.5	**44.19** (+2.01)
Paracrawl English-German			
`all`	22.2	-	19.27
`sim`	15.0	-	21.52 (+2.25)
`sim`	17.5	-	21.97 (+2.70)
`sim+fix`	15.0	2.5	**22.42** (+3.15)

Table 3: BLEU scores obtained by neural MT using different subsets of the OpenSubtitles and Paracrawl corpora.

Results obtained after filtering sentence pairs (`sim`) clearly outperform the baseline (`all`) by +0.94 and +2.25 BLEU respectively. Regarding OpenSubtitles, when fixing 2.5M sentences (4^{th} row) the accuracy is further boosted to +2.01, whereas the same sentence pairs do not show any improvement when added in their original form (3^{rd} row). Similar results are obtained for the Paracrawl corpus. Results after fixing 2.5M sentences ($4^{th} row$) outperform those obtained with their original form ($3^{rd} row$).

6 Conclusions and outlook

We presented an unsupervised method based on deep neural networks for detecting translation divergences in parallel corpora. Our model optimizes word alignments, and computes a fine grained divergence prediction at the level of words. Misaligned/divergent words can then be filtered out, yielding larger and better training sets. Our experiments on two machine translation tasks show significant improvements in comparison to training with the entire data set.

We plan to use our model to predict sentence embeddings over monolingual corpora, allowing to collect parallel pairs through vector similarity measures. In addition, we would like to measure the performance of our model after applying subword tokenisation, as well as using multiple LSTM layers, a technique well known to capture hierarchical structure in the context of MT.

Acknowledgements

We are grateful to J. Legrand for his fruitful comments regarding the neural divergence classifier.

---

[9] Paracrawl contains more than 100M sentences. We reduced its size to 22.2M using standard filtering techniques.

Adversarial Evaluation of Multimodal Machine Translation

Desmond Elliott[*]
Department of Computer Science
University of Copenhagen
`de@di.ku.dk`

Abstract

The promise of combining vision and language in multimodal machine translation is that systems will produce better translations by leveraging the image data. However, inconsistent results have lead to uncertainty about whether the images actually improve translation quality. We present an adversarial evaluation method to directly examine the utility of the image data in this task. Our evaluation measures whether multimodal translation systems perform better given either the congruent image or a random incongruent image, in addition to the correct source language sentence. We find that two out of three publicly available systems are sensitive to this perturbation of the data, and recommend that all systems pass this evaluation in the future.

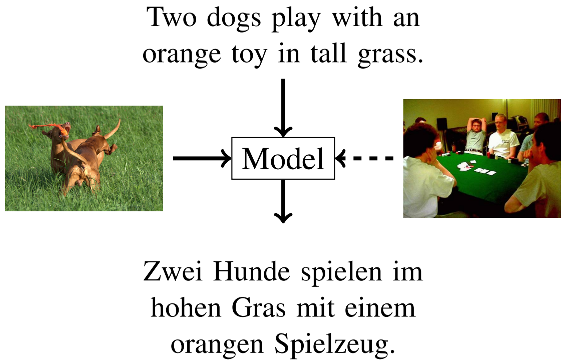

Figure 1: An adversarial evaluation for multimodal translation. We measure the difference in performance when a model sees a congruent image (left) or an incongruent image (right).

1 Introduction

Multimodal machine translation is the task of translating sentences situated in a visual context, such as captioned images on social media. The core argument of this area of research is that we can produce better translations by exploiting both the source language sentence and the visual context (Elliott et al., 2015; Hitschler et al., 2016). There is some evidence to support this argument for human translation: Frank et al. (2018) found that 13% of the German evaluation data in the Multi30K dataset (Elliott et al., 2016) needed at least one post-edit to reflect the joint meaning of the visual and linguistic context. However, the evidence that visual context helps computational models is less clear. Consider the three teams that submitted contrastive multimodal and text-only variants of their systems to the 2017 Multimodal Translation Shared Task (Elliott et al., 2017): the University of Le Mans' multimodal system outperformed their text-only variant (Caglayan et al., 2017); the Oregon State University text-only system outperformed their multimodal variant (Ma et al., 2017); and the performance of the Charles University systems depended on the language pair (Libovický and Helcl, 2017). In light of these results, we need a better understanding of the role of visual context in multimodal translation systems.

We propose an adversarial evaluation Method to determine whether multimodal translation systems are aware of the visual context. We introduce a measure of *image awareness* to quantify the difference in performance in two settings: (i) when a system is presented with congruent visual data; (ii) when it is presented with incongruent visual data. In both settings, a system is presented with the correct source language sentence. See Figure 1 for an illustration of our evaluation. We hypothesise that if a system is aware of the visual context, i.e. it is actually using the image for translation, then the system will perform better when it is presented with the congruent visual data than incongruent visual data. Our evaluation is related

---

[*] Work carried out at the University of Edinburgh.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2974–2978
Brussels, Belgium, October 31 - November 4, 2018.

to the foiled image captions evaluation, in which the performance of an image captioning system is measured when a single word is replaced with an incorrect, but similar word (Shekhar et al., 2017); the main difference is that we *replace* the visual data instead of manipulating the text. Our work is also related to a study of question-answering systems, in which additional text was appended to the end of a document (Jia and Liang, 2017). They found that these additional text segments distracted QA systems from producing the correct answer. In contrast, our evaluation does not manipulate the textual data, instead we replace the original visual input with a random distractor.

We evaluate three publicly available multimodal translation systems with our adversarial evaluation. The main finding of this paper is that one publicly available multimodal translation system is not aware of the congruent image data. This finding raises doubts about whether state-of-the-art multimodal translation systems actually use the visual context to produce better translations. We conclude this paper by discussing whether this is likely to be due to problems with the data or with the model architectures.

2 Adversarial Evaluation

2.1 Image Awareness

We propose an adversarial evaluation method for multimodal machine translation. This method measures how a system performs when it is presented with the correct text data and either the congruent image or with an incongruent image. In this section we define two image awareness functions to measure whether a multimodal translation system is aware of the congruent visual data.

Let x be a source language sentence, y be a target language sentence, v be the congruent image, and $\bar{v}$ be an incongruent image. Image awareness is calculated using an evaluable performance measure $\mathcal{E}$. The overall image awareness of a model $\mathcal{M}$ on an evaluation dataset $\mathcal{D}$ is:

$$\Delta\text{-Awareness} = \frac{1}{|\mathcal{D}|} \sum_{i}^{|\mathcal{D}|} a_{\mathcal{M}}(x_i, y_i, v_i, \bar{v}_i) \quad (1)$$

The image awareness of a model $\mathcal{M}$ for a single instance $a_{\mathcal{M}}(x_i, y_i, v_i, \bar{v}_i)$ is given by:

$$a_{\mathcal{M}}(x_i, y_i, v_i, \bar{v}_i) = \mathcal{E}(x_i, y_i, v_i) - \mathcal{E}(x_i, y_i, \bar{v}_i) \quad (2)$$

Under this definition, the output of the evaluable performance measure should be higher in the presence of the congruent data than the incongruent data, i.e. $\mathcal{E}(x_i, y_i, v_i) > \mathcal{E}(x_i, y_i, \bar{v}_i)$.[1] If this is the case, on average, then the overall image awareness of a model Δ-Awareness is positive. This can only happen when model outputs are evaluated more favourably in the presence of the the congruent image data than the incongruent image data.

2.2 Model-internal awareness Δ_I

A model-internal image measure of awareness is the difference in the probability assigned to the target language sentence y in the congruent and incongruent conditions. This is model-internal because it has the same form as the maximum-likelihood objective used to train the translation model. In this case, $\mathcal{E} = p(y|x, \cdot)$, and the difference in performance for a single instance is:

$$a_{\mathcal{M}} = \Delta_I = p(y_i|x_i, v_i) - p(y_i|x_i, \bar{v}_i) \quad (3)$$

2.3 Model-external awareness Δ_E

A model-external awareness measure could be a text-similarity evaluation or human judgement. In this paper, we use the Meteor text-similarity score (Denkowski and Lavie, 2014) because it naturally decomposes to the sentence level, and it is already the de-facto evaluation metric for multimodal machine translation (Specia et al., 2016). Let $\mathcal{E}$ be any text-similarity scoring function T that decomposes to the sentence level. The difference in performance for a single instance is defined as:

$$a_{\mathcal{M}} = \Delta_E = T(x_i, y_i, v_i) - T(x_i, y_i, \bar{v}_i) \quad (4)$$

3 Systems Evaluation

We evaluate the image awareness of three pretrained multimodal translations systems that we received by direct correspondence:

decinit: The initial state of the decoder network is set with a learned transformation of the visual data (Caglayan et al., 2017).

trgmul: The target language word embeddings are modulated by an element-wise multiplication with a learned transformation of the visual data (Caglayan et al., 2017).

---

[1] This assumes that a higher score means better performance for the performance measure $\mathcal{E}$. Swap the order of the operands if lower performance means better.

	C	**I**	Δ_E-Awareness
trgmul	57.3	57.3 $\pm$ 0.2	-0.001 $\pm$ 0.002
decinit	57.0	56.8 $\pm$ 0.1	0.003 $\pm$ 0.001
hierattn	55.0	53.3 $\pm$ 0.3	0.019 $\pm$ 0.003

Table 1: Corpus-level Meteor scores in the **C**ongruent and **I**ncongruent settings, along with the Meteor-awareness results. Incongruent and Δ_E-Awareness scores are the mean and standard deviation of five permutations of the visual data.

hierattn: The decoder network learns to selectively attend to a combination of the source language and the visual data (Libovický and Helcl, 2017).

Each system was trained on the 29,000 English–German–image tuples in the Multi30K dataset (Elliott et al., 2016). We evaluate the image awareness of these systems using the 1,014 tuples in the validation data, which is typically used for model selection. We select the incongruent images $\bar{v}$ by randomly shuffling the order in which the images v are associated with the source language text x. In our evaluation, we report the mean and standard deviation of randomly shuffling the image data five times. The code to evaluate your own system is publicly available.[2]

3.1 Statistical test

To determine if a model passes the proposed evaluation, we conduct a non-parametric Wilcoxon signed-rank test of the following hypothesis:

> H_1: Congruent images *improve* the quality of multimodal translation compared to incongruent images.
>
> H_0: Congruent images *make no difference* to the quality of multimodal translation compared to incongruent images.

We conduct this statistical test using the pairs of values that are calculated in the process of computing the the image awareness scores (Eq. 2), i.e. $\mathcal{E}(x_i, y_i, v_i)$ and $\mathcal{E}(x_i, y_i, \bar{v}_i)$.

We combine the k=5 separate p values from each test using Fisher's method and reject the null hypothesis H_0 if the result of the χ^2 test with $2k$ degrees of freedom is $p \leq 0.005$.[3]

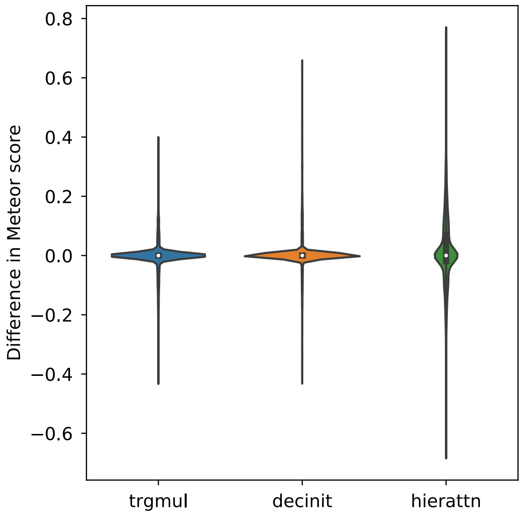

Figure 2: Violin plots of the Meteor-awareness scores for evaluated models. The white dot marks the median value, the thick gray bar shows the interquartile range, and the thin gray bar is the 95% confidence interval. The width of the plots show the kernel density estimate of the distributions.

3.2 Results

Table 1 shows the corpus-level results of a Meteor-based evaluation and the Meteor-awareness evaluation. We find that images improve the quality of the **hierattn** system (χ^2 = 136.74, p < 0.0001), and images also improve the quality of the **decinit** system (χ^2 = 32.79, $p = 0.0003$). Images make no difference to the quality of the translations generated by the **trgmul** system (χ^2 = 8.98, $p = 0.533$). To complement these tests, Figure 2 shows violin plots of the Meteor-awareness scores. These show that the translations generated by the **trgmul** and **decinit** systems are most likely to result in no difference in Meteor score between the congruent and incongruent conditions.

We now turn our attention to the results of the probability-awareness evaluation. Images improve the quality of the **trgmul** system (χ^2 = 52.55, p < 0.0001), and images also improve the quality of the **hierattn** system (χ^2 = 622.03, p < 0.0001). Images make no difference to the quality of **decinit** system (χ^2 = 6.49, p = 0.772).

Figure 3 shows examples of translations pro-

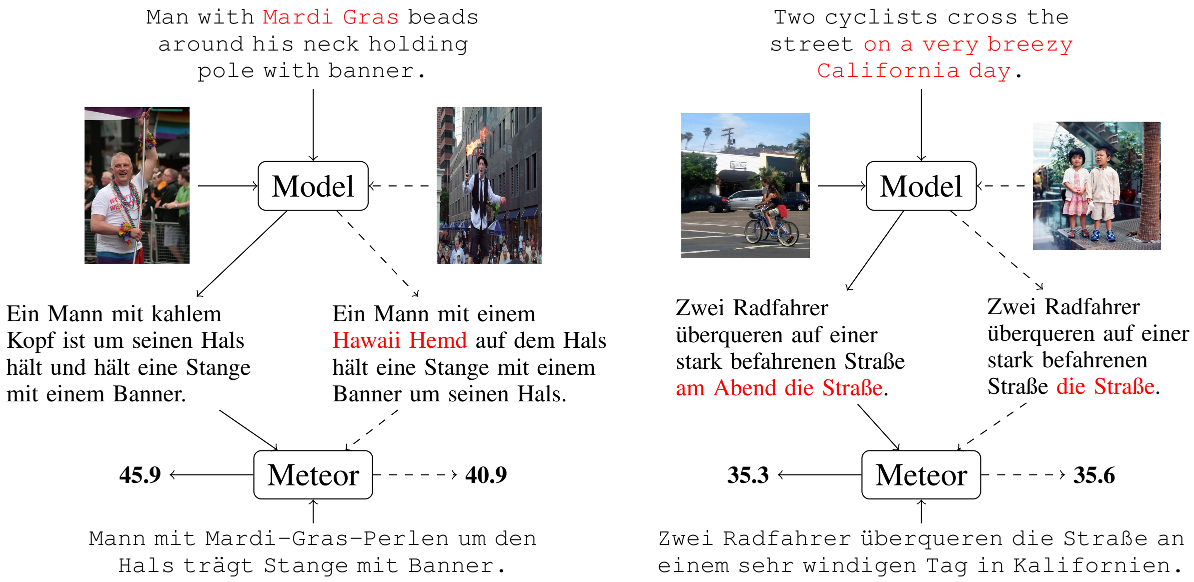
[3] We use a stricter threshold to reduce the chance of false positive findings (Benjamin et al., 2018).



(a) Congruent is better than Incongruent

(b) Incongruent is better than Congruent

Figure 3: Examples of the difference in Meteor awareness for the **hierattn** system. In each example, the source sentence is shown at the top and the reference sentence is shown at the bottom, both in `Typewriter` font. The congruent image is on the left, and the incongruent image is on the right.

duced by the **hierattn** system for sentences paired with congruent / incongruent images. Figure 3 (a) shows an example with high positive difference in Meteor score. The incongruent image causes the translation system to refer to an unseen Hawaiian shirt. In neither setting does the system translate the phrase “Mardi Gras”. Figure 3 (b) shows an example with a negative difference in Meteor score. The congruent image results in a long translation with poor coverage of the reference, which Meteor punishes more severely than the shorter translation arising from the incongruent image. In neither setting does the model translate the prepositional phrase “on a very breezy California day”.

4 Discussion

4.1 Data problems

We posit that the current Multi30K training data does not necessarily require systems to use the visual context to solve the translation task. Elliott et al. (2016) note that the German translation data was produced without showing the translators the images, and Frank et al. (2018) found that 13% of the Multi30K test data needed to be post-edited to reflect the joint semantics of both modalities. We recommend that entirety of the German Multi30K training data should be post-edited so that future systems are more likely to require a joint understanding of the visual and linguistic context.[4] We note that a similar issue was found in a visual question answering dataset, resulting in the creation of a new “balanced” dataset (Goyal et al., 2017).

4.2 The role of model architectures

The key difference between the systems evaluated in this paper is how they use the visual context. The **hierattn** system learns a timestep-dependent context vector over a location-preserving 3D volume of image features, whereas the **trgmul** and **decinit** systems use an average-pool of the 3D location-preserving features. In our evaluation, the only system that is aware of the congruent image data for both types of image-awareness is the **hierattn** system that learns a spatial context over the image. Learning to attend to specific regions of the image may prove to be crucial to improving translations with visual context.

5 Conclusion

We proposed an adversarial evaluation method to determine whether multimodal translation systems are aware of the visual context. This evaluation method measures the difference in the perfor-

---

[4] We planned to repeat the adversarial evaluation with the Multi30K French data, which *was* created by showing the annotators the images. However, we did not receive pre-trained models for all the systems for English–French translation.

mance of a system given the congruent or an incongruent image as additional context. We found that two out of three publicly available multimodal translation systems were improved by the congruent visual context, when compared to the incongruent visual context. We encourage researchers to use this method to evaluate their own systems. Future work includes augment existing multimodal translation models with an additional adversarial objective that forces the model to perform better in the presence of the congruent image than a random incongruent image. We will also apply this evaluation method to other tasks that use additional context, e.g. images in visual-question answering, or part-of-speech tags in neural machine translation.

Acknowledgements

Barry Haddow asked if we knew whether the additional image data actually improved the quality of multimodal machine translation. I claimed that there was indisputable evidence, given the results of the human evaluation at the 2017 Multimodal Translation Shared Task. I am not sure if I agree with myself any more.

Loss in Translation:
Learning Bilingual Word Mapping with a Retrieval Criterion

`{ajoulin,bojanowski,tmikolov,rvj,egrave}@fb.com`

Abstract

Continuous word representations learned separately on distinct languages can be aligned so that their words become comparable in a common space. Existing works typically solve a quadratic problem to learn a orthogonal matrix aligning a bilingual lexicon, and use a retrieval criterion for inference. In this paper, we propose an unified formulation that directly optimizes a retrieval criterion in an end-to-end fashion. Our experiments on standard benchmarks show that our approach outperforms the state of the art on word translation, with the biggest improvements observed for distant language pairs such as English-Chinese.

1 Introduction

Previous work has proposed to learn a linear mapping between continuous representations of words by employing a small bilingual lexicon as supervision. The transformation generalizes well to words that are not observed during training, making it possible to extend the lexicon. Another application is to transfer predictive models between languages (Klementiev et al., 2012).

The first simple method proposed by Mikolov *et al.* (2013b) has been subsequently improved by changing the problem parametrization. One successful suggestion is to ℓ_2–normalize the word vectors and to constrain the linear mapping to be orthogonal (Xing et al., 2015). An alignment is then efficiently found using orthogonal Procrustes (Artetxe et al., 2016; Smith et al., 2017), improving the accuracy on standard benchmarks.

Yet, the resulting models suffer from the so-called “hubness problem”: some word vectors tend to be the nearest neighbors of an abnormally high number of other words. This limitation is now addressed by applying a corrective metric at inference time, such as the inverted softmax (ISF) (Smith et al., 2017) or the cross-domain similarity local scaling (CSLS) (Conneau et al., 2017). This is not fully satisfactory because the loss used for inference is not consistent with that employed for training. This observation suggests that the square loss is suboptimal and could advantageously be replaced by a loss adapted to retrieval.

In this paper, we propose a training objective inspired by the CSLS retrieval criterion. We introduce convex relaxations of the corresponding objective function, which are efficiently optimized with projected subgradient descent. This loss can advantageously include unsupervised information and therefore leverage the representations of words not occurring in the training lexicon.

Our contributions are as follows. First we introduce our approach and empirically evaluate it on standard benchmarks for word translation. We obtain state-of-the-art bilingual mappings for more than 25 language pairs. Second, we specifically show the benefit of our alternative loss function and of leveraging unsupervised information. Finally, we show that with our end-to-end formulation, a non-orthogonal mapping achieves better results. The code for our approach is a part of the fastText library[1] and the aligned vectors are available on `https://fasttext.cc/`.

2 Preliminaries on bilingual mappings

This section introduces pre-requisites and prior works to learn a mapping between two languages, using a small bilingual lexicon as supervision.

We start from two sets of continuous representations in two languages, each learned on monolingual data. Let us introduce some notation. Each word $i \in \{1, \dots, N\}$ in the source language (respectively target language) is associated with a vector $\mathbf{x}_i \in \mathbb{R}^d$ (respectively $\mathbf{y}_i \in \mathbb{R}^d$). For simplicity,

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2979–2984
Brussels, Belgium, October 31 - November 4, 2018.

we assume that our initial lexicon, or seeds, corresponds to the first n pairs $(\mathbf{x}_i, \mathbf{y}_i)_{i\in\{1,\ldots,n\}}$. The goal is to extend the lexicon to all source words $i \in \{n+1, \ldots, N\}$ that are not seeds. Mikolov *et al.* (2013b) learn a linear mapping $\mathbf{W} \in \mathbb{R}^{d\times d}$ between the word vectors of the seed lexicon that minimizes a measure of discrepancy between mapped word vectors of the source language and word vectors of the target language:

$$\min_{\mathbf{W}\in\mathbb{R}^{d\times d}} \quad \frac{1}{n}\sum_{i=1}^{n} \ell(\mathbf{W}\mathbf{x}_i, \mathbf{y}_i), \tag{1}$$

where ℓ is a loss function, typically the square loss $\ell_2(\mathbf{x}, \mathbf{y}) = \|\mathbf{x} - \mathbf{y}\|_2^2$. This leads to a least squares problem, which is solved in closed form.

Orthogonality. The linear mapping $\mathbf{W}$ is constrained to be orthogonal, *i.e.* such that $\mathbf{W}^\top\mathbf{W} = \mathbf{I}_d$, where $\mathbf{I}_d$ is the d-dimensional identity matrix. This choice preserves distances between word vectors, and likewise word similarities. Previous works (Xing et al., 2015; Artetxe et al., 2016; Smith et al., 2017) experimentally observed that constraining the mapping in such a way improves the quality of the inferred lexicon. With the square loss and by enforcing an orthogonal mapping $\mathbf{W}$, Eq. (1) admits a closed form solution (Gower and Dijksterhuis, 2004): $\mathbf{W}^* = \mathbf{U}\mathbf{V}^\top$, where $\mathbf{U}\mathbf{D}\mathbf{V}^\top$ is the singular value decomposition of the matrix $\mathbf{Y}^\top\mathbf{X}$.

Inference. Once a mapping $\mathbf{W}$ is learned, one can infer word correspondences for words that are not in the initial lexicon. The translation $t(i)$ of a source word i is obtained as

$$t(i) \in \operatorname*{arg\,min}_{j\in\{1,\ldots,N\}} \ \ell(\mathbf{W}\mathbf{x}_i, \mathbf{y}_j). \tag{2}$$

When the squared loss is used, this amounts to computing $\mathbf{W}\mathbf{x}_i$ and to performing a nearest neighbor search with respect to the Euclidean distance:

$$t(i) \in \operatorname*{arg\,min}_{j\in\{1,\ldots,N\}} \|\mathbf{W}\mathbf{x}_i - \mathbf{y}_j\|_2^2. \tag{3}$$

Hubness. A common observation is that nearest neighbor search for bilingual lexicon inference suffers from the “hubness problem” (Doddington et al., 1998; Dinu et al., 2014). Hubs are words that appear too frequently in the neighborhoods of other words. To mitigate this effect, a simple solution is to replace, at inference time, the square ℓ_2-norm in Eq. (3) by another criterion, such as ISF (Smith et al., 2017) or CSLS (Conneau et al., 2017).

This solution, both with ISF and CSLS criteria, is applied with a transformation $\mathbf{W}$ learned using the square loss. However, replacing the loss in Eq. (3) creates a discrepancy between the learning of the translation model and the inference.

3 Word translation as a retrieval task

In this section, we propose to directly include the CSLS criterion in the model in order to make learning and inference consistent. We also show how to incorporate unsupervised information..

The CSLS criterion is a similarity measure between the vectors $\mathbf{x}$ and $\mathbf{y}$ defined as:

$$\begin{aligned}&\mathrm{CSLS}(\mathbf{x}, \mathbf{y}) = -2\cos(\mathbf{x}, \mathbf{y}) \\ &+\frac{1}{k}\sum_{\mathbf{y}'\in\mathcal{N}_Y(\mathbf{x})} \cos(\mathbf{x}, \mathbf{y}') + \frac{1}{k}\sum_{\mathbf{x}'\in\mathcal{N}_X(\mathbf{y})} \cos(\mathbf{x}', \mathbf{y}),\end{aligned}$$

where $\mathcal{N}_Y(\mathbf{x})$ is the set of k nearest neighbors of the point $\mathbf{x}$ in the set of target word vectors $Y = \{\mathbf{y}_1, \ldots, \mathbf{y}_N\}$, and cos is the cosine similarity. Note, the second term in the expression of the CSLS loss does not change the neighbors of $\mathbf{x}$. However, it gives a loss function that is symmetrical with respect to its two arguments, which is a desirable property for training.

Objective function. Let us now write the optimization problem for learning the bilingual mapping with CSLS. At this stage, we follow previous work and constrain the linear mapping $\mathbf{W}$ to belong to the set of orthogonal matrices $\mathcal{O}_d$. Here, we also assume that word vectors are ℓ_2-normalized. Under these assumptions, we have $\cos(\mathbf{W}\mathbf{x}_i, \mathbf{y}_i) = \mathbf{x}_i^\top\mathbf{W}^\top\mathbf{y}_i$. Similarly, we have $\|\mathbf{y}_j - \mathbf{W}\mathbf{x}_i\|_2^2 = 2 - 2\mathbf{x}_i^\top\mathbf{W}^\top\mathbf{y}_j$. Therefore, finding the k nearest neighbors of $\mathbf{W}\mathbf{x}_i$ among the elements of Y is equivalent to finding the k elements of Y which have the largest dot product with $\mathbf{W}\mathbf{x}_i$. We adopt this equivalent formulation because it leads to a convex formulation when relaxing the orthogonality constraint on $\mathbf{W}$. In summary, our optimization problem with the Relaxed CSLS loss (RCSLS) is written as:

$$\begin{aligned}\min_{\mathbf{W}\in\mathcal{O}_d} \frac{1}{n}\sum_{i=1}^{n} & -2\mathbf{x}_i^\top\mathbf{W}^\top\mathbf{y}_i \\ &+\frac{1}{k}\sum_{\mathbf{y}_j\in\mathcal{N}_Y(\mathbf{W}\mathbf{x}_i)} \mathbf{x}_i^\top\mathbf{W}^\top\mathbf{y}_j \\ &+\frac{1}{k}\sum_{\mathbf{W}\mathbf{x}_j\in\mathcal{N}_X(\mathbf{y}_i)} \mathbf{x}_j^\top\mathbf{W}^\top\mathbf{y}_i.\end{aligned} \tag{4}$$

Convex relaxation. Eq. (4) involves the minimization of a non-smooth cost function over the manifold of orthogonal matrices $\mathcal{O}_d$. As such, it can be solved using manifold optimization tools (Boumal et al., 2014). In this work, we consider as an alternative to the set $\mathcal{O}_d$, its convex hull $\mathcal{C}_d$, *i.e.*, the unit ball of the spectral norm. We refer to this projection as the "Spectral" model. We also consider the case where these constraints on the alignment matrix are simply removed.

Having a convex domain allows us to reason about the convexity of the cost function. We observe that the second and third terms in the CSLS loss can be rewritten as follows:

$$\sum_{\mathbf{y}_j \in \mathcal{N}_k(\mathbf{W}\mathbf{x}_i)} \mathbf{x}_i^\top \mathbf{W}^\top \mathbf{y}_j = \max_{S \in \mathcal{S}_k(n)} \sum_{j \in S} \mathbf{x}_i^\top \mathbf{W}^\top \mathbf{y}_j,$$

where $\mathcal{S}_k(n)$ denotes the set of all subsets of $\{1, \dots, n\}$ of size k. This term, seen as a function of $\mathbf{W}$, is a maximum of linear functions of $\mathbf{W}$, which is convex (Boyd and Vandenberghe, 2004). This shows that our objective function is convex with respect to the mapping $\mathbf{W}$ and piecewise linear (hence non-smooth). Note, our approach could be generalized to other loss functions by replacing the term $\mathbf{x}_i^\top \mathbf{W}^\top \mathbf{y}_j$ by any function convex in $\mathbf{W}$. We minimize this objective function over the convex set $\mathcal{C}_d$ by using the projected subgradient descent algorithm.

The projection onto the set $\mathcal{C}_d$ is solved by taking the singular value decomposition (SVD) of the matrix, and thresholding the singular values to one.

Extended Normalization. Usually, the number of word pairs in the seed lexicon n is small with respect to the size of the dictionaries N. To benefit from unlabeled data, it is common to add an iterative "refinement procedure" (Artetxe et al., 2017) when learning the translation model $\mathbf{W}$. Given a model $\mathbf{W}_t$, this procedure iterates over two steps. First it augments the training lexicon by keeping the best-inferred translation in Eq. (3). Second it learns a new mapping $\mathbf{W}_{t+1}$ by solving the problem in Eq. (1). This strategy is similar to standard semi-supervised approaches where the training set is augmented over time. In this work, we propose to use the unpaired words in the dictionaries as "negatives" in the RCSLS loss: instead of computing the k-nearest neighbors $\mathcal{N}_Y(\mathbf{W}\mathbf{x}_i)$ amongst the annotated words $\{\mathbf{y}_1, \dots, \mathbf{y}_n\}$, we do it over the whole dictionary $\{\mathbf{y}_1, \dots, \mathbf{y}_N\}$.

4 Experiments

This section reports the main results obtained with our method. We provide complementary results and an ablation study in the appendix. We refer to our method without constraints as RCSLS and as RCSLS+spectral if the spectral constraints are used.

4.1 Implementation details

We choose a learning rate in $\{1,\ 10,\ 25,\ 50\}$ and a number of epochs in $\{10,\ 20\}$ on the validation set. For the unconstrained RCSLS, a small ℓ_2 regularization can be added to prevent the norm of $\mathbf{W}$ to diverge. In practice, we do not use any regularization. For the English-Chinese pairs (en-zh), we center the word vectors. The number of nearest neighbors in the CSLS loss is 10. We use the ℓ_2-normalized fastText word vectors by Bojanowski *et al.* (2017) trained on Wikipedia.

4.2 The MUSE benchmark

Table 1 reports the comparison of RCSLS with standard supervised and unsupervised approaches on 5 language pairs (in both directions) of the MUSE benchmark (Conneau et al., 2017). Every approach uses the Wikipedia fastText vectors and supervision comes in the form of a lexicon composed of 5k words and their translations. Regardless of the relaxation, RCSLS outperforms the state of the art by, on average, 3 to 4% in accuracy. This shows the importance of using the same criterion during training and inference. Note that the refinement step ("refine") also uses CSLS to finetune the alignments but leads to a marginal gain for supervised methods.

Interestingly, RCSLS achieves a better performance without constraints (+0.8%) for all pairs. Contrary to observations made in previous works, this result suggests that preserving the distance between word vectors is not essential for word translation. Indeed, previous works used a ℓ_2 loss where, indeed, orthogonal constraints lead to an improvement of +5.3% (Procrustes versus Least Square Error). This suggests that a linear mapping $\mathbf{W}$ with no constraints works well only if it is learned with a proper criterion.

Impact of extended normalization. Table 2 reports the gain brought by including words not in the lexicon (unannotated words) to the performance of RCSLS. Extending the dictionary significantly improves the performance on all language pairs.

4.3 The WaCky dataset

Dinu et al. (2014) introduce a setting where word vectors are learned on the WaCky datasets (Baroni et al., 2009) and aligned with a noisy bilingual lexicon. We select the number of epochs within $\{1, 2, 5, 10\}$ on a validation set. Table 3 shows that RCSLS is on par with the state of the art. RCSLS is thus robust to relatively poor word vectors and noisy lexicons.

4.4 Comparison with existing aligned vectors

Recently, word vectors based on fastText have been aligned and released by Smith *et al.* (2017, BabylonPartners, BP) and Conneau *et al.* (2017, MUSE). Both use a variation of Procrustes to align word vectors in the same space.

We compare these methods to RCSLS and report results in Table 5. RCSLS improves the performance by $+3.5\%$ over MUSE vectors when trained with the same lexicon (Original). Training RSCSL on the full training lexicon (Full) brings an additional improvement of $+2.9\%$ on average with a CSLS criterion, and $+6.1\%$ with a NN criterion. For reference, the performance of Procrustes only improves by $+1.4\%$ with CSLS and even degrades with a NN criterion. RCSLS benefits more from additional supervision than Procrustes. Finally,

Table 5: Comparison with publicly available aligned vectors over 28 languages. All use supervision. Alignements are learned either on the "Original" or "Full" MUSE training. We report the detailed performance with a CSLS criterion and the average for both NN and CSLS criteria.

*BP uses a different training set of comparable size.

the gap between RCSLS and the other methods is higher with a NN criterion, suggesting that RCSLS imports some of the properties of CSLS to the dot product between aligned vectors.

4.5 Impact on word vectors

Non-orthogonal mapping of word vectors changes their dot products. We evaluate the impact of this mapping on word analogy tasks (Mikolov et al., 2013a). In Table 4, we report the accuracy on analogies for raw word vectors and our vectors mapped to English with an alignement trained on the full MUSE training set. Regardless of the source language, the mapping does not negatively impact the word vectors. Similarly, our alignement has also little impact on word similarity, as shown in Table 6.

		Original	Aligned

Zh	Sim	35	**44**
Avg.		58.8	**59.2**

Table 6: Performance on word similarities for different languages. We compare the original embeddings to their mapping to English. The mappings are learned with the full MUSE bilingual lexicons over the fastText vectors of Bojanowski et al. (2017).

We confirm this observation by running the reverse mapping, i.e., by mapping the English word vectors of Mikolov et al. (2018) to Spanish. It leads to an improvement of 1% both for vectors trained on Common Crawl (85% to 86%) and Wikipedia + News (87% to 88%).

5 Conclusion

This paper shows that minimizing a convex relaxation of the CSLS loss significantly improves the quality of bilingual word vector alignment. We use a reformulation of CSLS that generalizes to convex functions beyond dot products and provides a single end-to-end training that is consistent with the inference stage. Finally, we show that removing the orthogonality constraint does not degrade the quality of the aligned vectors.

Abstract

Most of the Neural Machine Translation (NMT) models are based on the sequence-to-sequence (Seq2Seq) model with an encoder-decoder framework equipped with the attention mechanism. However, the conventional attention mechanism treats the decoding at each time step equally with the same matrix, which is problematic since the softness of the attention for different types of words (e.g. content words and function words) should differ. Therefore, we propose a new model with a mechanism called Self-Adaptive Control of Temperature (SACT) to control the softness of attention by means of an attention temperature. Experimental results on the Chinese-English translation and English-Vietnamese translation demonstrate that our model outperforms the baseline models, and the analysis and the case study show that our model can attend to the most relevant elements in the source-side contexts and generate the translation of high quality.

1 Introduction

In recent years, Neural Machine Translation (NMT) has become the mainstream method of machine translation as it, in a great number of cases, outperforms most models based on Statistical Machine Translation (SMT), let alone the linguistics-based methods. One of the most popular baseline models is the sequence-to-sequence (Seq2Seq) model (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014) with attention mechanism (Bahdanau et al., 2014; Luong et al., 2015). However, the conventional attention mechanism is problematic in real practice. The same weight matrix for attention is applied to all decoder outputs at all time steps, which, however, can cause inaccuracy. Take a typical example from the perspective of linguistics. Words can be categorized into two types, function word, and content word. Function words and content words execute different functions in the construction of a sentence, which is relevant to syntactic structure and semantic meaning respectively. Our motivation is that the attention mechanism for different types of words, especially function word and content word, should be different. When decoding a content word, the attention scores on the source-side contexts should be harder so that the decoding can be more focused on the concrete word that is semantic referent in the source text. But when decoding a function word, the attention scores should be softer so that the decoding can pay attention to its syntactic constituents in the source text that may be several words instead of one word.

To tackle the problem mentioned above, we propose a mechanism called Self-Adaptive Control of Temperature (SACT) to control the softness of attention for the RNN-based Seq2Seq model[1]. We set a temperature parameter, which can be learned by the model based on the attention in the previous decoding time steps as well as the output of the decoder at the current time step. With the temperature parameter, the model is able to automatically tune the degree of softness of the distribution of the attention scores. To be specific, the model can learn a soft distribution of attention which is more uniform for generating function word and a hard distribution which is sparser for generating content words.

Our contributions in this study are in the following: (1). We propose a new model for NMT, which contains a mechanism called Self-Adaptive Control of Temperature (SACT) to control the softness of the attention score distribution. (2). Experimental results demonstrate that our model outperforms the attention-based Seq2Seq model in both Chinese-English and English-Vietnamese translation, with a 2.94 BLEU point and 2.19 BLEU

---

[1] The code is available at `https://github.com/lancopku/SACT`

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2985–2990
Brussels, Belgium, October 31 - November 4, 2018.

score advantage respectively[2]. (3). The analysis shows that our model is more capable of translating long texts, compared with the baseline models.

2 Our Model

As is mentioned above, our model is substantially a Seq2Seq framework improved by the SACT mechanism. In this section, we first briefly describe the Seq2Seq model, then introduce the SACT mechanism in detail.

2.1 Seq2Seq Model

We implement the encoder with bidirectional Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997), where the encoder outputs from two directions at each time step are concatenated, and we implement the decoder with unidirectional LSTM. We train our model with the Cross-Entropy Loss, which is equivalent to the maximum likelihood estimation. In the following, we introduce the details of our proposed attention mechanism.

2.2 Self-Adaptive Control of Temperature

In our assumption, due to the various functions of words, decoding at each time step should not use the identical attention mechanism to extract the required information from the source-side contexts. Therefore, we propose our Self-Adaptive Control of Temperature (SACT) to improve the conventional attention mechanism, so that the model can learn to control the scale of the softness of attention for the decoding of different words. In the following, we present the details of our design of the mechanism.

We set a temperature parameter τ to control the softness of the attention at each time step. The temperature parameter τ can be learned by the model itself. In our assumption, the temperature parameter is learned based on the information of the decoding at the current time step as well as the attention in the previous time steps, referring to the information about what has been translated and what is going to be translated. Specifically, it is defined as below:

$$\tau_t = \lambda^{\beta_t} \tag{1}$$

$$\beta_t = \tanh(W_c\tilde{c}_{t-1} + U_s s_t) \tag{2}$$

where s_t is the output of the LSTM decoder as mentioned above, $\tilde{c}_{t-1}$ is the context vector generated by our attention mechanism at the last time step (initialized with the initial state of the decoder for the decoding at the first time step), and λ is a hyper-parameter, which decides the upper bound and the lower bound of the scale for the softness of attention. To be specific, λ should be a number larger than 1[3]. The range of the output value of $\tanh$ function is $(-1, 1)$, so the range of the τ is $(\frac{1}{\lambda}, \lambda)$. Furthermore, the temperature parameter is applied to the conventional attention mechanism.

Different from the conventional attention mechanism, the temperature parameter is applied to the computation of attention score α so that the scale of the softness of attention can be changed. We define the new attention score and context vector as $\tilde{\alpha}$ and $\tilde{c}$, which are computed as:

$$\tilde{c}_t = \sum_{i=1}^{n} \tilde{\alpha}_{t,i} h_i \tag{3}$$

$$\tilde{\alpha}_{t,i} = \frac{exp(\tau_t^{-1} e_{t,i})}{\sum_{j=1}^{n} exp(\tau_t^{-1} e_{t,j})} \tag{4}$$

From the definition above, it can be inferred that when the temperature increases, the distribution of the attention score α is smoother, meaning that softer attention is required, and when the temperature is low, the distribution is sparser, meaning that harder attention is required. Therefore, the model can tune the softness of the attention distribution self-adaptively based on the current output for the decoder and the history of attention, and learns when to attend to only corresponding words and when to attend to more relevant words for further syntactic and semantic information.

3 Experiment

In the following, we introduce the experimental details, including the datasets and the experiment setting.

---

[2] What should be mentioned is that though the "Transformer" model is recently regarded as the best, the model architecture is not the focus of our study. Furthermore, our proposed mechanism can also be applied to the aforementioned model, which will be a part of our future study.

[3] In our experiments, we use λ of different values, ranging from 2 to 10. The performance differences of models with different λ values are not significant, and we report the results of the model with 4 as the value of λ as it achieves the best performance.

Model	MT-03	MT-04	MT-05	MT-06	Ave.

Table 1: **Results of the models on the Chinese-English translation**

3.1 Datasets

Chinese-English Translation We train our model on 1.25M sentence pairs[4] with 27.9M Chinese words and 34.5M English words, and we validate our model on the dataset for the NIST 2002 translation task and test our model on the datasets for the NIST 2003, 2004, 2005, 2006 translation tasks. We use the most frequent 30K words for the Chinese vocabulary and the English vocabulary respectively, covering about 97.4% and 99.7% of the corpora. The evaluation metric is case-insensitive BLEU score computed by `mteval-13a.perl` (Papineni et al., 2002).

English-Vietnamese Translation The training data is from the translated TED talks, containing 133K training sentence pairs provided by the IWSLT 2015 Evaluation Campaign (Cettolo et al., 2015). The validation set is the TED tst2012 with 1553 sentences and the test set is the TED tst2013 with 1268 sentences. The English vocabulary is 17.7K words and the Vietnamese vocabulary is 7K words. The evaluation metric is also BLEU as mentioned above[5].

3.2 Setting

Our model is implemented with PyTorch on an NVIDIA 1080Ti GPU. Both the size of word embedding and the size of the hidden layers in the encoder and decoder are 512. Gradient clipping for the gradients is applied with the largest gradient norm 10 in our experiments. Dropout is used with the dropout rate set to 0.3 for the Chinese-English translation and 0.4 for the English-Vietnamese translation, in accordance with the evaluation on the development set. Batch size is set to 64. We use Adam optimizer (Kingma and Ba, 2014) to train the model[6].

3.3 Baselines

In the following, we introduce our baseline models for the Chinese-English translation and the English-Vietnamese translation respectively.

For the Chinese-English translation, we compare our model with the most recent NMT systems, illustrated in the following. **Moses** is an open source phrase-based translation system with default configurations and a 4-gram language model trained on the training data for the target language; **RNNSearch** is an attention-based Seq2Seq with fine-tuned hyperparameters; **Coverage** is the attention-based Seq2Seq model with a coverage model (Tu et al., 2016); **MemDec** is the attention-based Seq2Seq model with the external memory (Wang et al., 2016).

For the English-Vietnamese translation, the models to be compared are presented below. **RNNSearch** The attention-based Seq2Seq model as mentioned above, and we present the results of (Luong and Manning, 2015); **NPMT** is the Neural Phrase-based Machine Translation model by Huang et al. (2017).

4 Results and Analysis

In the following, we present the experimental results as well as our analysis of temperature and case study.

4.1 Results

We present the performance of the baseline models and our model on the Chinese-English translation in Table 1. As to the recent models on the same task with the same training data, we extract their results from their original articles. Compared with the baseline models, our model with the SACT for the softness of attention achieves

---

[4] The dataset is extracted from LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06

[5] For comparison with the existing system, we use `multi-bleu.perl` instead.

[6] $\alpha = 0.0003$, $\beta_1 = 0.9$, $\beta_2 = 0.999$ and $\epsilon = 1 \times 10^{-8}$

Model	BLEU
RNNSearch	26.10
NPMT	27.69
Seq2Seq	26.93
+SACT	**29.12**

Table 2: **Results of the models on the English-Vietnamese translation**

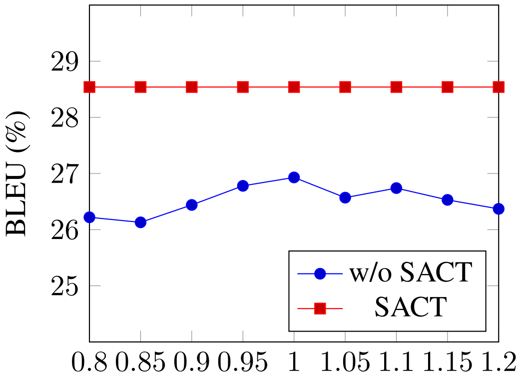

Figure 1: BLEU scores of the Seq2Seq models with fixed values for the temperature parameter. Models are tested on the test set of the English-Vietnamese translation.

better performance, with the advantages of BLEU score 2.94 over the conventional attention-based Seq2Seq model. The SACT effectively learns the temperature to control the softness of attention so that the model can utilize the information from the source-side contexts more efficiently.

We present the results of the models on the English-Vietnamese translation in Table 2. Compared with the attention-based Seq2Seq model, our model with the SACT can outperform it with a clear advantage of 2.17 BLEU score. We also display the most recent model NPMT (Huang et al., 2017) trained and tested on the dataset. Compared with NPMT, our model has an advantage of BLEU score of 1.43. It can be indicated that for low-resource translation, the information from the deconvolution-based decoder is important, which brings significant improvement to the conventional attention-based Seq2Seq model.

4.2 Analysis

In order to verify whether the automatically changing temperature can positively impact the performance of the model, we implement a series of models with fixed values, ranging from 0.8 to 1.2, for the temperature parameter. From the results shown in Figure1, it can be found that the automatically changing temperature can encourage the model to outperform those with fixed temperature parameter.

Furthermore, as our model generates a temperature parameter at each time step of decoding, we present the heatmaps of two translations from the testing on the NIST 2003 for the Chinese-English translation on Figure 2. From the heatmaps, it can be found that the model can adapt the temperature parameter to the generation at the current time step. In Figure 2(a), when translating words such as "to" and "from", which are syntactic-relevant prepositions and both lack direct corresponding words in the source text or pronoun such as "they", whose corresponding word "tamen" in the source may be a part of the possessive case or the objective case, the temperature parameter increases to soften the attention distribution so that the model can attend to more relevant elements for accurate extraction of the information from the source-side contexts. On the contrary, when translating content words or phrases such as "pay attention" and "nuclear", where there are direct corresponding words "zhuyi" and "hezi" in the source text, the temperature decreases to harden the attention distribution so that the model can focus on the corresponding information in the source text for accurate translation. In Figure 2(b), the temperature parameters for the punctuations are high as they are highly connected to the syntactic structure and those for the content words with concrete correspondences such as location "paris", name of organization "xinhua", name of person "wang" and nationality "french".

4.3 Case Study

We present two examples of the translation of our model in comparison with the translation of the conventional attention-based Seq2Seq model and the golden translation. In Table 3(a), it can be found that the translation of the conventional Seq2Seq model does not give enough credit to the word "chengzhang" (meaning "growth"), while our model can not only concentrate on the word but also recognize the word as a noun ("chengzhang" in Chinese can be both noun and verb). Even compared with the golden translation, the translation of our model seems better, which is a grammatical and coherent sentence. In Table 3(b), although the Seq2Seq model can generate the

translation about the increase in the crude oil, it wrongly connects the increase with the threat of war in Iraq. In contrast, as our model has more capability of analyzing the syntactic structure by softening the attention distribution in the generation of syntax-relevant words, it extracts the causal relationship in the source text and generates the correct translation.

5 Related Work

Most systems for Neural Machine Translation are based on the sequence-to-sequence model (Seq2Seq) (Sutskever et al., 2014), which is an encoder-decoder framework (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Sutskever et al., 2014). To improve NMT, a significant mechanism for the Seq2Seq model is the attention mechanism (Bahdanau et al., 2014). Two types of attention are the most common, which are proposed by Bahdanau et al. (2014) and Luong et al. (2015) respectively.

Though the attention mechanism is powerful for the requirements of alignment in NMT, some prominent problems still exist. To tackle the impact of the attention historyTu et al. (2016); Mi et al. (2016); Meng et al. (2016); Wang et al. (2016); Lin et al. (2018a) take the attention history into consideration. An important breakthrough in NMT is that Vaswani et al. (2017) applied the fully-attention-based model to NMT and achieved the state-of-the-art performance. To further evaluate the effect of our attention temperature mechanism, we will implement it to the “Transformer” model in the future. Besides, the studies on the attention mechanism have also contributed to some other tasks (Lin et al., 2018b; Liu et al., 2018)

Beyond the attention mechanism, there are also important methods for the Seq2Seq that contribute to the improvement of NMT. Ma et al. (2018) incorporates the information about the bag-of-words of the target for adapting to multiple translations, and Lin et al. (2018c) takes the target context into consideration.

6 Conclusion and Future Work

In this paper, we propose a novel mechanism for the control over the scope of attention so that the softness of the attention distribution can be changed adaptively. Experimental results demonstrate that the model outperforms the baseline models, and the analysis shows that our temperature parameter can change automatically when decoding diverse words. In the future, we hope to find out more patterns and generalized rules to explain the model’s learning of the temperature.

Abstract

In order to extract the best possible performance from asynchronous stochastic gradient descent one must increase the mini-batch size and scale the learning rate accordingly. In order to achieve further speedup we introduce a technique that delays gradient updates effectively increasing the mini-batch size. Unfortunately with the increase of mini-batch size we worsen the stale gradient problem in asynchronous stochastic gradient descent (SGD) which makes the model convergence poor. We introduce local optimizers which mitigate the stale gradient problem and together with fine tuning our momentum we are able to train a shallow machine translation system 27% faster than an optimized baseline with negligible penalty in BLEU.

1 Introduction

With training times measured in days, parallelizing stochastic gradient descent (SGD) is valuable for making experimental progress and scaling data sizes. Synchronous SGD sums gradients computed by multiple GPUs into one update, equivalent to a larger batch size. But GPUs sit idle unless workloads are balanced, which is difficult in machine translation and other natural language tasks because sentences have different lengths. Asynchronous SGD avoids waiting, which is faster in terms of words processed per second. However asynchronous SGD suffers from stale gradients (Abadi et al., 2016) that degrade convergence, resulting in an almost no improvement in time to convergence (Hadjis et al., 2016). This paper makes asynchronous SGD even faster and deploys a series of convergence optimizations.

In order to achieve fastest training (and inspired by Goyal et al. (2017) we increase the mini-batch size, making the matrix operations more efficient and reducing the frequency of gradient communication for the optimizer step. Unlike their task (image classification), text training consumes a lot of GPU Memory (Table 1) for word embedding activations making it impossible to fit mini-batches of similar magnitude as Goyal et al. (2017).

Our main contributions are as follows:

1. We introduce a delayed gradient updates which allow us to work with much larger mini-batches which would otherwise not be possible due to limited GPU memory.
2. We introduce local optimizers which run on each worker to mitigate the extra staleness and convergence issues (Dekel et al., 2010; Keskar et al., 2017) caused by large mini-batches.
3. We highlight the importance of tuning the optimizer momentum and show how it can be used as a cooldown strategy.

VRAM	τ	**Words**	**WPS**
3 GB	1	3080	19.5k
7 GB	1	7310	36.6k
10 GB	1	10448	40.2k
20* GB	2	20897	44.2k
30* GB	2	31345	46.0k
40* GB	4	41794	47.6k

Table 1: Relationship between the GPU Memory (VRAM) budget for batches (* means emulated by summing τ smaller batches), number of source words processed in each batch and words-per-second (WPS) measured on a shallow model.

2 Experiments

This section introduces each optimization along with an intrinsic experiment on the WMT 2016 Romanian→English task (Bojar et al., 2016).

The translation system is equivalent to Sennrich et al. (2016), which was the first place constrained system (and tied for first overall in the WMT16

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 2991–2996
Brussels, Belgium, October 31 - November 4, 2018. ©2018 Association for Computational Linguistics

shared task.). The model is a shallow bidirectional GRU (Bahdanau et al., 2014) encoder-decoder trained on 2.6 million parallel sentences. Due to variable-length sentences, machine translation systems commonly fix a memory budget then pack as many sentences as possible into a dynamically-sized batch. The memory allowance for mini-batches in our system is 3 GB (for an average batch size of 2633 words). Adam (Kingma and Ba, 2015) is used to perform asynchronous SGD with learning rate of 0.0001. This is our baseline system. We also compare with a synchronous baseline which uses modified Adam parameters, warmup of 16000 mini-batches and inverse square root cooldown following Vaswani et al. (2017). We used 4 Tesla P 100 GPUs in a single node with the Marian NMT framework for training (Junczys-Dowmunt et al., 2018). Since we apply optimizations over asynchronous SGD we performed a learning rate and mini-batch-size parameter sweep over the baseline system and settled on a learning rate of 0.00045 and 10 GB memory allowance for mini-batches (average batch size of 10449 words). This is the fastest system we could train without sacrificing performance before adding our improvements. In our experiments on Table 2 we refer to this system as ”Optimized asynchronous”. All systems were trained until 5 consecutive stalls in the cross-entropy metric of the validation set. Note that some systems require more epochs to reach this criteria which indicates poor model convergence.

2.1 Larger Batches and delayed updates

This experiment aims to increase speed, in words-per-second (WPS), by increasing the batch size. Larger batches have two well-known impacts on speed: making more use of GPU parallelism and communicating less often.

After raising the batch size to the maximum that fits on the GPU,[1] we emulate even larger batches by processing multiple mini-batches and summing their gradients locally without sending them to the optimizer. This still increases speed because communication is reduced (Table 1). We introduce parameter τ, which is the number of iterations a GPU performs locally before communicating externally as if it had run one large batch. The Words-per-second (WPS) column on Table 1 shows the effect on corpora processing speed when applying delayed gradients updates for different values of τ. While we reduce the overall training time if we just apply delayed gradient updates we worsen the overall convergence (Table 2).

When increasing the mini-batch size τ times without touching the learning rate, we effectively do τ times less updates per epoch. On the surface, it might seem that these less frequent updates are counterbalanced by the fact that each update is accumulated over a larger batch. But practical optimization heuristics like gradient clipping mean that in effect we end up updating the model less often, resulting in slower convergence. Goyal et al. (2017) recommend scaling the learning rate linearly with the mini-batch size in order to maintain convergence speed.

2.2 Warmup

Goyal et al. (2017) point out that just increasing the learning rate performs poorly for very large batch sizes, because when the model is initialized at a random point, the training error is large. Large error and large learning rate result in bad ”jerky” updates to the model and it can’t recover from those. Goyal et al. (2017) suggest that initially model updates should be small so that the model will not be pushed in a suboptimal state. Afterwards we no longer need to be so careful with our updates.

2.2.1 Lowering initial learning rate

Goyal et al. (2017) lower the initial learning rate and gradually increase it over a number of mini-batches until it reaches a predefined maximum. This technique is also adopted in the work of Vaswani et al. (2017). This is the canonical way to perform warmup for neural network training.

2.2.2 Local optimizers

We propose an alternative warm up strategy and compare it with the canonical method. Since we emulate large batches by running multiple smaller batches, it makes sense to consider whether to optimize locally between each batch by adapting the concept of local per-worker optimizers from Zhang et al. (2014). In asynchronous SGD setting each GPU has a full copy of the model as well as the master copy of $1/N$th of the parameters in its capacity as parameter server. We use the local optimizers to update the local model shard in between delayed gradient updates, which helps mitigate staleness.

---

[1] The Tesla P100 has 16 GB of GPU memory and we opt to use 10 GBs of mini-batches and the rest is used to store model parameters, shards, optimizers and additional system specific elements such as the cache vectors for gradient dropping (Aji and Heafield, 2017).

Unlike prior work, we also update the shard of the global model that happens to be on the same GPU. Local updates are almost free because we avoid remote device communication.

Updating the parameter shard of the global model bears some resemblance to the Hogwild method (Recht et al., 2011) as we don't synchronize the updates to the shard, however, global updates are still synchronised. As before, once every τ iterations we run a global optimizer that updates the sharded parameter set and then distributes the updated model across all devices. Any local model divergences are lost at this point. We found that this strategy improves model convergence in the early epochs but tends to be harmful later on. We hypothesize that initially partial model updates reduce staleness, but when the model starts to converge, local optimizers introduce extra noise in the training, which is harmful. We use local optimizers purely as a warmup strategy, turning them off after the initial phase of the training. Empirically, we found that we can get the best convergence by using them for the first 4000 mini-batches that each device sees. On Table 2 we compare and contrast the two warmup strategies. By itself learning-rate warmup offers slower convergence but to a better point compared to local optimizers. The reader may notice that if we apply delayed gradient updates, the effective batch size that the global optimizer deals with is τ times larger than the mini-batch size on which the local optimizers runs. Therefore we use τ times lower learning rate for the local optimizers compared to the global optimizers.

2.3 Momentum cooldown and tuning

Goyal et al. (2017) and Vaswani et al. (2017) both employ cooldown strategies that lower the learning rate towards the end of training. Inspired by the work of Hadjis et al. (2016) however we decided to pursue a different cooldown strategy by modifying the momentum inside Adam's parameters.

Momentum tuning is not a well explored area in deep learning. Most researchers simply use the default values for momentum for a chosen optimizer (Hadjis et al., 2016) (in the case of NMT, this is usually Adam). Hadjis et al. (2016) argue that this is an oversight especially when it comes to asynchronous SGD, because the asynchronisity adds extra implicit momentum to the training which is not accounted for. Because of this, asynchronous SGD has been deemed ineffective, as without momentum tuning, the observed increase in training speed is negated by the lower convergence rate, resulting in near-zero net gain (Abadi et al., 2016). However, Hadjis et al. (2016) show that after performing a grid search over momentum values, it is possible to achieve convergence rates typical for synchronous SGD even when working with many asynchronous workers. The downside of momentum tuning is that we can't offer rule-of-thumb values, as they are individually dependent on the optimizer used, the neural model, the number of workers and the batch size. In our experiments, we lowered the overall momentum and in addition performed momentum cooldown where we reduced the momentum of our optimizer (Adam) after the first few thousand batches.

2.4 Results

Table 2 shows the effect of modifying momentum values. When using just delayed gradient updates, training is noticeably faster, but there are significant regressions in BLEU and CE (system 2). In order to mitigate those, when using delayed gradient updates, we tune the momentum and apply momentum cooldown on top of either of our warmup strategies. By doing this we not only further reduce training time, but also recover the loss of accuracy. Compared to the optimized baseline system (1), our best system (4) reduces the training time by 27%. Progression of the training can be seen on figures 1 and 2. Our system starts poorly compared to the baselines in terms of epoch-for-epoch convergence, but catches up in the later epochs. Due to faster training speed however, the desired BLEU score is achieved faster (Figure 2).

Local optimizers as a warmup strategy show faster convergence compared to learning rate warmup at almost no penalty to BLEU or cross-entropy (System 4 vs system 6). Against the system used in WMT 16 (Sennrich et al., 2016), we achieve nearly 4 times faster training time with no discernible penalty in BLEU or CE. In contrast, the other communication reducing method tested, the work of Aji and Heafield (2017), is slower than our work and achieves worse BLEU and CE.

2.5 Using even larger mini-batches

We can achieve even greater processing speed by further increasing τ but we were unable to maintain the same convergence with the Romanian-English shallow model. We found that larger τ values are useful when dealing with the larger deep RNN mod-

System	Time (hours)	Epochs	BLEU	CE	WPS
synchronous	14.3	11	35.3	50.63	15.7k
asynchronous (0)	12.2	13	35.61	50.47	19.5k
(0) + Aji and Heafield (2017)	6.23	12	35.16	50.86	26.9k
optimized asynchronous (1)	4.97	10	35.56	50.90	40.2k
(1) + Aji and Heafield (2017)	4.32	11	35.16	52.02	41.5k
(1) + delayed updates $\tau = 2$ (2)	4.20	11	34.82	51.68	44.2k
(2) + local optimizers (3)	3.66	10	35.45	51.32	44.2k
(3) + momentum tuning (4)	**3.66**	**10**	**35.48**	**50.87**	**44.2k**
(2) + warmup (5)	4.87	13	35.29	50.78	44.2k
(5) + momentum tuning (6)	3.98	11	35.76	50.73	44.2k

Table 2: Romanian-English results from our exploration and optimizations. We also compare our methods against the work of Aji and Heafield (2017) which also reduces communication. We use system (1) as our reference baseline upon which we improve. The system that achieved the best training time is bolded.

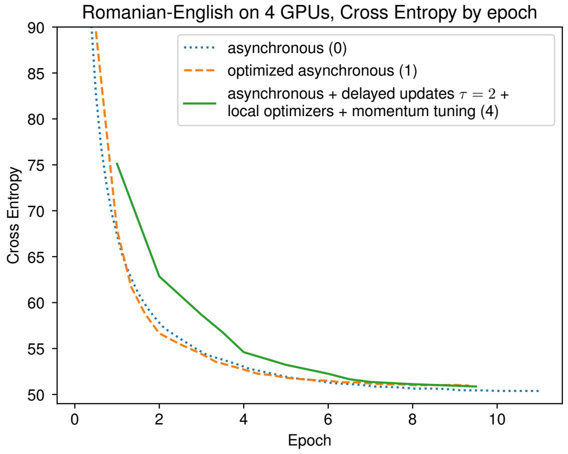

Figure 1: Cross-entropy training progression per epoch for our ro-en systems.

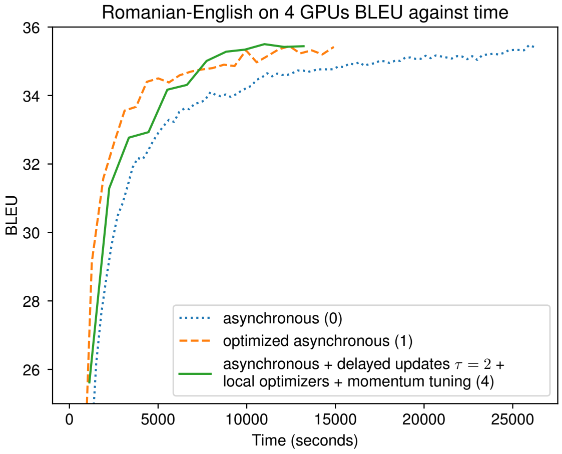

Figure 2: BLEU scores for our ro-en systems.

els. With deep RNN models the parameters take the majority of the available VRAM leaving very little for mini-batches. In this scenario we can apply $\tau = 4$ without negative effect towards convergence. We demonstrate the effectiveness of larger τ on Table 3. The baseline system is equivalent to the winning system for English-German at the WMT 2017 competition (Sennrich et al., 2017). The baseline is trained with synchronous SGD and our system uses asynchronous SGD, delayed gradient updates by a factor of 4, local optimizers and the momentum is tuned and further reduced after the first 16000 mini-batches. We found learning rate of 0.0007 to work the best. We do not report the numbers for asynchronous baseline because we were unable to achieve competitive BLEU scores without using delayed gradient updates. We speculate this is because with this type of deep model, our mini-batch size is very small leading to very jerky and unstable training updates. Larger mini-batches ensure the gradients produced by different workers are going to be closer to one another. Our training progression can be seen on figures 3 and 4. We show that even though we use 4 times larger mini-batches we actually manage to get lower Cross-Entropy epoch for epoch compared to the baseline (Figure 3). This coupled with out higher training speed makes our method reach the best BLEU score 1.6 times faster than the baseline (Figure 4).

3 Related work

We use larger mini-batches and delay gradient updates in order to increase the speed at which the dataset is processed. The principal reason why this works is because when mini-batch size is increased n (also includes delayed updates) times, communication is reduced by the same amount. This as-

System	**Time (h)**	**BLEU**	**CE**
Baseline	51.3	25.1	47.31
Async (4) + $\tau = 4$	39.7	25.07	46.59

Table 3: Training times for English-German deep RNN system trained on WMT17 data. Our asynchronous system includes the optimizations of system (4) from Table 2.

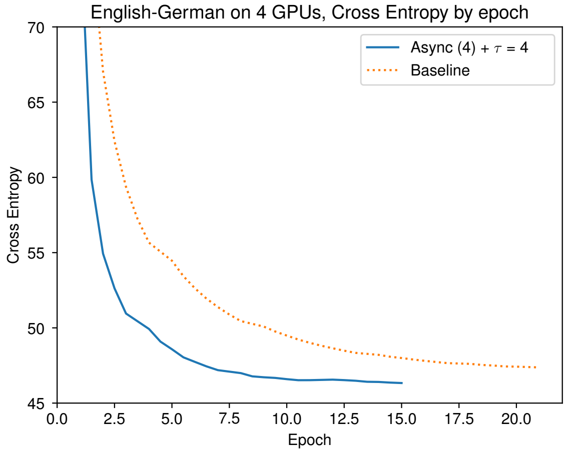

Figure 3: CE scores for our en-de systems.

pect of our work is similar to the work of Aji and Heafield (2017) where they drop the lower 99% of the gradient updates based on absolute value thus reducing the memory traffic. Compared with them we achieve faster dataset processing speed and also better model convergence as shown on Table 2.

Independently from us Mao et al. (2018) extend the work of Aji and Heafield (2017) aiming to reduce gradient communication without suffering any of the negative effects we have noted. In process they independently arrive to some of the methods that we use, notably tuning the momentum and applying warmup to achieve better convergence.

Independently from us Shazeer and Stern (2018) have done further exploratory work on ADAM's momentum parameters using the Transformer model (Vaswani et al., 2017) as a case study and have offered a mathematical explanation about why different stages of the training require different momentum values.[2]

Independently from us Saunders et al. (2018) have employed delayed gradient updates in syntax NMT setting, where the sequences are much longer due to the syntax annotation and delayed updates are necessary because video RAM is limited.[3]

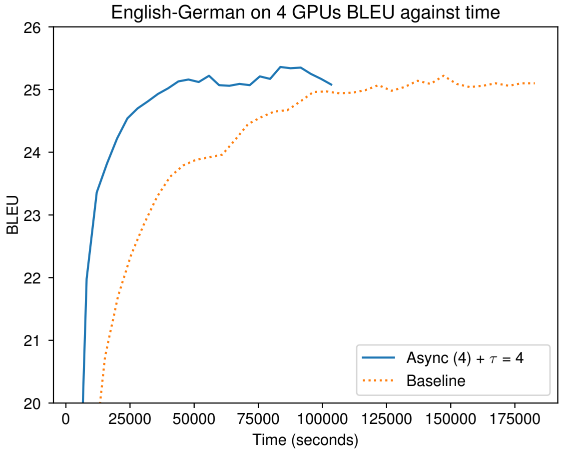

Figure 4: BLEU scores for our en-de systems.

Independently from us Lin et al. (2018) have developed their own local optimizer solution as an alternative to increasing mini-batch sizes.[4]

4 Conclusion and Future work

We show that we can increase speed and maintain convergence rate for very large mini-batch asynchronous SGD by carefully adjusting momentum and applying warmup and cooldown strategies. While we have demonstrated our methods on GPUs, they are hardware agnostic and can be applied to neural network training on any multi-device hardware such as TPUs or Xeon Phis. We were able to achieve end-to-end training on multiple tasks a lot faster than the baseline systems. For our Romanian-English model, we train nearly 3X faster than the commonly used baseline and 1.5X faster over a specifically optimised baseline. When experimenting with English-German we are able to train our model 1.3X faster than the baseline model, achieving practically the same BLEU score and much better model cross-entropy.

In the future we would like to apply local optimizers in distributed setting where the communication latency between local and remote devices varies significantly we could use local optimizers to synchronize remote models less often.

Abstract

Pronouns are frequently omitted in pro-drop languages, such as Chinese, generally leading to significant challenges with respect to the production of complete translations. Recently, Wang et al. (2018) proposed a novel reconstruction-based approach to alleviating dropped pronoun (DP) translation problems for neural machine translation models. In this work, we improve the original model from two perspectives. First, we employ a shared reconstructor to better exploit encoder and decoder representations. Second, we jointly learn to translate and predict DPs in an end-to-end manner, to avoid the errors propagated from an external DP prediction model. Experimental results show that our approach significantly improves both translation performance and DP prediction accuracy.

1 Introduction

Pronouns are important in natural languages as they imply rich discourse information. However, in pro-drop languages such as Chinese and Japanese, pronouns are frequently omitted when their referents can be pragmatically inferred from the context. When translating sentences from a pro-drop language into a non-pro-drop language (*e.g.* Chinese-to-English), translation models generally fail to translate invisible dropped pronouns (DPs). This phenomenon leads to various translation problems in terms of completeness, syntax and even semantics of translations. A number of approaches have been investigated for DP translation (Le Nagard and Koehn, 2010; Xiang et al., 2013; Wang et al., 2016, 2018).

Wang et al. (2018) is a pioneering work to model DP translation for neural machine translation (NMT) models. They employ two *separate* reconstructors (Tu et al., 2017) to respectively reconstruct encoder and decoder representations back to the DP-annotated source sentence. The annotation of DP is provided by an *external* prediction model, which is trained on the parallel corpus using automatically learned alignment information (Wang et al., 2016). Although this model achieved significant improvements, there nonetheless exist two drawbacks: 1) there is no interaction between the two separate reconstructors, which misses the opportunity to exploit useful relations between encoder and decoder representations; and 2) the external DP prediction model only has an accuracy of 66% in F1-score, which propagates numerous errors to the translation model.

In this work, we propose to improve the original model from two perspectives. First, we use a *shared* reconstructor to read hidden states from both encoder and decoder. Second, we integrate a DP predictor into NMT to *jointly* learn to translate and predict DPs. Incorporating these as two auxiliary loss terms can guide both the encoder and decoder states to learn critical information relevant to DPs. Experimental results on a large-scale Chinese–English subtitle corpus show that the two modifications can accumulatively improve translation performance, and the best result is +1.5 BLEU points better than that reported by Wang et al. (2018). In addition, the jointly learned DP prediction model significantly outperforms its external counterpart by 9% in F1-score.

2 Background

As shown in Figure 1, Wang et al. (2018) introduced two independent reconstructors with their own parameters, which reconstruct the DP-annotated source sentence from the encoder and decoder hidden states, respectively. The central

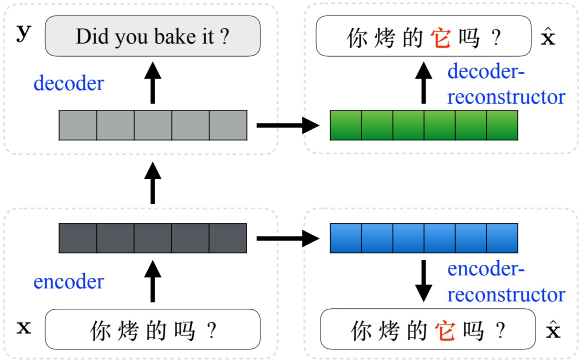

Figure 1: Architecture of separate reconstructors.

Prediction	F1-score	Example
DP Position	88%	你 烤 的 #DP# 吗 ?
DP Words	66%	你 烤 的 它 吗 ?

Table 1: Evaluation of external models on predicting the positions of DPs ("DP Position") and the exact words of DP ("DP Words").

idea underpinning their approach is to guide the corresponding hidden states to embed the recalled source-side DP information and subsequently to help the NMT model generate the missing pronouns with these enhanced hidden representations.

The DPs can be automatically annotated for training and test data using two different strategies (Wang et al., 2016). In the *training phase*, where the target sentence is available, we annotate DPs for the source sentence using alignment information. These annotated source sentences can be used to build a neural-based DP predictor, which can be used to annotate test sentences since the target sentence is not available during the *testing phase*. As shown in Table 1, Wang et al. (2016, 2018) explored to predict the exact DP words[1], the accuracy of which is only 66% in F1-score. By analyzing the translation outputs, we found that 16.2% of errors are newly introduced and caused by errors from the DP predictor. Fortunately, the accuracy of predicting DP positions (DPPs) is much higher, which provides the chance to alleviate the error propagation problem. Intuitively, we can learn to generate DPs at the predicted positions using a jointly trained DP predictor, which is fed with informative representations in the reconstructor.

3 Approach

3.1 Shared Reconstructor

Recent work shows that NMT models can benefit from sharing a component across different tasks and languages. Taking multi-language translation as an example, Firat et al. (2016) share an attention model across languages while Dong et al. (2015) share an encoder. Our work is most similar to the work of Zoph and Knight (2016) and Anastasopoulos and Chiang (2018), which share a decoder and two separate attention models to read from two different sources. In contrast, we share information at the level of reconstructed frames.

The architectures of our proposed shared reconstruction model are shown in Figure 2(a). Formally, the reconstructor reads from both the encoder and decoder hidden states, as well as the DP-annotated source sentence, and outputs a reconstruction score. It uses two separate attention models to reconstruct the annotated source sentence $\hat{\mathbf{x}} = \{\hat{x}_1, \hat{x}_2, \dots, \hat{x}_T\}$ word by word, and the reconstruction score is computed by

$$R(\hat{\mathbf{x}}|\mathbf{h}^{enc}, \mathbf{h}^{dec}) = \prod_{t=1}^{T} g_r(\hat{x}_{t-1}, \mathbf{h}_t^{rec}, \hat{\mathbf{c}}_t^{enc}, \hat{\mathbf{c}}_t^{dec})$$

where $\mathbf{h}_t^{rec}$ is the hidden state in the reconstructor, and computed by Equation (1):

$$\mathbf{h}_t^{rec} = f_r(\hat{x}_{t-1}, \mathbf{h}_{t-1}^{rec}, \hat{\mathbf{c}}_t^{enc}, \hat{\mathbf{c}}_t^{dec}) \quad (1)$$

Here $g_r(\cdot)$ and $f_r(\cdot)$ are respectively softmax and activation functions for the reconstructor. The context vectors $\hat{\mathbf{c}}_t^{enc}$ and $\hat{\mathbf{c}}_t^{dec}$ are the weighted sum of $\mathbf{h}^{enc}$ and $\mathbf{h}^{dec}$, respectively, as in Equation (2) and (3):

$$\hat{\mathbf{c}}_t^{enc} = \textstyle\sum_{j=1}^{J} \hat{\alpha}_{t,j}^{enc} \cdot \mathbf{h}_j^{enc} \quad (2)$$

$$\hat{\mathbf{c}}_t^{dec} = \textstyle\sum_{i=1}^{I} \hat{\alpha}_{t,i}^{dec} \cdot \mathbf{h}_i^{dec} \quad (3)$$

Note that the weights $\hat{\alpha}^{enc}$ and $\hat{\alpha}^{dec}$ are calculated by two separate attention models. We propose two attention strategies which differ as to whether the two attention models have interactions or not.

Independent Attention calculates the two weight matrices independently, as in Equation (4) and (5):

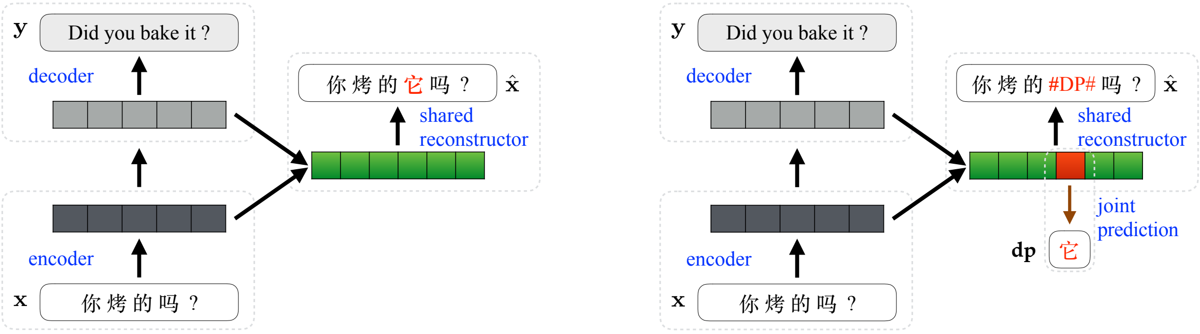
$$\hat{\alpha}^{enc} = \text{ATT}_{enc}(\hat{x}_{t-1}, \mathbf{h}_{t-1}^{rec}, \mathbf{h}^{enc}) \quad (4)$$

$$\hat{\alpha}^{dec} = \text{ATT}_{dec}(\hat{x}_{t-1}, \mathbf{h}_{t-1}^{rec}, \mathbf{h}^{dec}) \quad (5)$$

where $\text{ATT}_{enc}(\cdot)$ and $\text{ATT}_{dec}(\cdot)$ are two separate attention models with their own parameters.

---

[1] Unless otherwise indicated, in the paper, the terms "DP" and "DP word" are identical.



(a) Shared reconstructor.

(b) Shared reconstructor with joint prediction.

Figure 2: Model architectures in which the words in red are automatically annotated DPs and DPPs.

Interactive Attention feeds the context vector produced by one attention model to another attention model. The intuition behind this is that the interaction between two attention models can lead to a better exploitation of the encoder and decoder representations. As the interactive attention is directional, we have two options (Equation (6) and (7)) which modify either $\text{ATT}_{enc}(\cdot)$ or $\text{ATT}_{dec}(\cdot)$ while leaving the other one unchanged:

- *enc→dec*:

$$\hat{\alpha}^{dec} = \text{ATT}_{dec}(\hat{x}_{t-1}, \mathbf{h}_{t-1}^{rec}, \mathbf{h}^{dec}, \hat{\mathbf{c}}_t^{enc}) \quad (6)$$

- *dec→enc*:

$$\hat{\alpha}^{enc} = \text{ATT}_{enc}(\hat{x}_{t-1}, \mathbf{h}_{t-1}^{rec}, \mathbf{h}^{enc}, \hat{\mathbf{c}}_t^{dec}) \quad (7)$$

3.2 Joint Prediction of Dropped Pronouns

Inspired by recent successes of multi-task learning (Dong et al., 2015; Luong et al., 2016), we propose to jointly learn to translate and predict DPs (as shown in Figure 2(b)). To ease the learning difficulty, we leverage the information of DPPs predicted by an external model, which can achieve an accuracy of 88% in F1-score. Accordingly, we transform the original DP prediction problem to DP word generation given the pre-predicted DP positions. Since the DPP-annotated source sentence serves as the reconstructed input, we introduce an additional *DP-generation loss*, which measures how well the DP is generated from the corresponding hidden state in the reconstructor.

Let $\mathbf{dp} = \{dp_1, dp_2, \dots, dp_D\}$ be the list of DPs in the annotated source sentence, and $\mathbf{h}^{rec} = \{\mathbf{h}_1^{rec}, \mathbf{h}_2^{rec}, \dots, \mathbf{h}_D^{rec}\}$ be the corresponding hidden states in the reconstructor. The generation probability is computed by

$$\begin{aligned} P(\mathbf{dp}|\mathbf{h}^{rec}) &= \prod_{d=1}^{D} P(dp_d|\mathbf{h}_d^{rec}) \\ &= \prod_{d=1}^{D} g_p(dp_d|\mathbf{h}_d^{rec}) \end{aligned} \quad (8)$$

where $g_p(\cdot)$ is softmax for the DP predictor.

3.3 Training and Testing

We train both the encoder-decoder and the shared reconstructors together in a single end-to-end process, and the training objective is

$$\begin{aligned} J(\theta, \gamma, \psi) = \arg\max_{\theta,\gamma,\psi} \Big\{ & \underbrace{\log L(\mathbf{y}|\mathbf{x}; \theta)}_{likelihood} \\ & + \underbrace{\log R(\hat{\mathbf{x}}|\mathbf{h}^{enc}, \mathbf{h}^{dec}; \theta, \gamma)}_{reconstruction} \\ & + \underbrace{\log P(\mathbf{dp}|\hat{\mathbf{h}}^{rec}; \theta, \gamma, \psi)}_{prediction} \Big\} \end{aligned} \quad (9)$$

where $\{\theta, \gamma, \psi\}$ are respectively the parameters associated with the encoder-decoder, shared reconstructor and the DP prediction model. The auxiliary reconstruction objective $R(\cdot)$ guides the related part of the parameter matrix θ to learn better latent representations, which are used to reconstruct the DPP-annotated source sentence. The auxiliary prediction loss $P(\cdot)$ guides the related part of both the encoder-decoder and the reconstructor to learn better latent representations, which are used to predict the DPs in the source sentence.

Following Tu et al. (2017) and Wang et al. (2018), we use the reconstruction score

#	Model	#Params	Speed		BLEU
			Train	Decode	
	Existing system (Wang et al., 2018)				
1	Baseline	86.7M	1.60K	15.23	31.80
2	Baseline (+DPs)	86.7M	1.59K	15.20	32.67
3	Separate-Recs⇒(+DPs)	+73.8M	0.57K	12.00	35.08
	Our system				
4	Baseline (+DPPs)	86.7M	1.54K	15.19	33.18
5	Shared-Rec$_{independent}$⇒(+DPPs)	+86.6M	0.52K	11.87	35.27†‡
6	Shared-Rec$_{independent}$⇒(+DPPs) + joint prediction	+87.9M	0.51K	11.88	35.88†‡
7	Shared-Rec$_{enc\rightarrow dec}$⇒(+DPPs) + joint prediction	+91.9M	0.48K	11.84	**36.53**†‡
8	Shared-Rec$_{dec\rightarrow enc}$⇒(+DPPs) + joint prediction	+89.9M	0.49K	11.85	35.99†‡

Table 2: Evaluation of translation performance for Chinese–English. "Baseline" is trained and evaluated on the original data, while "Baseline (+DPs)" and "Baseline (+DPPs)" are trained on the data annotated with DPs and DPPs, respectively. Training and decoding (beam size is 10) speeds are measured in words/second. "†" and "‡" indicate statistically significant difference ($p < 0.01$) from "Baseline (+DDPs)" and "Separate-Recs⇒(+DPs)", respectively.

as a reranking technique to select the best translation candidate from the generated n-best list at testing time. Different from Wang et al. (2018), we reconstruct DPP-annotated source sentence, which is predicted by an external model.

4 Experiment

4.1 Setup

To compare our work with the results reported by previous work (Wang et al., 2018), we conducted experiments on their released Chinese⇒English TV Subtitle corpus.[2] The training, validation, and test sets contain 2.15M, 1.09K, and 1.15K sentence pairs, respectively. We used case-insensitive 4-gram NIST BLEU metrics (Papineni et al., 2002) for evaluation, and *sign-test* (Collins et al., 2005) to test for statistical significance.

We implemented our models on the code repository released by Wang et al. (2018).[3] We used the same configurations (*e.g.* vocabulary size = 30K, hidden size = 1000) and reproduced their reported results. It should be emphasized that we did not use the pre-train strategy as done in Wang et al. (2018), since we found training from scratch achieved a better performance in the shared reconstructor setting.

4.2 Results

Table 2 shows the translation results. It is clear that the proposed models significantly outperform the baselines in all cases, although there are considerable differences among different variations.

Baselines (Rows 1-4): The three baselines (Rows 1, 2, and 4) differ regarding the training data used. "Separate-Recs⇒(+DPs)" (Row 3) is the best model reported in Wang et al. (2018), which we employed as another strong baseline. The baseline trained on the DPP-annotated data ("Baseline (+DPPs)", Row 4) outperforms the other two counterparts, indicating that the error propagation problem does affect the performance of translating DPs. It suggests the necessity of jointly learning to translate and predict DPs.

Our Models (Rows 5-8): Using our shared reconstructor (Row 5) not only outperforms the corresponding baseline (Row 4), but also surpasses its separate reconstructor counterpart (Row 3). Introducing a joint prediction objective (Row 6) can achieve a further improvement of +0.61 BLEU points. These results verify that shared reconstructor and jointly predicting DPs can accumulatively improve translation performance.

Among the variations of shared reconstructors (Rows 6-8), we found that an interaction attention from encoder to decoder (Row 7) achieves the best performance, which is +3.45 BLEU points better than our baseline (Row 4) and +1.45 BLEU points

---

[2] `https://github.com/longyuewangdcu/tvsub`

[3] `https://github.com/tuzhaopeng/nmt`

better than the best result reported by Wang et al. (2018) (Row 3). We attribute the superior performance of "Shared-Rec$_{enc \rightarrow dec}$" to the fact that the attention context over encoder representations embeds useful DP information, which can help to better attend to the representations of the corresponding pronouns in the decoder side. Similar to Wang et al. (2018), the proposed approach improves BLEU scores at the cost of decreased training and decoding speed, which is due to the large number of newly introduced parameters resulting from the incorporation of reconstructors into the NMT model.

4.3 Analysis

Models	Precision	Recall	F1-score
External	0.67	0.65	0.66
Joint	0.74	0.76	0.75

Table 3: Evaluation of DP prediction accuracy. "External" model is *separately* trained on DP-annotated data with external neural methods (Wang et al., 2016), while "Joint" model is *jointly* trained with the NMT model (Section 3.2).

DP Prediction Accuracy As shown in Table 3, the jointly learned model significantly outperforms the external one by 9% in F1-score. We attribute this to the useful contextual information embedded in the reconstructor representations, which are used to generate the exact DP words.

Model	Test	△
Baseline (+DPPs)	33.18	–
Separate-Recs (+DPs)	34.02	+0.84
Shared-Rec (+DPPs)	**34.80**	**+1.62**

Table 4: Translation results when *reconstruction is used in training only while not used in testing*.

Contribution Analysis Table 4 lists translation results when the reconstruction model is used in training only. We can see that the proposed model outperforms both the strong baseline and the best model reported in Wang et al. (2018). This is encouraging since no extra resources and computation are introduced to online decoding, which makes the approach highly practical, for example for translation in industry applications.

Model	Auto.	Man.	△
Seperate-Recs (+DPs)	35.08	38.38	+3.30
Shared-Rec (+DPPs)	36.53	38.94	+2.41

Table 5: Translation performance gap ("△") between manually ("Man.") and automatically ("Auto.") labelling DPs/DPPs for input sentences in testing.

Effect of DPP Labelling Accuracy For each sentence in testing, the DPs and DPPs are labelled automatically by two separate external prediction models, the accuracy of which are respectively 66% and 88% measured in F1 score. We investigate the best performance the models can achieve with manual labelling, which can be regarded as an "Oracle", as shown in Table 5. As seen, there still exists a significant gap in performance, and this could be improved by improving the accuracy of our DPP generator. In addition, our models show a relatively smaller distance in performance from the oracle performance ("Man"), indicating that the error propagation problem is alleviated to some extent.

5 Conclusion

In this paper, we proposed effective approaches of translating DPs with NMT models: *shared* reconstructor and *jointly* learning to translate and predict DPs. Through experiments we verified that 1) shared reconstruction is helpful to share knowledge between the encoder and decoder; and 2) joint learning of the DP prediction model indeed alleviates the error propagation problem by improving prediction accuracy. The two approaches accumulatively improve translation performance. The method is not restricted to the DP translation task and could potentially be applied to other sequence generation problems where additional source-side information could be incorporated.

In future work we plan to: 1) build a fully end-to-end NMT model for DP translation, which does not depend on any external component (*i.e.* DPP predictor); 2) exploit cross-sentence context (Wang et al., 2017) to further improve DP translation; 3) investigate a new research strand that adapts our model in an inverse translation direction by learning to drop pronouns instead of recovering DPs.

Abstract

Speakers of different languages must attend to and encode strikingly different aspects of the world in order to use their language correctly (Sapir, 1921; Slobin, 1996). One such difference is related to the way gender is expressed in a language. Saying "I am happy" in English, does not encode any additional knowledge of the speaker that uttered the sentence. However, many other languages do have grammatical gender systems and so such knowledge would be encoded. In order to correctly translate such a sentence into, say, French, the inherent gender information needs to be retained/recovered. The same sentence would become either "Je suis heureux", for a male speaker or "Je suis heureuse" for a female one. Apart from morphological agreement, demographic factors (gender, age, etc.) also influence our use of language in terms of word choices or even on the level of syntactic constructions (Tannen, 1991; Pennebaker et al., 2003). We integrate gender information into NMT systems. Our contribution is twofold: (1) the compilation of large datasets with speaker information for 20 language pairs, and (2) a simple set of experiments that incorporate gender information into NMT for multiple language pairs. Our experiments show that adding a gender feature to an NMT system significantly improves the translation quality for some language pairs.

1 Introduction

In the field of linguistics, the differences between male and female traits within spoken and written language have been studied both empirically and theoretically, revealing that the language used by males and females differs in terms of style and syntax (Coates, 2015). The increasing amount of work on automatic author classification (or 'author profiling') reaching relatively high accuracies on domain-specific data corroborates these findings (Rangel et al., 2013; Santosh et al., 2013). However, determining the gender of an author based solely on text is not a solved issue. Likewise, the selection of the most informative features for gender classification remains a difficult task (Litvinova et al., 2016).

When translating from one language into another, original author traits are partially lost, both in human and machine translations (Mirkin et al., 2015; Rabinovich et al., 2017). However, in the field of Machine Translation (MT) one of the most observable consequences of this missing information are morphologically incorrect variants due to a lack of agreement in number and gender with the subject. Such errors harm the overall fluency and adequacy of the translated sentence. Furthermore, gender-related errors are not just harming the quality of the translation as getting the gender right is also a matter of basic politeness. Current systems have a tendency to perpetuate a male bias which amounts to negative discrimination against half the population and this has been picked up by the media.[1]

Human translators rely on contextual information to infer the gender of the speaker in order to make the correct morphological agreement. However, most current MT systems do not; they simply exploit statistical dependencies on the sentence level that have been learned from large amounts of parallel data. Furthermore, sentences are translated in isolation. As a consequence, pieces of information necessary to determine the gender of the speakers, might get lost. The MT system will, in such cases, opt for the statistically most likely variant, which depending on the training data, will

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3003–3008
Brussels, Belgium, October 31 - November 4, 2018.

be either the male or the female form. Additionally, in the field of MT, training data often consists of both original and translated parallel texts: large parts of the texts have already been translated, which, as studied by Mirkin et al. (2015), does not preserve the original demographic and psychometric traits of the author, making it very hard for a Neural MT (NMT) system to determine the gender of the author.

With this in mind, a first step towards the preservation of author traits would be their integration into an NMT system. As ‘gender’ manifests itself not only in the agreement with other words in a sentence, but also in the choice of context-based words or on the level of syntactic constructions, the sets of experiments conducted in this paper focus on the integration of a gender feature into NMT for multiple language pairs.

The structure of the paper is the following: related work is described in Section 2; Section 3 describes and analyses the datasets that were compiled; the experimental setup is discussed in Section 4; the results are presented in Section 5; finally, we conclude and provide some ideas for future work in Section 6.

2 Related Work

Differences in the language between male and female speakers have been studied within various fields related to linguistics, including Natural Language Processing (NLP) for author profiling, conversational agents, recommendation systems etc. Mirkin et al. (2015) motivated the need for more personalized MT. Their experiments show that MT is detrimental to the automatic recognition of linguistic signals of traits of the original author/speaker. Their work suggests using domain-adaptation techniques to make MT more personalized but does not include any actual experiments on the inclusion of author traits in MT.

Rabinovich et al. (2017) conducted a series of experiments on preserving original author traits, focusing particularly on gender. As suggested by Mirkin et al. (2015), they treat the personalization of Statistical MT (SMT) systems as a domain-adaptation task treating the female and male gender as two different domains. They applied two common simple domain-adaptation techniques in order to create personalized SMT: (1) using gender-specific phrase-tables and language models, and (2) using a gender-specific tuning set. Although their models did not improve over the baseline, their work provides a detailed analysis of gender traits in human and machine translation.

Our work is, to the best of our knowledge, the first to attempt building a speaker-informed NMT system. Our approach is similar to the work of Sennrich et al. (2016) on controlling politeness, where some sentence of the training data are followed with an ‘informal’ or ‘polite’ tag indicating the level of politeness expressed.

3 Compilation of Datasets

One of the main obstacles for more personalized MT systems is finding large enough annotated parallel datasets with speaker information. Rabinovich et al. (2017) published an annotated parallel dataset for EN–FR and EN–DE. However, for many other language pairs no sufficiently large annotated datasets are available.

To address the aforementioned problem, we published online a collection of parallel corpora licensed under the Creative Commons Attribution 4.0 International License for 20 language pairs (Vanmassenhove and Hardmeier, 2018).[2]

We followed the approach described by Rabinovich et al. (2017) and tagged parallel sentences from Europarl (Koehn, 2005) with speaker information (name, gender, age, date of birth, euroID and date of the session) by retrieving speaker information provided by tags in the Europarl source files. The Europarl source files contain information about the speaker on the paragraph level and the filenames contain the data of the session. By retrieving the names of the speakers together with meta-information on the members of the European Parliament (MEPs) released by Rabinovich et al. (2017) (which includes among others name, country, date of birth and gender predictions per MEP), we were able to retrieve demographic annotations (gender, age, etc.). An overview of the language pairs as well as the amount of annotated parallel sentences per language pair is given in Table 1.

3.1 Analysis of the EN–FR Annotated Dataset

We first analysed the distribution of male and female sentence in our data. In the 10 different

Table 1: Overview of annotated parallel sentences per language pair

datasets we experimented with, the percentage of sentences uttered by female speakers is very similar, ranging between 32% and 33%. This similarity can be explained by the fact that Europarl is largely a multilingual corpus with a big overlap between the different language pairs.

We conducted a more focused analysis on one of the subcorpora (EN–FR) with respect to the percentage of sentences uttered by males/females for various age groups to obtain a better grasp of what kind of data we are using for training. As can be seen from Figure 1, with the exception of the youngest age group (20–30), which represents only a very small percentage of the total amount of sentences (0.71%), more male data is available in all age groups. Furthermore, when looking at the entire dataset, 67.39% of the sentences are produced by male speakers. Moreover, almost half of the total number of sentences are uttered by the 50–60 age group (43.76%).

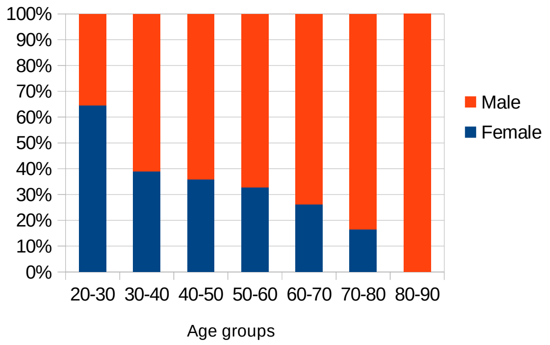

Figure 1: Percentage of female and male speakers per age group

The analysis shows that indeed, there is a gender unbalance in the Europarl dataset, which will be reflected in the translations that MT systems trained on this data produce.

4 Experimental Setup

4.1 Datasets

We carried out a set of experiments on 10 language pairs (the ones for which we compiled more than 500k annotated Europarl parallel sentences): EN–DE, EN–FR, EN–ES, EN–EL, EN–PT, EN–FI, EN–IT, EN–SV, EN–NL and EN–DA. We augmented every sentence with a tag on the English source side, identifying the gender of the speaker, as illustrated in (1). This approach for encoding sentence-specific information for NMT has been successfully exploited to tackle other types of issues, multilingual NMT systems (e.g., Zero Shot Translation (Johnson et al., 2017)), domain adaptation (Sennrich et al., 2016), etc.

(1) “FEMALE Madam President, as a...”

For each of these language pairs we trained two NMT systems: a baseline and a tagged one. We evaluated the performance of all our systems on a randomly selected 2K general test set. Moreover, we further evaluated the EN–FR systems on 2K male-only and female-only test sets to have a look at the system performance with respect to gender-related issues. We also looked at two additional male and female test sets in which the first person singular pronoun appeared.

4.2 Description of the NMT Systems

We used the OpenNMT-py toolkit (Klein et al., 2017) to train the NMT models. The models are sequence-to-sequence encoder-decoders with LSTMs as the recurrent unit (Bahdanau et al., 2014; Cho et al., 2014; Sutskever et al., 2014) trained with the default parameters. In order to bypass the OOV problem and reduce the number of dictionary entries, we use word-segmentation with BPE (Sennrich, 2015). We ran the BPE algorithm with 89,500 operations (Sennrich, 2015). All systems are trained for 13 epochs and the best model is selected for evaluation.

5 Results

In this section we discuss some of the results obtained. We hypothesized that the male/female tags would be particularly helpful for French, Portuguese, Italian, Spanish and Greek, where adjectives and even verb forms can be marked by the gender of the speaker. Since, according to the literature, women and men also make use of different syntactic constructions and make different word choices, we also tested the approach on other languages that do not have morphological agreement with the gender of the speaker such as Danish (DA), Dutch (NL), Finnish (FI), German (DE) and Swedish (SV).

First, we wanted to see how our tagged systems performed on the general test set compared to the baseline. In Table 2, the BLEU scores for 10 baseline and 10 gender-enhanced NMT systems are presented.

Systems	**EN**	**EN-TAG**

Table 2: BLEU scores for the 10 baseline (denoted with **EN**) and the 10 gender-enhanced NMT (denoted with **EN-TAG**) systems. Entries labeled with * present statistically significant differences ($p < 0.05$). Statistical significance was computed with the MultEval tool (Clark et al., 2011).

While most of the BLEU-scores (Papineni et al., 2002) in Table 2 are consistent with our hypothesis, showing (significant) improvements for the NMT systems enriched with a gender tag (EN-TAG) over the baseline systems (EN) for French, Italian, Portuguese and Greek, the Spanish enriched system surprisingly does not (–0.19 BLEU). As hypothesized, the Dutch, German, Finnish and Swedish systems do not improve. However, the Danish (EN–DA) enriched NMT system does achieve a significant +0.31 BLEU improvement.

We expected to see the strongest improvements in sentences uttered by female speakers as, according to our initial analysis, the male data was overrepresented in the training. To test this hypothesis, we evaluated all systems on a male-only and female-only test set. Furthermore, we also experimented on test sets containing the pronoun of the first person singular as this form is used when a speaker refers to himself/herself. The results on the specific test set for the EN–FR dataset are presented in Table 3. As hypothesized, the biggest BLEU score improvement is observed on the female test set, particularly, the test sets containing first person singular pronouns (F1).

Test Sets	**EN**	**EN-TAG**
FR (M)	37.58	**38.71***
FR (F)	37.75	**38.97***
FR (M1)	39.00	**39.66***
FR (F1)	37.32	**38.57***

Table 3: BLEU-scores on EN–FR comparing the baseline (EN) and the tagged systems (EN–TAG) on 4 different test sets: a test set containing only male data (M), only female data (F), 1st person male data (M1) and first person female data (F1). All the improvements of the EN-TAG system are statistically significant ($p < 0.5$), as indicated by *.

We had a closer look at some of the translations.[3] There are cases where the gender-informed (TAG) system improves over the baseline (BASE) due to better agreement. Interestingly, in (2) the French female form of vice-president (vice-présidente) appears in the translation produced by the BASE system while the male form is the correct one. The gender-informed system does make the correct agreement by using the female variant. In (3) the speaker is female but the baseline system outputs a male form of the adjective 'happy' ('heureux').

(2) (Ref) En tant que *vice-président*...
(BASE) En tant que *vice-présidente*...
(TAG) En tant que *vice-président*...

(3) (Ref) ... je suis *heureuse* que...
(BASE) ... je suis *heureux* que...
(TAG) ... je suis *heureuse* que...

However, we also encountered cases where the gender-informed system fails to produce the correct agreement, as in (4), where both the BASE and the TAG system produce a male form ('embarassé') instead of the correct female one ('embarassée' or 'gênée').

(4) (Ref) je suis *gênée* que...
(BASE) je suis *embarassé* que...
(TAG) je suis *embarassé* que...

For some language pairs the gender-informed system leads to a significant improvement even on a general test set. This implies that the improvement is not merely because of better morphological agreement, as these kinds of improvements are very hard to measure with BLEU, especially given the fact that Europarl consists of formal spoken language and does not contain many sentences using the first person singular pronoun. From our analysis, we observe that in many cases the gender-informed systems have a higher BLEU

---

[3] We used the tool provided by Tilde `https://www.letsmt.eu/Bleu.aspx` to see where the BLEU score between the baseline and our tagged systems varied the most.

score than the baseline system due to differences in word choices as in (5) and (6), where both translations are correct, but the gender-informed system picks the preferred variant.

The observations with respect to differences in word preferences between male and female speakers are in accordance with corpus linguistic studies, which have shown that gender does not only have an effect on morphological agreement, but also manifests itself in other ways as males and females have different preferences when it comes to different types of constructions, word choices etc. (Newman et al., 2008; Coates, 2015). This also implies that, even for languages that do not mark gender overtly (i.e. grammatically), it can still be beneficial to take the gender of the author/speaker into account.

(5) (Ref) Je pense que ...
(BASE) Je crois que...
(TAG) Je pense que...

Although more research is required in order to draw general conclusions on this matter, from other linguistic studies, it appears that it is indeed the case that there is a relation between the use of the word "pense" ("think") / "crois" ("believe") and the gender of the speaker. To see whether there is a difference in word choice and whether this is reflected in our data, we compiled a list of the most frequent French words for the male data and the female data. Our analysis reveals that "crois" is, in general, used more by males (having position 303 in the most frequent words for males, but only position 373 for females), while "pense" is found at a similar position in both lists (position 151 and 153). These findings are in accordance with other linguistic corpus studies on language and gender stating that women use less assertive speech (Newman et al., 2008). "Croire" and "penser" are both verbs of cognition but there is a difference in the degree of confidence in the truth value predicated: the verb "croire" denotes more confidence in the truth of the complement clause than the verb "penser" does. In the future, we would like to perform a more detailed analysis of other specific differences in lexical choices between males and females on multiple language pairs.

(BASE) J' ai un nombre de commentaires...
(TAG) J' ai plusieurs remarques...

6 Conclusions and Future Work

In this work, we experimented with the incorporation of speaker-gender tags during the training of NMT systems in order to improve morphological agreement. We focused particularly on language pairs that express grammatical gender but included other language pairs as well, as linguistic studies have shown that the style and syntax of language used by males and females differs (Coates, 2015).

From the experiments, we see that informing the NMT system by providing tags indicating the gender of the speaker can indeed lead to significant improvements over state-of-the-art baseline systems, especially for those languages expressing grammatical gender agreement. However, while analyzing the EN–FR translations, we observed that the improvements are not always consistent and that, apart from morphological agreement, the gender-aware NMT system differs from the baseline in terms of word choices.

In the future, we would like to conduct further manual evaluation on the translations to further analyze the differences with the baseline system. Furthermore, we aim to experiment with other ways of integrating speaker information. We envisage working on gender classification techniques in order to work on other types (more informal) of corpora that are more likely to express speaker characteristics.

Abstract

This work investigates an alternative model for neural machine translation (NMT) and proposes a novel architecture, where we employ a multi-dimensional long short-term memory (MDLSTM) for translation modeling. In the state-of-the-art methods, source and target sentences are treated as one-dimensional sequences over time, while we view translation as a two-dimensional (2D) mapping using an MDLSTM layer to define the correspondence between source and target words. We extend beyond the current sequence to sequence backbone NMT models to a 2D structure in which the source and target sentences are aligned with each other in a 2D grid. Our proposed topology shows consistent improvements over attention-based sequence to sequence model on two WMT 2017 tasks, German↔English.

1 Introduction

The widely used state-of-the-art neural machine translation (NMT) systems are based on an encoder-decoder architecture equipped with attention layer(s). The encoder and the decoder can be constructed using recurrent neural networks (RNNs), especially long-short term memory (LSTM) (Bahdanau et al., 2014; Wu et al., 2016), convolutional neural networks (CNNs) (Gehring et al., 2017), self-attention units (Vaswani et al., 2017), or a combination of them (Chen et al., 2018). In all these architectures, source and target sentences are handled separately as a one-dimensional sequence over time. Then, an attention mechanism (additive, multiplicative or multihead) is incorporated into the decoder to selectively focus on individual parts of the source sentence.

One of the weaknesses of such models is that the encoder states are computed only once at the beginning and are left untouched with respect to the target histories. In this case, at every decoding step, the same set of vectors are read repeatedly. Hence, the attention mechanism is limited in its ability to effectively model the coverage of the source sentence. By providing the encoder states with the greater capacity to remember what has been generated and what needs to be translated, we believe that we can alleviate the coverage problems such as over- and under-translation.

One solution is to assimilate the context from both source and target sentences jointly and to align them in a two-dimensional grid. Two-dimensional LSTM (2DLSTM) is able to process data with complex interdependencies in a 2D space (Graves, 2012).

To incorporate the solution, in this work, we propose a novel architecture based on the 2DLSTM unit, which enables the computation of the encoding of the source sentence as a function of the previously generated target words. We treat translation as a 2D mapping. One dimension processes the source sentence, and the other dimension generates the target words. Each time a target word is generated, its representation is used to compute a hidden state sequence that models the source sentence encoding. In principle, by updating the encoder states across the second dimension using the target history, the 2DLSTM captures the coverage concepts internally by its cell states.

2 Related Works

MDLSTM (Graves, 2008, 2012) has been successfully used in handwriting recognition (HWR) to automatically extract features from raw images which are inherently two-dimensional (Graves and Schmidhuber, 2008; Leifert et al., 2016a; Voigtlaender et al., 2016). Voigtlaender et al. (2016) explore a larger MDLSTM for deeper and wider architectures using an implementation for the

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3009–3015
Brussels, Belgium, October 31 - November 4, 2018.

graphical processing unit (GPU). It has also been applied to automatic speech recognition (ASR) where a 2DLSTM scans the input over both time and frequency jointly (Li et al., 2016; Sainath and Li, 2016). As an alternative architecture to the concept of MDLSTM, Kalchbrenner et al. (2015) propose a grid LSTM that is a network of LSTM cells arranged in a multidimensional grid, in which the cells are communicating between layers as well as time recurrences. Li et al. (2017) also apply the grid LSTM architecture for the endpoint detection task in ASR.

This work, for the first time, presents an end-to-end 2D neural model where we process the source and the target words jointly by a 2DLSTM layer.

3 Two-Dimensional LSTM

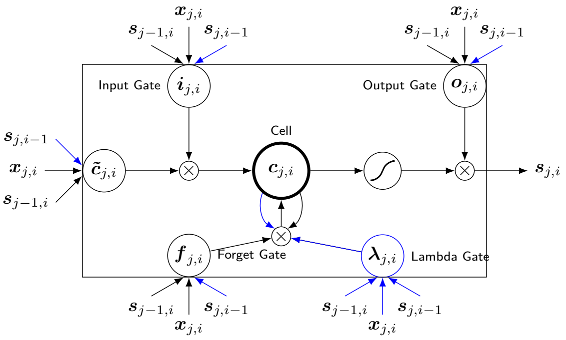

Figure 1: 2DLSTM unit. The additional links vs. standard LSTM are marked in blue.

The 2DLSTM has been introduced by (Graves, 2008) as a generalization of standard LSTM. Figure 1 illustrates one of the stable variants proposed by (Leifert et al., 2016b). A 2DLSTM unit processes a 2D sequential data $x \in \mathbb{R}^{J \times I}$ of arbitrary lengths, J and I. At time step (j, i), the computation of its cell depends on both vertical $s_{j,i-1}$ and horizontal hidden states $s_{j-1,i}$ (see Equations (1)–(5)). Similar to the LSTM cell, it maintains some state information in an internal cell state $c_{j,i}$. Besides the input $i_{j,i}$, the forget $f_{j,i}$ and the output $o_{j,i}$ gates that all control information flows, 2DLSTM employs an extra `lambda gate` $\lambda_{j,i}$. As written in Equ. 5, its activation is computed analogously to the other gates. The lambda gate is used to weight the two predecessor cells $c_{j-1,i}$ and $c_{j,i-1}$ before passing them through the forget gate (Equation 6). g and σ are the tanh and the sigmoid functions. Vs, Ws and Us are the weight matrices.

In order to train a 2DLSTM unit, back-propagation through time (BPTT) is performed over two dimensions (Graves, 2008, 2012). Thus, the gradient is passed backwards from the time step (J, I) to $(1, 1)$, the origin. More details, as well as the derivations of the gradients, can be found in (Graves, 2008).

$$i_{j,i} = \sigma\Big(W_1 x_{j,i} + U_1 l s_{j-1,i} + V_1 s_{j,i-1}\Big) \tag{1}$$

$$f_{j,i} = \sigma\Big(W_2 x_{j,i} + U_2 s_{j-1,i} + V_2 s_{j,i-1}\Big) \tag{2}$$

$$o_{j,i} = \sigma\Big(W_3 x_{j,i} + U_3 s_{j-1,i} + V_3 s_{j,i-1}\Big) \tag{3}$$

$$\tilde{c}_{j,i} = g\Big(W_4 x_{j,i} + U_4 s_{j-1,i} + V_4 s_{j,i-1}\Big) \tag{4}$$

$$\lambda_{j,i} = \sigma\Big(W_5 x_{j,i} + U_5 s_{j-1,i} + V_5 s_{j,i-1}\Big) \tag{5}$$

$$\begin{aligned} c_{j,i} = {} & f_{j,i} \circ \big[l\lambda_{j,i} \circ c_{j-1,i} + (1 - \lambda_{j,i}) \circ c_{j,i-1}\big] \\ & + \tilde{c}_{j,i} \circ i_{j,i} \end{aligned} \tag{6}$$

$$s_{j,i} = g\left(c_{j,i}\right) \circ o_{j,i} \tag{7}$$

4 Two-Dimensional Sequence to Sequence Model

We aim to apply a 2DLSTM to map the source and the target sequences into a 2D space as shown in Figure 2. We call this architecture, the two-dimensional sequence to sequence (`2D-seq2seq`) model.

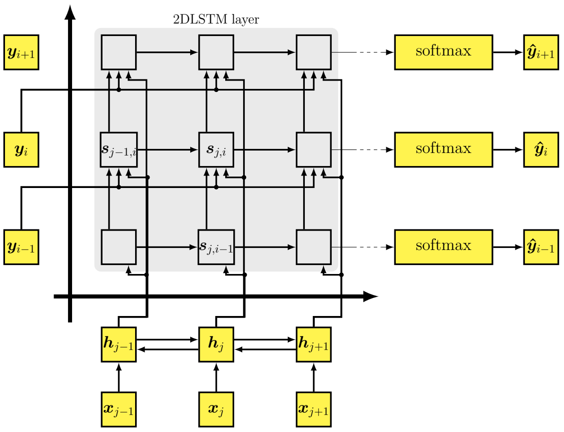

Figure 2: Two-dimensional sequence to sequence model (2D-seq2seq).

Given a source sequence $x_1^J = x_1, \ldots, x_J$ and a target sequence $y_1^I = y_1, \ldots, y_I$, we scan the source sequence from left to right and the target sequence from bottom to top as shown in Figure 2. In the 2D-seq2seq model, one dimension of the 2DLSTM (horizontal-axis in the figure) serves as the encoder and another (vertical axis) plays the role of the decoder. As a pre-step before the 2DLSTM, in order to have the whole source context, a bidirectional LSTM scans the input words once from left to right and once from right to left to compute a sequence of encoder states $h_1^J = h_1, \ldots, h_J$. At time step (j, i), the 2DLSTM receives both encoder state, h_j, and the last target embedding vector, y_{i-1}, as an input. It repeatedly updates the source information, h_1^J, while generating new target word, y_i. The state of the 2DLSTM is computed as follows.

$$s_{j,i} = \psi\Big(W\big[h_j; y_{i-1}\big], U s_{j-1,i}, V s_{j,i-1}\Big) \quad (8)$$

where ψ stands for the 2DLSTM as a function. At each decoder step, once the whole source sequence is processed from 1 to J, the last hidden state of the 2DLSTM, $s_{J,i}$, is used as the context vector. It means, at time step i, $t_i = s_{J,i}$. In order to generate the next target word, y_i, a transformation followed by a softmax operation is applied. Therefore:

$$p_i(y_i = w | y_1^{i-1}, x_1^J) = \frac{\exp(W_o t_{iw})}{\sum_{v=1}^{|V_t|} \exp(W_o t_{iv})} \quad (9)$$

where W_o and $|V_t|$ are the weight matrix and the target vocabulary respectively.

4.1 Training versus Decoding

One practical concern that should be noticed is the difference between the training and the decoding. Since the whole target sequence is known during training, all states of the 2DLSTM can be computed once at the beginning. Slices of it can then be used during the forward and backward training passes. In theory, the complexity of training is $\mathcal{O}(JI)$. But, in practice, the training computation can be optimally parallelized to take linear time (Voigtlaender et al., 2016). During the decoding, only the already generated target words are available. Thus, either all 2DLSTM states have to be recomputed, or it has to be extended by an additional row at every time step i that cause higher complexity.

5 Experiments

We have done the experiments on the WMT 2017 German→English and English→German news tasks consisting of 4.6M training samples collected from the well-known data sets `Europarl-v7`, `News-Commentary-v10` and `Common-Crawl`. We use `newstest2015` as our development set and `newstest2016` and `-2017` as our test sets, which contain 2169, 2999 and 3004 sentences respectively. No synthetic data and no additional features are used. Our goal is to keep the baseline model simple and standard to compare methods rather that advancing the state-of-the-art systems.

After tokenization and true-casing using `Moses` toolkit (Koehn et al., 2007), byte pair encoding (BPE) (Sennrich et al., 2016) is used jointly with 20k merge operations. We remove sentences longer than 50 subwords and batch them together with a batch size of 50. All models are trained from scratch by the Adam optimizer (Kingma and Ba, 2014), dropout of 30% (Srivastava et al., 2014) and the norm of the gradient is clipped with the threshold of 1. The final models are the average of the 4 best checkpoints of a single run based on the perplexity on the development set (Junczys-Dowmunt et al., 2016). Decoding is performed using beam search of size 12, without ensemble of various networks.

We have used our in-house implementation of the NMT system which relies on Theano (Bastien et al., 2012) and Blocks (Merriënboer et al., 2015). Our implementation of 2DLSTM is based on CUDA code adapted from (Voigtlaender et al., 2016; Zeyer et al., 2018), leveraging some speedup.

The models are evaluated using case-sensitive BLEU (Papineni et al., 2002) computed by `mteval-v13a`[1] and case-sensitive TER (Snover et al., 2006) using `tercom`[2]. We also report perplexities on the development set.

Attention Model: the attention based sequence to sequence model (Bahdanau et al., 2014) is selected as our baseline that performs quite well. The model consists of one layer bidirectional encoder and a unidirectional decoder with an additive attention mechanism. All words are projected into a 500-dimensional embedding on both sides. To explore the performance of the models with respect to hidden size, we try LSTMs (Hochreiter and Schmidhuber, 1997) with both 500 and 1000 nodes.

2D-Seq2Seq Model: we apply the same embedding size of that of the attention model. The 2DLSTM, as well as the bidirectional LSTM

Table 1: BLEU [%] and TER [%] on the test sets and perplexity (PPL) on the development set.

layer, are structured using the same number of nodes (500 or 1000). The 2D-seq2seq model is trained with the learning rate of 0.0005 vs. 0.001 for the attention model.

Translation Performance: in the first set of experiments, we compare the 2D-seq2seq model with the attention sequence to sequence model. The results are shown in Table 1 in the rows 1 and 2. As it is seen, for size $n = 500$, the 2D-seq2seq model outperforms the standard attention model on average by 0.7% BLEU and 0.6% TER on De→En, 0.4% BLEU and no improvements in TER on En→De. The model is also superior for larger hidden size ($n = 1000$) on average by 0.5% BLEU and 0.3% TER on De→En, 0.9% BLEU and 1.0% TER on En→De. In both cases, the perplexity of the 2D-seq2seq model is lower compared to that of the attention model.

The 2D-seq2seq topology is analogous to the bidirectional encoder-decoder model without attention. To examine whether the 2DLSTM reduces the need of attention, in the second set of experiments, we equip our model with a weighted sum of 2DLSTM states, t_i, over j positions to dynamically select the most relevant information. In other words:

$$\gamma_{j,i} = \underset{j}{softmax}\Big(v^T \tanh\big(W s_{j,i}\big)\Big) \tag{10}$$

$$t_i = \sum_{j=1}^{J} \gamma_{j,i} s_{j,i} \tag{11}$$

In these equations, $\gamma_{j,i}$ is the normalized weight over source positions, $s_{j,i}$ is the 2DLSTM states and W and v are weight matrices. As the results shown in the Table 1 in the rows 2 and 3, adding an additional weighting layer on top of the 2DLSTM layer does not help in terms of BLEU and rarely helps in TER.

By updating the encoder states across the second dimension with respect to the target history, the 2D-seq2seq model can internally indicate which source words have already been translated and where it should focus next. Therefore, it reduces the risk of over- and under-translation. To examine our assumption, we compare the 2D-seq2seq model with two NMT models where the concepts such as fertility and coverage have been addressed (Tu et al., 2016; Cohn et al., 2016).

Coverage Model: in the coverage model, we feed back the last alignments from the time step $i-1$ to compute the attention weight at time step i. Therefore, in the coverage model, we redefine the attention weight, $\alpha_{i,j}$, as:

$$\alpha_{i,j} = a\big(s_{i-1}, h_j, \alpha_{i-1,j}\big) \tag{12}$$

where a is an attention function followed by the softmax. h_j and s_{i-1} are the the encoder and the previous decoder states respectively. In our experiments, we use additive attention similar to (Bahdanau et al., 2014).

Fertility Model: in the fertility model, we feed back the sum of the alignments over the past decoder steps to indicate how much attention has been given to the source position j up to step i and divide it over the fertility of source word at position j. This term depends on the encoder states and it varies if the word is used in a different context (Tu et al., 2016).

$$\beta_{i,j} = \frac{1}{N \cdot \sigma(v_\phi^\top \cdot h_j)} \sum_{k=1}^{i-1} \alpha_{i,j} \tag{13}$$

$$\alpha_{i,j} = a\big(s_{i-1}, h_j, \beta_{i,j}\big) \tag{14}$$

where N specifies the maximum value for the fertility which set to 2 in our experiments. v_ϕ is a weight vector.

source	HP beschäftigte zum Ende des Geschäftsjahres 2013/14 noch rund 302.000 Mitarbeiter.
reference	At the end of the 2013/14 business year HP still employed around 302,000 staff.
attention	At the end of the financial year, HP employed some 302,000 employees at the end of the financial year of 2013/14.
2D-seq2seq	HP still employs about 302,000 people at the end of the financial year 2013/14.
coverage	HP employed around 302,000 employees at the end of the fiscal year 2013/14.
fertility	HP employed some 302,000 people at the end of the fiscal year 2013/14.

Table 2: An example of over-translation.

As it is seen in Table 1, rows 2, 4 and 5, our proposed model is 0.3% BLEU ahead and 0.3% TER worse compared to the fertility approach and slightly better compared to the coverage one. We note, the fertility and coverage models were trained using embedding size of 620.

We have also qualitatively verified the coverage issue in Table 2 by showing an example from the test set. Without the knowledge of which source words have already been translated, the attention layer is at risk of attending to the same positions multiple times. This could lead to over-translation. Similarly, under-translation could be occur when the attention model rarely focusing at the corresponding source positions. As shown in the example, the 2DLSTM can internally track which source positions have already contributed to the target generation.

Speed: we have also compared the models in terms of speed on a single GPU training. In general, the training and decoding speed of the 2D-seq2seq model is 791 and 0.7 words/s respectively compared to those of standard attention model which is 2944 and 48 words/s. The computation of the added weighting mechanism is negligible in this case. This is still an initial architecture which indicates the necessity of multi-GPU usage. We also expect to speedup the decoding phase by avoiding the unnecessary recomputation of previous 2DLSTM states. In the current implementation, at each target step, we re-compute the 2DLSTM states from time step 0 to $i-1$, while we only need to store the states from the last step $i-1$. This does not influence our results, as it is purely an implementation issue, not algorithm. However, decoding will still be slower than the training. One suggestion for further speedup of training phase is applying truncated BPTT on both directions to reduce the number of updates.

The 2DLSTM can be simply combined with self-attention layers (Vaswani et al., 2017) in the encoder and the decoder for better context representation as well as RNMT+ (Chen et al., 2018) that is composed of standard LSTMs. We believe that 2D-seq2seq model can be potentially applied to the other applications where sequence to sequence modeling is helpful.

6 Conclusion and Future Works

We have introduced a novel 2D sequence to sequence model (2D-seq2seq), a network that applies a 2DLSTM unit to read both the source and the target sentences jointly. Hence, in each decoding step, the network implicitly updates the source representation conditioned on the generated target words so far. The experimental results show that we outperform the attention model on two WMT 2017 translation tasks. We have also shown that our model implicitly handles the coverage issue.

As future work, we aim to develop a bidirectional 2DLSTM and consider stacking up 2DLSTMs for a deeper model. We consider the results promising and try more language pairs and fine-tune the hyperparameters.

Abstract

Autoregressive decoding is the only part of sequence-to-sequence models that prevents them from massive parallelization at inference time. Non-autoregressive models enable the decoder to generate all output symbols independently in parallel. We present a novel non-autoregressive architecture based on connectionist temporal classification and evaluate it on the task of neural machine translation. Unlike other non-autoregressive methods which operate in several steps, our model can be trained end-to-end. We conduct experiments on the WMT English-Romanian and English-German datasets. Our models achieve a significant speedup over the autoregressive models, keeping the translation quality comparable to other non-autoregressive models.

1 Introduction

Parallelization is the key ingredient for making deep learning models computationally tractable. While the advantages of parallelization are exploited on many levels during training and inference, autoregressive decoders require sequential execution.

Training and inference algorithms in sequence-to-sequence tasks with recurrent neural networks (RNNs) such as neural machine translation (NMT) have linear time complexity w.r.t. the target sequence length, even when parallelized (Sutskever et al., 2014; Bahdanau et al., 2014).

Recent approaches such as convolutional sequence-to-sequence learning (Gehring et al., 2017) or self-attentive networks a.k.a. the Transformer (Vaswani et al., 2017) replace RNNs with parallelizable components in order to reduce the time complexity of the training. In these models, the decoding is still sequential, because the probability of emitting a symbol is conditioned on the previously decoded symbols.

In non-autoregressive decoders, the inference algorithm can be parallelized because the decoder does not depend on its previous outputs. The apparent advantage of this approach is the near-constant time complexity achieved by the parallelization. On the other hand, the drawback is that the model needs to explicitly determine the target sentence length and reorder the state sequence before it starts generating the output. In the current research contributions on this topic, these parts are trained separately and the inference is done in several steps.

In this paper, we propose an end-to-end non-autoregressive model for NMT using Connectionist Temporal Classification (CTC; Graves et al. 2006). The proposed technique achieves promising results on translation between English-Romanian and English-German on the WMT News task datasets.

The paper is organized as follows. In Section 2, we summarize the related work on non-autoregressive NMT. Section 3 describes the architecture of our proposed model. Section 4 presents details of the conducted experiments. The results are discussed in Section 5. We conclude and present ideas for future work in Section 6.

2 Non-Autoregressive NMT

In this section, we describe two methods for non-autoregressive decoding in NMT. Both of them are based on the Transformer architecture (Vaswani et al., 2017), with the encoder part unchanged.

Gu et al. (2017) use a latent fertility model to copy the sequence of source embeddings which is then used for the target sentence generation. The fertility (i.e. the number of target words for each source word) is estimated using a softmax on the encoder states. In the decoder, the input embeddings are repeated based on their fertility.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3016–3021
Brussels, Belgium, October 31 - November 4, 2018.

The decoder has the same architecture as the encoder plus the encoder attention. The best results were achieved by sampling fertilities from the model and then rescoring the output sentences using an autoregressive model. The reported inference speed of this method is 2–15 times faster than of a comparable autoregressive model, depending on the number of fertility samples.

Lee et al. (2018) propose an architecture with two decoders. The first decoder generates a candidate translation from a source sentence padded to an estimated target length. The explicit length estimate is done with a softmax over possible sentence lengths (up to a fixed maximum). The output of the first decoder is then fed as an input to the second decoder. The second decoder is used as a denoising auto-encoder and can be applied iteratively. Both decoders have the same architecture as in Gu et al. (2017). They achieved a speedup of 16 times over the autoregressive model with a single denoising iteration. They report the best result in terms of BLEU (Papineni et al., 2002) after 20 iterations with almost no inference speedup compared to their autoregressive baseline.

3 Proposed Architecture

Similar to the previous work (Gu et al., 2017; Lee et al., 2018), our models are based on the Transformer architecture as described by Vaswani et al. (2017), keeping the encoder part unchanged. Figure 1 illustrates our method and highlights the differences from the Transformer model.

In order to generate output words in parallel, we formulate the translation as a sequence labeling problem. Neural architectures used for encoding input in NLP tasks usually generate sequences of hidden states of the same or shorter length as the input sequence. For this reason, we cannot apply the sequence labeling directly over the states because the target sentence might be longer than the source sentence.

To enable the labeler to generate sentences that are longer than the source sentence, we project the encoder output states $\mathbf{h}$ into a k-times longer sequence $\mathbf{s}$, such that:

$$s_{ci+b} = \left(W_{\text{spl}} h_c + b_{\text{spl}}\right)_{bd:(b+1)d} \qquad (1)$$

for $b = 0 \dots k-1$, and $c = 0 \dots T_x$ where d is the Transformer model dimension, T_x is the length of the source sentence, and $W_{\text{spl}} \in \mathbb{R}^{d \times kd}$ and $b_{\text{spl}} \in \mathbb{R}^{kd}$ are trainable projection parameters. In other words, after a linear projection, each state is sliced to k vectors, creating a sequence of length kT_x.

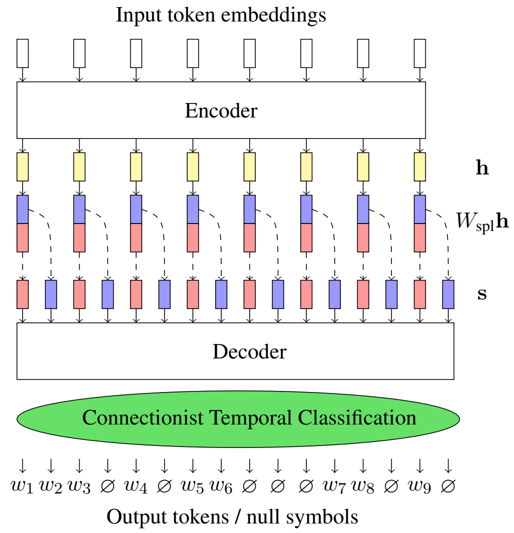

Figure 1: Scheme of the proposed architecture. The part between the encoder and the decoder is expressed by Equation 1.

In the next step, we process the sequence $\mathbf{s}$ with a decoder. Unlike the Transformer architecture, our decoder does not use the temporal mask in the self-attention step.

Finally, the decoder states are labeled either with an output token or a null symbol. The number of combinations of the possible positions of the null symbols in the output sequence given reference sequence length T_y is $\binom{kT_x}{T_y}$. Because there is no prior alignment between the input and output symbols, we consider all output sequences that yield the correct output in the loss function. Because summing the exponential number of combinations directly is not tractable, we we use the CTC loss (Graves et al., 2006) which employs dynamic programming to compute the negative log-likelihood of the output sequence, summed over all the combinations.

The loss can be computed using a linear algorithm similar to training Hidden Markov Models (Rabiner, 1989). The algorithm computes and stores partial log-probabilities sums for all prefixes and suffixes of the output symbol sequence using dynamic programming. The table of precomputed log-probablities allows us to compute the probability of being a part of a correct output sequence by combining the log-probabilities of its prefix and suffix.

An appealing property of training using the

CTC loss is that the models support left-to-right beam search decoding by recombining prefixes that yield the same output. Unlike the greedy decoding this can no longer be done in parallel. However, the linear computation is in theory still faster than autoregressive decoding.

4 Experiments

We experiment with three variants of this architecture. All of them have the same total number of layers. First, the *deep encoder* uses a stack of self-attentive layers only. We apply the state splitting and the labeler on the output of the last encoder layer. In contrast to Figure 1, this variant omits the decoder part. Second, the *encoder-decoder* consists of two stacks of self-attentive layers – encoder and decoder. The outputs of the encoder are transformed using Equation 1 and processed by the decoder. In each layer, the decoder part attends to the encoder output. Third, we extend the encoder-decoder variant with positional encoding (Vaswani et al., 2017). The positional encoding vectors are added to the decoder input $\mathbf{s}$.

In all the experiments, we used the same hyperparameters. We set the model dimension to 512 and the feed-forward layer dimension to 4096. We use multi-head attention with 16 heads. In the deep encoder setup, we use 12 layers in the encoder, in the encoder-decoder setup, we use 6 layers for the encoder and 6 layers for the decoder. We set the split factor k to 3, so the encoder states are projected to vectors of 1536 units.

We conduct our experiments on English-Romanian and English-German translation. These language pairs were selected by the authors of the previous work because the training datasets for these language pairs are of considerably different sizes. We follow these choices in order to present comparable results.

For English-Romanian experiments, we used the WMT16 (Bojar et al., 2016) news dataset. The training data consists of 613k sentence pairs, validation 2k and test 2k. We used a shared vocabulary of 38k wordpieces (Wu et al., 2016; Johnson et al., 2017).

The English-German dataset consists of 4.6M training sentence pairs from WMT competitions. As a validation set, we used the test set from WMT13 (Bojar et al., 2013), which contains 3k sentence pairs. To enable comparison to other non-autoregressive approaches, we evaluate our models on the test sets from WMT14 (Bojar et al., 2014) with 3k sentence pairs and WMT15 (Bojar et al., 2015) with 2.1k sentence pairs. As in the previous case, we used shared vocabulary for both languages which contained 41k wordpieces.

The experiments were conducted using Neural Monkey[1] (Helcl and Libovický, 2017). We evaluate the models using BLEU score (Papineni et al., 2002) as implemented in SacreBLEU,[2] originally a part of the Sockeye toolkit (Hieber et al., 2017).

5 Results

Quantitative results are tabulated in Table 1. In general, our models achieve a similar performance to other non-autoregressive models. In case of English-German, our results in both directions are comparable on the WMT 14 test set and slightly better on the WMT 15 test set. This might be given by the fact that our autoregressive baseline performs better for this language pair than for English-Romanian.

The encoder-decoder setup outperforms the deep encoder setup. Including positional encoding seems beneficial when translating into German. Weight averaging from the 5 models with the highest validation score during the training improves the performance consistently.

We performed a manual evaluation on 100 randomly sampled sentences from the English-German test sets in both directions. The results of the analysis are summarized in Table 2.

Non-autoregressive translations of sentences that had errors in the autoregressive translation were often incomprehensible. In general, less than a quarter of the sentences was completely correct and over two thirds (one half in the de→en direction) were comprehensible. The most frequent errors include omitting verbs at the end of German sentences and corruption of named entities and infrequent words that are represented by more wordpieces. Most of these errors can be attributed to insufficient language-modeling capabilities of the model. The results suggest that integrating an external language model into an efficient beam search implementation could boost the translation quality while preserving the speedup over the auto-regressive models.

We also evaluated the translations using sentence-level BLEU score (Chen and Cherry,

2014) and measure the Pearson correlation with the length of the source sentence and the number of null symbols generated in the output. With a growing sentence length, the scores degrade more in the non-autoregressive model ($r = -0.42$) than in its autoregressive counterpart ($r = -0.39$). The relation between sentence-level BLEU and the source length is plotted in Figure 2. The sentence-level score is mildly correlated with the number of null symbols in the non-autoregressive output ($r = 0.15$). This suggests that increasing the splitting factor k in Equation 1 might improve the model performance. However, it also reduces the efficiency in terms of GPU memory usage.

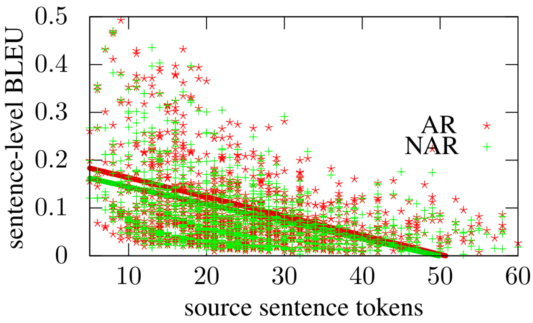

Figure 2: Comparison of the sentence-level BLEU of our English-to-German autoregresssive (AR) and non-autoregressive (NAR) models given the length of the source sentence.

Figure 3 shows the comparison of the decoding time by autoregressive and non-autoregressive models. The average times of decoding a single sentence are shown in Table 3. We suspect that the small difference between CPU and GPU times in the non-autoregressive setup is caused by the CPU-only implementation of the CTC decoder in TensorFlow (Abadi et al., 2015).

6 Conclusions

In this work, we presented a novel method for training a non-autoregressive model end-to-end using connectionist temporal classification. We evaluated the proposed method on neural machine

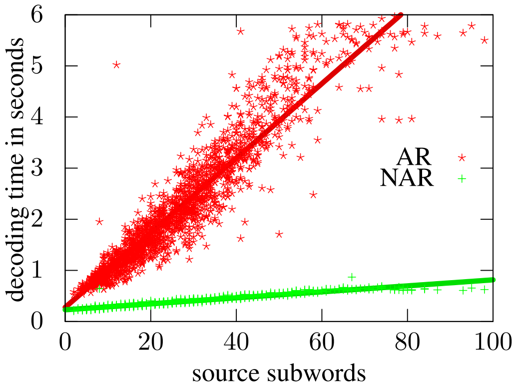

Figure 3: Comparison of CPU decoding time by our autoregressive (AR) and non-autoregressive (NAR) models based on the source sentence length.

Table 3: Average per sentence decoding time for en-de translation.

translation in two language pairs and compared the results to the previous work.

In general, the results match the translation quality of equivalent variants of the models presented in the previous work. The BLEU score is usually around 80–90% of the score of the autoregressive baselines. We measured a 4-times speedup compared to our autoregressive baseline, which is a smaller gain than reported by the authors of the previous work. We suspect this might be due to a larger overhead with data loading and processing in Neural Monkey compared to Tensor2Tensor (Vaswani et al., 2018) used by others.

As a future work, we can try to improve the performance of the model by iterative denoising as done by Lee et al. (2018) while keeping the non-autoregressive nature of the decoder.

Another direction of improving the model might be efficient implementation of beam search which can contain rescoring using an external language model as often done in speech recognition (Graves et al., 2013). The non-autoregressive model would play a role a of the translation model in the traditional statistical MT problem decomposition.

Prediction Improves Simultaneous Neural Machine Translation

Abstract

Simultaneous speech translation aims to maintain translation quality while minimizing the delay between reading input and incrementally producing the output. We propose a new general-purpose prediction action which predicts future words in the input to improve quality and minimize delay in simultaneous translation. We train this agent using reinforcement learning with a novel reward function. Our agent with prediction has better translation quality and less delay compared to an agent-based simultaneous translation system without prediction.

1 Introduction

One of the next significant challenges in machine translation research is to make translation ubiquitous using real-time translation. Simultaneous machine translation aims to address this issue by interleaving reading the input with writing the output translation. Current Simultaneous Neural Machine Translation (SNMT) systems (Satija and Pineau, 2016; Cho and Esipova, 2016; Gu et al., 2017) use an AGENT to control an incremental encoder-decoder (or sequence to sequence) NMT model. Each READ adds more information to the encoder RNN, and each WRITE produces more output using the decoder RNN. In this paper, we propose adding a new action to the AGENT: a PREDICT action that predicts what words might appear in the input stream. Prediction was previously proposed in simultaneous statistical machine translation (Grissom II et al., 2014) but has not been studied in the context of Neural Machine Translation (NMT). In SNMT systems, prediction of future words augments the encoder-decoder model with possible future contexts to produce output translations earlier (minimize delay) and/or produce better output translations (improve translation quality). Our experiments show that prediction improves SNMT in both these measures.

2 Simultaneous Translation Framework

An agent-based framework whose actions decide whether to translate or wait for more input is a natural way to extend neural MT to simultaneous neural MT and has been explored in (Satija and Pineau, 2016; Gu et al., 2017) which contains two main components: The ENVIRONMENT which receives the input words $X = \{x_1, \dots, x_N\}$ from the source language and incrementally generates translated words $W = \{w_1, \dots, w_M\}$ in the target language; And the AGENT which decides an action for each time step, a_t. The AGENT generates an action sequence $A = \{a_1, \dots, a_T\}$ to control the ENVIRONMENT.

Previous models only include two actions: READ and WRITE. We extend the model by adding the third action called PREDICT. Action READ is simply sending a new word to the ENVIRONMENT and generating a candidate word in the target language. In action WRITE, the AGENT takes current candidate word and sends it to the output. For PREDICT, the AGENT predicts the next word in the input and treats it like a READ action. The following section explains how the ENVIRONMENT deals with different actions.

2.1 ENVIRONMENT

The ENVIRONMENT is an attention-based Encoder-Decoder MT system (Bahdanau et al., 2014) which is adopted to simultaneous translation task. The Encoder receives the embedded representation of the input words (including predicted ones) and converts them into context vectors $H_n^\rho = \{h_1, \dots, h_{n+\rho}\}$ using a gated RNN (GRU) where n is the number of input words so far and ρ is the number of predicted words since the last READ. Whenever the AGENT decides to READ, ρ will be set to 0, and $h_n = f_{\text{ENC}}(h_{n-1}, x_n)$, where x_n is the next input words ($n \le N$). But if the action is PREDICT, $\rho > 0$, the AGENT predicts a new word x'_ρ and the

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3022–3027
Brussels, Belgium, October 31 - November 4, 2018.

context vector $h_{n+\rho} = f_{\text{ENC}}(h_{n+\rho-1}, x'_\rho)$ will be added to $H_n^\rho = \{h_1, \ldots, h_{n+\rho}\}$.

At each time step t, the decoder uses the current context vectors (H_n^ρ) to generate the next candidate output (y_t):

$$\begin{aligned} c_t &= a_{\text{ATT}}(z_{m-1}, H_n^\rho) \\ s_t &= f_{\text{DEC}}(z_{m-1}, w_{m-1}, c_t) \\ p(y_t|y_{<t}, H_n^\rho) &= g(w_{m-1}, z_m, c_t) \\ y_t &= \arg\max_y p(y|y_{<t}, H_n^\rho) \end{aligned}$$

where w_{m-1} is the previous output word, and a_{ATT} is an attention model (Bahdanau et al., 2014), f and g are nonlinear functions, and c_t is the current context vector.

If the action a_t is either READ or PREDICT the current candidate y_t will be ignored (wait for better predictions). But in the case of WRITE, the candidate y_t is produced as the next output word w_m and then the decoder state will be updated ($w_m \leftarrow y_t$, $z_m \leftarrow s_t$).

Note that as soon as the AGENT decides to READ, all the hidden vectors generated by PREDICT actions will be discarded ($H_n^\rho = H_n^0 = \{h_1, \ldots, h_n\}$).

Figure 1 shows an example of how a sentence can be translated using our modified translation framework [1].

2.2 AGENT

The AGENT is a separate component which examines the ENVIRONMENT at each time step and decides on the actions that lead to better translation quality and lower delay. The agent in the *greedy decoding* framework (Gu et al., 2017) was trained using reinforcement learning with the policy gradient algorithm (Williams, 1992), which observes the current state of the ENVIRONMENT at time step t as o_t where $o_t = [c_t;\ s_t;\ w_m]$. A RNN with one hidden layer passed through a softmax function generates the probability distribution over the actions a_t at each step. Therefore, policy π_θ will be computed as:

$$\begin{aligned} u_t &= f_\theta(u_{t-1}, o_t) \\ \pi_\theta(a_t|a < t, o \leq t) &\propto g_\theta(u_t) \end{aligned}$$

Where u_t is the hidden state of the AGENT's RNN.

3 Training the AGENT with Prediction

In order to speed-up the training process, we have restricted AGENT's options by removing redundant operations. As illustrated in Figure 2, after a series of WRITE, the AGENT cannot choose to PREDICT, and after a sequence of PREDICTs, READ is not an option.

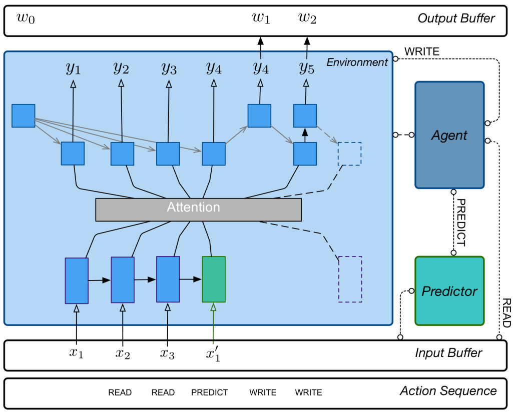

Figure 1: A schematic of our model. The ENVIRONMENT starts with reading the 'Start of Sentence' symbol as x_1 and generating y_1 from the decoder. Based on the output of the network at each time step, the AGENT decides whether to READ, WRITE or PREDICT for the following time steps.

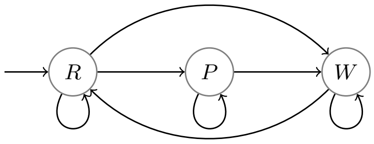

Figure 2: Action transition graph. R, P, and W stands for READ, PREDICT and WRITE actions respectively.

Reward Function: The total reward at any time step is calculated as the cumulative sum of rewards for actions at each preceding step. All the evaluation metrics have been modified to be computed for every time step.

Quality: We use a modified smoothed version of BLEU score (Chen and Cherry, 2014) multiplied by Brevity Penalty (Lin and Och, 2004) for evaluating the impact of each action on translation quality. At each point in time, the reward for translation quality is:

$$r_t^Q = \begin{cases} \Delta\text{BLEU}(t) & t < T \\ \text{BLEU}(W, W^*) & t = T \end{cases}$$

The $\Delta\text{BLEU}(t)$ is the difference between BLEU score of the translated sentence at the previous time step and the current time step; $\Delta\text{BLEU}(t) = \text{BLEU}(W^t, W^*) - \text{BLEU}(W^{t-1}, W^*)$; where W^t is the prefix of the translated sentence at time t.

Delay: The Delay reward is used to motivate the AGENT to minimize delay. We use Average Proportion (AP) (Cho and Esipova, 2016) for this purpose, which is the average number of source words

---

[1] The pseudo-code is available in supplementary material (Algorithm 1).

needed when translating each word. Given the source words X and translated words W, AP can be computed as:

$$d(X, W) = \frac{1}{|X||W|} \sum_t s(t)$$

$$r_t^D = \begin{cases} 0 & t < T \\ d(X, W) & t = T \end{cases}$$

Where $s(t)$ denotes the number of source words the WRITE action uses at time step t (for any other actions, $s(t)$ would be zero). The delay reward is smoothed using a *Target Delay* which is a scalar constant denoted by d^* (Gu et al., 2017):

$$r_t^D = \lfloor d_t - d^* \rfloor$$

Prediction Rewards for Quality and Delay alone do not motivate the AGENT to choose prediction and in preliminary experiments, after a number of steps, the number of prediction actions became zero. We address this problem by defining Prediction Quality (PQ) which rewards the AGENT for changes in BLEU score after each prediction action. By initializing $r_0^p = 0$, the prediction reward can be written as:

$$r_t^p = \begin{cases} \Delta\text{BLEU}(t) & a_t = \text{W}, a_{t-1} = \text{P} \\ r_{t-1}^p & a_t = \text{W}, a_{t-1} \neq \text{P} \\ 0 & \text{otherwise} \end{cases}$$

Final Reward The final reward function is calculated as the combination of quality, delay, and prediction rewards:

$$r_t = \alpha\, r_t^Q + \beta\, r_t^D + \lambda\, r_t^p \qquad (1)$$

The trade-off between better translation quality and minimal delay is achieved by modifying the parameters α, β, and λ.

Reinforcement Learning is used to train the AGENT using a policy gradient algorithm (Gu et al., 2017; Williams, 1992) which searches for the maximum in $J(\theta) = \mathbb{E}_{\pi_\theta}\left[\sum_{t=1}^{T} r_t\right]$ using the gradient: $\nabla_\theta J(\theta) = \mathbb{E}_{\pi_\theta}\left[\nabla_\theta \log \pi_\theta(a|s) Q^{\pi_\theta}(s, a)\right]$ where $Q = \sum_{t=1}^{T} r_t$. The gradient for a sentence is the cumulative sum of gradients at each time step. We pre-train the ENVIRONMENT on full sentences using log-loss $\log p(\mathbf{y}|\mathbf{x})$.

4 Experiments

We train and evaluate our model on English-German (EN-DE) in both directions. We use WMT 2015 for training and Newstest 2013 for validation and testing. All sentences have been tokenized and the words are segmented using byte pair encoding (BPE) (Sennrich et al., 2016).

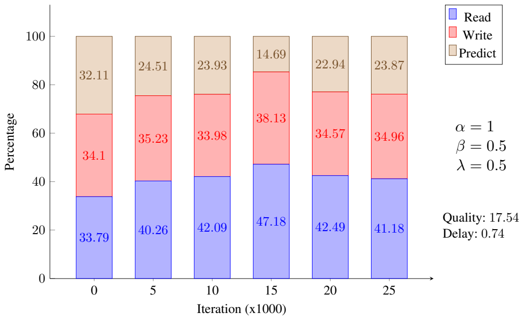

Figure 3: Action distribution for English to German translation in the first 25000 iterations. The numbers in each bar are the average action percentage over the previous 5000 iterations.

Model Configuration For a fair comparison, we follow the settings that worked the best for the greedy decoding model in (Gu et al., 2017) and set the target delay d^* for the AGENT to 0.7. The ENVIRONMENT consists of two unidirectional layers with 1028 GRU units for encoder and decoder. We train the network using AdaDelta optimizer, a batch of size 32 and a fixed learning rate of 0.0001 without decay. We use softmax policy via recurrent networks with 512 GRU units and a softmax function for the AGENT and train it using Adam optimizer (Kingma and Ba, 2014). The batch size for the AGENT is 10, and the learning rate is 2e-6. The word predictor is a two layer RNN Language model which consists of two layers of 1024 units, followed by a softmax layer. The batch size is 64 with a learning rate of 2e-5. The predictor has been trained on the WMT'16 dataset and tested on Newstest'16 corpora for both languages. The perplexity of our language model is reported in Table 1. We set $\alpha = 1$, $\beta = 0.5$ and $\lambda = 0.5$. We tried different settings for these hyperparameters during training and picked values that gave us the best Quality and Delay on the training data.

Results and Analysis Figure 4 shows that as the sentence length increases, prediction helps translation quality due to complex reordering and multiclausal sentences; However, for shorter samples where the structure of the sentences are simpler, the prediction action cannot improve translation quality. Table 2 compares our model with the Greedy Decoding (GD) model in terms of translation quality and latency. It shows that the prediction mechanism outperforms the GD model in terms of BLEU and average proportion (AP).

The delay evaluation measure (AP) counts about the same number of READs and WRITEs. It

Figure 4: Comparing translation quality between prediction model and greedy decoding method for various sentence lengths.

	Perplexity	
	Test	Train
English	17.5917	8.1350
German	19.8532	11.1808

Table 1: Performance of our predictor for both English and German languages.

	EN→DE			DE→EN		
	BLEU	AP	μ	BLEU	AP	μ
GD	16.75	0.79	5.6	21.43	0.77	6
PM	**17.54**	**0.74**	**4.7**	**21.83**	**0.70**	**5.2**

Table 2: Comparison of translation quality (BLEU), Average Proportion (AP), and average segment length (μ) for Greedy Decoding (GD) model with Prediction Mechanism (PM) model.

does not account for less delay as longer sentences are produced. A better measure than AP might be needed to emphasize delay differences. Therefore we also report the average segment length (μ), which is computed as the average number of consecutive READs in each sentence. In both EN→DE and DE→EN experiments, our model constantly decreases the segment length by around 1 word which results in less latency.

In order to evaluate the effectiveness of our proposed reward function for PREDICT action, we have explored various values for its hyper-parameters (α, β, and λ). Our empirical results show that the best trade-off between quality and delay is achieved when around 20 percent of the actions are PREDICT for both EN→DE and DE→EN translation tasks (Figure 3). When there is no reward for PREDICT action ($\lambda = 0$), the AGENT prefers other actions, and the number of PREDICT actions turns into zero immediately after training the AGENT. If the reward for prediction is valued too highly, the ENVIRONMENT depends more on predicted words and the translation quality decreases[2].

5 Related work

Early work in SNMT was done in speech, where the incoming signals were segmented based on acoustic or statistical cues (Bangalore et al., 2012; Fügen et al., 2007). (Sridhar et al., 2013; Matusov et al., 2007; Yarmohammadi et al., 2013; Siahbani et al., 2014) use a separate segmentation step and incrementally translate each segment using a standard phrase-based MT system. (Matsubara et al., 2000) applied pattern matching to predict target-side verbs in Japanese to English translation. (Grissom II et al., 2014) used reinforcement learning to predict the next word and the sentence-final verb in a statistical MT model. These models reduce the delay but are not trained end-to-end like our agent-based SNMT system. (Cho and Esipova, 2016) proposed a non-trainable heuristic agent which is not able to trade-off quality with delay. It always prefers to read more words from the input and this approach does not work well in practice. (Satija and Pineau, 2016) introduced a trainable agent which they trained using Deep Q networks (Mnih et al., 2015). We modified the SNMT trainable agent in (Gu et al., 2017) and added a new non-trivial PREDICT action to the agent. We compare to their model and show better results in delay and quality.

6 Conclusion

We introduce a new prediction action in a trainable agent for simultaneous neural machine translation. With prediction, the agent can be informed about future time steps in the input stream. Compared to a very strong baseline our results show that prediction can lower delay and improve the

---

Abstract

While current state-of-the-art NMT models, such as RNN seq2seq and Transformers, possess a large number of parameters, they are still shallow in comparison to convolutional models used for both text and vision applications. In this work we attempt to train significantly (2-3x) deeper Transformer and Bi-RNN encoders for machine translation. We propose a simple modification to the attention mechanism that eases the optimization of deeper models, and results in consistent gains of 0.7-1.1 BLEU on the benchmark WMT'14 English-German and WMT'15 Czech-English tasks for both architectures.

1 Introduction

The past few years have seen significant advances in the quality of machine translation systems, owing to the advent of neural sequence to sequence models. While current state of the art models come in different flavours, including Transformers (Vaswani et al., 2017), convolutional seq2seq models (Gehring et al., 2017) and LSTMs (Chen et al., 2018), all of these models follow the seq2seq with attention (Bahdanau et al., 2015) paradigm.

While revolutionary new architectures have contributed significantly to these quality improvements, the importance of larger model capacities cannot be downplayed. The first major improvement in NMT quality since the switch to neural models, amongst other factors, was brought about by a huge scale up in model capacity (Zhou et al., 2016; Wu et al., 2016). While there are multiple approaches to increase capacity, deeper models have been shown to extract more expressive features (Mhaskar et al., 2016; Telgarsky, 2016; Eldan and Shamir, 2015), and have resulted in significant gains for vision tasks over the past few years (He et al., 2015; Srivastava et al., 2015).

Despite this being an obvious avenue for improvement, research in deeper models is often restricted by computational constraints. Additionally, deep models are often plagued by trainability concerns like vanishing or exploding gradients (Bengio et al., 1994). These issues have been studied in the context of capturing long range dependencies in recurrent architectures (Pascanu et al., 2012; Hochreiter et al., 2001), but resolving these deficiencies in Transformers or LSTM seq2seq models deeper than 8 layers is unfortunately under-explored (Wang et al., 2017; Barone et al., 2017; Devlin, 2017).

In this study we take the first step towards training extremely deep models for translation, by training deep encoders for Transformer and LSTM based models. As we increase the encoder depth the vanilla Transformer models completely fail to train. We also observe sub-optimal performance for LSTM models, which we believe is associated with trainability issues. To ease optimization we propose an enhancement to the attention mechanism, which allows us to train deeper models and results in consistent gains on the WMT'14 En→De and WMT'15 Cs→En tasks.

2 Transparent Attention

While the effect of attention on the forward pass is exalted with visualizations and linguistic interpretations, its influence on the gradient flow is often forgotten. Consider the original seq2seq model *without* attention (Sutskever et al., 2014). To propagate the error signal from the last layer of the decoder to the first layer of the encoder, it has to pass through multiple time-steps in the decoder, survive the encoder-decoder bottleneck, and pass through multiple time-steps in the encoder, before reaching the parameter to be updated. There is some loss of information at every step, especially in

the early stages of training. Attention (Bahdanau et al., 2015) creates a direct path from the decoder to the topmost layer of the encoder, ensuring its efficient dispersal over time. This increase in inter-connectivity significantly shortens the credit-assignment path (Britz et al., 2017), making the network less susceptible to optimization pathologies like vanishing gradients.

For deeper networks the error signal also needs to traverse along the depth of the encoder. We propose an extension to the attention mechanism that behaves akin to creating weighted residual connections along the encoder depth, allowing the dispersal of error signal simultaneously over encoder depth and time. Using trainable weights, this 'transparent' attention allows the model the flexibility to adjust the gradient flow to different layers in the encoder depending on its training phase.

2.1 Experimental Setup

We train our models on the standard WMT'14 En→De dataset. Each sentence is tokenized with the Moses tokenizer before breaking into subword units similar to (Sennrich et al., 2016). We use a shared vocabulary of 32k units for each language pair. We report all our results on newstest 2014, and use a combination of newstest 2012 and newstest 2013 for validation. To verify our results, we also evaluate our models on WMT'15 Cs→En. Here we use newstest 2013 for validation and newstest 2015 as the test set. To evaluate the models we compute BLEU on the tokenized, true-case output. We report the mean post-convergence score over a window of 21 checkpoints, obtained using dev performance, following (Chen et al., 2018).

2.2 Baseline Experiments

We base our study on two architectures: Transformer (Vaswani et al., 2017) and RNMT+ (Chen et al., 2018). We choose a smaller version of each model to fit deep encoders with up to 20 layers on a single GPU. All our models are trained on eight P100 GPUs with synchronous training, and optimized using Adam (Kingma and Ba, 2014). For both architectures we train four models, with 6, 12, 16 and 20 encoder layers. We use 6 and 8 decoder layers for all our transformers and RNMT+ experiments respectively. We also report performance for the standard Transformer Big and RNMT+ setups, as described in (Chen et al., 2018), for comparison against higher capacity models.

Transformer: We use the latest version of the Transformer base model, using the implementation from (Chen et al., 2018). We modify the learning rate schedule to use a learning rate of 3.0 and $40,000$ warmup steps.

RNMT+: We implemented a smaller version of the En→De RNMT+ model based on the description in (Chen et al., 2018), with 512 LSTM nodes in both encoder and decoder.

2.3 Analysis

From Tables 1 and 2, we notice that the deeper Transformer encoders completely fail to train. To understand what goes wrong we keep track of the grad norm ratio $r_t = \left(\|\nabla_{h_1} L^{(t)}\| \big/ \|\nabla_{h_N} L^{(t)}\|\right), t = 1 \ldots T$, where $L^{(t)}$ is the loss at time step t, N is the number of layers in the encoder, h_1 is the output of the first encoder layer, h_N is the output of the N-th encoder layer, and T is the total number of train-

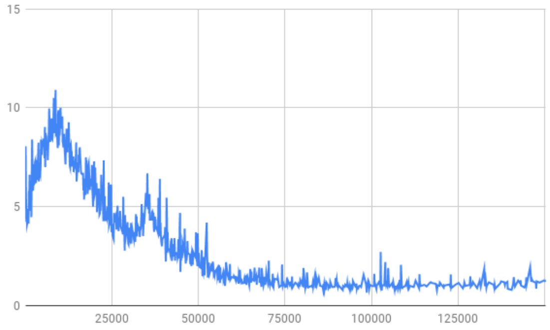

Figure 3: Grad-norm ratio (r_t) vs training step for 20 layer Transformer with transparent attention.

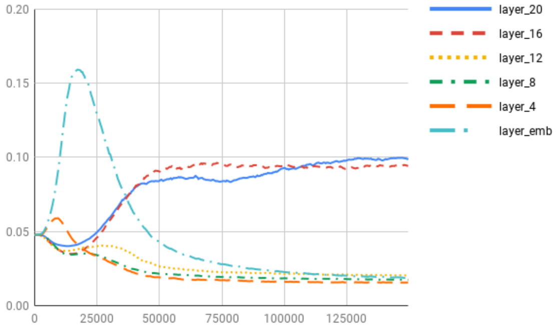

Figure 4: Plot illustrating the variations in the learned attention weights $s_{i,6}$ for the 20 layer Transformer encoder over the training process.

ing steps. We use r_t as a diagnostic measure for two reasons: First, it indicates if training is suffering from exploding or vanishing gradients. Second, when a network is properly trained the lowest layers usually converge quickly, whereas the topmost layers take longer (Raghu et al., 2017). We therefore expect that, for a healthy training process, r_t is relatively large during the early stages of training when updates to lower layers are larger than upper layers. We observe this in most successful Transformer and RNMT+ training runs.

Figure 1 illustrates the r_t curves for the 6-layer and 20-layer Transformers. As expected, the shallow model has a high r_t value during early stages of training. For the deep model, however, r_t remains flat at a much smaller value throughout training. We also observe that r_t remains below 1.0 for both models, although the problem seems much less severe for the shallow model.

From Tables 3 and 4, we also observe that the performance of deep RNMT+ encoders is not significantly impacted, reaching the level of the 6 layer model. This is supported by the RNMT+ r_t curves in Figure 2, which indicate few differences in the learning dynamics of the shallow and deep models. This contrasts with the Transformer experiments, where increasing the depth leads to an unstable training process.

To gain further insights into the stability of the two architectures we completely remove the residual connections from their encoders. Residual connections have been shown, in theory and practice, to improve training stability and performance of deeper networks (see (He et al., 2015; Philipp et al., 2017; Hardt and Ma, 2017; Orhan, 2017)). Removing residual connections leads to disastrous results for the Transformer, where the training process either does not converge or results in significantly worse results. On the other hand, the 6 layer RNMT+ converges with only a slight degradation in quality. Deeper versions of RNMT+ fail to train in the absence of residual connections.

2.4 Regulating Deep Encoder Gradients with Transparent Attention

Our baseline experiments reveal that mechanisms to regulate gradient flow can be critical to improving the optimization of deeper encoders. Since the only difference between our shallow and deep models is the number of layers in the encoder, the trainability issues are likely to be associated with gradient flow through the encoder.

To improve gradient flow we let the decoder attend weighted combinations of all encoder layer outputs, instead of just the top encoder layer. Similar approaches have been found to be useful in deep convolutional networks, for example (Shen and Zeng, 2016; Huang et al., 2016a; Srivastava et al., 2015; Huang et al., 2016b), but this remains un-investigated in sequence-to-sequence models. We formulate our proposal below.

Assume the model has N encoder layers and M encoder-decoder attention modules. For Transformer models each decoder layer attends the encoder, so M is equivalent to the number of decoder layers ($M = 6$). For RNMT+, attention is only applied in the first decoder layer, thus $M = 1$. Let the activations from the i-th encoder layer be $\{h_t^i | t = 1 \dots T\}$, and embeddings be layer 0. Then the traditional attention module attends to $\{h_t^N | \quad t = 1 \dots T\}$. In transparent attention we evaluate M weighted combinations of the encoder outputs, one corresponding to each attention mod-

Table 2: BLEU scores Cs→En newstest 2015 with Transformers. * indicates that a model failed to train.

ule. We define a $(N+1) \times M$ weight vector W, which is learned during training.[1] We apply dropout to W since we empirically found it helpful to stabilize training. We then compute softmax s to normalize the weights.

$$s_{i,j} = \frac{e^{W_{i,j}}}{\Sigma_{k=0}^{N} e^{W_{k,j}}}, \quad j = 1 \dots M \tag{1}$$

We now define

$$z_t^j = \Sigma_{i=1}^{N+1} s_{i,j} h_t^i, \quad t = 1 \dots T, \quad j = 1 \dots M \tag{2}$$

Now attention module j attends to $\{z_t^j | \quad t = 1 \dots T\}$. Since in RNMT+ a projection is applied to the encoder final layer output, we apply a projection to the weighted combination of encoder outputs before the attention module.

3 Results and Analysis

Our results, from tables 1 and 2, indicate that adding transparent attention improves the performance of most of our transformer experiments, but the gains are most pronounced for deeper models. While the baseline transformer fails to train with 12 layers or deeper encoders, transparent attention allows us to train encoders with up to 20 layers, improving by more than 0.7 BLEU points on both datasets. Relative to Transformer Big, deeper models seem to result in better or comparable performance with less than half the model capacity.

We also observe gains of 0.7 and 1.0 BLEU for RNMT+ models, on En→De and Cs→En respectively, as indicated by Tables 3 and 4. However, experiments comparing wide models against deeper ones are inconclusive. While deeper models perform slightly better than a wide model with double their capacity on Cs-En, they are clearly out-performed by the larger model on En-De.

The r_t plot in Figure 3, also indicates that the learning dynamics now resemble what we expect to see with stable training. We also notice that the scale of r_t now resembles that of the RNMT+ model, although the lower layers converge more slowly for the Transformer, possibly because it uses a much smaller learning rate.

A plot of the weights $s_{i,j}$, in Figure 4, also seems to support our findings. The scalar weights for the lowest embeddings layer grow rapidly in the early stages of training, but once these layers converge the weights for layers 16 and 20 become much larger. The weights for the top few layers remain comparable at convergence, suggesting that the observed gains in performance might also be partially associated with an ensembling effect of the encoder features, similar to the effect observed in (Peters et al., 2018).

4 Conclusions and Future Work

In this work we explore deeper encoders for Transformer and RNMT+ based machine translation models. We observe that Transformer models are extremely difficult to train when encoder depth is increased beyond 12 layers. While RNMT+ models train with deeper encoders, we did not observe any big performance improvements.

We associated the difficulty in training deeper encoders with hindered gradient flow, and resolved it by proposing the transparent attention mechanism. This enabled us to successfully train deeper Transformer and RNMT+ models, resulting in consistent gains in translation quality on both WMT'14 En→De and WMT'15 Cs→En.

Our results show that there is potential for improvement in translation quality by training deeper architectures, even though they pose optimization challenges. While this study explores training deeper encoders for narrow models, we plan to further study extremely deep and wide models to utilize the full strength of these architectures.

Context and Copying in Neural Machine Translation

Rebecca Knowles

Philipp Koehn
Dept. of Computer Science
Johns Hopkins University
`phi@jhu.edu`

Abstract

Neural machine translation systems with subword vocabularies are capable of translating or copying unknown words. In this work, we show that they learn to copy words based on both the context in which the words appear as well as features of the words themselves. In contexts that are particularly copy-prone, they even copy words that they have already learned they should translate. We examine the influence of context and subword features on this and other types of copying behavior.

1 Introduction

In translation, certain tokens – often names and numbers – should be copied from the source sentence to the target sentence. Word copying is fairly straightforward in phrase-based statistical machine translation, where unknown words can be left untranslated (copied to the target). It poses more of a challenge in neural machine translation systems, which often use limited or subword vocabularies and soft attention rather than strict alignment. This has resulted in a variety of approaches to copying, which make use of pre-/post-processing and/or network modifications (e.g. explicit switching between generation and copying).

Neural machine translation models that use subword vocabularies to perform open-vocabulary translation have been observed to correctly translate unknown words or copy words (one subword at a time, if need be) even when the full word to be translated or copied was not observed in training. Koehn and Knowles (2017) found that neural machine translation systems using subword vocabularies outperformed phrase-based statistical machine translation systems on the translation of unknown words. This raises the questions that we seek to answer: to what extent does byte-pair encoding[1] solve the copying problem (without requiring modifications to the network structure)? More generally, what are subword neural machine translation models learning about copying?

We find that neural machine translation systems (with attention, trained on subword vocabularies) learn to copy words (both novel and observed) based on their sentential contexts. Additionally, though the models have no knowledge about the components of each subword unit, they learn that certain categories of tokens (e.g. capitalized tokens) tend to be copied. We use quantitative and qualitative evaluations to shed light on what these models learn about copying tokens and about the contexts in which copying occurs.

2 Related Work

Prior work on copying in neural machine translation has typically focused on rare or unknown words. Luong et al. (2015) augment data with word alignments to train a neural machine translation system (without attention) that emits both a translation and source word positions for any out-of-vocabulary (OOV) tokens emitted. They post-process OOVs with a dictionary or by copying. Currey et al. (2017) augment training data with monolingual target language text as bitext and find that it improves copying in low-resource settings. Ott et al. (2018) and Khayrallah and Koehn (2018) examine negative effects of source copying.

Both Gu et al. (2016) and Gulcehre et al. (2016) modify neural sequence to sequence models to explicitly perform copying. Gu et al. (2016) focus on monolingual tasks (dialogue systems and summarization), proposing a model that can both generate and copy text. Gulcehre et al. (2016) perform experiments on neural machine translation (with attention), using whole-word vocabularies (and an UNK token to represent unknown words). Their model incorporates a switching variable that determines whether to copy or generate a translation.

In this work, we focus on subword vocabularies for neural machine translation, using byte-pair en-

coding (BPE, Sennrich et al. (2016b)). The other approaches described are somewhat orthogonal to the use of subword vocabularies, but may require modifications to handle subwords.

3 Data and Models

We train German–English (DE–EN) and English–German (EN–DE) neural machine translation models with attention, similar to the University of Edinburgh's WMT 2016 submissions (Sennrich et al., 2016a). Models are trained using the Marian toolkit (Junczys-Dowmunt et al., 2018).[2] We use the WMT parallel text[3] (Europarl, News Commentary, and CommonCrawl) along with synthetic backtranslated data.[4]

4 Initial Analysis

We analyze the training data to learn about the prevalence and characteristics of words that should be copied in translation and the contexts in which they occur. We consider both the full training data (including backtranslations and CommonCrawl) and cleaner subsets. We restrict our search for copied words to tokens of length 3 or more characters.[5] Our heuristic for detecting copied tokens is this: a word is a "copied token" if it appears the same number of times in both the source and target sentence.[6] As we will show, copied words tend to belong to specific categories (proper nouns, numbers, etc.) which coincide with their repeated appearance in certain contexts (e.g. names following titles like "Ms" or "Prime Minister").

4.1 Where do copied words appear?

In Table 1, we see that between 1.8% and 9.2% of tokens are copied.[7] Though the majority (or near-majority) of sentences do not contain any copied words (of length 3 or more), copied words are still quite prevalent: approximately 18% of sentences in each full training dataset contain one, 4% to 5% contain four, and there is a long tail (one sentence contains 70). Sentences with many copied words often contain direct quotations, third language text (not source/target), or a sequence of copied words (e.g. comma-separated numbers or names).

The cleaner Europarl and News Commentary corpora have lower percentages of copied tokens than the overall training data. Of particular note, the backtranslated data contains some examples of copying that we'd prefer for the system *not* to learn, such as target language words appearing untranslated in the (backtranslated) source side data.

4.2 What words are copied?

We first examine the part-of-speech (POS) tags[8] of copied words. In the EN–DE training data, most copied words are tagged on the English side as NNP (proper noun, singular), including names of individuals, places, or organizations (eg. González, Wales, Union). The next most frequent categories are CD (cardinal number) – including numbers like *42* that should be copied and ones like *seven* which should be translated – and NN (noun, singular or mass). The results are similar for DE–EN training data (tagged on German with a different tag set): PROPN (proper noun) is the most frequent tag for copied words, followed by NUM (numbers) and NOUN. Punctuation would rank highly if we included short tokens.

5 Experiments and Analysis

We address two main questions: (1) Do certain *contexts* encourage copying? (2) Do certain *words* exhibit features that make them more likely to be copied (regardless of context)?

5.1 Contexts

Working from the intuition that certain contexts indicate that copying should occur – for example, a name following a title like "Ms" or "Frau"

---

[2] We use recommended settings and early stopping, with results comparable to WMT 2016 systems, with BLEU scores of 39.9 (DE–EN) and 33.2 (EN–DE) on the 2016 test set.

[3] http://www.statmt.org/wmt16/translation-task.html

[4] http://data.statmt.org/rsennrich/wmt16_backtranslations/

[5] This has the benefit of removing words like *in* which are the same in German and English, but may nonetheless be considered translations rather than copies.

[6] In DE–EN, we find one notable exception to this heuristic – *was* – which is a homograph, not a copy. It makes up $<1\%$ of copied tokens in Europarl/News Commentary.

[7] The two full training sets differ due to the synthetic backtranslated data; the rest of the corpora are identical.

[8] POS tags are generated by the Stanford POS tagger (Toutanova et al., 2003). For English: english-left3words-distsim.tagger. For German: german-ud.tagger.

Table 2: Source, reference, template, and examples of template-token combinations. *E1* has a word usually (76.0% of the time) copied in training, *E2* has one rarely (0.8% of the time) copied, and *E3* has a novel one. In training, 84.8% of NNPs with this left bigram context (“, Mrs”) were copied.

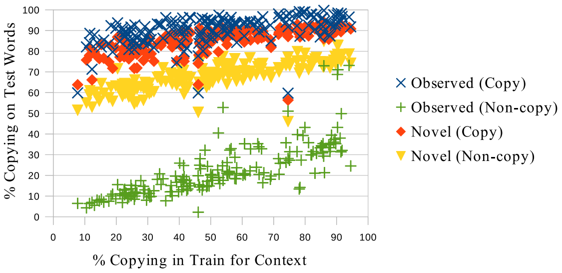

Figure 1: Percent of NNP (EN–DE) tokens copied by how copy-prone the context is, by category. Each point is the percentage of copying for all within-category words, across all example templates for one particular context (averaged over between 1,100 (novel-non-copy) and 13,150 (observed-non-copy) binary copy values).

should often be copied – we examine the relationship between context and copying, focusing on left bigram contexts. We show that the machine translation system learns that certain contexts are so indicative of copying that it will even copy (not translate) words that it has *learned to translate* if they are seen in a sufficiently copy-prone context.

For each POS, we collect a set of left bigram contexts that precede a word with that tag. We filter by frequency and diversity of tokens following the bigram.[9] For each context-POS pair, we select 50 random templates from the training data containing the bigram context followed by a word with that POS.[10] Each context-POS pair is associated with a percentage that represents how often it exhibited copying in the training data. For example, in the copy-prone context “thank Mrs [NNP]” the NNP was copied 91.1% of the time, compared to 15.3% of the time in “Republic of [NNP]”.[11]

We take all word types with a given POS tag from the WMT 2016 test set, dividing them into four categories based on two binary distinctions: *observed* (in training data) or *novel* (not observed in training), and *copy* (typically copied) or *non-copy* (not typically copied) and filter the observed ones based on training frequency. We count words as *non-copy* if they were copied $\leq$ 30% of the time, and as *copy* if they were copied $\geq$ 70% of the time.[12] We then combine each word with each POS-appropriate example template and perform preprocessing (including BPE) and translation.[13] Table 2 shows examples.

For each context, we calculate the percentage (across all example templates for that context and all words, separated by observed/novel and copy/non-copy categories) of the time that the words in that context were copied. We then compare it to the percentage of the time that copying occurred for that context-POS tag pair in training.

Figure 1 shows NNP (EN–DE) results. Both observed-copy and novel-copy words behave almost identically, with copying percentages generally above 80%, and a slight trend upward as contexts become more copy-prone (moving to the right along the horizontal axis). Novel-non-copy words shadow these, but with a drop in copying percentage (see Section 5.3). Most interesting is the observed-non-copy category. In contexts that are not copy-prone, minimal copying occurs.[14] However, as they are placed in increasingly copy-prone contexts, even these words that the system has learned it should *translate* are being copied. We observe the same trend for words tagged NN and CD, and for PROPN, NOUN, and NUM words in the DE–EN direction. This demonstrates that the machine translation system has learned that certain contexts are copy-prone.

We manually analyze outliers that appear much

---

[9] See Appendix A for details and examples of contexts.

[10] We select contexts and templates from the full training data, rather than only Europarl/News Commentary, because we are interested in what patterns the model is learning from *all* data to which it has been exposed.

[11] For DE–EN translation, we see similar patterns: two of the three most copy-prone PROPN left bigram contexts are “sagte Frau” and “sagte Herr” (“said Ms/Mr”), while many less copy-prone ones end with articles.

[12] See Appendix B for details.

[13] We use the Marian batch decoder, with recommended settings: beam size 6 and length normalization penalty of 0.6.

[14] Note that some of the non-copy words were sometimes copied in training data, even if only in backtranslations.

	Drop	**Change**	**Other**
Novel-Copy	24	102	60
Novel-Non-Copy	14	128	50
Observed-Copy	51	6	126
Observed-Non-Copy	12	1	186

Table 3: Counts of automatically detected output categories (*drop*, *change*, and *other*) for a sample of NNP tokens (EN–DE) that were not copied.

more or less copy-prone than expected. In both cases, the cause appears the same: the context occurred repeatedly in many very similar sentences in the training data. Highly copy-prone contexts that produced copying percentages greater than 70% even in observed-non-copy tokens often appeared in common boilerplate text (e.g. "stay at [NNP]" or "rates for [NNP]" followed by "Hotel").[15] Where we observe lower than expected rates (e.g. ") of [NNP]"), we find that the system may have memorized training sentences.

5.2 Analysis of Words That Are Not Copied

When words are not copied, what sort of output is the system producing? We find that it typically falls into one of four categories: *drop* (no target token aligns with the source token), *change* (the word is changed: partially translated, transliterated, or inflected even if it is not a target language word), *substitution* (the word is replaced with a fluent but not adequate substitute), or *translation* (translated into a target language word).

We begin with an automatic analysis. We randomly sample 200 examples each of sentences containing words that were not copied for novel-copy, novel-non-copy, observed-copy, and observed-non-copy NNPs (EN–DE). We retranslate each sentence and produce a soft alignment matrix from the attention mechanism, then convert the soft alignments between BPE segments into hard alignments between the source word and one or more target words.[16] A word has been *dropped* if it is unaligned. We count a word as being *changed* if any words it is aligned to have any subword (BPE segment) overlap with the original word's subwords. Both *substitution* and *translation* fall under *other*; we analyze those manually.

Results are shown in Table 3.[17] For all novel words, the most frequent output type is *change*. For example, the novel NNP *Bishnu* is changed into *Bischnu* in German.[18] Other changes include translations of parts of the word, and concatenation with other tokens. The output token often starts with the same character or sequence of characters as the source token.[19]

We manually inspect examples in the *other* category. For observed-non-copy words, almost all are translations (e.g. *Sea* translated correctly as *Meer*), as expected. For observed-copy words, we see a mix of translations and other changes to the words, which are almost evenly split between substitutions and small changes. These include inflections (e.g. *Bremen magazine* reasonably translated as *Bremer Magazin*[20]).

Within the *other* category, perhaps the most interesting cases are those where words appear to be substituted with a fluent but not adequate alternative. Many substitutions occur when the rare word is inserted next to a word that often forms a collocation (like "United States" – in sentences that include "in the [NNP] States" the translation sometimes defaults to a translation of "United States" regardless of the actual NNP inserted in place of "United"). Others have a less common NNP swapped for one that belongs to a similar semantic category (e.g. the place name *Dublin* being generated instead of the less common *Halle* – as Arthur et al. (2016) and others observed). For novel-copy words labeled as *other*, three quarters are substitutions and one quarter exhibit small changes. The reverse is true for novel-non-copy words: the majority exhibit small changes while almost thirty percent are substitutions.

5.3 Properties of Copied Words

Certain words exhibit properties that make them more likely to be copied, regardless of context. At first glance, it seems unintuitive that the rate of copying of novel-copy words and novel-non-copy words differs (Fig. 1) – the model has never observed any of these words, and they are being presented in identical contexts – why does it differentiate between them? Doing so indicates that the model has learned what makes a sequence of

---

[15] Since hidden representations contain whole sentence information, right side context may influence copying too.

[16] We use AmuNMT (Junczys-Dowmunt et al., 2016), producing slightly different output. See Appendix C for details.

[17] Rows do not sum to 200 because some words in our random sample were copied by the the AmuNMT decoder.

[18] A near-transliteration – the "sh"/"sch" transformation is seen in EN–DE cognates, e.g. "ship" and "Schiff".

[19] Appendix D contains examples of this and more.

[20] *Bremen* and *Bremer* are unique BPE segments, so the *change* heuristic could not be applied.

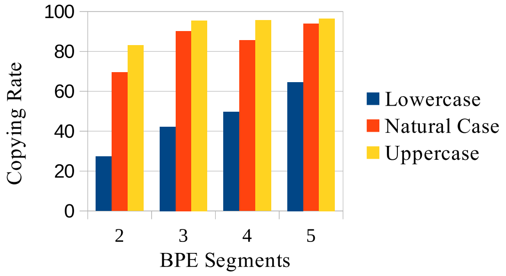

Figure 2: Copying rate based on casing and number of BPE segments for novel NNP words (EN–DE), averaged across all NNP contexts.

subwords likely to be copied.

Belinkov et al. (2017) observe that neural machine translation models may encode information about part-of-speech, which could be used when determining whether or not to copy (but does not explain within-POS differences). For numbers, it mainly learns to copy numerical portions while changing commas to periods and vice versa (as required by the target language's conventions). Nouns and proper nouns are more interesting: some should be translated (e.g. novel noun compounds like *hallmate*), or, in the case of misspellings (e.g. *manfacturer*), corrected, while others should be copied. For novel NN words, there is another striking difference between copy and non-copy: most of the former contain capital letters and most of the latter do not.

5.4 Capitalization and Copying

To experiment with the influence of capitalization on copying, we take each novel NNP word (96 copy and 22 non-copy) and convert it to lowercase, leave it in its natural case (all have at least one uppercase letter), or convert it to uppercase. We then translate all of them in all NNP contexts (from previous EN–DE experiments). Using only novel words sidesteps the issue of truecasing.

Lowercase words are the least frequently copied (average copy rate of 40.2%), uppercase words are the most copied (94.4%), and the natural case falls in the middle (81.7%). However, changing casing changes the BPE segmentation, and uppercase words tend to be split into more pieces: a mean of 4.4 segments, as compared to means of 3.1 (lowercase) and 2.9 (natural case). The number of subword segments correlates positively with copying rate (Fig. 2), but, controlling for that, we still find that NNP words that are completely capitalized tend to be copied more than those with the same number of subword segments but only lowercased letters, suggesting that the system is encoding information about the connection between capitalization and copying. We also perform this experiment with PROPN words in the DE–EN direction, and find that increased capitalization increases copying, though we do *not* find there that an increase in the number of BPE segments increases copying. The true casing of the word consistently falls between these two extremes. The high copying rate of fully-capitalized words is intuitive: acronyms are often both uppercased and copied from source to target. That is not to say that the model always learns to copy acronyms; it also learns to translate them when appropriate (such as *GDP* to *BIP*). There is always an interplay between learned translations and features that may encourage copying.

The connection between copying rate and capitalization provides one explanation for the gap in behavior of the two novel word types, and demonstrates that features of words influence copying. Note that it learns this behavior based on training data, without access to information at a finer granularity (character-level) than the subword units.

6 Conclusion

We show that subword vocabulary neural machine translation systems learn about copying from context and the subwords themselves. The effect of context is strong enough to cause words that would otherwise be translated to be copied. Characteristics of subword tokens play a role in copying behavior, with capitalized tokens more likely to be copied. We leave as future work a deeper analysis of the level of character-awareness encoded in representations of the BPE segments as a byproduct of training. We provide an analysis of what happens when words are not copied, showing expected differences between novel words and words that were observed during training. Additionally, we provide more examples and evidence of the problem of substituting fluent but non-adequate translations for rare or unknown words.

Appendices

A Collection of Left Bigram Contexts

We use left bigram contexts as a proxy to evaluate the contexts in which words are copied. Here, we provide details of the context selection process described in Section 5.1. In overview: for each POS, we collect the full set of left bigram contexts that ever precede a word with that tag, then filter by frequency and subsequent token diversity.

For each POS, first, we find all left bigram contexts $(tok0, tok1, copiedword)$ that occur in the training data (where the copied word was tagged with the given POS). We then filter this set so that it only contains contexts $(tok0, tok1)$ that appeared at least 1000 times (left of NNP/PROPN) or 500 times (left of CD/NN/NUM/NOUN) in the training data. To ensure that we're not simply capturing collocations ("European Union"), we filter out left bigram contexts that have been followed by fewer than 150 unique types with that particular POS. This results in between 53 and 276 contexts, as shown in Table 4.

POS	**Num. Contexts**
NNP	176
NN	82
CD	74
PROPN	276
NOUN	66
NUM	53

Table 4: Context counts by POS tag (NNP, NN, CD for EN–DE; PROPN, NOUN, NUM for DE–EN), selected as described in Appendix A.

Each context is then associated with a copying rate, calculated as the number of times the token (with the given POS tag) following $(tok0, tok1)$ is copied, divided by the total number of times $(tok0, tok1)$ was observed to be followed by a token with that POS tag. In Table 5, we show the most- and least-copy-prone contexts for EN–DE (those with the highest and lowest copying rates).

POS	**Context**	**Copy Rate**
NNP	Finance Minister	94.5%
	rates for	94.0%
	congratulate Mr	91.7%
	between the	10.5%
	President ,	7.7%
CD	updated on	94.0%
	the B	0.1%
NN	notified when	97.3%
	the first	0.6%

Table 5: Left bigram contexts with the highest/lowest copying rates (EN–DE), by POS tag.

	Novel		Observed	
POS	**Copy**	**Non-C.**	**Copy**	**Non-C.**
NNP	96	22	251	263
NN	14	16	13	1664
CD	3	29	60	44
PROPN	92	76	463	418
NOUN	12	222	29	2176
NUM	2	29	55	68

Table 6: Counts of each word type by novel/observed, copy/non-copy distinction and POS tag (NNP, NN, CD are EN–DE; PROPN, NOUN, NUM are DE–EN).

B Collection and Labeling of Copy/Non-Copy Words

In Section 5.1, we give a high-level description of how we collect and label words. All words that we examine are labeled as either *copy* or *non-copy*. For words that were observed in training, we filter out those that appeared fewer than 1000 times. We label them as *copy* if they were copied $\geq 70\%$ of the time in training data (according to the heuristic described in Section 4), and as *non-copy* if they were copied $\leq 30\%$ of the time in training data, discarding the remainder. For words that were unobserved in training, we used the same threshold but calculate it over all instances in the test data (with no requirement that they appear a certain number of times). Table 6 shows the number of words selected after filtering and thresholding.

C Attention and Alignments

We produce soft alignments (the attention matrix) using the AmuNMT decoder with the "return-nematus-alignment" flag set. It performs normalization differently than Marian's decoder (producing slightly different outputs for many sentences, including sometimes copying words that were not copied in our original translations).

For each target (subword) token, we align it to the source (subword) token with the highest soft alignment weight. Given our source word of interest s (composed of subword segments $s_1 \ldots s_n$), we define its translation to be the list of all target words t (composed of subword segments $t_1 \ldots t_m$) for which any subword t_i was aligned to a subword s_j of s.

D Additional Examples

D.1 Changes

Here we show additional examples of *changes*, like the transliteration-like change of *Bishnu* to *Bischnu* described in Section 5.2.

There are also partial translations when BPE segments are full source language words – like *Thneed* (segmented “Th@@ need”) becoming *ThNotwendigkeit* (segmented “Th@@ Notwendigkeit” – *Notwendigkeit* is a valid translation of *need*). Sometimes, a token *is* copied but then concatenated with another token.

Even without overlap of BPE segments between the source and the translation, changed words sometimes share a number of characters (especially at the beginning or end of a word). Half of the *other* category output of *Thneed* (“Th@@ need”) begin with the letter “T” (but not the BPE token “Th@@”). This may suggest some level of character-awareness in the representations of BPE segments, produced as a byproduct of training. We leave a deeper analysis of this to future work.

D.2 NNP Substitutions

Here we provide additional examples of substitutions, as seen in Section 5.2. These findings provide additional support and nuance to the study of this phenomenon of neural machine translation system errors.

Many substitutions occur when the rare word is inserted next to a word that often forms a collocation (like “United States” or “European Union” or “Madam President”). For example, in a template where “in the [NNP]” is followed by “States”, inserting the NNP *Accies* results in “in the *Accies* States” – which was then translated by the system as “in den Vereinigten Staaten” (gloss: “in the United States”).

We also observe examples that may have to do with a combination of (in)frequency of tokens and the context. For example, we have the novel NNP *Sloveina* (perhaps a misspelling of *Slovenia*), which is often replaced with *Slowaken* (*Slovakia*) when translated to German. In another sentence, we find that “this year, *Angela* expects” is translated to “in diesem Jahr erwartet *Merkel*” despite *Merkel* appearing nowhere in the source text. The first and last names of German chancellor Angela Merkel appear frequently together in training data, and thus likely have sufficiently similar representations. We see other similar substitutions: *Mitt* for *Romney*, *US* for *Obama*, and *Thomas* for *Sarah*. Sometimes a specific name is replaced with a title, such as “your prime minister, *York*” being translated as “ihr Premierminister, *Herr Präsident*” (glossed as “your prime minister, *Mr. President*”).

E Additional Plots

Here we include plots for DE–EN PROPN. Fig. 3 shows context experiments. It shows similar trends to Fig. 1, but with a greater gap between novel- copy/non-copy words. As noted, the DE–EN capitalization experiments (Fig. 4) show the same trends as EN–DE in terms of capitalization (despite the capitalization of all nouns in German), but not in terms of numbers of BPE segments.

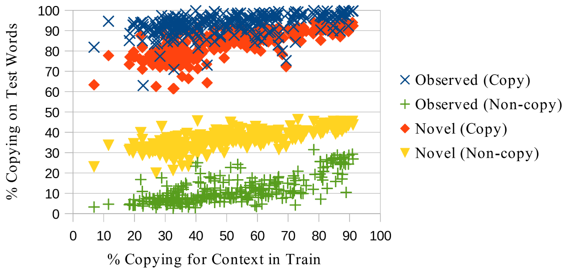

Figure 3: Percent of PROPN (DE–EN) tokens copied by how copy-prone the context is, by category. Each point is the percentage of copying for all within-category words, averaged across all example templates for one particular context.

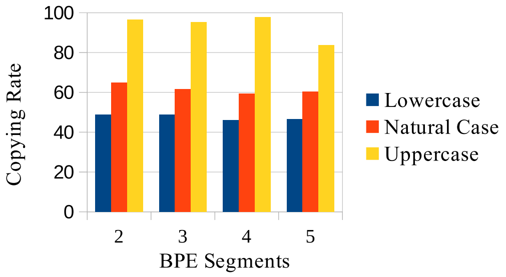

Figure 4: Copying rate based on casing and number of BPE segments for novel PROPN words (DE–EN), averaged across all PROPN contexts.

Encoding Gated Translation Memory into Neural Machine Translation

Qian Cao and **Deyi Xiong**[*]

Abstract

Translation memories (TM) facilitate human translators to reuse existing repetitive translation fragments. In this paper, we propose a novel method to combine the strengths of both TM and neural machine translation (NMT) for high-quality translation. We treat the target translation of a TM match as an additional reference input and encode it into NMT with an extra encoder. A gating mechanism is further used to balance the impact of the TM match on the NMT decoder. Experiment results on the UN corpus demonstrate that when fuzzy matches are higher than 50%, the quality of NMT translation can be significantly improved by over 10 BLEU points.

1 Introduction

Neural machine translation, an emerging machine translation (MT) technology, has made remarkable progress in the past few years (Cho et al., 2014; Sutskever et al., 2014), which strongly encourages many translation agencies to embrace it for product deployment. A natural question during this deployment is how the strengths of both the traditional TM and new NMT technologies can be combined together for professional high-quality translation.

Such attempts to the TM and MT combination have been already conducted in the context of statistical machine translation (SMT). A variety of efforts have been made to incorporate matched translation segments from TM into SMT (Koehn and Senellart, 2010). Partially inspired by these efforts, we aim at combining TM and NMT in this paper.

Different from TM and SMT, both of which use symbolic fragments to construct translations, NMT induces translations from a real-valued continuous space. Furthermore, NMT is trained in an end-to-end fashion, which makes it not easy to be amenable to external intervention. Therefore, incorporating TM as external knowledge into NMT is challenging.

In this paper, we propose a novel and effective method to address this issue in the combination of TM and NMT. The key idea behind this method is to mimic human translators in translating a source sentence given a similar source sentence with a translation. We treat the matched TM translation as an additional signal and try to encode it with a new encoder to guide the NMT decoder to translate the current sentence. Specifically, we first find the sentence that is most similar to the current source sentence from TM by calculating their semantic similarity based on sentence embeddings. In order to prevent the TM matched translation from dominating the decoding process, we introduce a gate mechanism to balance the TM translation signal and the current source sentence which are encoded separately by two different encoders.

A series of experiments on the Chinese-English UN corpus demonstrate that when fuzzy matches are over 50%, the proposed method can significantly improve NMT with the gated TM signal. We also conduct an in-depth analysis on the TM gate, which shows that the gate can indeed regulate the information flow from TM to the NMT decoder.

2 Encoding Gated TM into NMT

In this section, we elaborate our proposed method that encodes translation memories into neural machine translation with a gating mechanism. We refer to our method as NMT-GTM, which consists of three essential components: i) coupled encoders that encodes both the source sentence and matched TM translation separately, ii) a TM gating network that controls the encoded signal from the TM matched translation and iii) a TM-guided decoder

that incorporates the gated TM signal into the decoding. The diagram of NMT-GTM is shown in Figure 1.

For each source sentence src, we retrieve TM to find the most similar sentence to it. Different from the combination of TM and SMT, we define the best TM match as the sentence with the highest cosine similarity which is calculated based on sentence embeddings (Le and Mikolov, 2014), instead of being selected based on fuzzy match score. This is consistent with NMT that performs in an embedding-defined semantic space. But we display our results in experiments according to fuzzy match scores for easy understanding. We use tm_s to denote the most semantically similar sentence to src from TM and tm_t its translation.

2.1 Coupled Encoders

We use a pair of encoders to separately encode the source sentence src and its matched TM translation tm_t. Both encoders are running independently of each other with bidirectional GRU recurrent neural networks[1] (Chung et al., 2014). Accordingly, two separate attention networks are employed to obtain context representations for both src and tm_t, which we denote as c^{src} and c^{tm_t} respectively. The attention network for the TM matched translation is able to help detect matched translation segments from tm_t for the decoder.

2.2 TM Gating Network

When we translate a source sentence, in addition to the input of the sentence itself, we also have a TM matched translation (tm_t) semantically similar to the sentence as an additional input. We want the additional input to act as a translation example for providing positive guide to target word prediction. In order to balance the information flow from the two inputs (src and tm_t) into the decoder, we further introduce a TM gating network to control the respective proportions of tm_t and src, partially inspired by Tu et al. (2017) who propose a gating mechanism to combine source and target contexts. We formulate the TM gating network as follows:

$$g^{tm} = f(s_{t-1}, y_{t-1}, c^{src}, c^{tm\_t})$$

where s_{t-1} is the previous hidden state, y_{t-1} is the previously predicted target word, and f is a logistic sigmoid function.

#Sentences	1, 117, 452	804	1, 614
Average FMS	0.1890	0.5493	0.5392

Table 1: Statistics of the training data, development and test set. FMS: fuzzy match score.

2.3 TM-Guided Decoder

In the TM-guided decoder, we integrate the gated TM information into the decoding process and use the context representations of src and tm_t to predict the hidden state of the decoder in each time step. The decoder hidden state s_t is computed as follows:

$$s_t = GRU(s_{t-1}, y_{t-1}, c^{src} * (1 - g^{tm}), c^{tm\_t} * g^{tm})$$

where * is an element-wise multiplication.

The conditional probability of the next word y_t is calculated as follows:

$$p(y_t | y_{<t}, src) = g(f(s_t, y_{t-1}, c^{src}))$$

Please notice that we only incorporate the gated TM into the hidden state of the decoder, rather than the prediction of the next word. Our goal is to correctly translate the source sentence with reference to the translation of the TM match tm_t. In other words, tm_t only plays a supporting role in translation. We don't want too much information from TM to affect the translation of the source sentence. Therefore, we incorporate the gated TM in a way that it can only indirectly influence the target generation via hidden states. In our experiments, we observe that this helps our proposed model to faithfully translate a source sentence, instead of copying all information from the TM matched translation, especially for source sentences with slight differences (e.g., dates or numbers) from TM matches.

3 Experiments

We conducted a series of experiments on Chinese-English corpus to evaluate the effectiveness of the proposed NMT-GTM and analyzed the TM gate.

3.1 Experimental Settings

Our data come from the Chinese-English United Nations Parallel Corpus (Rafalovitch et al., 2009), which consists of official records and other parliamentary documents. Since large-scale public

translation memories are not easily available, we built a translation memory from the UN corpus. Specifically, we divided the Chinese-English UN corpus into two parts UN_a and UN_b with equal size. For each source sentence s_a from UN_a, we chose the source sentence s_b from UN_b that has the highest semantically similarity to s_a, computed in the way described in the last section. In doing so, we built a corpus with matched pairs $(s_a/t_a, s_b/t_b)$ where $t_{a/b}$ are translations corresponding to $s_{a/b}$. Then we computed the fuzzy match score for each pair of source sentences as follows:

$$FMS(s_a, s_b) = 1 - \frac{Levenshtein(s_a, s_b)}{max(|s_a|, |s_b|)}$$

where $Levenshtein(s_a, s_b)$ is the word-based Levenshtein Distance between s_a and s_b. The fuzzy match score can also be calculated with other methods, e.g., the method introduced in (Bloodgood and Strauss, 2015). We leave FMS estimated with different methods to our future work. We selected all pairs $(s_a/t_a, s_b/t_b)$ with a fuzzy match score $FMS >= 0.5$. From those pairs with $FMS < 0.5$, we randomly selected 20% of them. These selected pairs were then divided into 9 groups according to their fuzzy match scores (e.g., $FMS \in [0.5, 0.6)$). We randomly chose approximately the same number of sentences from each group to create a development set and test set. The remaining data were used to create the training data (i.e., $\{(s_a, t_b, t_a)_{selected}\}$) and translation memory (i.e., $\{(s_b, t_b)_{selected}\}$). Statistics of the training data, development and test set are shown in Table 1. The numbers of sentences of the test set in each fuzzy match score group are presented in Table 2.

We used RNNSearch as our NMT baseline. We set the maximum sentence length of training corpus to 50 words both for the Chinese and English sides. The sizes of vocabularies of both sides were

set to 30k. For those words that are not in the vocabulary, we replaced them with a special token UNK. We set the dropout to 0.5. All the other settings were the same as those described by Bahdanau et al. (2014). We used the stochastic gradient descent algorithm with Adam (Kingma and Ba, 2014) to train NMT models. The learning rate was set to 0.0004. The size of mini-batch was set to 80 sentences. The beam size was set to 10 during decoding.

For the proposed NMT-GTM model, we used tuples (src, tm_t, tgt) as input. The rest of the parameter settings were consistent with the baseline model. To calculate the cosine similarity, we used the fasttext tool [2] with the dimension of 100 to obtain sentence embeddings.

3.2 Experimental Results

Table 3 shows the results of different NMT systems measured by BLEU (Papineni et al., 2002). From the table, we can find that when fuzzy match scores are over 50%, the extra introduction of TM information can significantly help NMT to better translate. Even when fuzzy match scores are lower than 50%, the translation quality does not drop too much. On the entire test set, the proposed gated combination model of TM and NMT improves the translation quality by 10.32 BLEU points over the baseline.

In addition, in order to investigate how similar the matched TM translations tm_t are to the reference translations ref, we also measured the BLEU scores of the matched TM translations against the reference translations. The results are also shown in Table 3, indicated as TM.

3.3 Analysis

We further took a deep look into how the TM gate is varying when we incorporate TM matches with different fuzzy match scores. As a comparison, we used the reference translations as the matched TM translations and incorporated them into NMT-GTM to check the changes of the gate. The BLEU scores measured when we used reference translations as matched TM translations as well as average gate values are shown in Table 4. The results demonstrate that when the matched TM is semantically closer to the current source sentence, the TM gate is larger, indicating that more information from the matched TM translation is used to guide the decoder.

Table 5 shows an example from our test set. The highlighted fragments of the source sentence and the matched TM source sentence are not actually the same in terms of their surface forms. However, they are semantically close and can be translated into the same target translation. Our proposed NMT-GMT is able to successfully incorporate the translation of such a fragment into the decoder.

4 Related Work

Various strategies have been proposed to combine TM and SMT (Koehn and Senellart, 2010; He et al., 2010). Their key ideas are to integrate the translations of the same fragments from TM into SMT, and let SMT only translate those different parts. In order to better model this process, Wang et al. (2013, 2014) use different features to allow relevant TM information to guide SMT decoding.

Table 5: A translation example from the test set. Semantically similar fragments are highlighted with red color.

The related work on combining TM and NMT is quite limited. Gu et al. (2017) propose a TM-NMT model that first finds the most similar segments through search engines according to fuzzy match scores and saves them as key-value pairs in memory. In the subsequent decoding, the saved information is used to help decoding. Our work is significantly different from theirs in two aspects. First, we use semantic similarity based on sentence embeddings to detect the best TM matches rather than the fuzzy match score. Second, we encode the entire TM matched translation rather than segments into NMT with coupled encoders and a gating network.

Our work is also related to multi-source NMT (Zoph and Knight, 2016). The difference is that in our case, the multiple source inputs are just semantically similar, rather than identical. This is the reason that we use a gate to combine these inputs.

5 Conclusion and Future work

In this paper, we have presented a novel gated method to encode translation memory into NMT so as to convey the information of the matched TM translation into the NMT decoder. Extensive experiments verify that our method can indeed effectively improve translation quality, especially when fuzzy match scores are higher than 50%. Further analysis reveals that the proposed TM gate is able to vary according to the similarity between the matched TM translation and the current sentence.

Abstract

Automated Post-Editing (PE) is the task of automatically correcting common and repetitive errors found in machine translation (MT) output. In this paper, we present a neural programmer-interpreter approach to this task, resembling the way that humans perform post-editing using discrete edit operations, which we refer to as programs. Our model outperforms previous neural models for inducing PE programs on the WMT17 APE task for German-English up to +1 BLEU score and -0.7 TER scores.

1 Introduction

Automatic post-editing (APE) is the automated task that aims to correct common systematic and repetitive errors found in machine translation (MT) output. APE systems can also be used to adapt general-purpose MT output to specific domains without re-training MT models, or to incorporate information which is not available or expensive to compute at MT decoding stage. Post-editing is considered as the modification process of a machine translated text with a minimum labor effort rather than re-translation from scratch.

Previous studies in neural APE have primarily concentrated on formalizing APE as a monolingual MT problem in the target language, with or without conditioning on the source sentence (Pal et al., 2016; Chatterjee et al., 2017). MT approach has suffered from *over-correction* where APE system performs unnecessary correction leading to paraphasing and the degradation of the output quality (Bojar et al., 2016, 2017).

Recent works (Libovický et al., 2016; Berard et al., 2017) have attempted to learn the predict of sequence of post-editing operations, e.g. insertion and deletion, to induce APE *programs* to turn the machine translated text into the desired output. Previous program induction approaches suffer from *over-cautiousness*, where the APE system tends to keep the machine translated text without any modification (Bojar et al., 2017).

In this paper, we propose a programmer-interpreter approach to the APE task to address the over-cautiousness problem. Our architecture includes an interpreter module, which executes the previous editing action before generating the next one. This is in contrast to the previous work, where the *full* program is induced before it is *executed*. The ability of execution *immediately* at every time step provides a proper conditioning context based on the actual partial edited sentence to assist better prediction of the next operation. Moreover, the execution module can be pre-trained on monolingual target text, enabling our architecture to benefit from monolingual data in addition to PE data, which is hard to obtain. Our model is jointly trained on translation task and APE program induction task. The multi-task architecture allows the model to reconstruct the source-target alignment of the black-box MT system and inject it into post-editing task.

We compare our programmer-interpreter architecture against previous works on the English-German APE based on the data for this task in WMT16 and WMT17. Compared to the previous work on APE program induction, our architecture achieves improvements up to +1 BLEU and -0.7 TER scores. Our analysis also shows that APE programs generated by our model are not only better at correcting errors but also attempt to perform more editing actions.

was able to reduce the preposition related errors. Blindly performing edition over MT output, the monolingual APE has difficulty to correct missing word or information in the source sentence. Neural multi-source MT architectures are applied to better capture the connection between the source sentence/machine translated text and the PE output (Libovický et al., 2016; Varis and Bojar, 2017; Junczys-Dowmunt and Grundkiewicz, 2017). Chatterjee et al. (2017) ensemble several different models including monolingual MT (TGT→PE), bilingual MT (SRC→PE), and multi-source (SRC,TGT→PE). Libovický et al. (2016); Berard et al. (2017) have proposed learning to predict the sequence of edit operations, aka the program, to produce the post-editing sentence (c.f. §3).

Our work is motivated by Ling et al. (2017) on learning to indirectly solve an algebraic word problem by inducing a program which generates the answer together with an explanation. It further builds up on recent work on neural programmer-interpreter (Reed and De Freitas, 2016), where a neural network programmer learns to program an interpreter. The architecture is then trained using expert action trajectories as programs.

3 The NPI-APE Approach

Given a source sentence $\boldsymbol{s}$ and a machine translated sentence $\boldsymbol{m}$, the goal is to find a post-edited sentence $\boldsymbol{t} = \arg\max_{\boldsymbol{t}'} P_{\text{ape}}(\boldsymbol{t}'|\boldsymbol{m}, \boldsymbol{s})$ where $P_{\text{ape}}(.)$ is our probabilistic APE model. In our proposed approach, we aim to find an editing action sequence $\boldsymbol{z}$ to *execute* in order to generate the desired post-edited sentence,

$$P_{\text{ape}}(\boldsymbol{t}|\boldsymbol{m}, \boldsymbol{s}) = \sum_{\boldsymbol{z} \in \mathcal{Z}} P_{\text{ape}}(\boldsymbol{t}, \boldsymbol{z}|\boldsymbol{m}, \boldsymbol{s}).$$

We decompose the joint probability of a program and an output as:

$$P_{\text{ape}}(\boldsymbol{z}, \boldsymbol{t}|\boldsymbol{m}, \boldsymbol{s}) = \prod_{i=1}^{|\boldsymbol{z}|} P_{\text{prog}}(z_i|\boldsymbol{t}_{\leq j_{i-1}}, \boldsymbol{m}, \boldsymbol{s}) \quad (1)$$

$$\times P_{\text{intp}}(t_{j_i}|m_{k_i}, z_i) \quad (2)$$

where $P_{\text{prog}}(z_i|\boldsymbol{t}_{\leq j_{i-1}}, \boldsymbol{m}, \boldsymbol{s})$ is the programmer's probability in producing the next edit operation z_i given the post edited output $\boldsymbol{t}_{\leq j_{i-1}}$ generated from the operations so far $\boldsymbol{z}_{\leq i-1}$, and $P_{\text{intp}}(t_{j_i}|m_{k_i}, z_i)$ is the interpreter's probability of outputing t_{j_i} given the edit operation z_i and the MT word m_{k_i}.

Following Berard et al.(2017), our action sequence is performed on the MT sentence from left to right. At each position, we can take one of the following editing operations: (i) KEEP to keep the word and go to the next word, (ii) DELETE to delete the word and go to the next word, (iii) INSERT(WORD) to insert a new WORD and stay in that position, or (iv) STOP to terminate the process. In other words, the size of the operation set equals the size of the target vocabulary plus three, where we add the symbols KEEP, DELETE, and STOP as new tokens. Furthermore, j_i is the number of KEEP and INSERT(WORD) operations, and k_i is the number of KEEP and DELETE operations in the sequence of operations $\boldsymbol{z}_{\leq i}$. This *hard attention* mechanism is the outcome of the semantics of the operations, and injects task knowledge into the model. Moreover, $P_{\text{intp}}(t|m, z)$ is 1 if the output word t is consistent with performing the operation z on m, and zero otherwise.

Our decomposition of the joint probability of a program and post-edited output is distinguished from that proposed in (Berard et al., 2017), $P_{\text{ape}}(\boldsymbol{t}, \boldsymbol{z}|\boldsymbol{m}, \boldsymbol{s}) = P_{\text{intp}}(\boldsymbol{t}|\boldsymbol{z}, \boldsymbol{m}) P_{\text{prog}}(\boldsymbol{z}|\boldsymbol{m}, \boldsymbol{s})$. Crucially, in our decomposition (eqns 1 and 2), the programming and interpreting are interleaved at each position, whereas in (Berard et al., 2017) the programming is fully done before the interpretation phase and they are independent.

3.1 Neural Architecture and Joint Training

The architecture consists of three components (i) A SEQ2SEQ model to translate the source sentence to the target in the forced-decoding mode (MT), (ii) A SEQ2SEQ model to incrementally generate the sequence of edit operations (Action Generator), and (iii) An RNN to summarize the post edited sequence of words produced from the execution of actions generated so far (Interpreter).

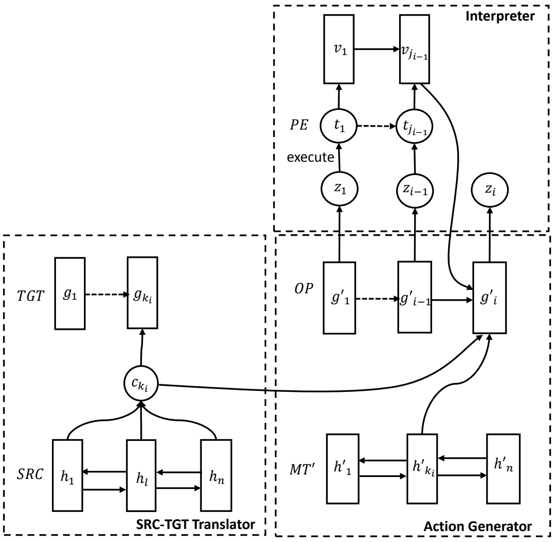

Figure 2: Our proposed NPI-APE model

The encoder and decoder of the MT component are a bidirectional and unidirectional LSTM, whose states are denoted by $\boldsymbol{h}_l$ and $\boldsymbol{g}_k$, respectively. Similarly, the encoder and decoder of the AG (Action Generator) component are a bidirectional and unidirectional LSTM, whose states are denoted by $\boldsymbol{h}'_k$ and $\boldsymbol{g}'_i$, respectively. The states of the unidirectional RNN in the interpreter are denoted by $\boldsymbol{v}_j$.

The next edit operation z_i is generated from the decoder state of the AG $\boldsymbol{g}'_i$ (see Figure 2), which is computed from the previous state $\boldsymbol{g}'_{i-1}$ and a context including the following: (i) $\boldsymbol{h}'_{k_i}$ where k_i is the index of the MT output word currently processed, (ii) $\boldsymbol{c}_{k_i}$ which is the context vector from the MT component when generating the current target word, and (iii) $\boldsymbol{v}_{j_{i-1}}$ which is the last hidden state of the interpreter RNN encoding the post edited sentence generated so far.

The model is trained *jointly* for the translation task (SRC→TGT), and for the post editing task (SRC,TGT→OP,PE). For the training data, we compute the lowest-cost sequence of editing operations (OP) using dynamic programming, where the cost of insertion and deletion are 1.

4 Experiments

Dataset. We evaluate the proposed approach on the English-to-German (En-De) post-editing task in the IT domain using the data from WMT16[1] and WMT17.[2] The official WMT'16 and WMT'17 dataset contains 12K and 11K post-editing triplets (English, translated German, post-edited German) respectively in IT domain. We concatenated them to an 23K triplets. A synthetic corpus of 500K triplets (Junczys-Dowmunt and Grundkiewicz, 2016) is also available as additional training data. We performed our experiment in two different settings with and without synthetic data for comparison with Berard et al. (2017).

The RNN in the interpreter component can be thought of as a language model. This paves the way to pre-train it using monolingual text. We collect in-domain IT text from OPUS[3] from the following sections: GNOME, KDE, KDEdoc, OpenOffice, OpenOffice3, PHP and Ubuntu. After tokenizing, filtering out sentences containing special characters, and removing duplications, we obtain around 170K sentences.

Setup. There are three components in our architecture: machine translation (MT), action generator (AG), and interpreter (LM). We compare our MT+AG+LM architecture against MT+AG[4] Berard et al. (2017) which does not have the LM component. The size of the hidden dimensions (LSTMs in the MT and AG, and simple RNN in the LM component) as well as word embedding in these models is set to 128.

Furthermore, we compare against monolingual SEQ2SEQ (TGT→PE) as well as the multi-source SEQ2SEQ (SRC+TGT→PE) (Varis and Bojar, 2017). Monolingual SEQ2SEQ (TGT→PE) model is an attentional SEQ2SEQ model (Bahdanau et al., 2015) that takes target sentence as input and outputs desired PE sentence. In multi-source SEQ2SEQ (SRC+TGT→PE), we use two encoders for source and target sentences and concatenate their context vectors. In both models, the encoder and decoder contain a single layer of bidirectional and unidirectional LSTM respectively. The size of the LSTM hidden dimensions and word embedding in these models is set to 256 and 128, respectively. This ensures almost the same number of parameters (~13M) in all architectures.

Training. We use a multi-task scenario to jointly train the parameters of the components in MT+AG as well as MT+AG+LM models. For the latter, we warm start the embedding of the target words with

those obtained from training the LM component on the monolingual text[5].

All models are trained with SGD, where the learning rate is initialised to 1 and decays after each epoch. The learning rate is decayed 0.8 after every epoch for model trained with official post-editing data, and 0.5 every half epoch for model with synthetic data. All models use the same vocabulary on the same data condition. The Vocabulary size is 30K for large dataset experiments, and 27K/19K for the 23K/12K data conditions. In all experiments, the best model is selected based on TER on the validation set. For decoding, we use beam search with the beam size of 10.

4.1 Results

Table 1 shows the result on different training datasets to compare our model against the baselines. Original MT is the strong standard *do-nothing* baseline, i.e. copying the MT translation as the PE output. In all settings, our MT+AG+LM models outperforms the MT+AG and monolingual/multi-source SEQ2SEQ models. Specifically, our model outperform MT+AG in 500K+12K training condition by almost 1 BLEU score on test2017.

As expected, the models trained on 23K data perform better than those trained on 12K; further gains are obtained by adding 500K synthetic data.

		Sentences		Actions	
	Model	Mod	Prec.	Mod.	Prec.
dev	MT+AG_23K	546	61.17%	986	60.45%
	MT+AG+LM_23K	558	65.59%	1098	65.21%
	MT+AG_500+23K	673	61.81%	1477	62.02%
	MT+AG+LM_500+23K	682	65.84%	1560	68.21%
test2016	MT+AG_23K	1039	60.92%	1766	62.63%
	MT+AG+LM_23K	1041	66.09%	1919	65.61%
	MT+AG_500+23K	1269	63.04%	2728	63.71%
	MT+AG+LM_500+23K	1251	63.87%	2814	63.50%
test2017	MT+AG_23K	897	55.85%	1535	57.79%
	MT+AG+LM_23K	952	61.24%	1853	60.44%
	MT+AG_500+23K	1182	54.99%	2599	55.71%
	MT+AG+LM_500+23K	1180	56.78%	2653	59.67%

Table 2: Sentence precision and action precision of models trained on 23K and 500K+23K dataset.

Interestingly, training MT+AG and MT+AG+LM models on 23K data lead to better TER/BLEU than those trained on 500K+12K. This implies the importance of in-domain training data, as the synthetic corpus is created using general domain *Common-Crawl* corpus.

4.2 Analysis

We perform fine-grained analysis of the changes made by our model vs MT+AG in order to understand the sources of improvements. For different data conditions, Table 2 shows the number of modified sentences by each model as well as the sentence level precision defined as the fraction of sentences with improved TER. Moreover, it reports the total number of actions generated by the model on sentences with improved TER, as well as the precision of such actions, i.e. the fraction of those observed in the ground truth action trajecto-

---

[5] The MT, AG, and LM components share the target word embedding table in our model. Similarly, MT and AG components share the target embedding in the MT+AG model.

ries.

As reported in Berard et al. (2017), one major challenge of predicting action sequences is the class imbalance. The model is often too conservative about its edits, and tends to use the KEEP far more than the INSERT and DELETE actions. Our Programmer-Interpreter model tackles this problem, as evidenced by its comparable number of modified sentences, but with higher sentence and action level precision in almost all cases.

5 Conclusion

In this paper, we have presented a neural programmer-interpreter approach to automated post-editing of MT output. Our approach interleaves generating the sequence of edit actions by a programmer component, and executing those actions with an interpreter component. This leads to better capturing the history of the past generated actions when generating the next action. Our approach achieves up to +1 BLEU and -.7 TER improvement compared to a variant in which programming is not interleaved with execution. Future work includes inducing macro-actions composed of simpler building block actions.

Breaking the Beam Search Curse: A Study of (Re-)Scoring Methods and Stopping Criteria for Neural Machine Translation

Abstract

Beam search is widely used in neural machine translation, and usually improves translation quality compared to greedy search. It has been widely observed that, however, beam sizes larger than 5 hurt translation quality. We explain why this happens, and propose several methods to address this problem. Furthermore, we discuss the optimal stopping criteria for these methods. Results show that our hyperparameter-free methods outperform the widely-used hyperparameter-free heuristic of length normalization by +2.0 BLEU, and achieve the best results among all methods on Chinese-to-English translation.

1 Introduction

In recent years, neural machine translation (NMT) has surpassed traditional phrase-based or syntax-based machine translation, becoming the new state of the art in MT (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2014). While NMT training is typically done in a "local" fashion which does not employ any search (bar notable exceptions such as Ranzato et al. (2016), Shen et al. (2016), and Wiseman and Rush (2016)), the decoding phase of all NMT systems universally adopts beam search, a widely used heuristic, to improve translation quality.

Unlike phrase-based MT systems which enjoy the benefits of very large beam sizes (in the order of 100–500) (Koehn et al., 2007) , most NMT systems choose tiny beam sizes up to 5; for example, Google's GNMT (Wu et al., 2016) and Facebook's ConvS2S (Gehring et al., 2017) use beam sizes 3 and 5, respectively. Intuitively, the larger the beam size is, the more candidates it explores, and the better the translation quality should be. While this definitely holds for phrase-based MT systems, surprisingly, it is *not* the case for NMT: many researchers observe that translation quality degrades with beam sizes beyond 5 or 10 (Tu et al., 2017; Koehn and Knowles, 2017). We call this phenomenon the *"beam search curse"*, which is listed as one of the six biggest challenges for NMT (Koehn and Knowles, 2017).

However, there has not been enough attention on this problem. Huang et al. (2017) hint that length ratio is the problem, but do not explain why larger beam sizes cause shorter lengths and worse BLEU. Ott et al. (2018) attribute it to two kinds of "uncertainties" in the training data, namely the *copying* of source sentence and the *non-literal* translations. However, the first problem is only found in European language datasets and the second problem occurs in all datasets but does not seem to bother pre-neural MT systems. Therefore, their explanations are not satisfactory.

On the other hand, previous work adopts several heuristics to address this problem, but with various limitations. For example, RNNSearch (Bahdanau et al., 2014) and ConvS2S use *length normalization*, which (we will show in Sec. 6) seems to somewhat alleviate the problem, but far from being perfect. Meanwhile, He et al. (2016) and Huang et al. (2017) use word-reward, but their *reward* is a hyper-parameter to be tuned on dev set.

Our contributions are as follows:

- We explain why the beam search curse exists, supported by empirical evidence (Sec. 3).
- We review existing rescoring methods, and then propose ours to break the beam search curse (Sec. 4). We show that our hyperparameter-free methods outperfrom the previous hyperparameter-free method (length normalization) by +2.0 BLEU (Sec. 6).
- We also discuss the stopping criteria for our rescoring methods (Sec. 5). Experiments

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3054–3059
Brussels, Belgium, October 31 - November 4, 2018.

show that with optimal stopping alone, the translation quality of the length normalization method improves by +0.9 BLEU.

After we finish our paper, we became aware of a parallel work (Murray and Chiang, 2018) that also reveals the same root cause we found for the beam search curse: the length ratio problem.

2 Preliminaries: NMT and Beam Search

We briefly review the encoder-decoder architecture with attention mechanism (Bahdanau et al., 2014). An RNN encoder takes an input sequence $\mathbf{x} = (x_1, ..., x_m)$, and produces a sequence of hidden states. For each time step, the RNN decoder will predict the probability of next output word given the source sequence and the previously generated prefix. Therefore, when doing greedy search, at time step i, the decoder will choose the word with highest probability as y_i. The decoder will continue generating until it emits `</eos>`. In the end, the generated hypothesis is $\mathbf{y} = (y_1, ..., y_n)$ with $y_n =$ `</eos>`, with model score

$$S(\mathbf{x}, \mathbf{y}) = \textstyle\sum_{i=1}^{|\mathbf{y}|} \log p(y_i \mid \mathbf{x},\, y_{1..\{i-1\}}) \qquad (1)$$

As greedy search only explores a single path, we always use beam search to improve search quality. Let b denote the beam size, then at step i the beam B_i is an *ordered* list of size b:

$$B_0 = [\langle \texttt{<s>},\ p(\texttt{<s>} \mid \mathbf{x})\rangle]$$

$$B_i = \overset{b}{\mathbf{top}}\{\langle \mathbf{y}' \circ y_i,\ s \cdot p(y_i | \mathbf{x}, \mathbf{y})\rangle \mid \langle \mathbf{y}', s\rangle \in B_{i-1}\}$$

In the most naive case, after reaching the maximum length (a hard limit), we get N possible candidate sequences $\{\mathbf{y}_1, ..., \mathbf{y}_N\}$. The *default* strategy chooses the one with highest model score. We will discuss more sophistcated ways of stopping and choosing candidates in later sections.

3 Beam Search Curse

The most popular translation quality metric, BLEU (Papineni et al., 2002), is defined as:

$$\text{BLEU} = bp \cdot \exp(1/4 \textstyle\sum_{n=1}^{4} \log p_n) \qquad (2)$$

$$\text{where } \ bp = \min\{e^{1-1/lr}, 1\} \qquad (3)$$

$$\text{where } \ lr = |\mathbf{y}| / |\mathbf{y}^*| \qquad (4)$$

Here p_n are the n-gram precisions, and $|\mathbf{y}|$ and $|\mathbf{y}^*|$ denote the hypothesis and reference lengths, while bp is the *brevity penalty* (penalizing short translations) and lr is the *length ratio* (Shi et al., 2016; Koehn and Knowles, 2017), respectively.

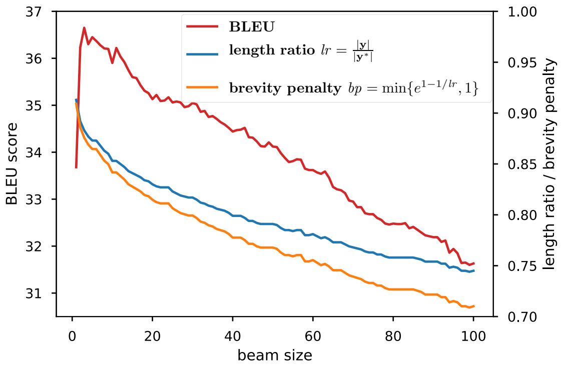

Figure 1: As beam size increases beyond 3, BLEU score on the dev set gradually drops. All terms are calculated by *multi-bleu.pl*.

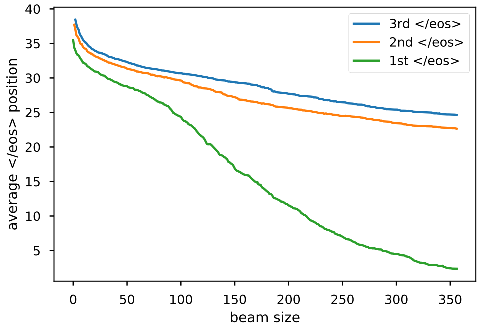

Figure 2: Searching algorithm with larger beams generates `</eos>` earlier. We use the average first, second and third `</eos>` positions on the dev set as an example.

With beam size increasing, $|\mathbf{y}|$ decrases, which causes the length ratio to drop, as shown in Fig. 1. Then the brevity penalty term, as a function of the length ratio, decreases even more severely. Since bp is a key factor in BLEU, this explains why the beam search curse happens.[1]

The reason why $|\mathbf{y}|$ decreases as beam size increases is actually twofold:

1. As beam size increases, the more candidates it could explore. Therefore, it becomes easier for the search algorithm to find the `</eos>` symbol. Fig. 2 shows that the `</eos>` indices decrease steadily with larger beams.[2]

---

[1] The length ratio is *not* just about BLEU: if the hypothesis length is only 75% of reference length, something that should have been translated must be missing; i.e., bad adequacy. Indeed, Murray and Chiang (2018) confirm the same phenomenon with METEOR.

[2] Pre-neural SMT models, being probabilistic, also favor short translations (and derivations), which is addressed by word (and phrase) reward. The crucial difference between SMT and NMT is that the former stops when covering the whole input, while the latter stops on emitting `</eos>`.

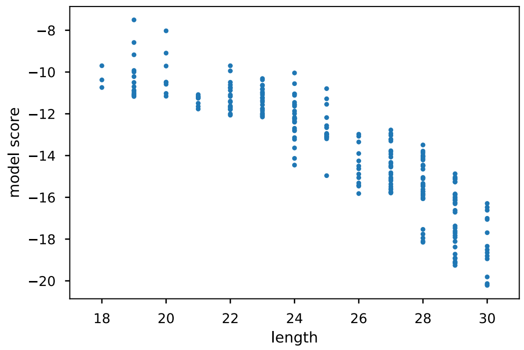

Figure 3: Candidate lengths vs. model score. This scatter plot is generated from 242 finished candidates when translated from one source sequence with beam size 80.

2. Then, as shown in Fig. 3, shorter candidates have clear advantages *w.r.t.* model score.

Hence, as beam size increases, the search algorithm will generate shorter candidates, and then prefer even shorter ones among them.[3]

4 Rescoring Methods

We first review existing methods to counter the length problem and then propose new ones to address their limitations. In particular, we propose to predict the target length from the source sentence, in order to choose a hypothesis with proper length.

4.1 Previous Rescoring Methods

RNNSearch (Bahdanau et al., 2014) first introduces the *length normalization* method, whose score is simply the average model score:

$$\hat{S}_{\text{length\_norm}}(\mathbf{x}, \mathbf{y}) = S(\mathbf{x}, \mathbf{y})/|\mathbf{y}| \qquad (5)$$

This is the most widely used rescoring method since it is hyperparameter-free.

GNMT (Wu et al., 2016) incorporates length and coverage penalty into the length normalization method, while also adding two hyperparameters to adjust their influences. (please check out their paper for exact formulas).

Baidu NMT (He et al., 2016) borrows the *Word Reward* method from pre-neural MT, which gives a reward r to every word generated, where r is a hyperparameter tuned on the dev set:

$$\hat{S}_{\text{WR}}(\mathbf{x}, \mathbf{y}) = S(\mathbf{x}, \mathbf{y}) + r \cdot |\mathbf{y}| \qquad (6)$$

Based on the above, Huang et al. (2017) propose a variant called *Bounded Word-Reward* which only rewards up to an “optimal” length. This length is calculated using a fixed “generation ratio” gr, which is the ratio between target and source sequence length, namely the average number of target words generated for each source word. It gives reward r to each word up to a bounded length $L(\mathbf{x}, \mathbf{y}) = \min\{|\mathbf{y}|, gr \cdot |\mathbf{x}|\}$:

$$\hat{S}_{\text{BWR}}(\mathbf{x}, \mathbf{y}) = S(\mathbf{x}, \mathbf{y}) + r \cdot L(\mathbf{x}, \mathbf{y}) \qquad (7)$$

4.2 Rescoring with Length Prediction

To remove the fixed generation ratio gr from Bounded Word-Reward, we use a 2-layer MLP, which takes the mean of source hidden states as input, to predict the generation ratio $gr^*(\mathbf{x})$. Then we replace the fixed ratio gr with it, and get our predicted length $L_{pred}(\mathbf{x}) = gr^*(\mathbf{x}) \cdot |\mathbf{x}|$.

4.2.1 Bounded Word-Reward

With predicted length, the new predicted bound and final score would be:

$$L^*(\mathbf{x}, \mathbf{y}) = \min\{|\mathbf{y}|, L_{pred}(\mathbf{x})\} \qquad (8)$$

$$\hat{S}_{\text{BWR}^*}(\mathbf{x}, \mathbf{y}) = S(\mathbf{x}, \mathbf{y}) + r \cdot L^*(\mathbf{x}, \mathbf{y}) \qquad (9)$$

While the predicted length is more accurate, there is still a hyperparameter r (word reward), so we design two methods below to remove it.

4.2.2 Bounded Adaptive-Reward

We propose *Bounded Adaptive-Reward* to automatically calculate proper reward based on the current beam. With beam size b, the reward for time step t is the average negative log-probability of the words in the current beam.

$$r_t = -(1/b)\sum_{i=1}^{b} \log p(\text{word}_i) \qquad (10)$$

Its score is very similar to (7):

$$\hat{S}_{\text{AdaR}}(\mathbf{x}, \mathbf{y}) = S(\mathbf{x}, \mathbf{y}) + \sum_{t=1}^{L^*} r_t \qquad (11)$$

4.2.3 BP-Norm

Inspired by the BLEU score definition, we propose *BP-Norm* method as follows:

$$\hat{S}_{bp}(\mathbf{x}, \mathbf{y}) = \log bp + S(\mathbf{x}, \mathbf{y})/|\mathbf{y}| \qquad (12)$$

bp is the same brevity penalty term as in (3). Here, we regard our predicted length as the reference

---

[3] Murray and Chiang (2018) attribute the fact that beam search prefers shorter candidates to the *label bias problem* (Lafferty et al., 2001) due to NMT’s local normalization.

length. The beauty of this method appears when we drop the logarithmic symbol in (12):

$$\begin{aligned}\exp(\hat{S}_{bp}(\mathbf{x},\mathbf{y})) &= bp \cdot \left(\prod_{i=1}^{|\mathbf{y}|} p(y_i|...)\right)^{1/|\mathbf{y}|} \\ &= bp \cdot \exp\left(\frac{1}{|\mathbf{y}|}\sum_{i=1}^{|\mathbf{y}|} \log p(y_i|...)\right)\end{aligned}$$

which is in the same form of BLEU score (3).

5 Stopping Criteria

Besides rescoring methods, the stopping criteria (when to stop beam search) is also important, for both efficiency and accuracy.

5.1 Conventional Stopping Criteria

By default, OpenNMT-py (Klein et al., 2017) stops when the topmost beam candidate stops, because there will not be any future candidates with higher model scores. However, this is not the case for other rescoring methods; e.g., the score of length normalization (5) could still increase.

Another popular stopping criteria, used by RNNSearch (Bahdanau et al., 2014), stops the beam search when exactly b finished candidates have been found. Neither method is optimal.

5.2 Optimal Stopping Criteria

For Bounded Word-Reward, Huang et al. (2017) introduces a provably-optimal stopping criterion that could stop both early and optimally. We also introduce an optimal stopping criterion for BP-Norm. Each time we generate a finished candidate, we update our best score $\hat{S}^\star$. Then, for the topmost beam candidate of time step t, we have:

$$\hat{S}_{bp} = \frac{S_{t,0}}{t} + \min\{1 - \frac{L_{pred}}{t}, 0\} \le \frac{S_{t,0}}{R} \quad (13)$$

where R is the maximum generation length. Since $S_{t,0}$ will drop after time step t, if $\frac{S_{t,0}}{R} \le \hat{S}^\star$, we reach optimality. This stopping criterion could also be applied to length normalization (5).

Meawhile, for Bounded Adaptive-Reward, we can have a similar optimal stopping criterion: If the score of topmost beam candidate at time step $t > L_{pred}$ is lower than $\hat{S}^\star$, we reach optimality.

Proof. The first part of $\hat{S}_{\text{AdaR}}$ in (11) will decrease after time step t, while the second part stays the same when $t > L_{pred}$. So the score in the future will monotonically decrease. ☐

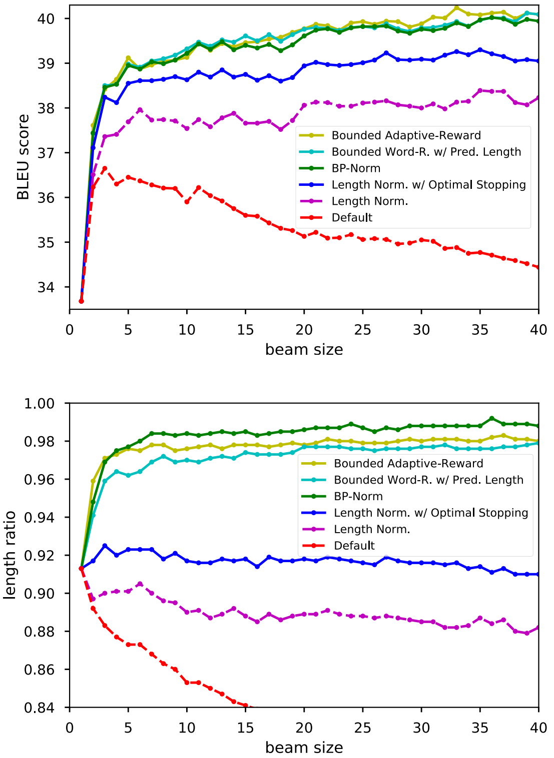

Figure 4: The BLEU scores and length ratios ($lr = |\mathbf{y}|/|\mathbf{y}^*|$) of various rescoring methods.

6 Experiments

Our experiments are on Chinese-to-English translation task, based on the OpenNMT-py codebase.[4] We train our model on 2M sentences, and apply BPE (Sennrich et al., 2015) on both sides, which reduces Chinese and English vocabulary sizes down to 18k and 10k respectively. We then exclude pairs with more than 50 source or target tokens. We validate on NIST 06 and test on NIST 08 (newswire portions only for both). We report case-insensitive, 4 reference BLEU scores.

We use 2-layers bidirectional LSTMs for the encoder. We train the model for 15 epochs, and choose the one with lowest perplexity on the dev set. Batch size is 64; both word embedding and hidden state sizes 500; and dropout 0.3. The total parameter size is 28.5M.

6.1 Parameter Tuning and Results

We compare all rescoring methods mentioned above. For the length normalization method, we also show its results with *optimal stopping*.

For Bounded Word-Reward method with and without our predicted length, we choose the best r on the dev set seperately. The length normal-

Table 1: Average BLEU scores and length ratios over small and large beams. $\star$ indicates our methods.

ization used by Wu et al. (2016) has two hyper-parameters, namely α for length penalty and β for coverage penalty. We jointly tune them on the dev set, and choose the best config. (α=0.3, β=0.3).

Figure 4 show our results on the dev set. We see that our proposed methods get the best performance on the dev set, and continue growing as beam size increases. We also observe that optimal stopping boosts the performance of length normalization method by around +0.9 BLEU. In our experiments, we regard our predicted length as the *maximum generation length* in (13). We further observe from Fig. 5 that our methods keep the length ratio close to 1, and greatly improve the quality on longer input sentences, which are notoriously hard for NMT (Shen et al., 2016).

Table 1 collects our results on both dev and test sets. Without loss of generality, we show results with both small and large beam sizes, which average over b=14,15,16 and b=39,40,41, respectively.

6.2 Discussion

From Table 1, we could observe that with our length prediction model, Bounded word-reward method gains consistent improvement. On the other hand, results from length normalization method show that optimal stopping technique gains significant improvement by around +0.9 BLEU. While with both, our proposed methods beat all previous methods, and gain improvement over hyperparameter-free baseline (i.e. length normalization) by +2.0 BLEU.

Among our proposed methods, Bounded word-reward has the reward r as an hyper-parameter, while the other two methods get rid of that. Among them, we recommend the BP-Norm method, because it is the simplest method, and yet works equally well with others.

7 Conclusions

We first explain why the beam search curse exists and then formalize all previous rescoring methods. Beyond that, we also propose several new methods to address this problem. Results from the Chinese-English task show that our hyperparameter-free methods beat the hyperparameter-free baseline (length normalization) by +2.0 BLEU.

Multi-Multi-View Learning:
Multilingual and Multi-Representation Entity Typing

Abstract

Knowledge bases (KBs) are paramount in NLP. We employ *multiview learning* for increasing accuracy and coverage of entity type information in KBs. We rely on two *metaviews*: language and representation. For language, we consider high-resource and low-resource languages from Wikipedia. For representation, we consider representations based on the context distribution of the entity (i.e., on its embedding), on the entity's name (i.e., on its surface form) and on its description in Wikipedia. The two metaviews language and representation can be freely combined: each pair of language and representation (e.g., German embedding, English description, Spanish name) is a distinct view. Our experiments on entity typing with fine-grained classes demonstrate the effectiveness of multiview learning. We release MVET, a large multiview – and, in particular, multilingual – entity typing dataset we created. Mono- and multilingual fine-grained entity typing systems can be evaluated on this dataset.

1 Introduction

Accurate and complete knowledge bases (KBs) are paramount in NLP. Entity typing, and in particular fine-grained entity typing, is an important component of KB completion with applications in NLP and knowledge engineering. Studies so far have been mostly for English (Yaghoobzadeh and Schütze, 2015), but also for Japanese (Suzuki et al., 2016).

We employ *multiview learning* for increasing accuracy and coverage of entity type information in KBs. We rely on two *metaviews*: language and representation. For language, we take high- and low-resource languages from Wikipedia. For representation, we consider representations based on the context distribution of the entity (i.e., on its embedding), on the entity's name (i.e., on its surface form) and on its description in Wikipedia. The two metaviews language and representation can be freely combined: each pair of language and representation (e.g., German embedding, English description, Spanish name) is a distinct view.

Views are defined as kinds of information about an instance that have three properties (Blum and Mitchell, 1998; Xu et al., 2013). (i) Sufficiency. Each view is sufficient for classification on its own. (ii) Compatibility. The target functions in all views predict the same labels for cooccurring features with high probability. (iii) Conditional independence. The views are conditionally independent given the class label.

As in most cases of multiview learning, these three properties are only approximately true for our problem. (i) Not every view is sufficient for every instance. While a name like "George Washington Bridge" is sufficient for typing the entity as "bridge", the name "Washington" is not sufficient for entity typing. (ii) Cases of incompatibility exist. For example, the "Bering Land Bridge" is not a bridge. (iii) Views have some degree of conditional dependence. For example, if a bridge is a viaduct, not a bridge proper, then the description of the bridge will contain more occurrences of the word "viaduct" than for proper bridges whose name does not contain the word "viaduct".

In summary, we make three main contributions. (i) We formalize entity typing as a multiview problem by introducing two metaviews, language and representation; each combination of instances of these two metaviews defines a distinct view. (ii) We show that this formalization is effective for entity typing as a key task in KB completion: multiview and crossview learning outperform single-view learning by a large margin, especially for rare entities and low-resource languages. (iii) We release MVET (Multiview Entity Typing), a large

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3060–3066
Brussels, Belgium, October 31 - November 4, 2018.

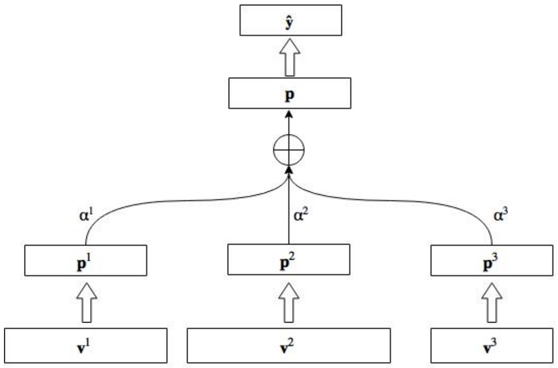

Figure 1: Attention-based multiview learning. View specific representations $\mathbf{v}^j$ of the entity are transformed to a shared space and summed by attention weights α^j into aggregated multiview representation $\mathbf{p}$. A one-hidden-layer perceptron computes output vector $\hat{\mathbf{y}}$.

multiview and, in particular, multilingual dataset, for entity typing[1]. This dataset can be used for mono- and multilingual fine-grained entity typing evaluations. In contrast to prior work on entity typing based on Clueweb (a commercial corpus), all our data can be released publicly because it is based on Wikipedia.

2 Multilingual Multi-Representation Entity Typing

We address the task of entity typing (Yaghoobzadeh and Schütze, 2015), i.e., assigning to a given entity one or more types from a set of types T. E.g., Churchill is a politician and writer.

Our key idea is that we can tap two different information sources for entity typing, which we will refer to as *metaviews*: language and representation. For the language metaview, we consider N languages (English, German, . . .). For the representation metaview, we consider three representations: based on the entity's context distribution, based on its canonical name and based on its description. Each combination of language and representation defines a separate view of the entity, i.e., we have up to $3N$ views. The views are not completely independent of each other: what is written about an entity in English and German is correlated and information derived from the entity name is correlated with its description; see discussion in §1. Still, each view contains information complementary to each other view.

For the *context view* of the representation metaview, we use entity embeddings (Yaghoobzadeh and Schütze, 2015): each mention of an entity in Wikipedia – identified using Wikipedia hyperlinks – is replaced by the entity's unique identifier. We can then run standard embedding learning. For the *name view*, we take the sum of the embeddings of the words of the entity name. The *description view* is based on the entity's Wikipedia page; see §3.

We represent view j of an entity e as the vector or embedding $\mathbf{v}^j \in \mathbb{R}^{d_j}$. We combine these embeddings into a multiview representation $\mathbf{p} \in \mathbb{R}^d$ of entity e. As discussed above, each $\mathbf{v}^j$ contributes potentially complementary information.

After learning $\mathbf{p}$, a one-hidden-layer perceptron computes the type predictions $\hat{\mathbf{y}} \in \mathbb{R}^{|T|}$:

$$\hat{\mathbf{y}} = \sigma\Big(\mathbf{W}_o f\big(\mathbf{W}_h \mathbf{p}\big)\Big) \qquad (1)$$

f is leaky rectifier, $\mathbf{W}_h \in \mathbb{R}^{h \times d}$, $\mathbf{W}_o \in \mathbb{R}^{|T| \times h}$.

The cost function is binary cross entropy summed over types and training examples:

$$\sum_{i,t} (\mathbf{y}_{i,t} \log(\hat{\mathbf{y}}_{i,t}) + (1{-}\mathbf{y}_{i,t})(\log(1{-}\hat{\mathbf{y}}_{i,t}))) \qquad (2)$$

where $\mathbf{y}_{i,t}$ and $\hat{\mathbf{y}}_{i,t}$ are the gold and prediction for type t of example i.

A simple and effective way of computing the representation $\mathbf{p}$ of an entity is what we refer to as **MULTIVIEW-CON**: a concatenation of the n view embeddings, followed by a non-linear transformation:

$$\mathbf{p} = \tanh(\mathbf{W}_1[\mathbf{v}^1; \mathbf{v}^2; ...; \mathbf{v}^n]^\intercal)$$

where $\mathbf{W}_1 \in \mathbb{R}^{d \times (\Sigma_{j=1}^{n} d_j)}$ is the transformation matrix.

Concatenation may not be effective because some entities have pages in all Wikipedias and thus have $200 \times 3 = 600$ views whereas others occur only in one. Also, the views might have different qualities. Therefore, we consider attention-based weighted average or **MULTIVIEW-ATT** as an alternative to MULTIVIEW-CON. Embeddings $\mathbf{v}^j$ live in different spaces, so we first transform them using language specific matrices $\mathbf{W}^j \in \mathbb{R}^{d \times d_j}$:

$$\mathbf{p}^j = \tanh(\mathbf{W}^j \mathbf{v}^j) \qquad (3)$$

Then, we compute the attention weights:

$$\alpha^j = \mathrm{softmax}(\mathbf{a}^T \mathbf{p}^j)$$

---

[1] Our dataset and code are available at: `http://github.com/yyaghoobzadeh/MVET`

where $\mathbf{a} \in \mathbb{R}^d$ is a vector that is trained to weight the vectors $\mathbf{p}^j$. The **MULTIVIEW-ATT** representation is then defined as:

$$\mathbf{p} = \sum_j \alpha^j \mathbf{p}^j$$

A schematic architecture is shown in Figure 1.

We also experiment with two alternatives. **MULTIVIEW-AVG**: We set all $\alpha^j = 1/n$, i.e., the entity representation is a simple average. **MULTIVIEW-MAX**: We apply per-dimension maxpooling, $\mathbf{p}_i = \max_j \mathbf{p}_i^j$. The idea here is to capture the most significant features across views.

3 Dataset and Experiments

In this section, we first introduce our new dataset and then describe our results.

Multiview entity typing (MVET) dataset. Wikipedia and Freebase are our sources for creation of MVET. We try to map each English Wikipedia article of an entity to Freebase. Freebase types are mapped to 113 FIGER tags (Ling and Weld, 2012). We use Wikipedia interlingual links to build multilingual datasets by identifying corresponding Wikipedia articles in non-English languages. So for each entity, we have the English article name as well as the names in other languages (if they exist) and FIGER types of the entity. We use these multilingual names and Wikipedias to build our representation views as described in §3.

We experiment with ten languages: English (EN), German (DE), Farsi (FA), Spanish (ES); and Arabic (AR), French (FR), Italian (IT). Polish (PL), Portuguese (PT), Russian (RU). The procedure described above gives us around 2M entities. We divide them into train (50%), dev (20%) and test (30%) and, for efficient training, sample them stratified by type to ensure enough entities per type. The final dataset used in our experiments contains about 74k / 35k / 50k train / dev / test entities and 102 FIGER types. Dev is used to optimize model hyperparameters. Appendix A gives some more statistics for MVET.

Learning representation views. We refer to the three instances of the representation metaview (see §1) as **CTXT** (contexts), **NAME** (name) and **DESC** (description).

For learning CTXT embeddings, we train WANG2VEC (Ling et al., 2015) on Wikipedia after having replaced hyperlinked mentions of an entity with its ID. NAME is derived from publicly available 300-dimensional fastText (Bojanowski et al., 2017) embeddings. We use the average of the words in a name as its NAME embedding[2]. If a word does not have a fastText embedding, we apply the fastText model to compute it. So there are no unknown words in our dataset. For DESC, we extract the keywords (using tf-idf) of the first paragraph of the Wikipedia article of an entity. The DESC embedding is the average fastText embedding of the keywords.

To reiterate the complementarity of the three representation views: names are ambiguous, but if we use the names of an entity in different languages, we can mitigate this ambiguity. E.g., “Apple” can refer to an entity or a fruit in English, but only to an entity in French. Similarly, the description of an entity is a high quality textual source to extract information from. The simplest case of complementarity is that not all views are available. An entity can be completely missing from one of the languages; it may not have a description because only a stub is provided; etc.

3.1 Results

Evaluation metric. Following prior work in entity typing (Yaghoobzadeh and Schütze, 2017), we evaluate by micro F_1, a global summary score of all system predictions. Entity frequency is an important variable, so we report results for tail (frequency <10, n=35,533), head (frequency >100, n=2,638) and all entities.

Table 1 shows results for entity typing on our dataset, MVET. We start with FIGMENT (Yaghoobzadeh and Schütze, 2017) baseline results on MVET dataset (line 0), which is the state-of-the-art system in entity typing. FIGMENT is equivalent to our MULTIVIEW-CON model with only English-CTXT, -NAME and -DESC representations.

Lines 1–4, 9–12, 17–20 are singleview results, e.g., F_1 for tail is 62.0 for the English-CTXT view. Lines 5–8, 13–16, 21–24 combine the four languages; so these are multiview results for the language metaview. All four multiview models are better than the corresponding singleview models in the same block. Lines 25–28 show results for the combination of the two metaviews; a total of

---

[2] Some of the Wikipedia titles contain a category inside parentheses, e.g.., “Washington (state)”. We remove these parentheses and their content from the titles, if they exist, and then use the titles as our names.

twelve views are combined (four languages times three representations). The multi-multi-view models on lines 25–28 outperform all other results. Comparing line 25 and FIGMENT (line 0), adding representations from three more languages result in .5%, .4%, .9% improvements for all, tail and head entities. Line 26 by using ATT improves the results further especially for the tail entities. These results confirm the effectiveness of our contributions: adding language as a metaview, and using ATT instead of CON to combine multiple views.

Lines 29–32 show results for using NAME representations in six additional languages: AR, FR, IT, PL, PT, RU. F_1 is up to more than one percent better than on lines 13–16. This demonstrates the benefit of using more languages – although the effect is limited since only the long tail of entities can improve.

Lines 33–36 vs. lines 25–28 make the same comparison (NAME4 vs. NAME10) for multi-multi-view. By ATT, we get a small improvement for tail, but not for head (line 34 vs. line 26). Apparently, there is noise added by considering more languages and this hurts the results for head entities.

A general tendency is that ATT performs better compared to MAX, AVG and CON as the number of views increases (lines 30 and 34) and so the average number of views without information (i.e., missing views) for an entity increases. In contrast to MAX, ATT can combine different views. In contrast to CON and AVG, ATT can ignore some of them based on low attention weights.

3.2 Analysis: Crossview Learning

To analyze whether sharing parameters across views is important, Table 2 compares (i) SINGLE: twelve different singleview models with (ii) CROSS: a single crossview model that is trained on a training set that combines the twelve individual singleview training sets. For CROSS, we use Eq. 3 with view specific transformation matrices, mapping views in different spaces into a common space, and then Eq. 1 with shared parameters across views. The number of parameters in application is the same for SINGLE and CROSS.

Table 2 shows consistent and clear improvements of CROSS compared to SINGLE, except for English CTXT and NAME. The English Wikipedia is much larger than the others, so that embeddings based on it have high quality. But our results demonstrate that training one model with common parameters over all inputs is helping the classification for non high-resource views.

Table 1: Micro F_1 for entity typing. NAME4/NAME10 = name embeddings from 4 or 10 languages.

Multiview learning exploits the complementarity of views: if an entity's type cannot be inferred from one view, then other views may have the required information. Table 2 shows that using multiple views has a second beneficial effect: even if applied to a single view, a model trained on multiple views performs better. Kan et al. (2016)'s image recognition and Pappas and Popescu-Belis (2017)'s document classification findings are similar. Thus, not only does the increased amount of available information boost performance in the multiview setup, but also we can enable crossview transfer and learn a model that makes better predictions even if information is only available from a single view.

4 Related Work

Entity and mention typing. In this work, we assume that a predefined set of fine-grained types is given. Entity typing, i.e., predicting types of a knowledge base entity (Neelakantan and Chang, 2015; Yaghoobzadeh and Schütze, 2015), is the focus of this paper. Mention typing, i.e., predicting types of a mention in a particular context (Ling and Weld, 2012; Rabinovich and Klein, 2017; Shimaoka et al., 2017; Murty et al., 2018), is a related task. Mention typing models can be evaluated for entity typing when aggregating their predictions (Yaghoobzadeh and Schütze, 2015; Yaghoobzadeh et al., 2017, 2018). Therefore, our public and large entity typing dataset, MVET, can be used as an alternative to the small manually annotated mention typing datasets like the commonly used FIGER (Ling and Weld, 2012). We leave this to the future work.

Multilingual entity typing. We build multilingual dataset and models for entity typing. Most work on entity typing has been monolingual; e.g., Yaghoobzadeh and Schütze (2015) (English); and Suzuki et al. (2016) (Japanese). There is work on mention typing (van Erp and Vossen, 2017). Lin et al. (2017) that uses mono- and crosslingual attention for relation extraction. Crosslingual entity linking is an important related task, where the task is to link mentions of entities in multilingual text to a knowledge base (Tsai and Roth, 2016). Many entities are not sufficiently annotated in Wikipedia, and therefore crosslingual entity linking is necessary to learn informative context representations from multiple languages.

Multi-representation of entities. Aggregating information from multiple sources to learn entity representations has been explored for entity typing (Yaghoobzadeh and Schütze, 2017; Yaghoobzadeh et al., 2018), entity linking (Gupta et al., 2017) and relation extraction (Wang and Li, 2016). Here, we add language as a new "dimension" to multi-representations: each language contributes a different CTXT, NAME and DESC representation.

Our multilingual and multi-representation models are examples of **multiview learning**. Xu et al. (2013) and Zhao et al. (2017) review the literature on multiview learning. Amini et al. (2009) cast multilingual text classification, a task related to entity typing, as multiview learning. Qu et al. (2017) address node classification and link prediction by attention-based multiview representations of graph nodes. We also adopt a similar approach in our multiview representations for entity typing.

5 Conclusion

We formalized entity typing as a multiview problem by introducing two metaviews, language and representation; each combination of their instances defines a distinct view. Our experiments showed the effectivess of this formalization by outperforming the state-of-the-art model. Our basic idea of metaview learning is general and is applicable to related tasks, e.g., to relation extraction. We release a large and public multiview and, in particular, multilingual, entity typing dataset.

Word Embeddings for Code-Mixed Language Processing

Adithya Pratapa, Monojit Choudhury, Sunayana Sitaram
Microsoft Research, India
{t-pradi,monojitc,sunayana.sitaram}@microsoft.com

Abstract

We compare three existing bilingual word embedding approaches, and a novel approach of training skip-grams on synthetic code-mixed text generated through linguistic models of code-mixing, on two tasks - sentiment analysis and POS tagging for code-mixed text. Our results show that while CVM and CCA based embeddings perform as well as the proposed embedding technique on semantic and syntactic tasks respectively, the proposed approach provides the best performance for both tasks overall. Thus, this study demonstrates that existing bilingual embedding techniques are not ideal for code-mixed text processing and there is a need for learning multilingual word embedding from the code-mixed text.

1 Introduction

Word embeddings are useful for a variety of NLP tasks, as they allow to generalize the system on much larger corpora than the annotated dataset for the task. In recent times, there has been some interest in bilingual word embeddings, where words from two languages are embedded into the same space. The primary advantage of bilingual embeddings is in solving tasks involving reasoning across two languages, such as Machine Translation (Zou et al., 2013; Gouws et al., 2015; Vulić and Moens, 2016) and cross-lingual IR (Vulić and Moens, 2015), as well as allowing transfer of models learnt on a resource-rich language on to a resource poor language (Adams et al., 2017; Fang and Cohn, 2017). One of the potential, yet unexplored, applications of bilingual word embeddings is in the processing of code-mixed language.

Code-mixing (CM) refers to fluid alternation between two or more languages in a single conversation/sentence (Myers-Scotton, 1993). CM is a common phenomenon observed in almost all multilingual societies (Parshad et al., 2016; Rijhwani et al., 2017). Consequently, in recent times, processing of CM text and speech has been receiving a growing amount of interest and attention from the NLP community (Solorio and Liu, 2008; Li and Fung, 2014; Solorio et al., 2014; Sharma et al., 2016; Rudra et al., 2016). Since CM text draws words and linguistic structures from multiple languages, use of bilingual word embeddings for processing of such text could not only be useful, but also necessary. On the other hand, while there is some work that uses embeddings for CM text (Prabhu et al., 2016) (at sub-word level), we do not know of any study that systematically explores the usefulness of bilingual word embedding techniques in CM text processing.

Further, we argue that since all the standard bilingual word embedding techniques are designed to work on or across monolingual texts rather than on a mixture of the two languages, these techniques may not be ideal for learning embeddings for CM tasks. There are emergent syntactic structures and cross-lingual semantic associations in CM text, that do not exist in the individual monolingual corpora (Sec 3). Hence, ideally, word embeddings for CM tasks should be trained on real CM data.

In this paper, we compare three popular bilingual word embedding techniques (Sec 2): Bilingual correlation based embeddings (BiCCA) (Faruqui and Dyer, 2014), Bilingual compositional model (BiCVM) (Hermann and Blunsom, 2014) and Bilingual Skip-gram (BiSkip) (Luong et al., 2015) on two tasks for CM text - sentiment analysis, a semantic task, and POS tagging, a syntactic task. On the same tasks, we also compare word embeddings learnt from synthetic CM data (generated using linguistic models as proposed in a recent work (Pratapa et al., 2018)) (Sec 3). Note that Wick et al. (2016) use artificial code mixed data to learn

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3067–3072
Brussels, Belgium, October 31 - November 4, 2018.

multilingual embeddings for cross-lingual tasks, but their aim is to generate bilingual embeddings for monolingual or cross-lingual tasks.

Our study shows that even though in certain NLP tasks specific embeddings might perform well, in general bilingual embedding techniques like BiCCA, BiCVM and BiSkip are not ideal for processing CM language. Embeddings learnt from CM data, even if artificially generated, performs consistently better across tasks. Our initial results are promising and provide several interesting directions for further exploration.

2 Bilingual Embeddings

In the past few years, there has been a growing interest in learning bilingual embeddings (Upadhyay et al., 2016; Ruder et al., 2017) with a focus on cross-lingual transfer, which helps in building NLP models for low-resource languages. Upadhyay et al. (2016) provide an empirical comparison of four cross-lingual word embedding models varying in terms of the amount of supervision. Ruder et al. (2017) establishes the similarities among numerous cross-lingual word embedding models and shows that many models optimize for similar objectives. Along similar lines as Upadhyay et al. (2016), in this work, we chose the following three representative bilingual word embedding models for CM tasks. Training data is described later in Section 4.

2.1 Bilingual Correlation Based Embeddings (BiCCA)

Faruqui and Dyer (2014) proposed CCA based bilingual embeddings, where bilingual evidence is incorporated into word representations by performing canonical correlation analysis (CCA) on monolingual embeddings using a bilingual dictionary. The monolingual embedding matrices W_{L_1} and W_{L_2} can be of different dimensions and words with their translations from the dictionary are used to obtain matrices W'_{L_1} and W'_{L_2}. Using CCA, the individual projection matrices are computed, which are then utilized to project the embeddings into the same embedding space.

BiCCA embeddings were shown to perform well on syntactic tasks like cross lingual dependency parsing, but performed relatively poorly on cross lingual semantic tasks (Upadhyay et al., 2016). We learn the monolingual embeddings by training a skip-gram model (Mikolov et al., 2013) for 5 iterations with a window size of 5 and 10 negative samples. We built a bilingual dictionary of approximately 38k pairs by using word alignments. The dictionary contains word pairs (w_1, w_2), such that w_2 is aligned to w_1 the highest number of times and vice-versa. We use the `crosslingual-cca`[1] toolkit. To remain consistent with other embedding models, we choose the top (k=) 200 correlated dimensions.

2.2 Bilingual Compositional Model (BiCVM)

This approach, proposed by Hermann and Blunsom (2014), is based on the assumption that parallel sentences from different languages have equivalent meanings and thus should have similar sentence representations. Along with monolingual regularizers, the model optimizes for the aligned sentences to be closer to each other than randomly chosen negative samples, using a noise-contrastive update.

BiCVM is found to perform well on monolingual word similarity (SimLex-999, Upadhyay et al. (2016)) and is comparable to BiSkip on semantic tasks like cross-lingual document classification. We use the `bicvm`[2] toolkit to generate embeddings using the parallel English-Spanish data. We train an additive model for 100 iterations, with a hinge loss margin of 200, noise parameter of 10 and batch size of 50.

2.3 Bilingual Skip-gram Model (BiSkip)

The Skip-gram model proposed by Mikolov et al. (2013) has been adapted to the bilingual setting in Luong et al. (2015), where the model learns to predict word contexts cross-lingually. Along with the monolingual skip-gram with negative sampling objectives, BiSkip includes two more objectives L_{12} and L_{21} when predicting cross-lingually from L_1 to L_2 and vice-versa.

It has the best performance compared to the other embedding techniques on semantic tasks like cross-lingual dictionary induction and cross-lingual document classification. We use parallel sentences and word level alignments to train the `biskip`[3] model. We train the model using the toolkit for 5 iterations with 10 negative samples, high frequency threshold of 0.001, window size of 5 and cross-lingual weight as 1.

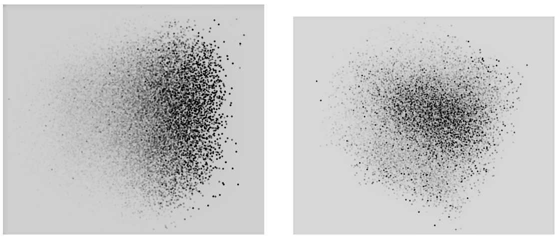
3 Synthetic CM data (gCM) based Embeddings

The aforementioned embedding techniques, owing to their ability to project the words of the two languages into a single space, are expected to be helpful in processing of CM text. However, we believe that CM text is distinct in its syntactic, semantic and statistical properties from the corresponding monolingual texts. For example, there has been a lot of work on understanding and establishing the grammatical constraints of CM (Joshi, 1985; Poplack, 1980; DiSciullo et al., 1986) and these syntactic constraints might introduce interesting collocations in the word space, such as that between English verbs and the Hindi verb "kar" (to do) in English-Hindi CM (Kachru, 1978).

In a recent work (Pratapa et al., 2018), we presented a methodology to generate linguistic theory based synthetic CM data (gCM) and showed its effectiveness in CM language modeling. Synthetic CM data was generated by employing Equivalence Constraint (EC) theory (Poplack, 1980; Sankoff, 1998). The generation model builds a lattice of grammatically valid CM sentences by imposing the EC theory constraints while utilizing monolingual parallel data, word-level alignments and the parse of English sentences. The Spanish parse is formed by projecting the English parse onto the Spanish sentence. For each monolingual pair of input sentences, a large number (generally exponential in terms of average input sentence length) of CM sentences were generated. We observed a non-uniform scaling of low and high frequency words and proposed two sampling techniques to overcome this frequency bias.

In the current work, we use this generation model (as proposed in (Pratapa et al., 2018)) to create training data for learning CM word embeddings. In fact, we also noticed the frequency bias in the word embedding space (Figure 1a). We adapt the two sampling strategies from the original paper, 1. Random sampling (χ-***gCM***), for every monolingual pair, sample random k CM sentences and, 2. SPF-based sampling (ρ-***gCM***), sample k CM sentences for each monolingual pair such that they have SPF (switch point fraction, i.e fraction of word boundaries where the language changes) distribution similar to real CM data (Pratapa et al., 2018). We were able to alleviate the frequency bias using the SPF-based sampling (Figure 1b).



(a) (b)

Figure 1: (a) PCA projections of skip-gram (with negative sampling) embeddings trained on entire gCM corpus, (b) ρ-sampled gCM. The color gradient (light → dark) is based on the frequency of word (low → high) in gCM corpus.

4 Evaluation

Data: Though CM is a common phenomenon, there is a scarcity of real code-mixed data in textual form. Hence, we learn CM embeddings from the English-Spanish parallel corpora (for BiCCA, BiCVM and BiSkip models) and the synthetic CM data obtained from Pratapa et al. (2018). This constitutes to approximately 4.5M parallel sentences and also bilingual supervision in the form of word and sentence alignments. The synthetic data creation procedure is described in the original paper. Both the sampling techniques, with k=2 result in a gCM corpus of approx. 8M sentences. We also combine monolingual data with these gCM corpus resulting in approx. 17M sentences. We train a skip-gram model for 10 iterations, with a window size of 5 and 5 negative samples, resulting in χ-***gCM-Skip*** and ρ-***gCM-Skip*** embeddings.

To quantitatively compare the embedding models, we chose two CM tasks, one semantic (Sentiment Analysis) and one syntactic task (POS tagging). Our choice of tasks is primarily motivated by the availability of annotated CM data. There has been prior work on CM sentiment identification (Vilares and Alonso, 2016; Joshi et al., 2016; Rudra et al., 2016; Prabhu et al., 2016) and POS tagging (Solorio and Liu, 2008; Vyas et al., 2014; AlGhamdi et al., 2016; Ghosh et al., 2016). But we are not aware of any work that utilizes pre-trained bilingual embeddings for these tasks.

4.1 Sentiment Analysis

Vilares and Alonso (2016) provide 2103 sentiment annotated CM tweets. The data contains 650 positive, 529 negative and 924 neutral tweets and we split the data in 8:1:1 ratio (train:validation:test)

Embedding	**Sentiment**			**POS**	
	CM Overall	SemEval 2014	TASS 2016	CM Overall	at SP
None	54.4 (1.3)	64.5 (0.6)	61.4 (1.0)	84.5 (0.3)	74.0 (0.7)
BiCCA	57.6 (3.0)	64.6 (1.0)	59.5 (1.8)	**84.7** (0.8)	**75.0** (1.8)
BiCVM	**64.3** (1.3)	66.8 (1.0))	61.9 (1.0)	82.0 (0.5)	70.6 (1.7)
BiSkip	61.5 (1.7)	66.6 (0.9)	**63.9** (1.2)	84.4 (0.7)	73.8 (0.9)
χ-gCM-Skip	62.0 (1.9)	**67.4** (1.3)	63.2 (1.5)	**84.8** (0.6)	74.0 (0.6)
ρ-gCM-Skip	**64.6** (2.0)	**67.7** (1.4)	**63.8** (2.2)	**84.9** (0.7)	**75.3** (1.7)

Table 1: The performance of different pre-trained embeddings on Sentiment (F1 score) and POS tasks (Accuracy). The reported values are mean and deviation (in parentheses) values computed over multiple runs.

while ensuring the sentiment distribution remains the same[4].

Model: We train a LSTM based sequence classifier with single hidden layer (dim=50) and dropout of 0.5. We use ADAM optimizer with learning rate of 0.001 and momentum parameter of 0.9. We train the model for a maximum of 10 epochs with a mini-batch size of 100. Our model is built using the Microsoft CNTK framework. We varied the CM sample size (k) (described in 3) over $\{1,2,5,10,20\}$ and found the best performance with k=2. To check the robustness of CM embeddings, we also evaluate them on monolingual English[5] (SemEval 2014 Subtask B, (7177, 1199, 2865)) and Spanish[6] (TASS 2016, (6000, 1220, 1000)) tasks. The numbers in the parenthesis indicate the number of train, validation and test instances.

Results: Table 1 shows the results on Sentiment task. While all embedding models significantly improve over the baseline ('None'), ρ-gCM-Skip and BiCVM perform the best. Instead of linguistically motivated data, we tried with CM data created by random juxtaposition of monolingual fragments and it gave a F1 score of 56.0% and the minimal gain is possibly only because of the monolingual fragments in the embedding training data.

4.2 Part of Speech (POS) Tagging

Of the two corpora utilized in AlGhamdi et al. (2016), we chose Bangor Miami Corpus[7] over Spanglish Corpus (Solorio and Liu, 2008) owing to the larger size of the former corpus. Bangor Miami corpus consists of conversations of Spanish speakers in Florida but also fluent in English. In contrast to AlGhamdi et al. (2016), we only consider the code mixed utterances with significant ($\geq$30%) fraction of English and Spanish. This accounts to 982 sentences and 7705 tokens, split in 8:1:1 ratio.

Model: We use a bidirectional LSTM model with CRF as the output layer (Rei and Yannakoudakis, 2016)[8], with hidden layer dimension of 50 and dropout of 0.5. The model trains for a maximum of 20 epochs and terminates if there is no improvement in validation accuracy for 5 consecutive epochs. We use ADADELTA optimizer with a learning rate of 1.0.

Results: ρ-gCM-Skip, χ-gCM-Skip perform the best on the POS task (see Table. 1). Unlike the sentiment task, BiCCA performs close to the best while BiCVM does the worst. We also report accuracies at switch points (SP), which we believe is challenging for a CM POS tagger. As expected these accuracies are lower, but ρ-gCM-Skip and BiCCA still perform the best.

5 Conclusion

As we expected, pretrained bilingual word embeddings help improve syntactic and semantic CM processing tasks. Similar to (Upadhyay et al., 2016), we also note that BiCVM operating at sentence level performs better only on semantic tasks, while BiCCA does well only on syntactic tasks due to their usage of word alignments. Though ρ-gCM-Skip embeddings learnt from synthetic data

---

performed only marginally better than BiCVM and BiCCA on semantic and syntactic tasks respectively, it is the only embedding model that did consistently well across tasks. Thus, our study shows that standard bilingual embeddings are not well suited, in general, for CM tasks; embeddings learnt from CM data, either real or synthetic, seems much more useful. Further, along the lines of (Pratapa et al., 2018), our study also shows that synthetic CM data is a reasonably good proxy for real data.

While our experiments show a promising direction towards obtaining bilingual embeddings for CM tasks, there are several interesting ideas that are worth exploring. In particular, the linguistic model used for generating artificial CM data only addresses the syntactic constraints of CM, but not other kinds of constraints such as *lexical choice* which in a particular CM context might be overly skewed towards one language (like the English words 'school' and 'vote' are more common than their Hindi translations in English-Hindi CM (Bali et al., 2014)), and semantic/pragmatic constraints that make the choice of a particular language more common in some contexts (e.g., Hindi used more commonly for negative sentiment during English-Hindi CM (Rudra et al., 2016)). Similarly, the sense distribution of polysemous words can vary widely between a monolingual and CM corpus. For instance, the word 'school' in English has several meanings such as (a) an institute of education, (b) group of artists, writers etc., and (c) a large group of fish. However, in a Spanish dominant sentence or corpus, school is primarily, if not only, used in sense (a).

As future work, it will be interesting to explore techniques that can generate artificial CM data following the lexical, semantic and pragmatic constraints, or develop novel embedding techniques that can appropriately interpolate between real and artificial CM data to learn collocations that arise due to not only syntactic but also lexical, semantic and pragmatic aspects of code-mixing.

Acknowledgements

We would like to thank Kalika Bali, Gayatri Bhat and Sandipan Dandapat for their valuable suggestions and help in the creation of the synthetic CM corpus.

On the Strength of Character Language Models for Multilingual Named Entity Recognition

Xiaodong Yu[†], Stephen Mayhew[*], Mark Sammons[†], Dan Roth[*]
[†]University of Illinois, Urbana-Champaign, [*]University of Pennsylvania
`{xyu71,mssammon}@illinois.edu, {mayhew,danroth}@seas.upenn.edu`

Abstract

Character-level patterns have been widely used as features in English Named Entity Recognition (NER) systems. However, to date there has been no direct investigation of the inherent differences between name and non-name tokens in text, nor whether this property holds across multiple languages. This paper analyzes the capabilities of corpus-agnostic Character-level Language Models (CLMs) in the binary task of distinguishing name tokens from non-name tokens. We demonstrate that CLMs provide a simple and powerful model for capturing these differences, identifying named entity tokens in a diverse set of languages at close to the performance of full NER systems. Moreover, by adding very simple CLM-based features we can significantly improve the performance of an off-the-shelf NER system for multiple languages.[1]

1 Introduction

In English, there is strong empirical evidence that the character sequences that make up proper nouns tend to be distinctive. Even divorced of context, a human reader can predict that "hoekstenberger" is an entity, but "abstractually"[2] is not. Some NER research explores the use of character-level features including capitalization, prefixes and suffixes (Cucerzan and Yarowsky, 1999; Ratinov and Roth, 2009), and character-level models (CLMs) (Klein et al., 2003) to improve the performance of NER, but to date there has been no systematic study isolating the utility of CLMs in capturing distinctions between name and non-name tokens in English or across other languages.

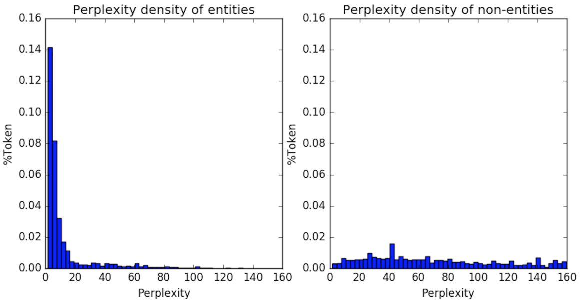

Figure 1: Perplexity histogram of entity (left) and non-entity tokens (right) in CoNLL Train calculated by entity CLM for both sides. The graphs show the percentage of tokens (y axis) with different levels of CLM perplexities (x axis). The entity CLM gives a low average perplexity and small variance to entity tokens (left), while giving non-entity tokens much higher perplexity and higher variance (right).

We conduct an experimental assessment of the discriminative power of CLMs for a range of languages: English, Amharic, Arabic, Bengali, Farsi, Hindi, Somali, and Tagalog. These languages use a variety of scripts and orthographic conventions (for example, only three use capitalization), come from different language families, and vary in their morphological complexity. We demonstrate the effectiveness of CLMs in distinguishing name tokens from non-name tokens, as illustrated by Figure 1, which shows perplexity histograms from a CLM trained on entity tokens. Our models use only individual tokens, but perform extremely well in spite of taking no account of word context.

We then assess the utility of directly adding simple features based on this CLM implementation to an existing NER system, and show that they have a significant positive impact on performance across many of the languages we tried. By adding very simple CLM-based features to the system, our scores approach those of a state-of-the-art NER system (Lample et al., 2016) across multiple languages, demonstrating both the unique importance and the broad utility of this approach.

Table 1: Data statistics for all languages, showing number of entity and non-entity tokens in Train and Test.

2 Methods

2.1 Character Language Models

We propose a very simple model in which we train an entity CLM on a list of entity tokens, and a non-entity CLM on a list of non-entity tokens. Both lists are unordered, with all entries treated independently. Each token is split into characters and treated as a "sentence" where the characters are the "words." For example, "Obama" is an entity token, and is split into "O b a m a". From these examples we learn a score measuring how likely it is that a sequence of characters forms an entity. At test time, we also split each word into characters and determine perplexity using the entity and non-entity CLMs. We assign the label corresponding to the lower perplexity CLM.

We experiment with four different kinds of language model: N-gram model, Skip-gram model, Continuous Bag-of-Words model (CBOW), and Log-Bilinear model (LB). We demonstrate that the N-gram model is best suited for this task.

Following Peng and Roth (2016), we implement N-gram using SRILM (Stolcke, 2002) with order 6 and Witten-Bell discounting.[3] For Skip-Gram and CBOW CLMs, we use the Gensim implementation (Rehurek and Sojka, 2010) for training and inference, and we build the LB CLM using the OxLM toolkit (Baltescu et al., 2014).

2.2 Data

To determine whether name identifiability applies to languages other than English, we conduct experiments on a range of languages for which we had previously gathered resources (such as Brown clusters): English, Amharic, Arabic, Bengali, Farsi, Hindi, Somali, and Tagalog.

For English, we use the original splits from the ubiquitous CoNLL 2003 English dataset (Sang and Meulder, 2003), which is a newswire dataset annotated with Person (PER), Organization (ORG), Location (LOC) and Miscellaneous (MISC). To collect the list of entities and non-entities as the training data for the Entity and Non-Entity CLMs, we sample a large number of PER/ORG/LOC and non-entities from Wikipedia, using types derived from their corresponding FreeBase entities (Ling and Weld, 2012).

For all other languages, we use a subset of the corpora from the LORELEI project annotated for the NER task (Strassel and Tracey, 2016). We build our entity list using the tokens labeled as entities in the training data, and our non-entity list from the remaining tokens. These two lists are then used to train two CLMs, as described above.

Our datasets vary in size of entity and non-entity tokens, as shown in Table 1. The smallest, Farsi, has 4.5K entity and 50K non-entity tokens; the largest, English, has 29K entity and 170K non-entity tokens.

3 CLM for Named Entity Identification

In this section, we first show the power of CLMs for distinguishing between entity and non-entity tokens in English, and then that this power is robust across a variety of languages.

We refer to this task as Named Entity Identification (NEI), because we are concerned only with finding an entity span, not its label. We differentiate it from Named Entity Recognition (NER), in which both span and label are required. To avoid complicating this straightforward approach by requiring a separate mention detection step, we evaluate at the token-level, as opposed to the more common phrase-level evaluation. We also apply one heuristic: if a word has length 1, we automatically predict 'O' (or non-entity). This captures most punctuation and words like 'I' and 'a'.

Figure 1 shows that for the majority of entity tokens, the entity CLM computes a relatively low perplexity compared to non-entity tokens. Though there also exist some non-entities with low entity CLM perplexity, we can still reliably identify a large proportion of non-entity words by setting a threshold value for entity CLM perplexity. If a token perplexity lies above this threshold, we label it as a non-entity token. The threshold is tuned on development data.

---

[3] We experimented with different orders on development data, but found little difference between them.

Model	**eng**	**amh**	**ara**	**ben**	**fas**	**hin**	**som**	**tgl**	avg
Exact Match	43.4	54.4	29.3	47.7	30.5	30.9	46.0	23.7	37.5
Capitalization	79.5	-	-	-	-	-	69.5	77.6	-
SRILM	**92.8**	**69.9**	**54.7**	**79.4**	**60.8**	**63.8**	**84.1**	**80.5**	**70.5**
Skip-gram	76.0	53.0	29.7	41.4	30.8	29.0	51.1	61.5	42.4
CBOW	73.7	50.0	28.1	40.6	32.6	26.5	56.4	62.5	42.4
Log-Bilinear	82.8	64.5	46.1	70.8	50.4	54.8	78.1	74.9	62.8
CogCompNER (ceiling)	96.5	73.8	64.9	80.6	64.1	75.9	89.4	88.6	76.8
Lample et al. (2016) (ceiling)	96.4	84.4	69.8	87.6	76.4	86.3	90.9	91.2	83.8

Table 2: Token level identification F1 scores. Averages are computed over all languages other than English. Two baselines are also compared here: *Capitalization* tags a token in test as entity if it is capitalized; and *Exact Match* keeps track of entities seen in training, tagging tokens in Test that exactly match some entity in Train. The bottom section shows state-of-the-art models which use complex features for names, including contextual information. Languages in order are: English, Amharic, Arabic, Bengali, Farsi, Hindi, Somali, and Tagalog. The rightmost column is the average of all columns excluding English.

Since we also build a CLM for non-entities, we can also compare the entity and non-entity perplexity scores for a token. For those tokens not excluded using the threshold as described above, we compare the perplexity scores of the two models and assign the label corresponding to the model yielding the lower score.

We compare SRILM against Skip-gram and CBOW, as implemented in Gensim, and the Log-Bilinear (LB) model. We trained both CBOW and Skip-gram with window size 3, and size 20. We tuned LB, and report results with embedding size 150, and learning rate 0.1. Despite tuning the neural models, the simple N-gram model outperforms them significantly, perhaps because of the relatively small amount of training data.[4]

We compare the CLM's Entity Identification against two state-of-the-art NER systems: CogCompNER (Khashabi et al., 2018) and LSTM-CRF (Lample et al., 2016). We train the NER systems as usual, but at test time we convert all predictions into binary token-level annotations to get the final score. As Table 2 shows, the result of N-gram CLM, which yields the highest performance, is remarkably close to the result of state-of-the-art NER systems (especially for English) given the simplicity of the model.

4 Improving NER with CLM features

In this section we show that we can augment a standard NER system with simple features based on our entity/non-entity CLMs to improve performance in many languages. Based on their superior performance as reported in Section 3, we use the N-gram CLMs.

4.1 Features

We define three simple features that capture information provided by CLMs and which we expect to be useful for NER.

Entity Feature We define one "isEntity" feature based on the perplexities of the entity and non-entity CLMs. We compare the perplexity calculated by entity CLM and non-entity CLM described in Section 3, and return a boolean value indicating whether the entity CLM score is lower.

Language Features We define two language-related features: "isArabic" and "isRussian". We observe that there are many names in English text that originate from other languages, resulting in very different orthography than native English names. We therefore build two language-based CLMs for Arabic and Russian. We collect a list of Arabic names and a list of Russian names by scraping name-related websites, and train an Arabic CLM and a Russian CLM. For each token, when the perplexity of either the Arabic or the Russian CLM is lower than the perplexity of the Non-Entity CLM, we return True, indicating that this entity is likely to be a name from Arabic/Russian. Otherwise, we return False.

---

[4] We also tried a simple RNN+GRU language model, but found that the results were underwhelming.

Model		eng	amh	ara	ben	fas	hin	som	tgl	avg
Lample et al. (2016)	Full	90.94	**73.2**	57.2	**77.7**	**61.2**	**77.7**	81.3	**83.2**	**73.1**
	Unseen	86.11	51.9	30.2	57.9	41.4	62.2	66.5	72.8	54.7
CogCompNER	Full	90.88	67.5	54.8	74.5	57.8	73.5	82.0	80.9	70.1
	Unseen	84.40	42.7	25.0	51.9	31.5	53.9	67.2	68.3	48.6
CogCompNER+LM	Full	**91.21**	71.3	**59.1**	75.5	59.0	74.2	**82.1**	78.5	71.4
	Unseen	85.20	48.4	32.0	54.0	31.2	55.4	68.0	65.2	50.6

Table 3: NER results on 8 languages show that even a simplistic addition of CLM features to a standard NER model boosts performance. CogCompNER is run with standard features, including Brown clusters; (Lample et al., 2016) is run with default parameters and pre-trained embeddings. *Unseen* refers to performance on named entities in Test that were not seen in the training data. *Full* is performance on all entities in Test. Averages are computed over all languages other than English.

4.2 Experiments

We use CogCompNER (Khashabi et al., 2018) as our baseline NER system because it allows easy integration of new features, and evaluate on the same datasets as before. For English, we add all features described above. For other languages, due to the limited training data, we only use the "isEntity" feature. We compare with the state-of-the-art character-level neural NER system of (Lample et al., 2016), which inherently encodes comparable information to CLMs, as a way to investigate how much of that system's performance can be attributed directly to name-internal structure.

The results in Table 3 show that for six of the eight languages we studied, the baseline NER can be significantly improved by adding simple CLM features; for English and Arabic, it performs better even than the neural NER model of (Lample et al., 2016). For Tagalog, however, adding CLM features actually impairs system performance.

In the same table, the rows marked "unseen" report systems' performance on named entities in Test that were not seen in the training data. This setting more directly assesses the robustness of a system to identify named entities in new data. By this measure, Farsi NER is not improved by name-only CLM features and Tagalog is impaired. Benefits for English, Hindi, and Somali are limited, but are quite significant for Amharic, Arabic, and Bengali.

5 Discussion

Our results demonstrate the power of CLMs for recognizing named entity tokens in a diverse range of languages, and that in many cases they can improve off-the-shelf NER system performance even when integrated in a simplistic way.

However, the results from Section 4.2 show that this is not true for all languages, especially when only considering unseen entities in Test: Tagalog and Farsi do not follow the trend for the other languages we assessed even though CLM performs well for Named Entity Identification.

While the end-to-end model developed by (Lample et al., 2016) clearly includes information comparable to that in the CLM, it requires a fully annotated NER corpus, takes significant time and computational resources to train, and is non-trivial to integrate into a new NER system. The CLM approach captures a very large fraction of the entity/non-entity distinction capacity of full NER systems, and can be rapidly trained using only entity and non-entity token lists – i.e., it is corpus-agnostic. For some languages it can be used directly to improve NER performance; for others (such as Tagalog), the strong NEI performance indicates that while it does not immediately boost performance, it can ultimately be used to improve NER there too.

6 Related Work

Cucerzan and Yarowsky (1999) is one of the earliest works to use character-based features (character tries) for NER. The approach of Klein et al. (2003) was one of the original papers in the CoNLL 2003 NER shared task. Their approach, which ranked in the top 3 for both English and German shared tasks, used character-based features for NER. They do two experiments: one with a character-based HMM, another with using character n-grams as features to a maximum entropy model. The focus on character-level patterns is similar to our work, but without the specific exploration of language models alone.

Using character-based models similar to ours, Smarr and Manning (2002) show that unseen noun phrases can be accurately classified into a small number of categories using only a character-based model independent of context. We tackle a somewhat more challenging task of distinguishing entities from non-entities. Lample et al. (2016) use character embeddings in an LSTM-CRF model. Their ablation studies show that character-level features improve performance significantly.

We are not aware of any work that directly evaluates CLMs for identifying name tokens, nor of work that demonstrates the utility of character-level information for identifying names in multiple languages.

7 Conclusions and Future Work

We have shown, in a series of simple experiments, that in many languages names are identifiable by character patterns alone, and that character level patterns have strong potential for building better NER systems.

In the future, we plan to make a more thorough analysis of reasons for the high variance in NER performance. In particular, we will study why it is possible, as with Tagalog, to have high Named Entity Identification results but lose points in NER.

Code-switched Language Models
Using Dual RNNs and Same-Source Pretraining

Saurabh Garg* **Tanmay Parekh*** **Preethi Jyothi**

Indian Institute of Technology, Bombay
`{saurabhgarg,tanmayb,pjyothi}@cse.iitb.ac.in`

Abstract

This work focuses on building language models (LMs) for code-switched text. We propose two techniques that significantly improve these LMs: 1) A novel recurrent neural network unit with dual components that focus on each language in the code-switched text separately 2) Pretraining the LM using synthetic text from a generative model estimated using the training data. We demonstrate the effectiveness of our proposed techniques by reporting perplexities on a Mandarin-English task and derive significant reductions in perplexity.

1 Introduction

Code-switching is a widespread linguistic phenomenon among multilingual speakers that involves switching between two or more languages in the course of a single conversation or within a single sentence (Auer, 2013). Building speech and language technologies to handle code-switching has become a fairly active area of research and presents a number of interesting technical challenges (Çetinoglu et al., 2016). Language models for code-switched text is an important problem with implications to downstream applications such as speech recognition and machine translation of code-switched data. A natural choice for building such language models would be to use recurrent neural networks (RNNs) (Mikolov et al., 2010), which yield state-of-the-art language models in the case of monolingual text. In this work, we explore mechanisms that can significantly improve upon such a baseline when applied to code-switched text. Specifically, we develop two such mechanisms:

- We alter the structure of an RNN unit to include separate components that focus on each language in code-switched text separately while coordinating with each other to retain contextual information across code-switch boundaries. Our new model is called a *Dual RNN Language Model* (D-RNNLM), described in Section 2.
- We propose using *same-source pretraining* – i.e., pretraining the model using data sampled from a generative model which is itself trained on the given training data – before training the model on the same training data (see Section 3). We find this to be a surprisingly effective strategy.

We study the improvements due to these techniques under various settings (e.g., with and without access to monolingual text in the candidate languages for pretraining). We use perplexity as a proxy to measure the quality of the language model, evaluated on code-switched text in English and Mandarin from the SEAME corpus. Both the proposed techniques are shown to yield *significant perplexity improvements (up to 13% relative)* over different baseline RNNLM models (trained with a number of additional resources). We also explore how to combine the two techniques effectively.

Related Work: Adel et al. (2013) was one of the first works to explore the use of RNNLMs for code-switched text. Many subsequent works explored the use of external sources to enhance code-switched LMs, including the use of part-of-speech (POS) tags, syntactic and semantic features (Yeh et al., 2010; Adel et al., 2014, 2015) and the use of machine translation systems to generate synthetic text (Vu et al., 2012). Prior work has also explored the use of interpolated LMs trained separately on monolingual texts (Bhuvanagiri and Kopparapu, 2010; Imseng et al., 2011; Li et al., 2011; Baheti et al., 2017). Linguistic constraints governing code-switching have also

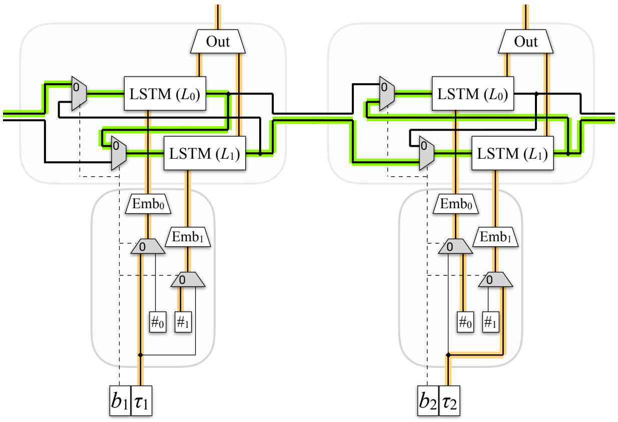

Figure 1: Illustration of the dual RNNLM (see the text for a detailed description). The highlighted left-to-right path (in green) indicates the flow of state information, when $b_1 = 0$ and $b_2 = 1$ (corresponding to token τ_1 belonging to language L_0 and τ_2 belonging to L_1). The highlighted bottom-to-top path (in orange) indicates the inputs and outputs.

been used as explicit priors to model when people switch from one language to another. Following this line of enquiry, (Chan et al., 2004) used grammar rules to model code-switching; (Li and Fung, 2013, 2014) incorporated syntactic constraints with the help of a code-switch boundary prediction model; (Pratapa et al., 2018) used a linguistically motivated theory to create grammatically consistent synthetic code-mixed text.

2 Dual RNN Language Models

Towards improving the modeling of code-switched text, we introduce Dual RNN Language Models (D-RNNLMs). The philosophy behind D-RNNLMs is that two different sets of neurons will be trained to (primarily) handle the two languages. (In prior work (Garg et al., 2018), we applied similar ideas to build dual N-gram based language models for code-switched text.)

As shown in Figure 1, the D-RNNLM consists of a “Dual LSTM cell” and an input encoding layer. The Dual LSTM cell, as the name indicates, has two long short-term memory (LSTM) cells within it. The two LSTM cells are designated to accept input tokens from the two languages L_0 and L_1 respectively, and produce an (unnormalized) output distribution over the tokens in the same language. When a Dual LSTM cell is invoked with an input token τ, the two cells will be invoked sequentially. The first (upstream) LSTM cell corresponds to the language that τ belongs to, and gets τ as its input. It passes on the resulting state to the downstream LSTM cell (which takes a dummy token as input). The unnormalized outputs from the two cells are combined and passed through a soft-max operation to obtain a distribution over the union of the tokens in the two languages. Figure 1 shows a circuit representation of this configuration, using multiplexers (shaded units) controlled by a selection bit b_i such that the i^{th} token τ_i belongs to L_{b_i}.

The input encoding layer also uses multiplexers to direct the input token to the upstream LSTM cell. Two dummy tokens $\#_0$ and $\#_1$ are added to L_0 and L_1 respectively, to use as inputs to the downstream LSTM cell. The input tokens are encoded using an embedding layer of the network (one for each language), which is trained along with the rest of the network to minimize a cross-entropy loss function.

The state-update and output functions of the Dual LSTM cell can be formally described as follows. It takes as input (b, τ) where b is a bit and τ is an input token, as well as a state vector of the form (h_0, h_1) corresponding to the state vectors produced by its two constituent LSTMs. Below we denote the state-update and output functions of these two LSTMs as $H_b(\tau, h)$ and $O_b(\tau, h)$ (for $b = 0, 1$):

$$H((b,\tau),(h_0,h_1)) = (h_0', h_1') \qquad \text{where}$$

$$(h_0', h_1') = \begin{cases} (H_0(\tau,h_0), H_1(\#_1,h_0')) & \text{if } b=0 \\ (H_0(\#_0,h_1'), H_1(\tau,h_1)) & \text{if } b=1 \end{cases}$$

$$O((b,\tau),(h_0,h_1)) = \text{softmax}(o_0,o_1) \qquad \text{where}$$

$$(o_0, o_1) = \begin{cases} (O_0(\tau,h_0), O_1(\#_1,h_0')) & \text{if } b=0 \\ (O_0(\#_0,h_1'), O_1(\tau,h_1)) & \text{if } b=1. \end{cases}$$

Note that above, the inputs to the downstream LSTM functions H_{1-b} and O_{1-b} are expressed in terms of h_b' which is produced by the upstream LSTM.

3 Same-Source Pretraining

Building robust LMs for code-switched text is challenging due to the lack of availability of large amounts of training data. One solution is to artificially generate code-switched to augment the training data. We propose a variant of this approach – called same-source pretraining – in which the actual training data itself is used to train a generative model, and the data sampled from this model is used to pretrain the language model.

Same-source pretraining can leverage powerful training techniques for generative models to train a

	Train	Dev	Test
# Utterances	$74,927$	$9,301$	$9,552$
# Tokens	$977,751$	$131,230$	$114,546$
# English Tokens	$316,726$	$30,154$	$50,537$
# Mandarin Tokens	$661,025$	$101,076$	$64,009$

Table 1: Statistics of data splits derived from SEAME.

language model. We note that the generative models by themselves are typically trained to minimize a different objective function (e.g., a discrimination loss) and need not perform well as language models.[*]

Our default choice of generative model will be an RNN (but see the end of this paragraph). To complete the specification of same-source pretraining, we need to specify how it is trained from the given data. Neural language models trained using the maximum likelihood training paradigm tend to suffer from the *exposure bias* problem during inference when the model generates a text sequence by conditioning on previous tokens that may never have appeared during training. Scheduled sampling (Bengio et al., 2015) can help bridge this gap between the training and inference stages by using model predictions to synthesize prefixes of text that are used during training, rather than using the actual text tokens. A more promising alternative to generate text sequences was recently proposed by Yu et al. (2017) where sequence generation is modeled in a generative adversarial network (GAN) based framework. This model – referred to as "SeqGAN" – consists of a generator RNN and a discriminator network trained as a binary classifier to distinguish between real and generated sequences. The main innovation of SeqGAN is to train the generative model using policy gradients (inspired by reinforcement learning) and use the discriminator to determine the reward function. We experimented with using both naïve and scheduled sampling based training; using SeqGAN was a consistently better choice (5 points or less in terms of test perplexities) compared to these two sampling methods. As such, we use SeqGAN as our training method for the generator. We also experiment with replacing the RNN with a Dual RNN as the generator in the SeqGAN training and observe small but consistent reductions in perplexity.

4 Experiments and Results

Dataset Preparation: For our experiments, we use code-switched text from the SEAME corpus (Lyu et al., 2010) which contains conversational speech in Mandarin and English. Since there is no standardized task based on this corpus, we construct our own training, development and test sets using a random 80-10-10 split. Table 1 shows more details about our data sets. (Speakers were kept disjoint across these datasets.)

Evaluation Metric: We use token-level perplexity as the evaluation metric where tokens are words in English and characters in Mandarin. The SEAME corpus provides word boundaries for Mandarin text. However, we used Mandarin characters as individual tokens since a large proportion of Mandarin words appeared very sparsely in the data. Using Mandarin characters as tokens helped alleviate this issue of data sparsity; also, applications using Mandarin text are typically evaluated at the character level and do not rely on having word boundary markers (Vu et al., 2012).

Outline of Experiments: Section 4.1 will explore the benefits of both our proposed techniques – (1) using D-RNNLMs and (2) using text generated from SeqGAN for pretraining – in isolation and in combination. Section 4.2 will introduce two additional resources (1) monolingual text for pretraining and (2) a set of syntactic features used as additional input to the RNNLMs that further improve baseline perplexities. We show that our proposed techniques continue to outperform the baselines albeit with a smaller margin. All these perplexity results have been summarized in Table 2.

4.1 Improvements Over the Baseline

This section focuses only on the numbers listed in the first two columns of Table 2. The Baseline model is a 1-layer LSTM LM with 512 hidden nodes, input and output embedding dimensionality of 512, trained using SGD with an initial learning rate of 1.0 (decayed exponentially after 80 epochs at a rate of 0.98 till 100 epochs) The development and test set perplexities using the baseline are 89.60 and 74.87, respectively.

The D-RNNLM is a 1-layer language model with each LSTM unit having 512 hidden nodes. The training paradigm is similar to the above-mentioned setting for the baseline model.[†] We see

---

[*] In our experiments, we found the preplexity measures for the generative models to be an *order of magnitude* larger than that of the LMs we construct.

[†] D-RNNLMs have a few additional parameters. How-

	w/o syntactic features				with syntactic features

Table 2: Development set and test set perplexities using RNNLMs and D-RNNLMs with various pretraining strategies.

consistent improvements in test perplexity when comparing a D-RNNLM with an RNNLM (i.e. 74.87 drops to 72.29).[‡]

Next, we use text generated from a SeqGAN model to pretrain the RNNLM.[§] We use our best trained RNNLM baseline as the generator within SeqGAN. We sample 157,440 sentences (with a fixed sentence length of 20) from the SeqGAN model; this is thrice the amount of code-switched training data. We first pretrain the baseline RNNLM with this sampled text, before training it again on the code-switched text. This gives significant reductions in test perplexity, bringing it down to 65.96 (from 74.87).

Finally, we combine both our proposed techniques by replacing the generator with our best-trained D-RNNLM within SeqGAN. Although there are other ways of combining both our proposed techniques, e.g. pretraining a D-RNNLM using data sampled from an RNNLM SeqGAN, we found this method of combination to be most effective. We see modest but consistent improvements with D-RNNLM SeqGAN over RNNLM SeqGAN in Table 2, further validating the utility of D-RNNLMs.

4.2 Using Additional Resources

We employed two additional resources to further improve our baseline models. First, we used monolingual text in the candidate languages to pretrain the RNNLM and D-RNNLM models. We used transcripts from the Switchboard corpus[¶] for English; AIShell[‖] and THCHS30[**] corpora for Mandarin monolingual text data. This resulted in a total of ≈3.1 million English tokens and ≈2.5 million Mandarin tokens. Second, we used an additional set of input features to the RNNLMs and D-RNNLMs that were found to be useful for code-switching in prior work (Adel et al., 2014). The feature set included part-of-speech (POS) tag features and Brown word clusters (Brown et al., 1992), along with a language ID feature. We extracted POS tags using the Stanford POS-tagger[††] and we clustered the words into 70 classes using the unsupervised clustering algorithm by Brown et al. (1992) to get Brown cluster features.

The last six columns in Table 2 show the utility of using either one of these resources or both of them together (shown in the last two columns). The perplexity reductions are largest (compared to the numbers in the first two columns) when combining both these resources together. Interestingly, all the trends we observed in Section 4.1 still hold. D-RNNLMs still consistently perform better than their RNNLM counterparts and we obtain the best overall results using D-RNNLM SeqGAN.

5 Discussion and Analysis

	Eng-Eng	Eng-Man	Man-Eng	Man-Man
RNNLM	133.18	157.18	2617.28	34.98
D-RNNLM	140.37	151.38	2452.16	32.89
Mono RNNLM	101.61	181.28	2510.48	30.00
Mono D-RNNLM	101.66	156.44	2442.81	29.64
RNNLM SeqGAN	120.28	154.44	2739.85	30.40
D-RNNLM SeqGAN	120.26	149.68	2450.85	30.60

Table 3: Decomposed perplexities on the development set on all four types of tokens from various models.

Table 3 shows how the perplexities on the development set from six of our prominent models decompose into the perplexities contributed by English tokens preceded by English tokens (Eng-Eng), Eng-Man, Man-Eng and Man-Man tokens. This analysis reveals a number of interesting observations. 1) The D-RNNLM mainly improves over the baseline on the "switching tokens", Eng-

---

ever, increasing the capacity of an RNNLM to exactly match this number makes its test perplexity worse; RNNLM with 720 hidden units gives a development set perplexity of 91.44 and 1024 hidden units makes it 91.46.

[‡] Since D-RNNLMs use language ID information, we also trained a baseline RNNLM with language ID features; this did not help reduce the baseline test perplexities. In future work, we will explore alternate LSTM-based models that incorporate language ID information (Chandu et al., 2018)

[§] To implement SeqGAN, we use code from `https://github.com/LantaoYu/SeqGAN`.

[††] `https://nlp.stanford.edu/software/tagger.shtml`

Man and Man-Eng. 2) The RNNLM with monolingual data improves most over the baseline on "the monolingual tokens", Eng-Eng and Man-Man, but suffers on the Eng-Man tokens. The D-RNNLM with monolingual data does as well as the baseline on the Eng-Man tokens and performs better than "Mono RNNLM" on all other tokens. 3) RNNLM SeqGAN suffers on the Man-Eng tokens, but helps on the rest; in contrast, D-RNNLM SeqGAN helps on *all tokens* when compared with the baseline.

	SeqGAN-RNNLM	SeqGAN-DLM
Bigram	25.57	31.33
Trigram	75.88	83.86
Quadgram	137.98	145.71

Table 4: Percentage of new n-grams generated.

As an additional measure of the quality of text generated by RNNLM SeqGAN and D-RNNLM SeqGAN, in Table 4, we measure the diversity in the generated text by looking at the increase in the number of unique n-grams with respect to the SEAME training text. D-RNNLM SeqGAN is clearly better at generating text with larger diversity, which could be positively correlated with the perplexity improvements shown in Table 2.

While we do not claim same-source pretraining may be an effective strategy in general, we show it is useful in low training-data scenarios. Even with only $\frac{1}{16}$th of the original SEAME training data used for same-source pretraining, development and test perplexities are reduced to 84.45 and 70.59, respectively (compared to 79.16 and 65.96 using the entire training data).

6 Conclusion

D-RNNLMs and same-source pretraining provide significant perplexity reductions for code-switched LMs. These techniques may be of more general interest. Leveraging generative models to train LMs is potentially applicable beyond code-switching; D-RNNLMs could be generalized beyond LMs, e.g. speaker diarization. We leave these for future work to explore.

Part-of-Speech Tagging for Code-Switched, Transliterated Texts without Explicit Language Identification

Kelsey Ball

dhgarrette@google.com

Abstract

Code-switching, the use of more than one language within a single utterance, is ubiquitous in much of the world, but remains a challenge for NLP largely due to the lack of representative data for training models. In this paper, we present a novel model architecture that is trained exclusively on monolingual resources, but can be applied to unseen code-switched text at inference time. The model accomplishes this by jointly maintaining separate word representations for each of the possible languages—or scripts in the case of transliteration—allowing each to contribute to inferences without forcing the model to commit to a language. Experiments on Hindi-English part-of-speech tagging demonstrate that our approach outperforms standard models when training on monolingual text without transliteration, and testing on code-switched text with alternate scripts.

1 Introduction

Code-switching,[1] the linguistic phenomenon of switching between more than one language within a single utterance, is ubiquitous in multilingual societies worldwide, but presents particular challenges for even the most standard NLP tasks. For example, state-of-the-art neural part-of-speech (POS) taggers are trained on POS-annotated data to learn the relationships between words and tags, and rely on word embeddings trained from large (usually unannotated) corpora to capture information about each word's typical contexts (Ling et al., 2015; Wang et al., 2015). But while monolingual corpora, both annotated and unannotated, are relatively easy to acquire, code-switched text is much more difficult to collect in large quantities. Annotated code-switched texts in particular are not only expensive to create, requiring particularly skilled bilingual linguists as annotators, but they will never exist for the complete set of pairs (or triples, etc.) of languages between which an individual may switch. Further complicating the problem is that texts featuring code-switching also tend to feature *transliteration*—writing in a non-standard script—to avoid having to switch keyboard settings mid-sentence. When Hindi is transliterated from Devanagari to Latin script, tokens are no longer easy to distinguish by language.[2] Previous work addresses this problem by first attempting to identify the correct language and form of a word before feeding it into an appropriate monolingual tagger (Vyas et al., 2014; Solorio and Liu, 2008; Sharma et al., 2016). As is typically the case in NLP, such pipelines suffer from the problem of cascading errors; e.g., failures of the language identification will cause problems in the tag prediction (Barman et al., 2016). Other approaches have trained supervised models on POS-annotated, code-switched data (Jamatia et al., 2015; Ghosh et al., 2016; Gupta et al., 2017; Barman et al., 2016; Sequiera et al., 2015, *inter alia*), resources which are expensive to create and unavailable for most language pairs.

In this work, we present a novel POS-tagging model architecture that can be trained exclusively on available monolingual standard-orthography resources, but that can be applied to texts that contain code-switching and transliteration. Because our model learns from monolingual training data, we are able to learn a code-switched POS-tagger for any combination of languages with POS-annotated data, regardless of whether any existing

---

[1] The terms *code-mixing* and *-switching* are used for similar phenomena; for simplicity, we use only *code-switching*.

[2] We will use the term *transliterated* to imply conversion from a standard script to a non-standard script, e.g., Devanagari to Latin for Hindi, and *detransliterated* to imply the reverse, and, for simplicity, when we say *written in Devanagari* or *Latin*, we mean Devanagari or Latin *script*.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3084–3089
Brussels, Belgium, October 31 - November 4, 2018.

(annotated or unannotated) code-switched corpus exists. By allowing multiple word embeddings (one for each of the possible languages) to jointly represent each token, we avoid explicit language identification and the resulting error propagation.

2 Task Setup

Training data We train our POS tagger using the Universal Dependencies (UD) treebanks for Hindi and English, which are annotated for part-of-speech (Nivre et al., 2016).[3] The English treebank contains roughly 22K sentences; the Hindi contains roughly 16K sentences. Sentences in both languages are taken from news text and similarly formal sources, and the Hindi is written entirely in Devanagari.

Test data We evaluated our POS tagging models on the code-switched Twitter data released by Bhat et al. (2018), which is annotated using the UD POS tag set.[4] All tweets are written entirely in Latin script and have at least one token of both Hindi and English, with 45% of the total tokens being Hindi, 38% English, 17% labeled as universal, mixed, named entity, or acronym.

Word embeddings For monolingual word embeddings, we use *indic-word2vec*,[5] for which the English embeddings are trained from 280M sentences and Hindi from 40M. The word vectors are learned using a skip-gram model with negative sampling, implemented in the word2vec toolkit (Mikolov et al., 2013). We use the 50,000 most frequent words in each vocabulary.

Transliteration To convert words between scripts, we make use of the *Indictrans* open-source transliterator,[6] which is able to convert, bidirectionally, between Latin and the scripts of Indic languages (Bhat et al., 2015). Because Hindi does not have a formal system for transliteration, those writing Hindi in Latin—or English in Devanagari—tend to write phonetically according to their own conventions. Thus, we make use of the ability of Indictrans to generate multiple transliteration alternatives, simulating the variation in Hindi transliterated writing.

3 Model

The central challenge of our task is to be able to train on data that differs drastically from the text seen at inference time. Because of the inherent limitations on what kinds of data are available—annotations and word embeddings are generally only available on monolingual data written in standard scripts—we are interested in designing a model that can be trained on monolingual sentences in which English is written in Latin script and Hindi in Devanagari, but is able to predict POS tags on code-mixed text in which both English and Hindi are written in Latin script.

We accomplish this by representing input words not as a single vector (or as a word embedding affixed to sub-word representations), but as a joint representation that maintains embeddings for each language such that they can be learned and updated during training from the monolingual data, and mixed appropriately at inference time without having to commit to one or the other language. As seen in Figure 1, our model represents an input as the concatenation of four parts: a Hindi word embedding, an English word embedding, the output of a bi-LSTM over Hindi character embeddings, and a bi-LSTM over English characters.

Since our model is trained on monolingual Hindi and English sentences, when a token is encountered during training, we know what language it is in. If we encounter an English sentence, then for each token, we look up its word embedding in the appropriate monolingual vector space to use in the English side of the full representation, and we use the word's characters as input to the English character LSTM. For Hindi sentences, the procedure is similar but for the other side of the full representation. In either case, when we are training on a word in one language, we use zero vectors as the inputs for the other language's side of the full input representation.

At inference time, we will encounter only Latin script words, but we will not know the language of any token. Therefore, we use our joint-representation model to represent the token as both languages simultaneously. The Latin word is looked up in the English word embeddings to use as input to the English side, and the Latin characters are used for the English character LSTM. For the Hindi side we detransliterate the input word to Devanagari and perform the same actions.

The design of our model has a few important

[4] `github.com/CodeMixed UniversalDependencies/UD_Hindi_English`

[5] `bitbucket.org/irshadbhat/indic-word2vec-embeddings`

[6] `github.com/libindic/indic-trans`

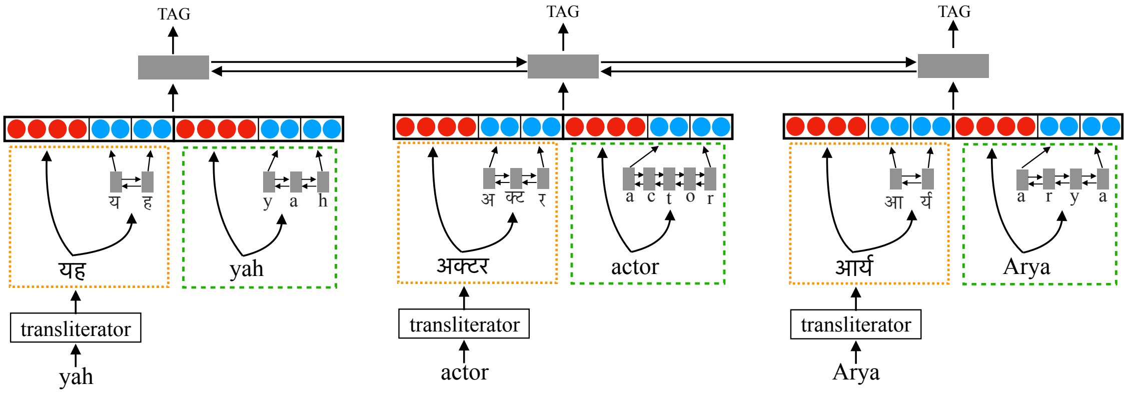

Figure 1: Our model. All inputs are treated simultaneously as both languages. At training time, for a (monolingual) Hindi input, only the contents of the orange/dotted boxes apply, and the English half of the vector is all zeros; for (monolingual) English, only the green/dashed boxes apply. At inference time, where the language of each token is unknown, the full figure applies.

advantages. First, because of Hindi's lack of a formalized transliteration system, Latin-script Hindi tends to have a very high amount of spelling variation. In our model (as opposed to the baseline model described below), the script conversion always goes from Latin to Devanagari, which naturally allows us to take unpredictable variant spellings and collapse them into standardized spellings, making it more likely for us to find the word in the embeddings listing. Second, there are some types of words for which it does not make sense to say that they are in one language or another. For example, a person's name might be equally valid as Devanagari Hindi or Latin English. In these cases, our model would allow both to influence a prediction as well as the rest of the bi-LSTM chain.

Finally, our model allows for the incorporation of external language prediction information, including soft predictions. To test this, we ran experiments in which we used a fully-unsupervised token-level language identification approach based on Rijhwani et al. (2017) to estimate a probability distribution over language labels for each token in the test data. Our approach was to run Forward-Backward on an HMM that was initialized to prefer same-language transitions and whose emissions were initialized using Laplace-smoothed maximum-likelihood-estimated character n-gram probabilities from each language's monolingual corpus (Dempster et al., 1977; Kupiec, 1992). We used the induced language probabilities to weight each side of the input representation at inference time: if the unsupervised model's output said that a particular test token's probability of being Hindi was 70%, then we would multiply the Hindi side of the input vector by 0.7 and the English side by 0.3, thus instructing the model to let the Hindi word embedding (and character-LSTM output) exert more influence during POS prediction.

4 Experiments

In our evaluation, we used the framework of a basic bi-LSTM tagger to compare our model for generating representations of tokens that maintain language ambiguity against a standard model that uses a single word embedding. In this section, we explain the experimental setup, baseline approach, and our experimental variants.[7]

4.1 POS tagger framework

For all of our experiments, we follow the basic structure of the bi-LSTM architecture of Bhat et al. (2018): word and sub-word embeddings are concatenated to form the input representations of each token, and connected together by a bi-LSTM that outputs POS predictions via multilayer perceptron and softmax layers (Hochreiter and Schmidhuber, 1997; Graves and Schmidhuber, 2005; Ling et al., 2015; Wang et al., 2015). Sub-word embeddings are the outputs of a bi-LSTM over characters (20-dim); word embeddings are initialized with *indic-word2vec* (64-dim) embeddings. Both character and word embeddings are updated during training. The bi-LSTM has 100

---

[7] Our code, implemented in DyNet (Neubig et al., 2017), can be found at https://github.com/kelseyball/cs-transliterated-pos-tagging.

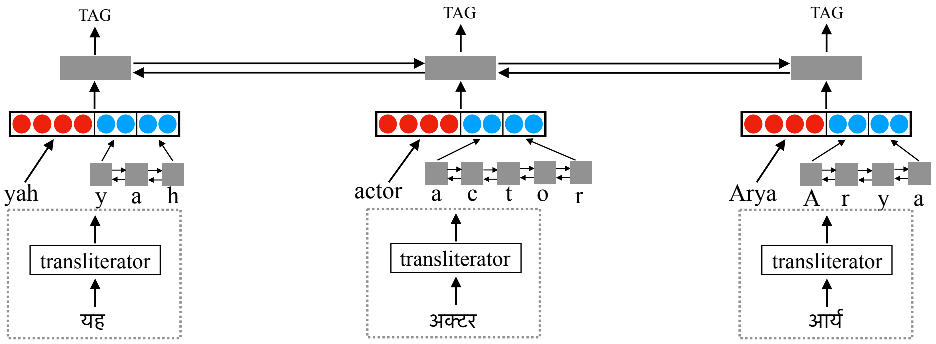

Figure 2: Baseline model. All inputs are treated as if they are one language. The contents of the dotted boxes only apply at training time and only to (monolingual) Hindi inputs since annotated Devanagari Hindi data must be converted to Latin script; at inference time, inputs are always in Latin script.

hidden states. We use an SGD trainer with learning rate=0.1 and dropout of 0.3 across 20 epochs. We train the model it by pooling POS-annotated English and Hindi UD sentences; the English is entirely Latin script, and Hindi is entirely Devanagari. Our baseline and experimental models differ in how a token is represented.

4.2 Baseline

Previous work on code-switched POS tagging has achieved accuracies as high as 90.20% (Bhat et al., 2018), but because those kinds of accuracies require supervised, in-domain training data, they are not directly comparable with the scenario that we are concerned with. Therefore, we compare against a natural baseline for our task: use a monolingual tagger and treat everything as if it were a single language. To deal with the problem of separately trained word embeddings, we use the approach and implementation of Artetxe et al. (2018)[8] to transform both sets of monolingual embeddings so that translationally equivalent words have similar embeddings. We also ran the baseline without this transformation, but found that using the transformed embeddings resulted in a 0.5% absolute improvement in accuracy over just using the separately trained embeddings directly.

Training For an English sentence, each token concatenates the English-lookup embedding to the character LSTM output, and similarly for Hindi, with the exception that the word is transliterated before inputting to the character LSTM. Because of the high spelling variation, we selected Latin spellings by sampling uniformly from the top-5 transliteration results. Always taking the 1-best resulted in a 4.3% absolute loss.

Model		**Acc.**
Baseline	(monolingual representation)	70.92
Ours	(multi-language representation)	75.29
Ours	w/ forced language choice	76.04
Ours	w/ languages weighted by HMM	**77.40**
Ours	w/ oracle language choice	80.53
Bhat et al. (2018)	w/ supervision	90.20

Table 1: Results showing POS prediction accuracy. The baseline model treats all inputs as effectively monolingual (§4.2); the middle three lines are our model: giving equal weight to each language's side of the token's representation, using the unsupervised HMM 1-best output to zero-out one language's side of the token's representation, and using the unsupervised HMM probability estimates to weight each side of the token's representation. The oracle line is our model using gold language labels to zero-out one language's side.

Inference Each word is looked up in the English embeddings *and* its detransliteration is looked up in the in the Hindi embeddings. If the word is found in only one, that vector is used, and if found in neither, we use an *unknown word* vector. For a fair comparison to our model, if both lookups return results, we use the 1-best prediction from the unsupervised language identification HMM as discussed in §3 to decide which to use.

4.3 Unsupervised soft language prediction

One feature of our model is its ability to incorporate externally-derived, per-token soft language

---

[8] `github.com/artetxem/vecmap`

predictions as weights at inference time without having to make hard language decisions. To evaluate whether this improves accuracy, we used the fully-unsupervised HMM language prediction (§3) and tested our model using: no weighting, leaving the embeddings untouched; using the HMM's 1-best prediction to zero out the other language's inputs; and multiplying each language's embeddings by its probability estimated by the HMM.

The results of our evaluation can be seen in Table 1. While the best scenario for the baseline tagger gives 70.92% accuracy, the most basic setup for our model yields 75.29%. Informing our model with some fully-unsupervised HMM-derived language information, but forcing a hard language decision, is somewhat beneficial, yielding 76.04%, though it trades off the benefits of flexibility and generality in representation for some extra information. And finally, using that unsupervised information for *soft* weighting performs even better, reaching 77.40%, a total absolute improvement over the baseline of ∼6.5%, clearly demonstrating the value of maintaining ambiguity about a word's language.

5 Conclusion

In this paper, we presented a novel POS-tagging model for code-mixed, transliterated text that avoids the need for expensive, supervised corpora or language-identification pipelines. We demonstrated that avoiding explicit language identification in code-switched contexts is beneficial. Though we emphasize the paucity of annotated code-switched corpora, previous work has demonstrated that a small amount of supervision can go a long way (Garrette and Baldridge, 2013); future work might explore how much supervision is needed to close the gap between our model and Bhat et al. (2018).

While we address some of the most prominent issues with code-switching, our model does not deal with style, formality, or domain mismatches between the formal training data and informal evaluation data. This problem is treated in recent work on POS-tagging for social media text (Owoputi et al., 2013; Gimpel et al., 2011), but these issues have yet to be fully explored in code-switched contexts. We leave these for future work.

Abstract

User intent detection plays a critical role in question-answering and dialog systems. Most previous works treat intent detection as a classification problem where utterances are labeled with predefined intents. However, it is labor-intensive and time-consuming to label users' utterances as intents are diversely expressed and novel intents will continually be involved. Instead, we study the zero-shot intent detection problem, which aims to detect emerging user intents where no labeled utterances are currently available. We propose two capsule-based architectures: INTENTCAPSNET that extracts semantic features from utterances and aggregates them to discriminate existing intents, and INTENTCAPSNET-ZSL which gives INTENTCAPSNET the zero-shot learning ability to discriminate emerging intents via knowledge transfer from existing intents. Experiments on two real-world datasets show that our model not only can better discriminate diversely expressed existing intents, but is also able to discriminate emerging intents when no labeled utterances are available.

1 Introduction

With the increasing complexity and accuracy of speech recognition technology, companies are striving to deliver intelligent conversation understanding systems as people interact with software agents that run on speaker devices or smart phones via natural language interface (Hoy, 2018). Products like Apple's Siri, Amazon's Alexa and Google Assistant are able to interpret human speech and respond them via synthesized voices.

With recent developments in deep neural networks, user intent detection models (Hu et al., 2009; Xu and Sarikaya, 2013; Zhang et al., 2016; Liu and Lane, 2016; Chen et al., 2016b) are proposed to classify user intents given their diversely expressed utterances in the natural language. The decent performances on intent detection usually come with deep neural network classifiers optimized on large-scale utterances which are human-labeled among existing predefined user intents.

As more features and skills are being added to devices which expand their capabilities to new programs, it is common for voice assistants to encounter the scenario where no labeled utterance of an emerging user intent is available in the training data, as illustrated in Figure 1. Current intent detection methods train classifiers in a supervised fashion and they are good at discriminating existing intents such as Get Weather and Play Music whose labeled utterances are already available. However, these models, by the nature of designs, are incapable to detect utterances of emerging intents like AddToPlaylist and RateABook, since no labeled utterances are available. Moreover, it's labor-intensive and time-consuming to annotate utterances of emerging intents and retrain the whole intent detection model.

Thus, it is imperative to develop intent detection models with the zero-shot learning (ZSL) ability (Lampert et al., 2014; Socher et al., 2013; Changpinyo et al., 2016): the ability to expand classifiers and the intent detection space beyond the existing intents, of which we have labeled utterances during training, to emerging intents, of which no labeled utterances are available.

The research on zero-shot intent detection is still in its infancy. Previous zero-shot learning methods for intent detection utilize external resources such as label ontologies (Ferreira et al., 2015a,b) or manually defined attributes that describe intents (Yazdani and Henderson, 2015) to associate existing and emerging intents, which require extra annotation. Compatibility-based methods for zero-shot intent detection (Chen et al., 2016a; Kumar et al., 2017) assume the capability

Brussels, Belgium, October 31 - November 4, 2018.

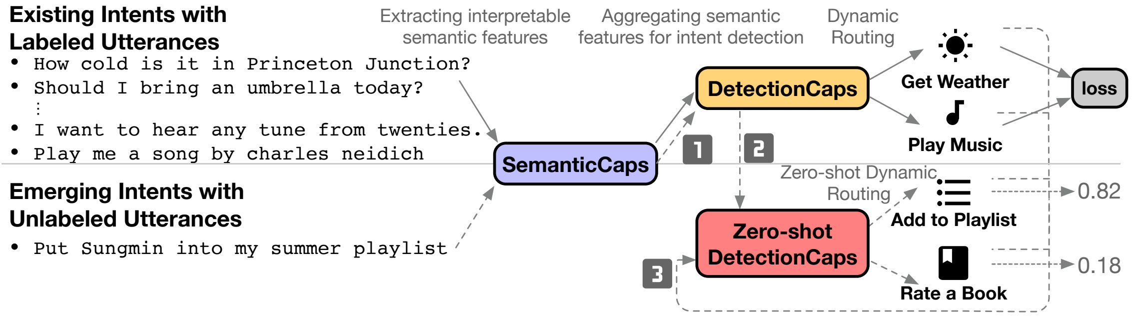

Figure 1: Illustration of the proposed IntentCapsNet-ZSL model for zero-shot intent detection: labeled utterances with existing intents like GetWeather and PlayMusic are used to train an intent detection classifier among existing intents, in which SemanticCaps extract intepretable semantic features and DetectionCaps dynamically aggregate semantic features for intent detection using a novel routing-by-agreement mechanism. For emerging intents, IntentCapsNet-ZSL builds zero-shot DetectionCaps that utilize the (1) outputs of SemanticCaps, (2) the routing information on existing intents from DetectionCaps, and (3) similarities of the emerging intent label to existing intent labels to discriminate emerging intents like AddToPlayist from RateABook. Solid lines indicate the training process and dash lines indicate the zero-shot inference process.

of learning a high-quality mapping from the utterance to its intent directly, so that such mapping can be further capitalized to measure the compatibility of an utterance with emerging intents. However, the diverse semantic expressions may impede the learning of such mapping.

In this work, we make the very first attempt to tackle the zero-shot intent detection problem with a capsule-based (Hinton et al., 2011; Sabour et al., 2017) model. A capsule houses a vector representation of a group of neurons, and the orientation of the vector encodes properties of an object (like the shape/color of a face), while the length of the vector reflects its probability of existence (how likely a face with certain properties exists). The capsule model learns a hierarchy of feature detectors via a routing-by-agreement mechanism: capsules for detecting low-level features (like nose/eyes) send their outputs to high-level capsules (such as faces) only when there is a strong agreement of their predictions to high-level capsules.

The aforementioned properties of capsule models could be quite appealing for text modeling, specifically in this case, modeling the user utterance for intent detection: low-level semantic features such as the get_action, time and city_name contribute to a more abstract intent (GetWeather) collectively. A semantic feature, which may be expressed quite differently among users, can contribute more to one intent than others. The dynamic routing-by-agreement mechanism can be used to dynamically assign a proper contribution of each semantic and aggregate them to get an intent representation.

More importantly, we discover the potential of zero-shot learning ability on the capsule model, which is not yet widely recognized. It makes the capsule model even more suitable for text modeling when no labeled utterances are available for emerging intents. The ability to neglect the disagreed output of low-level semantics for certain intents during routing-by-agreement encourages the learning of generalizable semantic features that can be adapted to emerging intents. For each emerging intent with no labeled utterances, a Zero-shot DetectionCaps is constructed explicitly by using not only semantic features SemanticCaps extracted, but also existing routing agreements from DetectionCaps and similarities of an emerging intent label to existing intent labels.

In summary, the contributions of this work are:

- Expanding capsule neural networks to text modeling, by extracting and aggregating semantics from utterances in a hierarchical manner;
- Proposing a novel and effective capsule-based model for zero-shot intent detection;
- Showing and interpreting the effectiveness of our model on two real-world datasets.

2 Problem Formulation

In this section, we first define related concepts, and formally state the problem.

Intent. An intent is a purpose, or a goal that underlies a user-generated utterance (Watson Assistant, 2017). An utterance can be associated with one or multiple intents. We only consider the basic case that an utterance is with a single intent. However, utterances with multiple intents can be handled by segmenting them into single-intent snippets using sequential tagging tools like CRF (Lafferty et al., 2001), which we leave for future works.

Intent Detection. Given a labeled training dataset where each sample has the following format: (x, y) where x is an utterance and y is its intent label, each training example is associated with one of K existing intents $y \in Y = \{y_1, y_2, ..., y_K\}$. The intent detection task tries to associate an utterance $x_{existing}$ with its correct intent category in the existing intent classes Y.

Zero-shot Intent Detection. Given the labeled training set $\{(x, y)\}$ where $y \in Y$, the zero-shot intent detection task aims to detect an utterance $x_{emerging}$ which belongs to one of L emerging intents $z \in Z = \{z_1, z_2, ..., z_L\}$ where $Y \cap Z = \varnothing$.

3 Approach

We propose two architectures based on capsule models: INTENTCAPSNET that is trained to discriminate among utterances with existing labels, e.g. existing intents for intent detection; INTENTCAPSNET-ZSL that gives zero-shot learning ability to INTENTCAPSNET for discriminating unseen labels, i.e. emerging intents in this case. As shown in Figure 2, the cores of the proposed architectures are three types of capsules: SemanticCaps that extract interpretable semantic features from the utterance, DetectionCaps that aggregate semantic features for intent detection, and Zero-shot DetectionCaps which discriminate emerging intents.

3.1 SemanticCaps

In the original capsule model (Sabour et al., 2017), convolution-based PrimaryCaps are introduced as the first layer to obtain different vectorized features from the raw input image. While in this work, an intrinsically similar motivation is adopted to extract different semantic features from the raw utterance by a new type of capsule named SemanticCaps. Unlike the PrimaryCaps which use convolution operators with a large reception field to extract spacial-proximate features, the SemanticCaps is based on a bi-direction recurrent neural network with multiple self-attention heads, where each self-attention head focuses on certain part of the utterance and extracts a semantic feature that may not be expressed by words in proximity.

Given an input utterance $x = (\mathbf{w_1}, \mathbf{w_2}, ..., \mathbf{w_T})$ of T words, each word is represented by a vector of dimension D_W that can be pre-trained using a skip-gram language model (Mikolov et al., 2013).

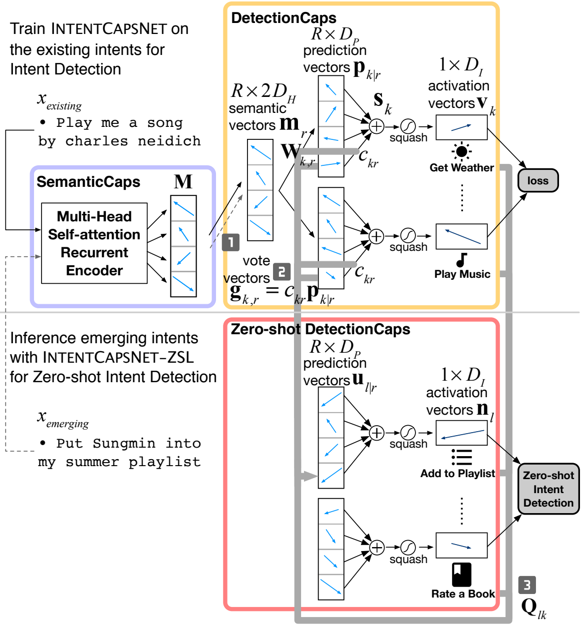

Figure 2: The architecture of INTENTCAPSNET and INTENTCAPSNET-ZSL. During training, utterances with existing intents are fed into the SemanticCaps which output vectorized semantic features, i.e. semantic vectors. Then DetectionCaps combine these features into higher-level prediction vectors and output an activation vector for intent detection on each existing intent. During inference, emerging utterances take advantages of the SemanticCaps trained in INTENTCAPSNET to extract semantic features from the utterance (shown in 1), then the vote vectors on the existing intents are transferred to emerging intents (shown in 2) using similarities between existing and emerging intents (shown in 3). The obtained activation vectors for emerging intents are used for zero-shot intent detection.

A recurrent neural network such as a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) is applied to sequentially encode the utterance into hidden states:

$$\begin{aligned}
\overrightarrow{\mathbf{h}}_t &= \text{LSTM}_{fw}(\mathbf{w}_t, \overleftarrow{\mathbf{h}}_{t-1}), \\
\overleftarrow{\mathbf{h}}_t &= \text{LSTM}_{bw}(\mathbf{w}_t, \overleftarrow{\mathbf{h}}_{t+1}).
\end{aligned} \tag{1}$$

For each word $\mathbf{w_t}$, we concatenate each forward hidden state $\overrightarrow{\mathbf{h}}_t$ obtained from the forward LSTM_{fw} with a backward hidden state $\overleftarrow{\mathbf{h}}_t$ from LSTM_{bw} to obtain a hidden state $\mathbf{h_t}$ for the word $\mathbf{w_t}$. The whole hidden state matrix can be defined as $\mathbf{H} = (\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_T) \in \mathbb{R}^{T \times 2D_H}$, where D_H is the number of hidden units in each LSTM.

Inspired by the success of self-attention mechanisms (Vaswani et al., 2017; Lin et al., 2017) for sentence embedding, we adopt a multi-head self-attention framework where each self-attention head is encouraged to be attentive to a specific semantic feature of the utterance, such as certain sets of keywords or phrases in the utterance: one self-attention may be attentive for the "get" action in GetWeather, while another one may be attentive to city_name in GetWeather: it decides for itself what semantics to be attentive to.

A self-attention weight matrix $\mathbf{A}$ is computed as:

$$\mathbf{A} = \text{softmax}\left(\mathbf{W}_{s2}\tanh\left(\mathbf{W}_{s1}\mathbf{H}^T\right)\right), \quad (2)$$

where $\mathbf{W}_{s1} \in \mathbb{R}^{D_A \times 2D_H}$ and $\mathbf{W}_{s2} \in \mathbb{R}^{R \times D_A}$ are weight matrices for the self-attention. D_A is the hidden unit number of self-attention and R is the number of self-attention heads. The softmax function makes sure for each self-attention head, the attentive scores on all the words sum to one.

A total number of R semantic features are extracted from the input utterance, each from a separate self-attention head: $\mathbf{M} = \mathbf{AH}$, where $\mathbf{M} = (\mathbf{m}_1, \mathbf{m}_2, ..., \mathbf{m}_R) \in \mathbb{R}^{R \times 2D_H}$. Each $\mathbf{m}_r$ is a $2D_H-$dimensional semantic vector.

Each semantic vector will have a distinguishable orientation when the objective is properly regularized (details in Equation 6), as we want each attention to be attentive to a unique semantic feature of the utterance. The vector representation adopted in capsules is suitable to portray the low-level semantic properties as well as high-level intents of the utterance, where the orientation of a vector represents semantic/intent properties that may slightly vary depending on the expressions. The capsule encourages the learning of generalizable semantic vectors: less informative semantic properties for one intent may not be penalized by their orientations: they simply possess small norms as they are less likely to exist.

3.2 DetectionCaps

The output of SemanticCaps are low-level vector representations of R different semantic features extracted from the utterances. To combine these features into higher-level representations, we build DetectionCaps that choose different semantic features dynamically so as to form an intent representation for each intent via an unsupervised routing-by-agreement mechanism.

As a semantic feature may contribute differently in detecting different intents, the DetectionCaps first encode semantic features with respect to each intent:

$$\mathbf{p}_{k|r} = \mathbf{m}_r \mathbf{W}_{k,r}, \quad (3)$$

where $k \in \{1, 2, ..., K\}$, $r \in \{1, 2, ..., R\}$. $\mathbf{W}_{k,r} \in \mathbb{R}^{2D_H \times D_P}$ is the weight matrix of the DetectionCaps, $\mathbf{p}_{k|r}$ is the prediction vector of the r-th semantic feature of an existing intent k, and D_P is the dimension of the prediction vector.

Dynamic Routing-by-agreement. The prediction vectors obtained from SemanticCaps route dynamically to DetectionCaps. The DetectionCaps computes a weighted sum over all prediction vectors:

$$\mathbf{s}_k = \sum_r^R c_{kr} \mathbf{p}_{k|r}, \quad (4)$$

where c_{kr} is the coupling coefficient that determines how informative, or how much contribution the r-th semantic feature is to the intent y_k. c_{kr} is calculated by an unsupervised, iterative dynamic routing-by-agreement algorithm (Sabour et al., 2017), which is briefly recalled in Algorithm 1. As shown in this algorithm, b_{kr} is the initial logit representing the log prior probability that a SemanticCap r is coupled to an DetectionCap k.

Algorithm 1 Dynamic routing algorithm

```
procedure DYNAMIC ROUTING($\mathbf{p}_{k|r}$, $iter$)
    for all semantic capsule r and intent capsule k: $b_{kr} \leftarrow 0$.
    for $iter$ iterations do
        for all SemanticCaps r: $c_r \leftarrow \text{softmax}(\mathbf{b}_r)$
        for all DetectionCaps k: $s_k \leftarrow \Sigma_r c_{kr} \mathbf{p}_{k|r}$
        for all DetectionCaps k: $v_k = \text{squash}(\mathbf{s}_k)$
        for all SemanticCaps r and DetectionCaps k:
            $b_{kr} \leftarrow b_{kr} + \mathbf{p}_{k|r} \cdot \mathbf{v}_k$
    end for
    Return $\mathbf{v}_k$
end procedure
```

The squashing function $\text{squash}(\cdot)$ is applied on $\mathbf{s}_k$ to get an activation vector $\mathbf{v}_k$ for each existing intent class k:

$$\mathbf{v}_k = \frac{\|\mathbf{s}_k\|^2}{1 + \|\mathbf{s}_k\|^2} \frac{\mathbf{s}_k}{\|\mathbf{s}_k\|}, \quad (5)$$

where the orientation of the activation vector $\mathbf{v}_k$ represents intent properties while its norm indicates the activation probability. The dynamic routing-by-agreement mechanism assigns low c_{kr} when there is inconsistency between $p_{k|r}$ and v_k, which ensures the outputs of the SemanticCaps get sent to appropriate subsequent DetectionCaps.

Max-margin Loss for Existing Intents. The loss function considers both the max-margin loss on each labeled utterance, as well as a regularization term that encourages each self-attention head to be attentive to a different semantic feature of the utterance:

$$\mathcal{L} = \sum_{k=1}^{K} \{ [\![y = y_k]\!] \cdot \max(0, m^+ - \|\mathbf{v}_k\|)^2 + \lambda\, [\![y \neq y_k]\!] \cdot \max(0, \|\mathbf{v}_k\| - m^-)^2 \} + \alpha ||\mathbf{A}\mathbf{A}^T - I||_F^2, \tag{6}$$

where $[\![]\!]$ is an indicator function, y is the ground truth intent label for the utterance x, λ is a down-weighting coefficient, m^+ and m^- are margins. α is a non-negative trade-off coefficient that encourages the discrepancies among different attention heads.

3.3 Zero-shot DetectionCaps

To detect emerging intents effectively, Zero-shot DetectionCaps are designed to transfer knowledge from existing intents to emerging intents.

Knowledge Transfer Strategies. As SemanticCaps are trained to extract semantic features from utterances with various existing intents, a self-attention head which has similar extraction behavior among existing and emerging intents may help transfer knowledge. For example, a self-attention head that extracts the "play" action mentioned by `turn on/I want to hear` in the beginning of an utterance for PlayMusic is helpful if it is also attentive to expressions for the "add" action like `add/I want to have` in the beginning of an utterance with an emerging intent AddtoPlaylist.

The coupling coefficient c_{kr} learned by DetectionCaps in a totally unsupervised fashion embodies rich knowledge of how informative r-th semantic is to the existing intent k. We can capitalize on the existing routing information for emerging intents. For example, how the word `play` routes to GetWeather can be helpful in routing the word `add` to AddtoPlaylist.

The intent labels also contain knowledge of how two intents are similar with each other. For example, an emerging intent AddtoPlaylist can be closer to one existing intent PlayMusic than GetWeather due to the proximity of the embedding of Playlist to Play or Music, than Weather.

Build Vote Vectors. As the routing information and the semantic extraction behavior are strongly coupled (c_{kr} is calculated by $\mathbf{p}_{k|r}$ iteratively in Line 4-6 of Algorithm 1) and their products are summarized to get the activation vector v_k for intent k (Line 5-6 of Algorithm 1), we denote vectors before summation as vote vectors:

$$\mathbf{g}_{k,r} = c_{kr}\mathbf{p}_{k|r}, \tag{7}$$

where $\mathbf{g}_{k,r}$ is the r-th vote vector for an existing intent k.

Zero-shot Dynamic Routing. The zero-shot dynamic routing utilizes vote vectors from existing intents to build intent representations for emerging intents via a similarity metric between existing intents and emerging intents.

Since there are K existing intents and L emerging intents, the similarities between existing and emerging intents form a matrix $\mathbf{Q} \in \mathbb{R}^{L \times K}$. Specifically, the similarity between an emerging intent $z_l \in Z$ and an existing intent $y_k \in Y$ is computed as:

$$q_{lk} = \frac{exp\left\{-d\left(\mathbf{e}_{z_l}, \mathbf{e}_{y_k}\right)\right\}}{\sum_{k=1}^{K} exp\left\{-d\left(\mathbf{e}_{z_l}, \mathbf{e}_{y_k}\right)\right\}}, \tag{8}$$

where

$$d\left(\mathbf{e}_{z_l}, \mathbf{e}_{y_k}\right) = \left(\mathbf{e}_{z_l} - \mathbf{e}_{y_k}\right)^T \Sigma^{-1} \left(\mathbf{e}_{z_l} - \mathbf{e}_{y_k}\right). \tag{9}$$

$\mathbf{e}_{z_l}, \mathbf{e}_{y_k} \in \mathbb{R}^{D_I \times 1}$ are intent embeddings computed by the sum of word embeddings of the intent label. Σ models the correlations among intent embedding dimensions and we use $\Sigma = \sigma^2 I$. σ is a hyper-parameter for scaling. The prediction vectors for emerging intents are thus computed as:

$$\mathbf{u}_{l|r} = \sum_{k=1}^{K} q_{lk}\mathbf{g}_{k,r}. \tag{10}$$

We feed the prediction vector $\mathbf{n}_l$ to Algorithm 1 and derive activation vectors $\mathbf{n}_l$ on emerging intents as the output. The final intent representation $\mathbf{n}_l$ for each emerging intent is updated toward the direction where it coincides with representative votes vectors.

We can easily classify the utterance of emerging intents by choosing the activation vector with the largest norm $\hat{z} = \arg\max_{z_l \in Z} \|\mathbf{n}_l\|$.

4 Experiment Setup

To demonstrate the effectiveness of our proposed models, we apply INTENTCAPSNET to detect existing intents in an intent detection task, and use INTENTCAPSNET-ZSL to detect emerging intents in a zero-shot intent detection task.

Datasets. For each task, we evaluate our proposed models by applying it on two real-word

Model	**SNIPS-NLU** (on 5 existing intents)				**CVA** (on 80 existing intents)

Table 2: Dataset statistics.

Baselines. We first compare the proposed capsule-based model INTENTCAPSNET with other text classification alternatives on the detection of existing intents: 1) TFIDF-LR/TFIDF-SVM: we use TF-IDF to represent the utterance and use logistic regression/support vector machine as classifiers. 2) CNN: a convolutional neural network (Kim, 2014) that uses convolution and pooling operations, which is popular for text classification. 3) RNN/GRU/LSTM/BiLSTM: we adopt different types of recurrent neural networks: the vanilla recurrent neural network (RNN), gated recurrent unit (GRU) (Tang et al., 2015), long short-term memory networks (LSTM) (Hochreiter and Schmidhuber, 1997), and bi-directional long short-term memory (Bi-LSTM) (Schuster and Paliwal, 1997). Their last hidden states are used for classification. 4) Self-Attention Bi-LSTM: we apply a Bi-LSTM model with self-attention mechanism (Lin et al., 2017) and the output sentence embedding is used for classification.

We also compare our proposed model INTENTCAPSNET-ZSL with different zero-shot learning strategies: 1) DeViSE (Frome et al., 2013) finds the most compatible emerging intent label for an utterance by learning a linear compatibility function between utterances and intents; 2) CMT (Socher et al., 2013) introduces non-linearity in the compatibility function; CMT and DeViSE are originally designed for zero-shot image classification based on pretrained CNN features. We use LSTM to encode the utterance and adopt their zero-shot learning strategies in our task; 3) CDSSM (Chen et al., 2016a) uses CNN to extract character-level sentence features, where the utterance encoder shares the weights with the label encoder; 4) Zero-shot DNN (Kumar et al., 2017) further improves the performance of CDSSM by using separate encoders for utterances and intent. The proposed model INTENTCAPSNET-ZSL can be seen as a hybrid model: it has the advantages of the compatibility models to model the correlations between utterances and intents directly; it also explicitly derives intent representations for emerging intents without labeled utterances.

Table 4: Zero-shot intention detection results using INTENTCAPSNET-ZSL on two datasets. All the metrics (Accuray, Precision, Recall and F1) are reported using the average value weighted by their support on per class.

rameters. The dimension of the prediction vector D_P is 10 for both datasets. $D_I = D_W$ because we use the averaged word embeddings contained in the intent label as the intent embedding. An additional input dropout layer with a dropout keep rate 0.8 is applied to the SNIPS-NLU dataset. In the loss function, the down-weighting coefficient λ is 0.5, margins m_k^+ and m_k^- are set to 0.9 and 0.1 for all the existing intents. The iteration number $iter$ used in the dynamic routing algorithm is 3. Adam optimizer (Kingma and Ba, 2014) is used to minimize the loss.

5 Results

Quantitative Evaluation. The intention detection results on two datasets are reported in Table 1, where the proposed capsule-based model INTENTCAPSNET performs consistently better than bag-of-word classifiers using TF-IDF, as well as various neural network models designed for text classification. These results demonstrate the novelty and effectiveness of the proposed capsule-based model INTENTCAPSNET in modeling text for intent detection.

Also, we report results on zero-shot intention detection task in Table 4, where our model INTENTCAPSNET-ZSL outperforms other baselines that adopt different zero-shot learning strategies. CMT has higher precision but low accuracy and recall on the SNIPS-NLU dataset. CDSSM fails on CVA dataset, probabily because the character-level model is suitable for English corpus but not for CVA, which is in Chinese.

Ablation Study. To study the contribution of different modules of INTENTCAPSNET-ZSL for zero-shot intent detection, we also report ablation test results in Table 4. "w/o Self-attention" is the model without self-attention: the last forward/backward hidden states of the bi-LSTM recurrent encoder are used; "w/o Bi-LSTM" uses the LSTM with only a forward pass; "w/o Regularizer" does not encourage discrepancies among different self-attention heads: it adopts $\alpha = 0$ in the loss function. Generally, from the lower part of Table 4 we can see that all modules contribute to the effectiveness of the model. On the SNIPS-NLU dataset, each of the three modules has a comparable contribution to the whole model (around 2-3% improvement in F1 score). While on the CVA dataset, the self-attention plays the most important role, which gives the model a 5.2% improvement in F1 score.

Discriminative Emerging Intent Representations. Besides quantitative evidences supporting the effectiveness of the INTENTCAPSNET-ZSL, we visualize activation vectors of emerging intents in Figure 3. Since the activation vectors of utterances with emerging intents are of high dimension and we are interested in their orientations which indicate their intent properties, t-SNE is applied on the normal vector of the activation vectors to reduce the dimension to 2. We color the utterances according to their ground-truth emerging intent labels.

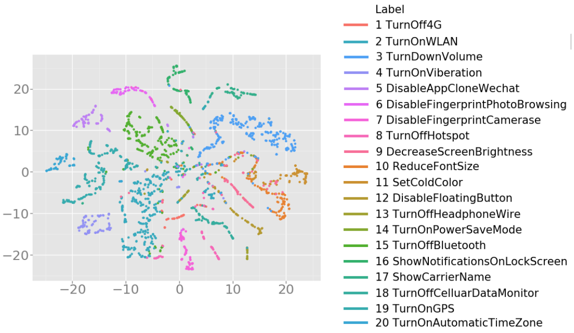

Figure 3: t-SNE visualization of normal activation vectors of utterances with 20 emerging intents in CVA.

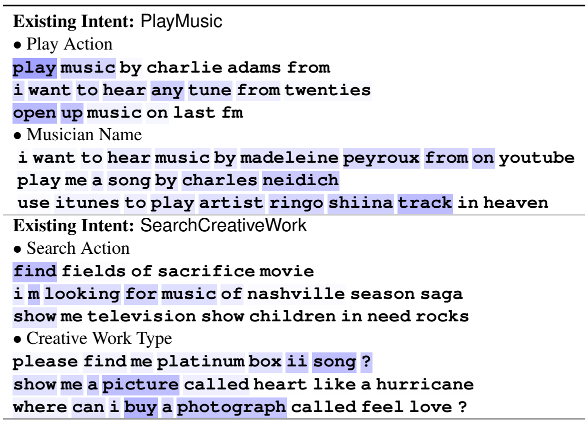
As illustrated in Figure 3, INTENTCAPSNET-ZSL has the ability to learn discriminative intent representations for emerging intents in zero-shot

DetectionCaps, so that utterances with different intents naturally have different orientations. In the meanwhile, utterances of the same emerging intent but with nuances in expressions result in their proximity in the t-SNE space. However, we do observe less satisfied cases where the model mistake an emerging intent DecreaseScreenBrightness (No. 9) with ReduceFontSize (No. 10) and SetColdColor (No. 11). When we check activation vectors of intents in Figure 3 we also find that these three intents tend to have similar representations around the area (15, -5). We think it is due to their inherent similarity as these three intents all try to tune display configurations.

6 Interpretability

Capsule models try to bring more interpretability when compared with traditional deep neural networks. We provide case studies here toward the intepretability of the proposed model in 1) extracting meaningful semantic features and 2) transferring knowledge from existing intents to emerging intents.

Extracting Meaningful Semantic Features. To show that SemanticCaps have the ability to extract meaningful semantic features from the utterance, we study the self-attention matrix **A** within the SemanticCaps and visualize the attention scores of utterances on both existing and emerging intents.



Existing Intent: PlayMusic
- Play Action

play music by charlie adams from
i want to hear any tune from twenties
open up music on last fm

- Musician Name

i want to hear music by madeleine peyroux from on youtube
play me a song by charles neidich
use itunes to play artist ringo shiina track in heaven

Existing Intent: SearchCreativeWork
- Search Action

find fields of sacrifice movie
i m looking for music of nashville season saga
show me television show children in need rocks

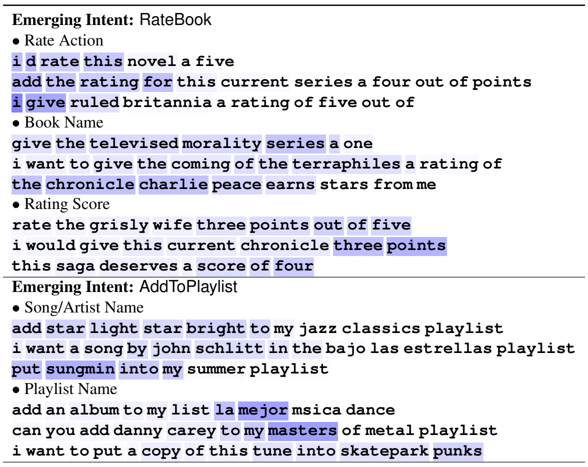
- Creative Work Type

please find me platinum box ii song ?
show me a picture called heart like a hurricane
where can i buy a photograph called feel love ?

Table 5: Attentions on utterances with existing intents on SNIPS-NLU.

From Table 5 we can see that each self-attention head almost always focuses on one unique semantic feature of the utterance. For example, in the intent of PlayMusic one self-attention head always focuses on the "play" action while another attention focuses on musician names. We also observe that the learned attention adopts well to diverse expressions. For example, the self-attention head in PlayMusic is attentive to various mentions of musician names when they are followed by words like `by`, `play` and `artist`, even when named entities are not tagged and given to the model. The self-attention head that extracts the "search" action in SearchCreativeWork is able to be attentive to various expressions such as `find`, `looking for` and `show`.

Extraction-behavior Transfer by SemanticCaps. More importantly, we observe appealing extraction behaviors of SemanticCaps on utterances of emerging intents as well, even if they are not trained to perform semantic extraction on utterances of emerging intents.



Emerging Intent: RateBook
- Rate Action

i d rate this novel a five
add the rating for this current series a four out of points
i give ruled britannia a rating of five out of

- Book Name

give the televised morality series a one
i want to give the coming of the terraphiles a rating of
the chronicle charlie peace earns stars from me

- Rating Score

rate the grisly wife three points out of five
i would give this current chronicle three points
this saga deserves a score of four

Emerging Intent: AddToPlaylist
- Song/Artist Name

add star light star bright to my jazz classics playlist
i want a song by john schlitt in the bajo las estrellas playlist
put sungmin into my summer playlist

- Playlist Name

add an album to my list la mejor msica dance
can you add danny carey to my masters of metal playlist
i want to put a copy of this tune into skatepark punks

Table 6: Attentions on utterances with emerging intents on SNIPS-NLU.

From Table 6 we observe that the same self-attention head that extracts "play" action in the existing intent PlayMusic is also attentive to words or phrases referring to the "rate" action in an emerging intent RateABook: like `rate`, `add the rating`, and `give`. Other self-attention heads are almost always focusing on other aspects of the utterances such as the book name or the actual rating score.

Such behavior not only shows that SemanticCaps have the capacity to learn an intent-independent semantic feature extractor, which extracts generalizable semantic features that either existing or emerging intent representations are built upon, but also indicates that SemanticCaps has the ability to transfer extraction behaviors among utterances of different intents.

Knowledge Transfer via Intent Similarity. Beside extracting semantic features and utilizing existing routing information, we use similarities between intent embeddings to help transfer vote vectors from INTENTCAPSNET to INTENTCAPSNET-ZSL. We study the similarity distribution of each emerging intents to all existing intents in Figure 4.

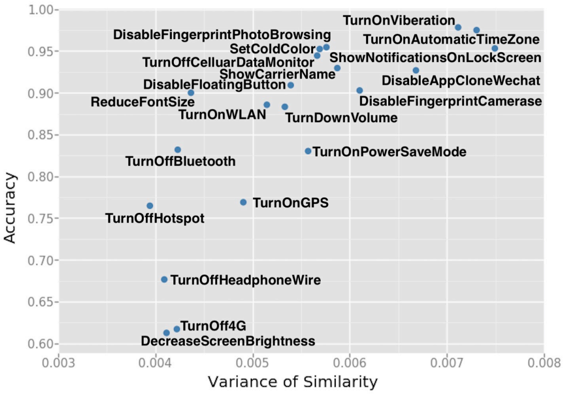


Figure 4: Accuracy vs. variance of the similarity distribution for 20 emerging intents in CVA dataset.

The y axis is the zero-shot detection accuracy on each emerging intent in the CVA dataset. The x axis measures var($\mathbf{q}_l$), the variance of the similarity distribution of each emerging intent l to all the existing intents. If an emerging intent has a high variance in the similarity distribution, it means that some existing intents have higher similarities with this emerging intent than others: the model is more certain about which existing intent to transfer the similarity knowledge from, based on intent label similarities. In this case, 13 out of 20 emerging intents with high variances where var($\mathbf{q}_l$) > 0.005 always have a decent performance (Accuracy$\geqslant$0.83). While a low variance does not necessarily always lead to less satisfied performances as some intents can rely on existing intents more evenly together, but with less confidence on each, for knowledge transfer.

7 Conclusions

In this paper, a capsule-based model, namely INTENTCAPSNET, is first introduced to harness the advantages of capsule models for text modeling in a hierarchical manner: semantic features are extracted from the utterances with self-attention, and aggregated via the dynamic routing-by-agreement mechanism to obtain utterance-level intent representations. We believe that the inductive biases subsumed in such capsule-based hierarchical learning schema have broader applicability on various text modeling tasks, besides its evidenced performance on the intent detection task we studied in this paper. The proposed INTENTCAPSNET-ZSL model further introduces zero-shot learning ability to the capsule model via various means of knowledge transfer from existing intents for discriminating emerging intents where no labeled utterances or excessive external resources are available. Experiments on two real-world datasets show the effectiveness and intepretability of the proposed models.

Hierarchical Neural Networks for Sequential Sentence Classification in Medical Scientific Abstracts

Abstract

Prevalent models based on artificial neural network (ANN) for sentence classification often classify sentences in isolation without considering the context in which sentences appear. This hampers the traditional sentence classification approaches to the problem of sequential sentence classification, where structured prediction is needed for better overall classification performance. In this work, we present a hierarchical sequential labeling network to make use of the contextual information within surrounding sentences to help classify the current sentence. Our model outperforms the state-of-the-art results by 2%-3% on two benchmarking datasets for sequential sentence classification in medical scientific abstracts.

1 Introduction

Since 1665, over 50 million scholarly research articles have been published (Jinha, 2010), with approximately 2.5 million new scientific papers coming out each year (Ware and Mabe, 2015). While this enormous corpus provides us with the ability to conclusively accept or reject hypotheses and yields insight into promising research directions, it is getting harder and harder to extract useful information from the literature in an efficient and timely manner due to its sheer amount. Therefore, an automatic and intelligent tool to help users locate the information of interest quickly and comprehensively is highly desired.

When searching for relevant literature for a certain field, investigators first check the abstracts of scientific papers to see whether they match the criterion of interest. This process can be expedited if the abstracts are structured; that is, if the rhetorical structural elements of scientific abstracts such as *purpose, methods, results, and conclusions* (American National Standards Institute, 1979) are explicitly stated. However, even today, a significant portion of scientific abstracts is still unstructured, which causes great difficulty in information retrieval. In this paper, we develop a machine-learning based approach to automatically categorize sentences in scientific abstracts into rhetorical sections so that the desired information can be efficiently retrieved.

In a scientific abstract, each sentence can be assigned to a rhetorical structural element sequentially. This rhetorical structure profiling process can be formulated as a sequential sentence classification task, as the element assignment of any single sentence is greatly associated with the assignments of the surrounding sentences. This is in contrast to the general sentence classification problem, where each sentence is classified individually and no contextual information can be used. Previous state-of-the-art methods relied on Conditional Random Fields (CRFs) to take into account the inter-dependence between subsequent labels, which improved joint sentence classification performance by considering the label sequence information. In this work, we add a bi-directional long short-term memory (bi-LSTM) layer over the representations of individual sentences so that it can encode the contextual content and semantics from preceding and succeeding sentences for better categorical inference of the current one.

In this work, we present a hierarchical neural network model for the sequential sentence classification task, which we call a hierarchical sequential labeling network (HSLN). Our model first uses a RNN or CNN layer to individually encode the sentence representation from the sequence of word embeddings, then uses another bi-LSTM layer to take as input the individual sentence representation and output the contextualized sentence representation, subsequently uses a single-hidden-layer feed-forward network to transform the sentence

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3100–3109
Brussels, Belgium, October 31 - November 4, 2018.

representation to the probability vector, and finally optimizes the predicted label sequence jointly via a CRF layer. We evaluate our model on two benchmarking datasets, PubMed RCT (Dernoncourt and Lee, 2017) and NICTA-PIBOSO (Kim et al., 2011), which were both generated from the PubMed database[1]. Our key contributions are summarized as follows:

1. Based on the previous best performing architecture for sequential sentence classification (Dernoncourt et al., 2016), we add one more layer to extract contextual information from surrounding sentences for more accurate prediction of the current one. Together with the CRF algorithm, this allows us to make use of not only the preceding labels' information but also the content and semantics of adjacent sentences to infer the label of the target sentence.

2. We remove the need for a character-based word embedding component without sacrificing performance. For individual sentence encoding, we propose the use of a CNN module as an alternative to RNN for small datasets, suffering less from over-fitting as evidenced by our experiments. Moreover, we incorporate attention-based pooling in both RNN and CNN models to further improve the performance.

3. We adopt dropout with expectation-linear regularization instead of the standard one to reduce the performance gap between training and test phases.

4. We obtain state-of-the-art results on two datasets for sequential sentence classification in medical abstracts, outperforming the previous best models by at least 2% in terms of F1 scores.

2 Related Work

Previous systems for sequential sentence classification concentrate on the rhetorical structure analysis of biomedical abstracts. They are mainly based on naive Bayes (Ruch et al., 2007), support vector machine (SVM) (McKnight and Srinivasan, 2003; Yamamoto and Takagi, 2005; Liu et al., 2013), Hidden Markov Model (HMM) (Lin et al., 2006), and CRF (Kim et al., 2011; Hassanzadeh et al., 2014; Hirohata et al., 2008; Chung, 2009). All these methods heavily rely on numerous carefully hand-engineered features such as lexical (bag-of-words (BOW)), semantic (hypernyms, synonyms), structural (part of speech (POS) tags, lemmas, orthographic shapes, headings), statistical (statistical distributions of token types) and sequential (sentence position, surrounding features, predicted labels) features.

In contrast, current emerging artificial neural network (ANN) based models have removed the need for manually selected features; instead, features are self-learned from the token and/or character embeddings. These deep learning models have revolutionized the natural language processing (NLP) field with state-of-the-art results achieved in various tasks, including the most relevant text classification task (Kim, 2014; Zhang et al., 2016; Conneau et al., 2017; Lai et al., 2015; Joulin et al., 2016; Ma et al., 2015). Most of these models are built upon deep CNNs or RNNs as well as combinations of them, where CNN is good at extracting local n-gram features while RNN is suitable for sequence modeling.

The above-mentioned works for short-text classification do not consider any context of sentence semantics in the models, making them underperform in the sequential sentence classification scenario, where surrounding sentences can play a big role in inferring the label of the current sentence. Recent works that apply deep neural networks to the sequential sentence classification problem include the system proposed by Lee et al. (Lee and Dernoncourt, 2016), where the preceding utterances were used to help classify the current utterance in a dialog into the corresponding dialogue act. Most recent work from Dernoncourt et al. (Dernoncourt et al., 2016) used a CRF layer to optimize the predicted label sequence, where the preceding labels have influence on determining the current label. This model outperformed the state-of-the-art results on two datasets PubMed RCT and NICTA-PIBOSO for sentence classification in medical abstracts.

3 Proposed Model

Notation We denote scalars in italic lowercase (e.g., k), vectors in bold italic lowercase (e.g., $\boldsymbol{s}$) and matrices in italic uppercase (e.g., W). Colon notations $x_{i:j}$ and $\boldsymbol{s}_{i:j}$ are used to denote the se-

---

[1] https://www.ncbi.nlm.nih.gov/pubmed/

quence of scalars $(x_i, x_{i+1}, ..., x_j)$ and vectors $(\boldsymbol{s}_i, \boldsymbol{s}_{i+1}, ..., \boldsymbol{s}_j)$.

Our model is composed of four components: the word embedding layer, the sentence encoding layer, the context enriching layer, and the label sequence optimization layer. In the following sections they will be discussed in detail.

3.1 Word Embedding Layer

Given a sentence $\boldsymbol{w} = \begin{bmatrix} w_1 & w_2 & \cdots & w_N \end{bmatrix}$ comprising N words, this layer maps each word to a real-valued vector as its lexical-semantic representation. Word representations are encoded by the column vector in the embedding matrix $W^{word} \in \mathbb{R}^{d^w \times |V|}$, where d^w is the dimension of the word vector and V is the vocabulary of the dataset. Each column $W_i^{word} \in \mathbb{R}^{d^w}$ is the word embedding vector for the i^{th} word in the vocabulary. The word embeddings W^{word} can be pre-trained on large unlabeled datasets using unsupervised algorithms such as word2vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014) and fastText (Bojanowski et al., 2016).

3.2 Sentence Encoding Layer

This layer takes as input the embedding vector of each token in a sentence from the word embedding layer and produces a vector **s** to encode this sentence. The sequence of embedding vectors is first processed by a bi-directional RNN (bi-RNN) or CNN layer, similar to the ones used in the text classification before (Kim, 2014; Lee and Dernoncourt, 2016; Liu et al., 2016). This layer outputs a sequence of hidden states $\boldsymbol{h}_{1:N}$ ($\boldsymbol{h} \in \mathbb{R}^{d^{hs}}$) for a sentence of N words with each hidden state corresponding to a word. To form the final representation vector $\boldsymbol{s}$ of this sentence, attention-based pooling is used, which can be described using the following equations:

$$A = \text{softmax}(U_s \tanh(W_s H + \boldsymbol{b}_s)), \quad (1)$$

$$S = AH^T, \quad (2)$$

where $H = \begin{bmatrix} h_1 & h_2 & \cdots & h_N \end{bmatrix} \in \mathbb{R}^{d^{hs} \times N}$, $W_s \in \mathbb{R}^{d^a \times d^{hs}}$ is the transformation matrix for soft alignment, $\boldsymbol{b}_s \in \mathbb{R}^{d^a}$ is the bias vector, $U_s \in \mathbb{R}^{r \times d^a}$ is the token level context matrix used to measure the relevance or importance of each token with respect to the whole sentence, softmax is performed along the second dimension of its input matrix, and $A \in \mathbb{R}^{r \times N}$ is the attention matrix.

Here each row of U_s is a context vector $\boldsymbol{u}_s \in \mathbb{R}^{d^a}$ and it is expected to reflect an aspect or component of the semantics of a sentence. To represent the overall semantics of the sentence, we use multiple context vectors to focus on different parts of this sentence.

Finally, the sentence encoding vector $\boldsymbol{s} \in \mathbb{R}^{rd^{hs}}$ is obtained by reshaping the matrix S into a vector.

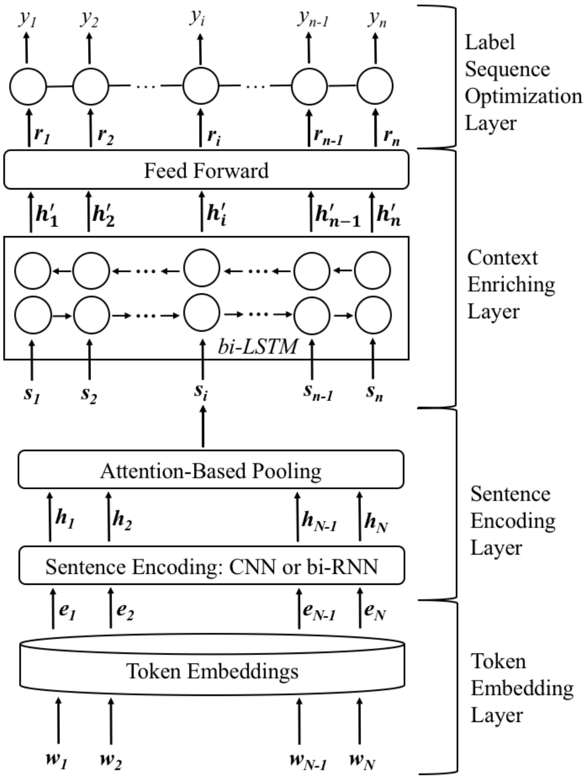

Figure 1: Model architecture. $\boldsymbol{w}$: original word; $\boldsymbol{e}$: word embedding vector; $\boldsymbol{h}$: sentence-level hidden state output by the bi-RNN or CNN layer; $\boldsymbol{s}$: sentence representation vector; $\boldsymbol{h'}$: abstract-level hidden state output by the bi-LSTM layer; $\boldsymbol{r}$: sentence label probability vector; y: predicted sentence label.

3.3 Context Enriching Layer

This layer takes as input the sequence of individual sentence encoding vectors in a given abstract of n sentences obtained from the last sentence encoding layer, with each vector corresponding to a sentence. It outputs a new sequence of contextualized sentence encoding vectors, which are enriched with the contextual information from surrounding sentences. Specifically, the sequence of individual sentence encoding vectors is input into a bi-LSTM layer, which produces a sequence of hidden state vectors $\boldsymbol{h'}_{1:n}$ ($\boldsymbol{h'} \in \mathbb{R}^{d^{hd}}$) with each corresponding to a sentence. Each of these vectors is subsequently input to a feed-forward neural network with only one hidden layer to get the corresponding probability vector $\boldsymbol{r} \in \mathbb{R}^{l}$, which represents the probability that this sentence belongs to each label, where l is the number of labels.

3.4 Label Sequence Optimization Layer

Within the abstract, the sequence of sentence categories implicitly follows some patterns. For example, the category *Results* is always followed by *Conclusion*, and the category *Methods* is certainly after the *Background*. Making use of such patterns can boost the classification performance via the CRF algorithm (Lample et al., 2016). Given the sequence of probability vectors $\boldsymbol{r}_{1:n}$ from the last context enriching layer for an abstract of n sentences, this layer outputs a sequence of labels $y_{1:n}$, where y_i represents the predicted label assigned to the i^{th} sentence.

In the CRF algorithm, in order to model dependencies between subsequent labels, we incorporate a matrix T that contains the transition probabilities between two subsequent labels; we define $T[i,j]$ as the probability that a token with label i is followed by a token with the label j. The score of a label sequence $y_{1:n}$ is defined as the sum of the probabilities of individual labels and the transition probabilities:

$$s(y_{1:n}) = \sum_{i=1}^{n} \boldsymbol{r}_i(y_i) + \sum_{i=2}^{n} T[y_{i-1}, y_i]. \qquad (3)$$

The score in the above equation can be transformed into the probability of a certain label sequence by taking a softmax operation over all possible label sequences:

$$p(y_{1:n}) = \frac{e^{s(y_{1:n})}}{\sum_{\hat{y}_{1:n} \in Y} e^{s(\hat{y}_{1:n})}}, \qquad (4)$$

where Y denotes the set of all possible label sequences. During the training phase, the objective is to maximize the probability of the gold label sequence. In the testing phase, given an input sequence, the corresponding sequence of predicted labels is chosen as the one that maximizes the score, computed via the Viterbi algorithm (Forney, 1973).

4 Experiments

4.1 Datasets

We evaluate our model on two sources of benchmarking datasets on medical scientific abstracts, where each sentence of the abstract is annotated with one label that is associated with the rhetorical structure. Table 1 summarizes the statistics of the two datasets.

NICTA-PIBOSO This dataset[2] was shared from the ALTA 2012 Shared Task (Amini et al., 2012), the goal of which is to build automatic sentence classifiers that can map the sentences from biomedical abstracts into a set of pre-defined categories for Evidence-Based Medicine (EBM).

PubMed RCT This new dataset was curated by (Dernoncourt and Lee, 2017)[3] and is currently the largest dataset for sequential sentence classification. It is based on the PubMed database of biomedical literature and each sentence of each abstract is labeled with its role in the abstract using one of the following classes: *background, objective, method, result, and conclusion*. Table 2 presents an example abstract comprising structured sentences with their annotated labels.

4.2 Training Settings

For both datasets, test performance is assessed on the training epoch with best validation performance and F1 scores (weighted average by support (the number of true instances for each label)) are reported as the results.

The token embeddings were pre-trained on a large corpus combining Wikipedia, PubMed, and PMC texts (Moen and Ananiadou, 2013) using the word2vec tool[4] (denoted as “Word2vec-wiki+P.M.”). They are fixed during the training phase to avoid over-fitting. We also tried other types of word embeddings, such as the word2vec embeddings pre-trained on the Google News dataset[5] (denoted as “Word2vec-News”), word2vec embeddings pre-trained on the Wikipedia corpus[6] (denoted as “Word2vec-wiki”), GloVe embeddings pre-trained on the cor-

Category	**Sentences**
BACKGROUND	Emotional eating is associated with overeating and the development of obesity. [...]
OBJECTIVES	The aim of this study was to test if attention bias for food moderates the effect of self-reported emotional eating during sad mood (vs neutral mood) on actual food intake. [...]
METHODS	Participants (N = 85) were randomly assigned to one of the two experimental mood induction conditions (sad/neutral). [...]
RESULTS	[...] Yet, attention maintenance on food cues was significantly related to increased intake specifically in the neutral condition, but not in the sad mood condition.
CONCLUSIONS	The current findings show that self-reported emotional eating (based on the DEBQ) might not validly predict who overeats when sad, at least not in a laboratory setting with healthy women. [...]

pus of Wikipedia 2014 + Gigaword 5[7] (denoted as "Glove-wiki"), fastText embeddings pre-trained on Wikipedia[8] (denoted as "FastText-wiki"), and fastText embeddings initialized with the standard GloVe Common Crawl embeddings and then fine-tuned on PubMed abstracts plus MIMIC-III notes (denoted as "FastText-P.M.+MIMIC"). The comparison results are summarized in the next section.

The model is trained using the Adam optimization method (Kingma and Ba, 2014). The learning rate is initially set as 0.003 and decayed by 0.9 after each epoch. For regularization, dropout (Srivastava et al., 2014) is applied to each layer. For the version of dropout used in practice (e.g., the dropout function implemented in the TensorFlow and Pytorch libraries), the model ensemble generated by dropout in the training phase is approximated by a single model with scaled weights in the inference phase, resulting in a gap between training and inference. To reduce this gap, we adopted the dropout with expectation-linear regularization introduced by Ma et al. (2016) to explicitly control the inference gap and thus improve the generalization performance.

Hyperparameters were optimized via grid search based on the validation set and the best configuration is shown in Table 3. The window sizes of the CNN encoder in the sentence encoding layer are 2, 3, 4 and 5. The RNN encoder in the sentence encoding layer is set as LSTM for the PubMed datasets and gated recurrent unit (GRU) for the NICTA-PIBOSO dataset. Code for this work is available online[9].

5 Results and Discussion

Table 4 compares our model against the best performing models in the literature (Dernoncourt et al., 2016; Liu et al., 2013). There are two variants of our model in terms of different implementations of the sentence encoding layer: the model that uses bi-RNN to encode the sentence is called HSLN-RNN; while the model that uses the CNN module is named HSLN-CNN. We have evaluated both model variants on all datasets. And as evidenced by Table 4, our best model can improve the F1 scores by 2%-3% in absolute number compared with the previous best published results for all

datasets. For the PubMed 20k and 200k datasets, our HSLN-RNN model achieves better results; however, for the NICTA dataset, the HSLN-CNN model performs better. This makes sense because the CNN sentence encoder has fewer parameters to be optimized, thus the HSLN-CNN model is less likely to over-fit in a smaller dataset such as NICTA. With sufficient data, however, the increased capacity of the HSLN-RNN model offers performance benefits. To be noted, this performance gap between RNN and CNN sentence encoder gets larger as the dataset size increases from 20k to 200k for the PubMed dataset.

HSLN-RNN	**92.6**	**93.9**	84.3

Table 4: Comparison of F1 scores (weighted average by support (the number of true instances for each label)) between our model and the best published methods. The presented results of our model are evaluated on the test set of the run with the highest F1 score on the validation set.

Table 5 presents the ablation analysis of our model (on the PubMed 20k dataset), where we remove one component at a time and quantify the performance drop (reported on F1 scores). As can be seen from Table 5, our HSLN-CNN model uniformly suffers a little more from the component removal than the HSLN-RNN model, indicating that the HSLN-RNN model is more robust. When the context enriching layer is removed, both models experience the most significant performance drop and can only be on par with the previous state-of-the-art results, strongly demonstrating that this proposed component is the key to the performance improvement of our model. Furthermore, even without the label sequence optimization layer, our model still significantly outperforms the best published methods that are empowered by this layer, indicating that the context enriching layer we propose can help optimize the label sequence by considering the context information from the surrounding sentences. Last but not the least, the dropout regularization and attention-based pooling components we add to our system can help further improve the model in a limited extent.

Model	HSLN-RNN	HSLN-CNN
Full Model	**92.6**	**92.2**
– context	90.0	89.0
– seq. opt.	92.3	91.8
– dropout reg.	92.4	91.9
– attention	92.4	91.7

Table 5: Ablation analysis. F1 scores are reported. "– context" is our model without the context enriching layer. "– seq. opt." is our model without the label sequence optimization layer. "– dropout reg.' is our model using the standard dropout strategy without the expectation-linearization regularization. "– attention" refers to the model without attention-based pooling, i.e., in the sentence encoding layer, the final hidden state is used for the HSLN-RNN model while max-pooling is used for the HSLN-CNN model.

Table 6 and 7 detail the results of classification for each label in terms of performance scores (precision, recall and F1) and confusion matrix, respectively (for our HSLN-RNN model trained on the PubMed 20k dataset). These show that the classifier is very good at predicting the labels *Methods*, *Results* and *Conclusions*, whereas the greatest difficulty the classifier has is in distinguishing *Background* sections from *Objectives* sections. One fifth of *Background* sentences are incorrectly classified as *Objectives*, while around one forth of *Objectives* sentences are wrongly assigned to the label of *Background*. We conjecture this difficulty mainly comes from the fact that the difference between *Background* and *Ob-*

jectives sentences in terms of writing style is less obvious compared with the other sections of the abstract. Moreover, our model has some difficulty in telling *Methods* sentences apart from *Results* sentences.

Label	P	R	F1	Support

Table 6: Results (presented in percentage) in terms of precision (P), recall (R) and F-measure (F1) on the test set for each label obtained by our HSLN-RNN model on the PubMed 20k dataset.

	B	**C**	**M**	**O**	**R**
B	2460	4	69	537	7
C	4	4413	11	1	142
M	37	11	9657	27	152
O	632	0	68	1630	3
R	2	95	362	1	9253

Table 7: Confusion matrix obtained by our model on the PubMed 20k dataset. Rows correspond to predicted labels, and columns correspond to true labels. B represents background, O represents objectives, M represents methods, R represents results, and C represents conclusions.

Table 8 presents a few examples of prediction errors that are produced by our HSLN-RNN model trained on the PubMed 20k dataset. This error analysis suggests that one of the biggest model error sources could be from the debatable gold standard labels of the dataset. For example, the sentence "Depressive disorders are one of the leading components of the global burden of disease with a prevalence of up to 14% in the general population." is indeed introducing the background of the problem (depressive disorders) on which this article is going to focus; however, the gold label classifies it into the *Objective* category. For another instance, the sentence "A post hoc analysis was conducted with the use of data from the evaluation study of congestive heart failure and pulmonary artery catheterization effectiveness (escape)." belongs to the *Result* label according to the gold standard, but it makes more sense that it should be classified as a *Method* label.

Figure 2 presents an example of the transition matrix after the HSLN-RNN model has been trained on the PubMed 20k dataset, which encodes the transition probability between two subsequent labels. It effectively reflects what label is the most likely one that follows the current one. For example, by comparing the transition scores in the *Result* row in Figure 2, we can conclude that a sentence pertaining to the *Result* is typically followed by a sentence pertaining to the *Conclusion* and is unlikely to be followed by a sentence in the *Background* category (transition scores of 2.48 vs -5.46), which makes sense. From this transition matrix, we can figure out the most probable label sequence: $Background \rightarrow Objective \rightarrow Method \rightarrow Result \rightarrow Conclusion$, which is also consistent with our expectations.

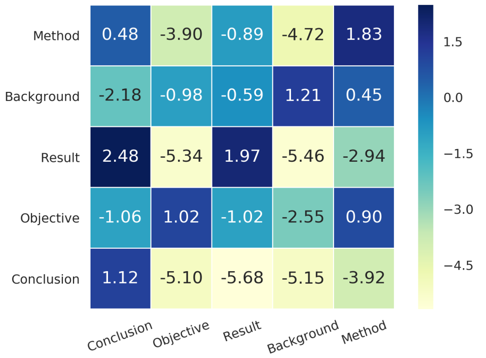

Figure 2: Transition matrix of label sequence after the HSLN-RNN model has been trained on the PubMed 20k dataset. The rows represent the label of the previous sentence, while the columns represent the label of the current sentence.

In order to test the importance of pretrained word embeddings, we performed experiments with different sets of publicly published word embeddings, as well as our locally curated word embeddings, to initialize our model. Table 9 gives the performance of six different word embeddings for our HSLN-RNN model trained on the PubMed 20k dataset. According to Table 9, the training methods that create the word embeddings do not have a strong influence on model performance, but the corpus they are trained on does. The combination of Wikipedia and PubMed abstracts as the corpus for unsupervised word embedding training yields the best result, and the individual use of either the Wikipedia corpus or the PubMed abstracts performs much worse. Although the dataset we

6 Conclusion

In this work, we have presented an ANN based hierarchical sequential labeling network to classify sentences that appear sequentially in text. We demonstrate that incorporating the contextual information from surrounding sentences to help classify the current one by using an LSTM layer to sequentially process the encoded sentence representations can improve the overall quality of predictions. Our model outperforms the state-of-the-art results by 2%-3% on two datasets for sequential sentence classification in medical abstracts. We expect that our proposed model can be generalized to any problem that is related to sequential sentence classification, such as the paragraph-level sequential sentence categorization in full-text articles for better text mining and document retrieval (Westergaard et al., 2018).

7 Future Work

Although the whole PubMed database contains over 2 million abstracts with part of them accompanied by full-text articles, only a small fraction of them are structured and contain the label information utilized in this work. We plan to make use of the rest unannotated abstracts or full texts to pre-train our model and then fine tune it to the target annotated datasets inspired by the work from (Howard and Ruder, 2018) so that the performance can be further boosted.

Abstract

In this study, we explore capsule networks with dynamic routing for text classification. We propose three strategies to stabilize the dynamic routing process to alleviate the disturbance of some noise capsules which may contain "background" information or have not been successfully trained. A series of experiments are conducted with capsule networks on six text classification benchmarks. Capsule networks achieve competitive results over the compared baseline methods on 4 out of 6 datasets, which shows the effectiveness of capsule networks for text classification. We additionally show that capsule networks exhibit significant improvement when transfer single-label to multi-label text classification over the competitors. To the best of our knowledge, this is the first work that capsule networks have been empirically investigated for text modeling[1].

1 Introduction

Modeling articles or sentences computationally is a fundamental topic in natural language processing. It could be as simple as a keyword/phrase matching problem, but it could also be a nontrivial problem if compositions, hierarchies, and structures of texts are considered. For example, a news article which mentions a single phrase "US election" may be categorized into the political news with high probability. But it could be very difficult for a computer to predict which presidential candidate is favored by its author, or whether the author's view in the article is more liberal or more conservative.

Earlier efforts in modeling texts have achieved limited success on text categorization using a simple bag-of-words classifier (Joachims, 1998; McCallum et al., 1998), implying understanding the meaning of the individual word or n-gram is a necessary step towards more sophisticated models. It is therefore not a surprise that distributed representations of words, a.k.a. word embeddings, have received great attention from NLP community addressing the question "what" to be modeled at the basic level (Mikolov et al., 2013; Pennington et al., 2014). In order to model higher level concepts and facts in texts, an NLP researcher has to think cautiously the so-called "what" question: *what is actually modeled beyond word meanings*. A common approach to the question is to treat the texts as sequences and focus on their spatial patterns, whose representatives include convolutional neural networks (CNNs) (Kim, 2014; Zhang et al., 2015; Conneau et al., 2017) and long short-term memory networks (LSTMs) (Tai et al., 2015; Mousa and Schuller, 2017). Another common approach is to completely ignore the order of words but focus on their compositions as a collection, whose representatives include probabilistic topic modeling (Blei et al., 2003; Mcauliffe and Blei, 2008) and Earth Mover's Distance based modeling (Kusner et al., 2015; Ye et al., 2017).

Those two approaches, albeit quite different from the computational perspective, actually follow a common measure to be diagnosed regarding their answers to the "what" question. In neural network approaches, spatial patterns aggregated at lower levels contribute to representing higher level concepts. Here, they form a recursive process to articulate what to be modeled. For example, CNN builds convolutional feature detectors to extract local patterns from a window of vector sequences

and uses max-pooling to select the most prominent ones. It then hierarchically builds such pattern extraction pipelines at multiple levels. Being a spatially sensitive model, CNN pays a price for the inefficiency of replicating feature detectors on a grid. As argued in (Sabour et al., 2017), one has to choose between replicating detectors whose size grows exponentially with the number of dimensions, or increasing the volume of the labeled training set in a similar exponential way. On the other hand, methods that are spatially insensitive are *perfectly* efficient at the inference time regardless of any order of words or local patterns. However, they are unavoidably more restricted to encode rich structures presented in a sequence. Improving the efficiency to encode spatial patterns while keeping the flexibility of their representation capability is thus a central issue.

A recent method called capsule network introduced by Sabour et al. (2017) possesses this attractive potential to address the aforementioned issue. They introduce an iterative routing process to decide the credit attribution between nodes from lower and higher layers. A metaphor (also as an argument) they made is that human visual system intelligently assigns parts to wholes at the inference time without hard-coding patterns to be perspective relevant. As an outcome, their model could encode the intrinsic spatial relationship between a part and a whole constituting viewpoint invariant knowledge that automatically generalizes to novel viewpoints. In our work, we follow a similar spirit to use this technique in modeling texts. Three strategies are proposed to stabilize the dynamic routing process to alleviate the disturbance of some noise capsules which may contain "background" information such as stop words and the words that are unrelated to specific categories. We conduct a series of experiments with capsule networks on top of the pre-trained word vectors for six text classification benchmarks. More importantly, we show that capsule networks achieves significant improvement when transferring single-label to multi-label text classifications over the compared baseline methods.

2 Our Methodology

Our capsule network, depicted in Figure 1, is a variant of the capsule networks proposed in Sabour et al. (2017). It consists of four layers: n-gram convolutional layer, primary capsule layer, convolutional capsule layer, and fully connected capsule layer. In addition, we explore two capsule frameworks to integrate these four components in different ways. In the rest of this section, we elaborate the key components in detail.

2.1 N-gram Convolutional Layer

This layer is a standard convolutional layer which extracts n-gram features at different positions of a sentence through various convolutional filters.

Suppose $\mathbf{x} \in \mathbb{R}^{L \times V}$ denotes the input sentence representation where L is the length of the sentence and V is the embedding size of words. Let $\mathbf{x}_i \in \mathbb{R}^V$ be the V-dimensional word vector corresponding to the i-th word in the sentence. Let $W^a \in \mathbb{R}^{K_1 \times V}$ be the filter for the convolution operation, where K_1 is the N-gram size while sliding over a sentence for the purpose of detecting features at different positions. A filter W^a convolves with the word-window $\mathbf{x}_{i:i+K_1-1}$ at each possible position (with stride of 1) to produce a column feature map $\mathbf{m}^a \in \mathbb{R}^{L-K_1+1}$, each element $m_i^a \in \mathbb{R}$ of the feature map is produced by

$$m_i^a = f(\mathbf{x}_{i:i+K_1-1} \circ W^a + \mathbf{b}_0) \qquad (1)$$

where $\circ$ is element-wise multiplication, $\mathbf{b}_0$ is a bias term, and f is a nonlinear activate function (i.e., ReLU). We have described the process by which one feature is extracted from one filter. Hence, for $a = 1, \ldots, B$, totally B filters with the same N-gram size, one can generate B feature maps which can be rearranged as

$$\mathbf{M} = [\mathbf{m}_1, \mathbf{m}_2, ..., \mathbf{m}_{\mathrm{B}}] \in \mathbb{R}^{(L-K_1+1) \times B} \qquad (2)$$

2.2 Primary Capsule Layer

This is the first capsule layer in which the capsules replace the scalar-output feature detectors of CNNs with vector-output capsules to preserve the instantiated parameters such as the local order of words and semantic representations of words.

Suppose $p_i \in \mathbb{R}^d$ denotes the instantiated parameters of a capsule, where d is the dimension of the capsule. Let $W^b \in \mathbb{R}^{B \times d}$ be the filter shared in different sliding windows. For each matrix multiplication, we have a window sliding over each N-gram vector denoted as $\mathbf{M}_i \in \mathbb{R}^B$, then the corresponding N-gram phrases in the form of capsule are produced with $p_i = (W^b)^T \mathbf{M}_i$.

The filter W^b multiplies each N-gram vector in $\{\mathbf{M_i}\}_{i=1}^{L-K_1+1}$ with stride of 1 to produce a

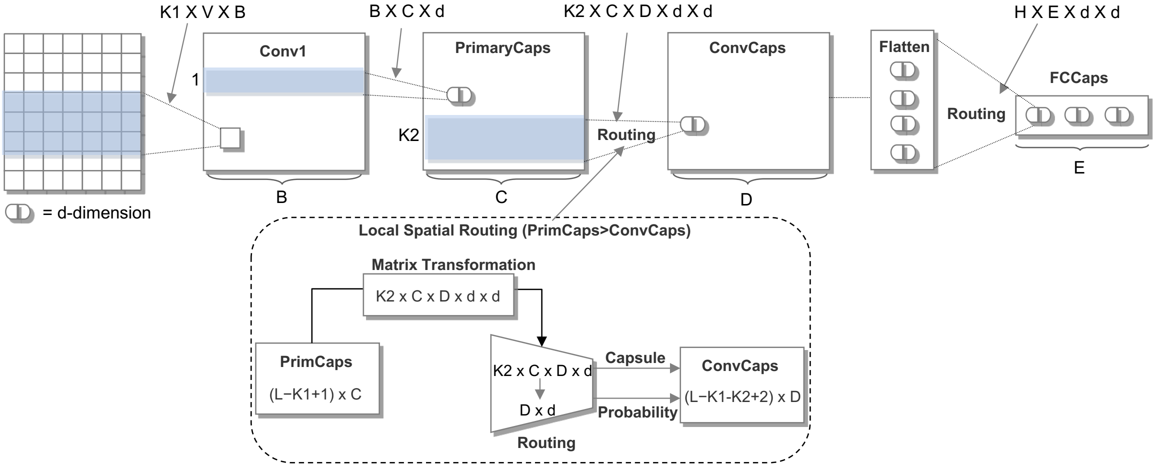

Figure 1: The Architecture of Capsule network for text classification. The processes of dynamic routing between consecutive layers are shown in the bottom.

column-list of capsules $\mathbf{p} \in \mathbb{R}^{(L-K_1+1)\times d}$, each capsule $p_i \in \mathbb{R}^d$ in the column-list is computed as

$$p_i = g(W^b \mathbf{M}_i + \mathbf{b}_1) \qquad (3)$$

where g is nonlinear squash function through the entire vector, $\mathbf{b}_1$ is the capsule bias term. For all C filters, the generated capsule feature maps can be rearranged as

$$\mathbf{P} = [\mathbf{p}_1, \mathbf{p}_2, ..., \mathbf{p}_C] \in \mathbb{R}^{(L-K_1+1)\times C\times d}, \qquad (4)$$

where totally $(L - K_1 + 1) \times C$ d-dimensional vectors are collected as capsules in $\mathbf{P}$.

2.2.1 Child-Parent Relationships

As argued in (Sabour et al., 2017), capsule network tries to address the representational limitation and exponential inefficiencies of convolutions with transformation matrices. It allows the networks to automatically learn child-parent (or part-whole) relationships constituting viewpoint invariant knowledge that automatically generalizes to novel viewpoints.

In this paper, we explore two different types of transformation matrices to generate prediction vector (vote) $\hat{u}_{j|i} \in \mathbb{R}^d$ from its child capsule i to the parent capsule j. The first one shares weights $W^{t_1} \in \mathbb{R}^{N\times d\times d}$ across child capsules in the layer below, where N is the number of parent capsules in the layer above. Formally, each corresponding vote can be computed by:

$$\hat{u}_{j|i} = W_j^{t_1} u_i + \hat{b}_{j|i} \in \mathbb{R}^d \qquad (5)$$

where u_i is a child-capsule in the layer below and $\hat{b}_{j|i}$ is the capsule bias term.

In the second design, we replace the shared weight matrix $W_j^{t_1}$ with non-shared weight matrix $W_{i,j}^{t_2}$, where the weight matrices $W^{t_2} \in \mathbb{R}^{H\times N\times d\times d}$ and H is the number of child capsules in the layer below.

2.3 Dynamic Routing

The basic idea of dynamic routing is to construct a non-linear map in an iterative manner ensuring that the output of each capsule gets sent to an appropriate parent in the subsequent layer:

$$\left\{\hat{u}_{j|i} \in \mathbb{R}^d\right\}_{i=1,...,H,j=1...,N} \mapsto \left\{v_j \in \mathbb{R}^d\right\}_{j=1}^{N}.$$

For each potential parent, the capsule network can increase or decrease the connection strength by dynamic routing, which is more effective than the primitive routing strategies such as max-pooling in CNN that essentially detects whether a feature is present in any position of the text, but loses spatial information about the feature. We explore three strategies to boost the accuracy of routing process by alleviating the disturbance of some noisy capsules:

Orphan Category Inspired by Sabour et al. (2017), an additional "orphan" category is added to the network, which can capture the "background" information of the text such as stop words and the words that are unrelated to specific categories, helping the capsule network model the child-parent relationship more efficiently. Adding "orphan" category in the text is more effective than in image since there is no single consistent "background" object in images, while the stop words are consistent in texts such as predicate “s”, “am” and pronouns “his”, “she”.

Leaky-Softmax We explore Leaky-Softmax Sabour et al. (2017) in the place of standard softmax while updating connection strength between the children capsules and their parents. Despite the orphan category in the last capsule layer, we also need a light-weight method between two consecutive layers to route the noise child capsules to extra dimension without any additional parameters and computation consuming.

Coefficients Amendment We also attempt to use the probability of existence of child capsules in the layer below to iteratively amend the connection strength as Eq.6.

Algorithm 1: Dynamic Routing Algorithm

```
procedure ROUTING($\hat{u}_{j|i}$, $\hat{a}_{j|i}$, $r$, $l$)
Initialize the logits of coupling coefficients
  $b_{j|i} = 0$
for $r$ iterations do
    for all capsule $i$ in layer $l$ and capsule $j$ in
      layer $l+1$:
      $c_{j|i} = \hat{a}_{j|i} \cdot \text{leaky-softmax}(b_{j|i})$
    for all capsule $j$ in layer $l+1$:
      $v_j = g(\sum_i c_{j|i}\hat{u}_{j|i}), \quad a_j = |v_j|$
    for all capsule $i$ in layer $l$ and capsule $j$ in
      layer $l+1$: $b_{j|i} = b_{j|i} + \hat{u}_{j|i} \cdot v_j$
return $v_j$,$a_j$
```

Given each prediction vector $\hat{u}_{j|i}$ and its probability of existence $\hat{a}_{j|i}$, where $\hat{a}_{j|i} = \hat{a}_i$, each iterative coupling coefficient of connection strength $c_{j|i}$ is updated by

$$c_{j|i} = \hat{a}_{j|i} \cdot \text{leaky-softmax}(b_{j|i}) \tag{6}$$

where $b_{j|i}$ is the logits of coupling coefficients. Each parent capsule v_j in the layer above is a weighted sum over all prediction vectors $\hat{u}_{j|i}$:

$$v_j = g(\sum_i c_{j|i}\hat{u}_{j|i}), \quad a_j = |v_j| \tag{7}$$

where a_j is the probabilities of parent capsules, g is nonlinear squash function Sabour et al. (2017) through the entire vector. Once all of the parent capsules are produced, each coupling coefficient $b_{j|i}$ is updated by:

$$b_{j|i} = b_{j|i} + \hat{u}_{j|i} \cdot v_j \tag{8}$$

For simplicity of notation, the parent capsules and their probabilities in the layer above are denoted as

$$v, a = \text{Routing}(\hat{\text{u}}) \tag{9}$$

where $\hat{u}$ denotes all of the child capsules in the layer below, v denotes all of the parent-capsules and their probabilities a.

Our dynamic routing algorithm is summarized in Algorithm 1.

2.4 Convolutional Capsule Layer

In this layer, each capsule is connected only to a local region $K_2 \times C$ spatially in the layer below. Those capsules in the region multiply transformation matrices to learn child-parent relationships followed by routing by agreement to produce parent capsules in the layer above.

Suppose $W^{c_1} \in \mathbb{R}^{D \times d \times d}$ and $W^{c_2} \in \mathbb{R}^{K_2 \times C \times D \times d \times d}$ denote shared and non-shared weights, respectively, where $K_2 \cdot C$ is the number of child capsules in a local region in the layer below, D is the number of parent capsules which the child capsules are sent to. When the transformation matrices are shared across the child capsules, each potential parent-capsule $\hat{u}_{j|i}$ is produced by

$$\hat{u}_{j|i} = W_j^{c_1} u_i + \hat{b}_{j|i} \tag{10}$$

where $\hat{b}_{j|i}$ is the capsule bias term, u_i is a child capsule in a local region $K_2 \times C$ and $W_j^{c_1}$ is the j_{th} matrix in tensor W^{c_1}. Then, we use routing-by-agreement to produce parent capsules feature maps totally $(L - K_1 - K_2 + 2) \times D$ d-dimensional capsules in this layer. When using the non-shared weights across the child capsules, we replace the transformation matrix $W_j^{c_1}$ in Eq. (10) with $W_j^{c_2}$.

2.5 Fully Connected Capsule Layer

The capsules in the layer below are flattened into a list of capsules and fed into fully connected capsule layer in which capsules are multiplied by transformation matrix $W^{d_1} \in \mathbb{R}^{E \times d \times d}$ or $W^{d_2} \in \mathbb{R}^{H \times E \times d \times d}$ followed by routing-by-agreement to produce final capsule $v_j \in \mathbb{R}^d$ and its probability $a_j \in \mathbb{R}$ for each category. Here, H is the number of child capsules in the layer below, E is the number of categories plus an extra orphan category.

2.6 The Architectures of Capsule Network

We explore two capsule architectures (denoted as Capsule-A and Capsule-B) to integrate these four

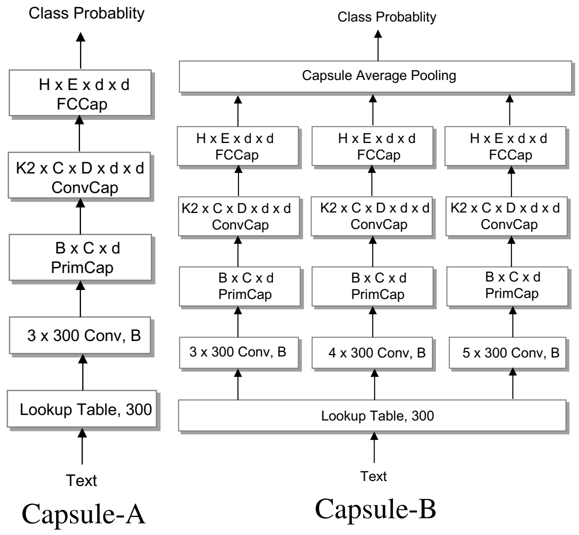

Figure 2: Two architectures of capsule networks.

components in different ways, as depicted in Figure 2.

Capsule-A starts with an embedding layer which transforms each word in the corpus to a 300-dimensional ($V = 300$) word vector, followed by a 3-gram ($K_1 = 3$) convolutional layer with 32 filters ($B = 32$) and a stride of 1 with ReLU non-linearity. All the other layers are capsule layers starting with a $B \times d$ primary capsule layer with 32 filters ($C = 32$), followed by a $3 \times C \times d \times d$ ($K_2 = 3$) convolutional capsule layer with 16 filters ($D = 16$) and a fully connected capsule layer in sequence.

Each capsule has 16-dimensional ($d = 16$) instantiated parameters and their length (norm) can describe the probability of the existence of capsules. The capsule layers are connected by the transformation matrices, and each connection is also multiplied by a routing coefficient that is dynamically computed by routing by agreement mechanism.

The basic structure of Capsule-B is similar to Capsule-A except that we adopt three parallel networks with filter windows (N) of 3, 4, 5 in the N-gram convolutional layer (see Figure 2). The final output of the fully connected capsule layer is fed into the average pooling to produce the final results. In this way, Capsule-B can learn more meaningful and comprehensive text representation.

3 Experimental Setup

3.1 Experimental Datasets

In order to evaluate the effectiveness of our model, we conduct a series of experiments on six benchmarks including: movie reviews (MR) (Pang and Lee, 2005), Stanford Sentiment Treebankan extension of MR (SST-2) (Socher et al., 2013), Subjectivity dataset (Subj) (Pang and Lee, 2004), TREC question dataset (TREC) (Li and Roth, 2002), customer review (CR) (Hu and Liu, 2004), and AG's news corpus (Conneau et al., 2017). These benchmarks cover several text classification tasks such as sentiment classification, question categorization, news categorization. The detailed statistics are presented in Table 1.

Dataset	Train	Dev	Test	Classes	Classification Task
MR	8.6k	0.9k	1.1k	2	review classification
SST-2	8.6k	0.9k	1.8k	2	sentiment analysis
Subj	8.1k	0.9k	1.0k	2	opinion classification
TREC	5.4k	0.5k	0.5k	6	question categorization
CR	3.1k	0.3k	0.4k	2	review classification
AG's news	108k	12.0k	7.6k	4	news categorization

Table 1: Characteristics of the datasets.

3.2 Implementation Details

In the experiments, we use 300-dimensional word2vec (Mikolov et al., 2013) vectors to initialize embedding vectors. We conduct mini-batch with size 50 for AG's news and size 25 for other datasets. We use Adam optimization algorithm with 1e-3 learning rate to train the model. We use 3 iteration of routing for all datasets since it optimizes the loss faster and converges to a lower loss at the end.

3.3 Baseline methods

In the experiments, we evaluate and compare our model with several widely used baseline methods including: LSTM/Bi-LSTM (Cho et al., 2014), tree-structured LSTM (Tree-LSTM) (Tai et al., 2015), LSTM regularized by linguistic knowledge (LR-LSTM) (Qian et al., 2016), CNN-rand/CNN-static/CNN-non-static (Kim, 2014), very deep convolutional network (VD-CNN) (Conneau et al., 2017), and character-level convolutional network (CL-CNN) (Zhang et al., 2015).

4 Experimental Results

4.1 Quantitative Evaluation

In our experiments, the evaluation metric is classification accuracy. We summarize the experimental results in Table 2. From the results, we observe that the capsule networks achieve best results on 4 out of 6 benchmarks, which verifies the effectiveness of the capsule networks. In particular, our model substantially and consistently outperforms

	MR	**SST2**	**Subj**	**TREC**	**CR**	**AG's**
LSTM	75.9	80.6	89.3	86.8	78.4	86.1

the simple deep neural networks such as LSTM, Bi-LSTM and CNN-rand by a noticeable margin on all the experimental datasets. Capsule network also achieves competitive results against the more sophisticated deep learning models such as LR-LSTM, Tree-LSTM, VC-CNN and CL-CNN. Note that Capsule-B consistently performs better than Capsule-A since Capsule-B allows to learn more meaningful and comprehensive text representation. For example, a combination of N-gram convolutional layer with filter windows of $\{3,4,5\}$ can capture the 3/4/5-gram features of the text which play a crucial role in text modeling.

4.2 Ablation Study

To analyze the effect of varying different components of our capsule architecture for text classification, we also report the ablation test of the capsule-B model in terms of using different setups of the capsule network. The experimental results are summarized in Table 5. Generally, all three proposed dynamic routing strategies contribute to the effectiveness of Capsule-B by alleviating the disturbance of some noise capsules which may contain "background" information such as stop words and the words that are unrelated to specific categories.

5 Single-Label to Multi-Label Text Classification

Capsule network demonstrates promising performance in single-label text classification which assigns a label from a predefined set to a text (see Table 2). Multi-label text classification is, however, a more challenging practical problem. From single-label to multi-label (with n category labels) text classification, the label space is expanded from n to 2^n, thus more training is required to cover the whole label space. For single-label texts, it is practically easy to collect and annotate the samples. However, the burden of collection and annotation for a large scale multi-label text dataset is generally extremely high. How deep neural networks (e.g., CNN and LSTM) best cope with multi-label text classification still remains a problem since obtaining large scale of multi-label dataset is a time-consuming and expensive process. In this section, we investigate the capability of capsule network on multi-label text classification by using only the single-label samples as training data. With feature property as part of the information extracted by capsules, we may generalize the model better to multi-label text classification without an over extensive amount of labeled data.

The evaluation is carried on the Reuters-21578 dataset (Lewis, 1992). This dataset consists of 10,788 documents from the Reuters financial newswire service, where each document contains either multiple labels or a single label. We re-process the corpus to evaluate the capability of capsule networks of transferring from single-label to multi-label text classification. For dev and training, we only use the single-label documents in the Reuters dev and training sets. For testing, Reuters-Multi-label only uses the multi-label documents in testing dataset, while Reuters-Full includes all documents in test set. The characteristics of these two datasets are described in Table 3.

Following (Sorower, 2010), we adopt Micro Averaged Precision (Precision), Micro Averaged Recall (Recall) and Micro Averaged F1 scores (F1) as the evaluation metrics for multi-label text classification. Any of these scores are firstly computed on individual class labels and then averaged over all classes, called label-based measures. In addition, we also measure the Exact Match Ratio (ER) which considers partially correct prediction as incorrect and only counts fully correct samples.

The experimental results are summarized in Table 4. From the results, we can observe that the capsule networks have substantial and significant improvement in terms of all four evaluation metrics over the compared baseline methods on the test sets in both Reuters-Multi-label and Reuters-Full datasets. In particular, larger improvement

	Reuters-Multi-label				Reuters-Full			
	ER	Precision	Recall	F1	ER	Precision	Recall	F1
LSTM	23.3	86.7	54.7	63.5	62.5	78.6	72.6	74.0
BiLSTM	26.4	82.3	55.9	64.6	65.8	83.7	75.4	77.8
CNN-rand	22.5	88.6	56.4	67.1	63.4	78.7	71.5	73.6
CNN-static	27.1	91.1	59.1	69.7	63.3	78.5	71.2	73.3
CNN-non-static	27.4	92.0	59.7	70.4	64.1	80.6	72.7	75.0
Capsule-A	57.2	88.2	80.1	82.0	66.0	83.9	**80.5**	80.2
Capsule-B	**60.3**	**95.4**	**82.0**	**85.8**	**67.7**	**86.4**	80.1	**81.4**

Table 4: Comparisons of the capability for transferring from single-label to multi-label text classification on Reuters-Multi-label and Reuters-Full datasets. For fair comparison, we use margin-loss for our model and other baselines.

	Iteration	**Accuracy**
Capsule-B + Sabour's routing	3	81.4
Capsule-B + our routing	1	81.4
Capsule-B + our routing	3	82.3
Capsule-B + our routing	5	81.6
w/o Leaky-softmax	3	81.7
w/o Orphan Category	3	81.9
w/o Amendent Coeffient	3	82.1

Table 5: Ablation study of Capsule-B on MR dataset. The standard routing is routing-by-agreement algorithm without leaky-softmax and orphan category in the last capsule layer. More ablations are discussed in Appendix.

is achieved on Reuters-Multi-label dataset which only contains the multi-label documents in the test set. This is within our expectation since the capsule network is capable of preserving the instantiated parameters of the categories trained by single-label documents. The capsule network has much stronger transferring capability than the conventional deep neural networks. In addition, the good results on Reuters-Full also indicate that the capsule network has robust superiority over competitors on single-label documents.

5.1 Connection Strength Visualization

To visualize the connection strength between capsule layers clearly, we remove the convolutional capsule layer and make the primary capsule layer followed by the fully connected capsule layer directly, where the primary capsules denote N-gram phrases in the form of capsules. The connection strength shows the importance of each primary capsule for text categories, acting like a parallel attention mechanism. This should allow the capsule networks to recognize multiple categories in the text even though the model is trained on single-label documents.

Due to space reasons, we choose a multi-label document from Reuters-Multi-label test set whose category labels (i.e., Interest Rates and Money/Foreign Exchange) are correctly predicted (fully correct) by our model with high confidence ($p > 0.8$) to report in Table 6. The category-specific phrases such as "interest rates" and "foreign exchange" are highlighted with red color. We use the tag cloud to visualize the 3-gram phrases for Interest Rates and Money/Foreign Exchange categories. The stronger the connection strength, the bigger the font size. From the results, we observe that capsule networks can correctly recognize and cluster the important phrases with respect to the text categories. The histograms are used to show the intensity of connection strengths between primary capsules and the fully connected capsules, as shown in Table 6 (bottom line). Due to space reasons, five histograms are demonstrated. The routing procedure correctly routes the votes into the Interest Rates and Money/Foreign Exchange categories.

To experimentally verify the convergence of the routing algorithm, we also plot learning curve to show the training loss over time with different iterations of routing. From Figure 3, we observe that the Capsule-B with 3 or 5 iterations of routing optimizes the loss faster and converges to a lower loss at the end than the capsule network with 1 iteration.

6 Related Work

Early methods for text classification adopted the typical features such as bag-of-words, n-grams, and their TF-IDF features (Zhang et al., 2008) as

U.K. MONEY RATES FIRM ON LAWSON STERLING TARGETS	Interest Rates	Money/Foreign Exchange
Interest rates on the London money market were slightly firmer on news U.K. Chancellor of the Exchequer Nigel Lawson had stated target rates for sterling against the dollar and mark, dealers said. They said this had come as a surprise and expected the targets, 2.90 marks and 1.60 dlrs, to be promptly tested in the foreign exchange markets. Sterling opened 0.3 points lower in trade weighted terms at 71.3. Dealers noted the chancellor said he would achieve his goals on sterling by a combination of intervention in currency markets and interest rates. Operators feel the foreign exchanges are likely to test sterling on the downside and that this seems to make a fall in U.K. Base lending rates even less likely in the near term, dealers said. The feeling remains in the market, however, that fundamental factors have not really changed and that a rise in U.K. Interest rates is not very likely. The market is expected to continue at around these levels, reflecting the current 10 pct base rate level, for some time. The key three months interbank rate was 1/16 point firmer at 10 9-7/8 pct.		

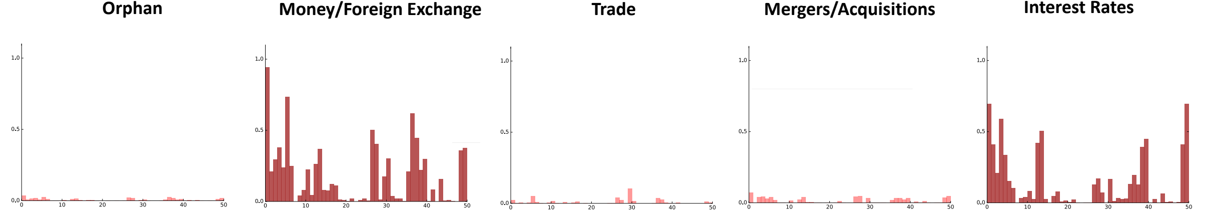

Table 6: Visualization of connection strength between primary capsules and the FC capsules by 3-gram phrases cloud and histogram of the their intensities. x axis denotes primary capsules (3-gram phrases) selected for demonstration, y axis denotes intensity of connection strength. The results are retrieved from Capsule-B trained with 3 routing iterations. The category-specific key-phrases in red color in raw text (first column) are annotated manually for reference.

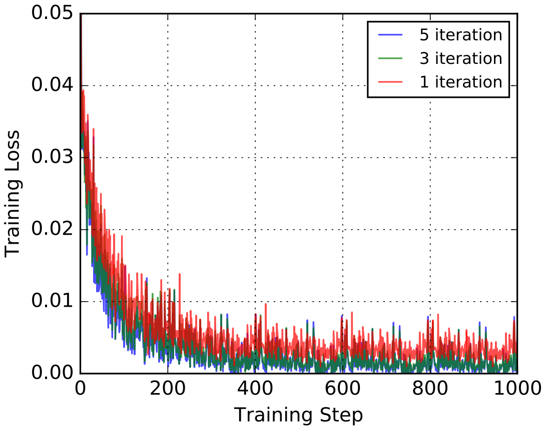

Figure 3: Training loss of Capsule-B on Reuters-Multi-label dataset.

input of machine learning algorithms such as support vector machine (SVM) (Joachims, 1998), logistic regression (Genkin et al., 2007), naive Bayes (NB) (McCallum et al., 1998) for classification. However, these models usually heavily relied on laborious feature engineering or massive extra linguistic resources.

Recent advances in deep neural networks and representation learning have substantially improved the performance of text classification tasks. The dominant approaches are recurrent neural networks, in particular LSTMs and CNNs. (Kim, 2014) reported on a series of experiments with CNNs trained on top of pre-trained word vectors for sentence-level classification tasks. The CNN models improved upon the state of the art on 4 out of 7 tasks. (Zhang et al., 2015) offered an empirical exploration on the use of character-level convolutional networks (Convnets) for text classification and the experiments showed that Convnets outperformed the traditional models. (Joulin et al., 2016) proposed a simple and efficient text classification method fastText, which could be trained on a billion words within ten minutes. (Conneau et al., 2017) proposed a very deep convolutional networks (with 29 convolutional layers) for text classification. (Tai et al., 2015) generalized the LSTM to the tree-structured network topologies (Tree-LSTM) that achieved best results on two text classification tasks.

Recently, a novel type of neural network is proposed using the concept of capsules to improve the representational limitations of CNN and RNN. Hinton et al. (2011) firstly introduced the concept of "capsules" to address the representational limitations of CNNs and RNNs. Capsules with transformation matrices allowed networks to automatically learn part-whole relationships. Consequently, Sabour et al. (2017) proposed capsule networks that replaced the scalar-output feature detectors of CNNs with vector-output capsules and max-pooling with routing-by-agreement. The capsule network has shown its potential by achieving a state-of-the-art result on MNIST data. Unlike max-pooling in CNN, however, Capsule network do not throw away information about the precise position of the entity within the region. For lowlevel capsules, location information is place-coded by which capsule is active. (Xi et al., 2017) further tested out the application of capsule networks on CIFAR data with higher dimensionality. (Hinton et al., 2018) proposed a new iterative routing procedure between capsule layers based on the EM algorithm, which achieves significantly better accuracy on the smallNORB data set. (Zhang et al., 2018) generalized existing routing methods within the framework of weighted kernel density estimation. To date, no work investigates the performance of capsule networks in NLP tasks. This study herein takes the lead in this topic.

7 Conclusion

In this paper, we investigated capsule networks with dynamic routing for text classification. Three strategies were proposed to boost the performance of the dynamic routing process to alleviate the disturbance of noisy capsules. Extensive experiments on six text classification benchmarks show the effectiveness of capsule networks in text classification. More importantly, capsule networks also show significant improvement when transferring single-label to multi-label text classifications over the co baseline methods.

Abstract

Many classification models work poorly on short texts due to data sparsity. To address this issue, we propose *topic memory networks* for short text classification with a novel topic memory mechanism to encode latent topic representations indicative of class labels. Different from most prior work that focuses on extending features with external knowledge or pre-trained topics, our model jointly explores topic inference and text classification with memory networks in an end-to-end manner. Experimental results on four benchmark datasets show that our model outperforms state-of-the-art models on short text classification, meanwhile generates coherent topics.

1 Introduction

Short texts have become an important form for individuals to voice opinions and share information on online platforms. A large body of daily-generated contents, such as tweets, web search snippets, news feeds, and forum messages, have far outpaced the reading and understanding capacity of individuals. As a consequence, there is a pressing need for automatic language understanding techniques for processing and analyzing such texts (Zhang et al., 2018). Among those techniques, text classification is a critical and fundamental one proven to be useful in various downstream applications, such as text summarization (Hu et al., 2015), recommendation (Zhang et al., 2012), and sentiment analysis (Chen et al., 2017).

Although many classification models like support vector machines (SVMs) (Wang and Manning, 2012) and neural networks (Kim, 2014; Xiao and Cho, 2016; Joulin et al., 2017) have demonstrated their success in processing formal and well-edited texts, such as news articles (Zhang et al., 2015b), their performance is inevitably compromised when directly applied to short and informal online texts. This inferior performance is attributed to the severe data sparsity nature of short texts, which results in the limited features available for classifiers (Phan et al., 2008). To alleviate the data sparsity problem, some approaches exploit knowledge from external resources like Wikipedia (Jin et al., 2011) and knowledge bases (Lucia and Ferrari, 2014; Wang et al., 2017a). These approaches, however, rely on a large volume of high-quality external data, which may be unavailable to some specific domains or languages (Li et al., 2016a).

Training instances
R_1: [SuperBowl] I'll do anything to see the **Steelers** win.
R_2: [New.Music.Live] Please give **wristbands**, she have major **Bieber** Fever.

Test instance
S: [New.Music.Live] I will do anything for **wristbands**, gonna tweet till I win.

Table 1: Tweet examples for classification. R_i denotes the i-th training instance; S denotes a test instance. [class] is the ground-truth label. **Bold** words are indicative of an instance's class label.

To illustrate the difficulties in classifying short texts, we take the tweet classification in Table 1 as an example. In the test instance S, only given the 11 words it contains, it is difficult to understand why its label is New.Music.Live. Without richer context, classifiers are likely to classify S into the same category as the training instance R_1, which happens to share many words with S, in spite of the different categories they belong to,[1] rather than R_2, which only shares the word "*wristbands*" with S. Under this circumstance, how might we enrich the context of these short texts? If looking at R_2, we can observe that the semantic meaning of "*wristbands*" can be extended from its co-

---

† Jing Li is the corresponding author.

[1] R_1 is about SuperBowl, the annual championship game of the National Football League. R_2 and S are both about New.Music.Live, the flagship live music show.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3120–3131
Brussels, Belgium, October 31 - November 4, 2018.

occurrence with "*Bieber*", which is highly indicative of New.Music.Live.[2] Such relation can further help in recognizing the word "*wristbands*" to be important when classifying the test instance S.

Motivated by the above-mentioned observations, we present a novel neural framework, named as *topic memory networks* (TMN), for short text classification that does not rely on external knowledge. Our model can identify the indicative words for classification, e.g., "*wristbands*" in S, via jointly exploiting the document-level word co-occurrence patterns, e.g., "*wristbands*" and "*Bieber*" in R_2. To be more specific, built upon the success of neural topic models (Srivastava and Sutton, 2017; Miao et al., 2017), our model is capable of discovering *latent topics*[3], which can capture the co-occurrence of words in document level. To employ the *latent topics* for short text classification, we propose a novel *topic memory mechanism*, which is inspired by memory networks (Weston et al., 2014; Graves et al., 2014), that allows the model to put attention upon the indicative latent topics useful to classification. With such corpus-level latent topic representations, each short text instance is enriched, which thus helps alleviate the data sparsity issues.

In prior research, though the effects of topic models for short text classification have been explored (Phan et al., 2008; Ren et al., 2016), existing methods tend to use pre-trained topics as features. To the best of our knowledge, our model is the first to encode latent topic representations via memory networks for short text classification, which allows joint inference of latent topics.

To evaluate our model, we experiment and compare it with existing methods on four benchmark datasets. Experimental results indicate that our model outperforms state-of-the-art counterparts on short text classification. The quantitative and qualitative analysis illustrate the capability of our model in generating topic representations that are meaningful and indicative of different categories.

2 Topic Memory Networks

In this section, we describe our topic memory networks (TMN), whose overall architecture is shown in Figure 1. There are three major components: (1) a neural topic model (NTM) to induce latent topics (described in Section 2.1), (2) a topic memory mechanism that maps the inferred latent topics to classification features (described in Section 2.2), and (3) a text classifier, which produces the final classification labels for instances. These three components can be updated simultaneously via a joint learning process, which is introduced in Section 2.3. In particular, for the classifier, our TMN framework allows the combination of multiple options, e.g., CNN and RNN, which can be determined by the specific application scenario.

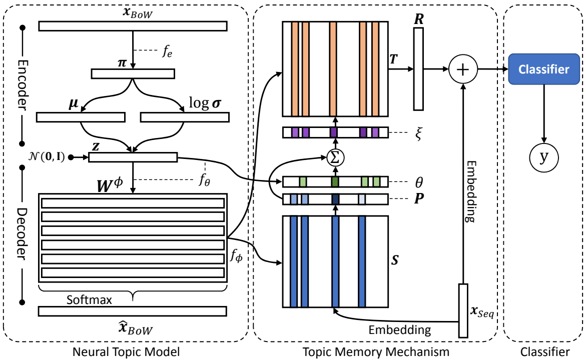

Figure 1: The overall framework of our topic memory networks. The dotted boxes from left to right show the neural topic model, the topic memory mechanism, and the classifier. Here the classifier allows multiple options and the details are left out.

Formally, given $\mathbf{X} = \{\mathbf{x}^1, \mathbf{x}^2, \ldots, \mathbf{x}^M\}$ as the input with M short text instances, each instance $\mathbf{x}$ is processed into two representations: bag-of-words (BoW) term vector $\mathbf{x}_{BoW} \in \mathbb{R}^V$ and word index sequence vector $\mathbf{x}_{Seq} \in \mathbb{R}^L$, where V is the vocabulary size and L is the sequence length. $\mathbf{x}_{BoW}$ is fed into the neural topic model to induce latent topics. Such topics are further matched with the embedded $\mathbf{x}_{Seq}$ to learn classification features in the topic memory mechanism. Then, the classifier concatenates the representations produced by the topic memory mechanism and the embedded $\mathbf{x}_{Seq}$ to predict the classification label y for $\mathbf{x}$.

2.1 Neural Topic Model

Our topic model is inspired by neural topic model (NTM) (Miao et al., 2017; Srivastava and Sutton, 2017) that induces latent topics in neural networks. NTM is based on variational auto-encoder (VAE) (Kingma and Welling, 2013), involved with a continuous latent variable $\mathbf{z}$ as an intermediate representation. Here in NTM, the latent variable

---

[2] Justine Bieber was on New.Music.Live in 2011. There was a business activity for this event that gave free wristbands to fans if they supported Bieber on Twitter.

[3] Latent topics are the distributional clusters of words that frequently co-occur in some of the instances instead of widely appearing throughout the corpus (Blei et al., 2003).

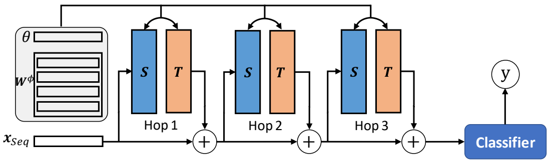

Figure 2: Topic memory network with three hops.

$\mathbf{z} \in \mathbb{R}^K$, where K denotes the number of topics. In the following, we describe the generation and the inference of the model in turn.

NTM Generation. Similar to LDA-style topic models, we assume $\mathbf{x}$ having a topic mixture θ represented as a K-dimensional distribution, which is generated via Gaussian softmax construction (Miao et al., 2017). Each topic k is represented by a word distribution ϕ_k over the vocabulary. Specifically, the generation story for $\mathbf{x}$ is:

- Draw latent variable $\mathbf{z} \sim \mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\sigma}^2)$
- $\theta = \text{softmax}(f_\theta(\mathbf{z}))$
- For the n-th word in $\mathbf{x}$:
  - Draw word $w_n \sim \text{softmax}(f_\phi(\theta))$

where $f_*(\cdot)$ is a neural perceptron that linearly transforms inputs, activated by a non-linear transformation. Here we use rectified linear units (ReLUs) (Nair and Hinton, 2010) as activate functions. The prior parameters of $\mathbf{z}$, $\boldsymbol{\mu}$ and $\boldsymbol{\sigma}$, are estimated from the input data and defined as:

$$\boldsymbol{\mu} = f_\mu(f_e(\mathbf{x}_{BoW})), \log \boldsymbol{\sigma} = f_\sigma(f_e(\mathbf{x}_{BoW})) \tag{1}$$

Note that NTM is based on VAE, where an encoder estimates the prior parameters and a decoder describes the generation story. Compared with the basic VAE, NTM includes the additional distributional vectors θ and ϕ, which can yield latent topic representations and thus ensuring their better interpretability in learning process (Miao et al., 2017).

NTM Inference. In NTM, we use variational inference (Blei et al., 2016) to approximate a posterior distribution over $\mathbf{z}$ given all the instances. The loss function of NTM is defined as

$$\mathcal{L}_{NTM} = D_{KL}(q(\mathbf{z}) \,||\, p(\mathbf{z} \,|\, \mathbf{x})) - \mathbb{E}_{q(\mathbf{z})}[p(\mathbf{x} \,|\, \mathbf{z})] \tag{2}$$

the negative of variational lower bound, where $q(\mathbf{z})$ is a standard Normal prior $\mathcal{N}(\mathbf{0}, \mathbf{I})$. $p(\mathbf{z} \,|\, \mathbf{x})$ and $p(\mathbf{x} \,|\, \mathbf{z})$ are probabilities to describe encoding and decoding processes, respectively.[4] Due to the space limitation, we leave out the derivation details and refer the readers to Miao et al. (2017).

2.2 Topic Memory Mechanism

We exploit a topic memory mechanism to map the latent topics produced by NTM (described in Section 2.1) to the features for classification. Inspired by memory networks (Weston et al., 2014; Sukhbaatar et al., 2015), we design two memory matrices, a source memory $\boldsymbol{S}$ and a target memory $\boldsymbol{T}$, both of which are in $K \times E$ size (K for the number of topics and E for the pre-defined size of word embeddings). $\boldsymbol{S}$ and $\boldsymbol{T}$ are produced by two ReLU-actived neural perceptrons, both taking the topic-word weight matrix $\boldsymbol{W}^\phi \in \mathbb{R}^{K \times V}$ as inputs. Recall that in NTM, we use $f_\phi(\cdot)$ to compute the word distributions given θ. $\boldsymbol{W}^\phi$ is the kernel weight matrix of $f_\phi(\cdot)$, where $\boldsymbol{W}^\phi_{k,v}$ represents the importance of the v-th word in reflecting the k-th topic. Assuming $\boldsymbol{U}$ as the embedded $\mathbf{x}_{Seq}$ (word sequence form of $\mathbf{x}$), in source memory, we compute the match between the k-th topic and the embedding of the l-th word in $\mathbf{x}_{Seq}$ by

$$\boldsymbol{P}_{k,l} = \text{sigmoid}(\mathbf{W}^s[\boldsymbol{S}_k; \boldsymbol{U}_l] + b^s) \tag{3}$$

where $[\mathbf{x}; \mathbf{y}]$ denotes the merge of $\mathbf{x}$ and $\mathbf{y}$, and we use concatenation operation here (Dou, 2017; Chen et al., 2017). $\mathbf{W}^s$ and b^s are parameters to be learned. To further combine the instance-topic mixture θ with $\boldsymbol{P}$, we define the integrated memory weights as

$$\xi_k = \theta_k + \gamma \sum_l \boldsymbol{P}_{k,l} \tag{4}$$

where γ is the pre-defined coefficient. Then, in target memory, via weighting target memory matrix $\boldsymbol{T}$ with ξ, we obtain the output representation $\boldsymbol{R}$ of the topic memory mechanism:

$$\boldsymbol{R}_k = \xi_k \boldsymbol{T}_k \tag{5}$$

The concatenation of $\boldsymbol{R}$ and $\boldsymbol{U}$ (embedded $\mathbf{x}_{Seq}$) further serves as the features for classification.

In particular, similar to the memory networks in prior research (Sukhbaatar et al., 2015; Chen et al., 2017), our model can be extended to handle multiple computation layers (hops). As shown in Figure 2, each hop contains a source matrix and a target matrix, and different hops are stacked following the way presented in Sukhbaatar et al. (2015).

---

[4] In implementation, to smooth the gradients, we apply reparameterization on $\mathbf{z}$ following previous work (Kingma and Welling, 2013; Rezende et al., 2014).

Dataset	# of labels	# of docs	Avg len per doc	Vocab size
Snippets	8	12,332	17	7,334
TagMyNews	7	32,567	8	9,433
Twitter	50	15,056	5	6,962
Weibo	50	21,944	6	10,121

Table 2: Statistics of the experimental datasets. Labels refers to class labels. Avg len per doc refers to the average count of words in each document instance.

2.3 Joint Learning

The entire TMN model integrates the three modules in Figure 1, i.e., the neural topic model, the topic memory mechanism, and the classifier, which can be updated simultaneously in one framework. In doing so, we jointly tackle topic modeling and classification, and define the loss function of the overall framework to combine the two effects as following:

$$\mathcal{L} = \mathcal{L}_{NTM} + \lambda \mathcal{L}_{CLS} \tag{6}$$

where $\mathcal{L}_{NTM}$ represents the loss of NTM and $\mathcal{L}_{CLS}$ is the cross entropy reflecting classification loss. λ is the trade-off parameter controlling the balance between topic model and classification.

3 Experiment Setup

3.1 Datasets

We conduct experiments on four short text datasets, namely, Snippets, TagMyNews, Twitter, and Weibo. Their details are described as follows.

Snippets. This dataset contains Google search snippets released by Phan et al. (2008). There are eight ground-truth labels, e.g., *health* and *sport*.

TagMyNews. We use the news titles as instances from the benchmark classification dataset released by Vitale et al. (2012).[5] This dataset contains English news from really simple syndication (RSS) feeds. Each news feed (with its title) is annotated with one from seven labels, e.g., *sci-tech*.

Twitter. This dataset is used to evaluate tweet topic classification, which is built on the dataset released by TREC2011 microblog track.[6] Following previous settings (Yan et al., 2013; Li et al., 2016a), hashtags, i.e., user-annotated topic labels in each tweet such as "*#Trump*" and "*#SuperBowl*", serve as our ground-truth class labels. Specifically, we construct the dataset with the following steps. First, we remove the tweets without hashtags. Second, we rank hashtags by their frequencies. Third, we manually remove the hashtags that cannot mark topics, such as "*#fb*" for indicating the source of tweets from Facebook, and combine the hashtags referring to the same topic, such as "*#DonaldTrump*" and "*#Trump*". Finally, we select the top 50 frequent hashtags, and all tweets containing these hashtags.

Weibo. To evaluate our model on a different language other than English, we employ a Chinese dataset with short segments of text for topic classification. This dataset is released by Li et al. (2016b) with a collection of messages posted in June 2014 on Weibo, a popular Twitter alike platform in China.[7] Similar to Twitter, Weibo allows up to 140 Chinese characters in its messages. In this Weibo dataset, each Weibo message is labeled with a hashtag as its category, and there are 50 distinct hashtag labels in total, following the same procedure performed for the Twitter dataset.

Table 2 shows the statistic information of the four datasets. Each dataset is randomly split into 80% for training and 20% for test. 20% of randomly selected training instances are used to form development set. We preprocess our English datasets, i.e., Snippets, TagMyNews, and Twitter, with *gensim tokenizer*[8] for tokenization. As to the Chinese Weibo dataset, we use FudanNLP toolkit (Qiu et al., 2013)[9] for word segmentation. In addition, for each dataset, we maintain a vocabulary built based on the training set with removal of stop words[10] and words occurring less than 3 times. The inputs of topic models $\mathbf{x}_{BoW}$ are constructed based on this vocabulary following common topic model settings (Blei et al., 2003; Miao et al., 2016). Differently, we use the raw word sequence (without words removal) for the inputs of classification $\mathbf{x}_{Seq}$ as is done in previous work of text classification (Kim, 2014; Liu et al., 2017).

3.2 Model Settings

We use pre-trained embeddings to initialize all word embeddings. For Snippets and TagMyNews

Table 3: Comparisons of accuracy (Acc) and average F1 (Avg F1) on four benchmark datasets. Our TMN, either with separate or joint TM inference, performs significantly better than all the comparisons ($p < 0.05$, paired t-test).

datasets, we use pre-trained `GloVe` embeddings (Pennington et al., 2014)[11]. For Twitter and Weibo datasets, we pre-train embeddings on large-scale external data with 99M tweets and 467M Weibo messages, respectively. For the number of topics, we follow previous settings (Yan et al., 2013; Das et al., 2015; Dieng et al., 2016) to set $K = 50$. For all the other hyperparameters, we tune them on the development set by grid search. For our classifier, we employ CNN in experiment because of its better performance in short text classification than its counterparts such as RNN (Wang et al., 2017a). The hidden size of CNN is set as 500. The dimension of word embedding $E = 200$. $\gamma = 0.8$ for trading off θ and $\boldsymbol{P}$, and $\lambda = 1.0$ for controlling the effects of topic model and classification. In the learning process, we run our model for 800 epochs with early-stop strategy applied (Caruana et al., 2000).

3.3 Comparison Models

For comparison, we consider a weak baseline of majority vote, which assigns the major class labels in training set to all test instances. We further compare with the widely-used baseline SVM+BOW, SVM with unigram features (Wang and Manning, 2012). We also consider other SVM-based baselines: SVM+LDA, SVM+BTM, SVM+NTM, whose features are topic distributions for instances learned by LDA (Blei et al., 2003), BTM (Yan et al., 2013), and NTM (Miao et al., 2017), respectively. In particular, BTM is one of the state-of-the-art topic models for short texts. To compare with neural classifiers, we test bidirectional long short-term memory with attention (AttBiLSTM) (Zhang et al., 2015a) and convolutional neural network (CNN) classifiers (Kim, 2014). No topic representation is encoded in these two classifiers. We also compare with the state-of-the-art short-text classifier CNN+TEWE (Ren et al., 2016), i.e., CNN classifier with topic-enriched word embeddings (TEWE), where the word embeddings are enriched by pre-trained NTM-inferred topic models. Moreover, to investigate the effectiveness of our proposed topic memory mechanism, we compare with CNN+NTM, which concatenates the representations learned by CNN and topics induced by NTM as classification features. In addition, we compare with our variant, TMN (*Separate TM Inference*), where topics are induced separately before classification, and only used for initializing the topic memory. To be consistent, our model with a joint learning process for topic modeling and classification, described in Section 2.3, is named as TMN (*Joint TM Inference*). Note that the comparison CNN-based models share the same settings as our model, and the hidden size for each direction of BiLSTM is set to 100.

4 Experimental Results

4.1 Classification Comparison

Table 3 shows the comparison on classification results, where the accuracy and average F1 scores on different classes labels are reported. We have the following observations.

• ***Topic representations are indicative features.*** On all four datasets, simply by combining topic representations into features, SVM models produce better results than the models without ex-

---

NTM	mubarak people egyptian egypt stay tomorrow protest news phone protester
TMN	mubarak protest protester tahrir square egyptian al jazeera repo cairo

Table 5: Top 10 representative terms of the sample latent topics discovered by various topic models from Twitter dataset. We interpret the topics as "*Egyptian revolution of 2011*" according to their word distributions. Non-topic words are wave-underlined and in blue, and off-topic words are underlined and in red.

ploiting topic features (*i.e.*, SVM+BOW). This observation indicates that latent topic representations captured at corpus level are helpful to alleviate the data sparsity problem in short text classification.

• ***Neural network models are effective.*** It is seen that neural models based on either CNN or AttBiLSTM yield better results than SVM. This observation shows the effectiveness of representation learning in neural networks for short texts.

• ***CNN serves as a better classifier for short texts than AttBiLSTM.*** In comparison of CNN and AttBiLSTM without taking topic features, we observe that CNN yields generally better results on all the four datasets. This is consistent with the discovery in Wang et al. (2017a), where CNN can better encode short texts than sequential models.

• ***Topic memory is useful to classification.*** By exploring topic representations in memory mechanisms, our TMN model, inferring topic models either separately or jointly with classification, significantly outperform the best comparison models on each of the four datasets. Particularly, when compared with CNN+TEWE and CNN+NTM, both concatenating topics as part of the features, the results yielded by TMN are better. This demonstrates the effectiveness of topic memory to learn indicative topic representations for short text classification.

• ***Jointly inferring latent topics is effective to text classification.*** In comparison between two TMN variants, TMN (*Joint TM Inference*) produces better classification results, though large margin improvements are not observed on the three English datasets, i.e., TagMyNews, Snippets, and Twitter. This may be because the classifiers do not rely too much on high-quality latent topics, since other features may be sufficient to indicate the labels, e.g., word positions in the instance. As a result, better topic models, learned via jointly induced with classification, may not provide richer information for classification. Nevertheless, we notice that on Chinese Weibo dataset, the jointly trained topic model improves the accuracy and average F1 by 2.3% and 2.0%, respectively. It may result from the prevalence of word order misuse in informal Weibo messages. This mis-order phenomenon is common in Chinese and generally does not affect understanding. The rich information conveyed by Chinese characters are capable of indicating semantic meanings of words even without correct orders (Qin et al., 2016; Wang et al., 2017b). As a result, the CNN classifier, which encodes orders of words, may also bring such mis-order noise to classification. For these instances with misordered words, a better topic model that learns text instances as unordered words, provides useful representations that compensate the loss of information in word orders and in turn improves the performance of text classification.

4.2 Topic Coherence Comparison

In Section 4.1, we find that TMN can significantly outperform comparison models on short text classification. In this section, we study whether jointly learning topic models and classification can be helpful in producing coherent and meaningful topics. We use the C_V metric (Röder et al., 2015) computed by Palmetto toolkit[12] to evaluate the topic coherence, which has been shown to give the closest scores to human evaluation compared to other widely-used topic coherence metrics like NPMI (Bouma, 2009). Table 4 shows the comparison results of LDA, BTM, NTM, and TMN on the three English datasets.[13] Note that we do not report C_V scores for Chinese Weibo dataset as the Palmetto toolkit cannot process Chinese topics.

---

[12] `https://github.com/dice-group/Palmetto`

[13] In the rest of this paper, without otherwise indicated, TMN is used as a short form for TMN (*Joint TM Inference*).

# of Hops	Snippets	TagMyNews	Twitter	Weibo
TMN-1H	0.958	0.841	0.382	0.568
TMN-2H	**0.964**	0.843	0.383	0.578
TMN-3H	0.962	0.845	0.384	0.581
TMN-4H	0.961	0.846	0.389	0.582
TMN-5H	0.960	**0.851**	**0.397**	**0.591**
TMN-6H	0.958	0.848	0.388	0.579

Table 6: The impact of the # of hops on accuracy.

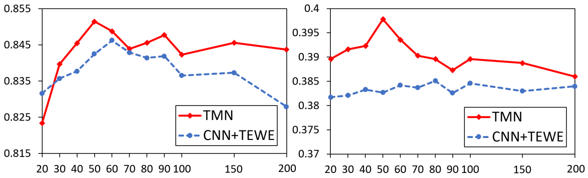
As can be seen, TMN yields higher C_V scores by large margins than all others in comparison. This indicates that jointly exploring classification would be effective in producing coherent topics. The reason is that the supervision from classification labels can guide unsupervised topic models in discovering meaningful and interpretable topics. We also observe that NTM produces better results than LDA and BTM, which implies the effectiveness of inducing topic models by neural networks.

To further analyze the quality of yielded topics, Table 5 shows the top 10 words of the sample latent topics reflecting "*Egyptian revolution of 2011*" discovered by various models. We find that LDA yields off-topic word "*bowl*". For the results of BTM and NTM, though we do not find off-topic words, non-topic words like "*need*" and "*stay*" are included.[14] The topic generated by TMN appears to be the best, which presents indicative words like "*tahrir*" and "*cairo*", for the event.

4.3 Results with Varying Hyperparameters

We further study the impact of two important hyperparameters in TMN, i.e., the hop number and the topic number, which will be discussed in turn.

Impact of Hop Numbers. Recall that Figure 2 shows the capacity of TMN in combining multiple hops. Here we analyze the effects of hop numbers on the accuracy of TMN. Table 6 reports the results, where NH refers to using N hops ($N = 1, 2, ..., 6$). As can be seen, generally, TMN with 5 hops achieves the best accuracy on most datasets except for Snippets dataset. We also observe that, although within a particular range, more hops can produce better accuracy, the increasing trends are not always monotonic. For example, TMN-6H always exhibits lower accuracy than TMN-5H. This observation implies that the overall representation ability of TMN is enhanced as the increasing complexity of the model via combining more hops. However, this enhancement will reach saturation when the hop number exceeds a threshold, which is 5 hops for most datasets in our experiment.



(a) TagMyNews (b) Twitter

Figure 3: The impact of topic numbers, where the horizontal axis shows the number of topics and the vertical axis shows the accuracy.

Impact of Topic Numbers. Figure 3 shows the accuracy of TMN and CNN+TEWE (the best comparison model in Table 3) given varying K, the number of topics on TagMyNews and Twitter datasets.[15] As we can see, the curves of all the models are not monotonic and the best accuracy is achieved given a particular number of topics, e.g., K=50 for TMN on TagMyNews dataset. When comparing different curves, we observe that TMN yields consistently better accuracy than CNN+TEWE, a comparison model shown in Table 3, which demonstrates the robust performance of TMN over varying number of topics.

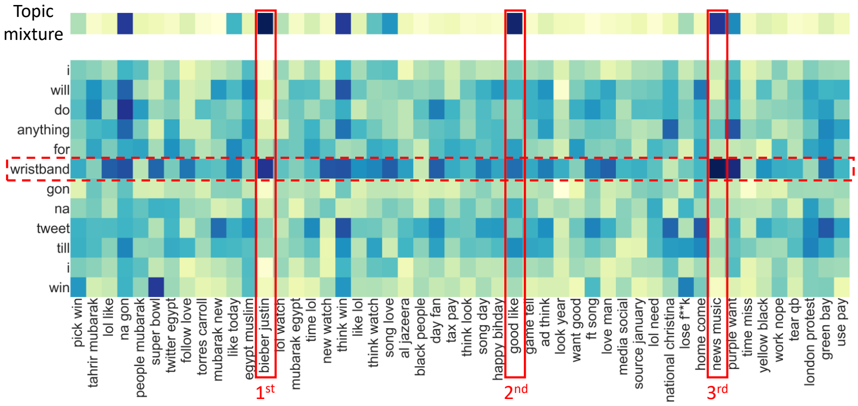
4.4 A Case Study on Topic Memory

Section 4.1 demonstrates the effectiveness of using topic memory on short text classification. To further understand why, in this section, we use the test instance S in Table 1 to analyze what the information captured by topic memory is indicative of class labels. Recall that the label of S, which should be New.Music.Live, can be indicated by containing word "*wristbands*" and the collocation of "*wristbands*" and "*Bieber*" in training instance R_2 labeled New.Music.Live. Figure 4 shows the heatmaps of the weight matrix $\boldsymbol{P}$ in topic memory and the topic mixture θ captured by NTM for instance S. As can be seen, the top 3 words for the latent topic with the largest value in θ are "*bieber*", "*justine*", and "*tuesday*", which can effectively indicate the class label of S to be *New.Music.Live* because Justine Bieber was there on Tuesday. Interestingly, S contains none of the top three words. The latent semantic relations of S and these words are purely uncovered by the co-occurrence of words in S with other instances in

---

[14] Off-topic words are more likely to be interpreted to reflect other topics. Non-topic words cannot clearly indicate the corresponding topic.

[15] We observe similar distributions on Snippets and Weibo.



(a)

1st Topic	2nd Topic	3rd Topic
bieber justin tuesday newmusiclive think thought jb new music live	good like fan look tweet thing know rumble na right	news music forever change right attack time wing aistdirect films

(b)

Figure 4: Topic memory visualization for test instance S shown in Table 1. (a) Heatmaps of topic mixture θ (the upper one) and topic memory weight matrix $\boldsymbol{P}$ (the lower one) illustrating the relevance between the words of S (left) and the learned topics (bottom, with top-2 words displayed). The red dotted rectangle indicates the representation for "*wristband*", the topical word in S. The red rectangles with solid frames indicates the 3 most relevant topics ordered by θ. (b) Top-10 words of these topics indicated by ϕ.

the corpus, which further shows the benefit of using latent topics for alleviating the sparsity in short texts. We also observe that topic memory learns different representations for topical word "*wristband*", highly indicating instance label, and background words, such as "*i*" and "*for*". This explains why topic memory is effective to classification.

4.5 Error Analysis

In this section, we take our classification results on TagMyNews dataset as an example to analyze our errors. We observe that one major type of incorrect prediction should be ascribed to the polysemy phenomenon. For example, the instance "*NBC gives 'the voice' post super bowl slot*" should be categorized as *entertainment*. However, failing to understand the particular meaning of "*the voice*" here as the name of a television singing competition, our model mistakenly categorizes this instance as sport because of the occurrence "*super bowl*". In future work, we would exploit context-sensitive topical word embeddings (Witt et al., 2016), which is able to distinguish the meanings of the same word in different contexts. Another main error type comes from the failure to capture phrase-level semantics. Taking "*On the merits of face time and living small*" as an example, without understanding "*face time*" as a phrase, our model wrongly predicts its category as business instead of its correct label as sci_tech. Such errors can be reduced by enhancing our NTM to phrase discovery topic models (Lindsey et al., 2012; He, 2016), which is worthy exploring in future work.

5 Related Work

Our work mainly builds on two streams of prior work: short text classification and topic models.

Short Text Classification. In the line of short text classification, most work focuses on alleviating the severe sparsity issues in short texts (Yan et al., 2013). Some previous efforts encode knowledge from external resource (Jin et al., 2011; Lucia and Ferrari, 2014; Wang et al., 2017a; Ma et al., 2018). Instead, our work learns effective representations only from internal data. For some specific classification tasks, such as sentiment analysis, manually-crafted features are designed to fit the target task (Pak and Paroubek, 2010; Jiang et al., 2011). Distinguished from them, we employ deep learning framework for representation learning, which requires no feature engineering process and thus ensures its general applicability to diverse classification scenarios. In comparison with the established classifiers applying deep learning methods (dos Santos and Gatti, 2014; Lee and Dernoncourt, 2016), our work differs from them in the leverage of corpus-level latent topic representations for alleviating data sparsity issues. In existing classification models using topic features, pre-trained topic mixtures are leveraged as part of features (Phan et al., 2008; Ren et al., 2016; Chen et al., 2017). Differently, our model encodes topic representations in a memory mechanism where topics are induced jointly with text classification in an end-to-end manner.

Topic Models. Well-known topic models, e.g., probabilistic latent semantic analysis (pLSA) (Hofmann, 1999) and latent Dirichlet allocation (LDA) (Blei et al., 2003), have shown advantages in capturing effective semantic representations, and proven beneficial to varying downstream applications, such as summarization (Haghighi and Vanderwende, 2009) and recommendation (Zeng et al., 2018; Bai et al., 2018). For short text data, topic model variants have been proposed to reduce the effects of sparsity issues on topic modeling, such as biterm topic model (BTM) (Yan et al., 2013) and LeadLDA (Li et al., 2016b). Recently, owing to the popularity of variational auto-encoder (VAE) (Kingma and Welling, 2013), it is able to induce latent topics in neural networks, namely, neural topic models (NTM) (Miao et al., 2017; Srivastava and Sutton, 2017). Although the concept of NTM has been mentioned earlier in Cao et al. (2015), their model is based on matrix factorization. Differently, VAE-style NTM (Srivastava and Sutton, 2017; Miao et al., 2017) follows the LDA fashion as probabilistic generative models, which is easy to interpret and extend. The NTM in our framework is in VAE-style, whose effects on short text classification serve as the key focus of our work.

6 Conclusion

We have presented topic memory networks that exploit corpus-level topic representations with a topic memory mechanism for short text classification. The model alleviates data sparsity issues via jointly learning latent topics and text categories. Empirical comparisons with state-of-the-art models on four benchmark datasets have demonstrated the validity and effectiveness of our model, where better results have been achieved on both short text classification and topic coherence evaluation.

Abstract

Large multi-label datasets contain labels that occur thousands of times (frequent group), those that occur only a few times (few-shot group), and labels that never appear in the training dataset (zero-shot group). Multi-label few- and zero-shot label prediction is mostly unexplored on datasets with large label spaces, especially for text classification. In this paper, we perform a fine-grained evaluation to understand how state-of-the-art methods perform on infrequent labels. Furthermore, we develop few- and zero-shot methods for multi-label text classification when there is a known structure over the label space, and evaluate them on two publicly available medical text datasets: MIMIC II and MIMIC III. For few-shot labels we achieve improvements of 6.2% and 4.8% in R@10 for MIMIC II and MIMIC III, respectively, over prior efforts; the corresponding R@10 improvements for zero-shot labels are 17.3% and 19%.

1 Introduction

Unlike in binary or multi-class problems, for multi-label classification a model assigns a set of labels to each input instance (Tsoumakas et al., 2010). Large-scale multi-label text classification problems can be found in several domains. For example, Wikipedia articles are annotated with labels used to organize documents and facilitate search (Partalas et al., 2015). Biomedical articles indexed by the PubMed search engine are manually annotated with medical subject headings (Tsatsaronis et al., 2012). In healthcare facilities, medical records are assigned a set of standardized codes for billing purposes (NCHS, 1978). Automatically annotating tweets with hashtags, while the labels are not fixed, can also be represented as a large-scale multi-label classification problem (Weston et al., 2014).

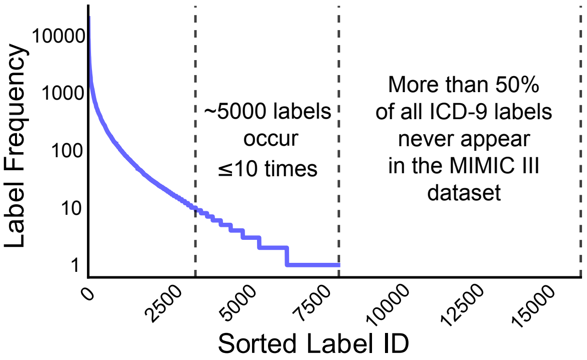

Figure 1: This plot shows the label frequency distribution of ICD-9 codes in MIMIC III.

There are two major difficulties when developing machine learning methods for large-scale multi-label text classification problems. First, the documents may be long, sometimes containing more than a thousand words (Mullenbach et al., 2018). Finding the relevant information in a large document for a specific label results in needle in a haystack situation. Second, data sparsity is a common problem; as the total number of labels grows, a few labels may occur frequently, but most labels will occur infrequently. Rubin et al. (2012) refer to datasets that have long-tail frequency distributions as "power-law datasets". Methods that predict infrequent labels fall under the paradigm of few-shot classification which refers to supervised methods in which only a few examples, typically between 1 and 5, are available in the training dataset for each label. With predefined label spaces, some labels may never appear in the training dataset. Zero-shot problems extend the idea of few-shot classification by assuming no training data is available for the labels we wish to predict at test time. In this paper, we explore both of these issues, long documents and power-law datasets, with an emphasis on analyzing the few- and zero-shot aspects of large-scale multi-label problems.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3132–3142
Brussels, Belgium, October 31 - November 4, 2018.

In Figure 1, we plot the label frequency distribution of diagnosis and procedure labels for the entire MIMIC III (Johnson et al., 2016) dataset. A few labels occur more than 10,000 times, around 5,000 labels occur between 1 and 10 times, and of the 17,000 diagnosis and procedure labels, more than 50% never occur. There are a few reasons a label may never occur in the training dataset. In healthcare, sevearl disorders are rare; therefore corresponding labels may not have been observed yet in a particular clinic. Sometimes new labels may be introduced as the field evolves leading to an *emerging label* problem. This is intuitive for applications such as hashtag prediction on Twitter. For example, last year it would not have made sense to annotate tweets with the hashtag #EMNLP2018. Yet, as this year's conference approaches, labeling tweets with the #EMNLP2018 will help users find relevant information.

Infrequent labels may not contribute heavily to the overall accuracy of a multi-label model, but in some cases, correct prediction of such labels is crucial but not straightforward. For example, in assigning diagnosis labels to EMRs, it is important that trained human coders are both accurate and thorough. Errors may cause unfair financial burden on the patient. Coders may have an easier time assigning frequent labels to EMRs because they are encountered more often. Also, frequent labels are generally easier to predict using machine-learning based methods. However, infrequent or obscure labels will be easily confused or missed causing billing mistakes and/or causing the coders to spend more time annotating each record. Thus, we believe methods that handle infrequent and unseen labels in the multi-label setting are important.

Current evaluation methods for large-scale multi-label classification mostly ignore infrequent and unseen labels. Popular evaluation measures focus on metrics such as micro-F1, recall at k (R@k), precision at k (P@k), and macro-F1. As it is well-known that micro-F1 gives more weight to frequent labels, papers on this topic also report macro-F1, the average of label-wise F1 scores, which equally weights all labels. Unfortunately, macro-F1 scores are generally low and the corresponding performance differences between methods are small. Moreover, it is possible to improve macro-F1 by only improving a model's performance on frequent labels, further confounding its interpretation. Hence we posit that macro-F1 is not enough to compare large-scale multi-label learning methods on infrequent labels and it does not directly evaluate zero-shot labels. Here, we take a step back and ask: can the model predict the correct few-shot (zero-shot) labels from the set of all few-shot (zero-shot) labels? To address this, we test our approach by adapting the *generalized zero-shot classification* evaluation methodology by Xian et al. (2017) to the multi-label setting.

In this paper, we propose and evaluate a neural architecture suitable for handling few- and zero-shot labels in the multi-label setting where the output label space satisfies two constraints: (1). the labels are connected forming a DAG and (2). each label has a brief natural language descriptor. These assumptions hold in several multi-label scenarios including assigning diagnoses/procedures to EMRs, indexing biomedical articles with medical subject headings, and patent classification. Taking advantage of this prior knowledge on labels is vital for zero-shot prediction. Specifically, using the EMR coding use-case, we make the following contributions:

1. We overcome issues arising from processing long documents by introducing a new neural architecture that expands on recent attention-based CNNs (ACNNs (Mullenbach et al., 2018)). Our model learns to predict few- and zero-shot labels by matching discharge summaries in EMRs to feature vectors for each label obtained by exploiting structured label spaces with graph CNNs (GCNNs (Kipf and Welling, 2017)).

2. We provide a fine-grained evaluation of state-of-the-art EMR coding methods for frequent, few-shot, and zero-shot labels. By evaluating power-law datasets using an extended generalized zero-shot methodology that also includes few-shot labels, we present a nuanced analysis of model performance on infrequent labels.

2 Related Work

Large-Scale Text Classification. Linear methods have been successfully applied to large-scale problems (Tang et al., 2009; Papanikolaou et al., 2015; Rios and Kavuluru, 2015). For traditional micro- and macro-F1 measures, Tang et al. (2009) show that linear methods suffer using naive thresholding strategies because infrequent labels generally need a smaller threshold. Generative models have also been promising for datasets with many labels (Rubin et al., 2012). Intuitively, by using a prior distribution over the label space, infrequent labels can be modeled better. Finally, large-scale classification is also pursued as "extreme classification" (Yu et al., 2014; Bhatia et al., 2015) where the focus is on ranking measures that ignore infrequent labels. Neural networks (NNs) perform well for many small-scale classification tasks (Kim, 2014; Kalchbrenner et al., 2014). Recently, researchers have been exploring NN methods for large-scale problems. Yang et al. (2016) develop a hierarchical attentive NN for datasets with over a million documents, but their datasets contain few labels. Nam et al. (2014) show that feed-forward NNs can be successfully applied to large-scale problems through the use of a multi-label binary cross-entropy loss function. Vani et al. (2017) introduce a grounded recurrent neural network (RNN) that iteratively updates its predictions as it processes a document word-by-word. Baumel et al. (2018) experiment with both CNNs and RNNs for medical coding. Finally, Mullenbach et al. (2018) expand on prior ACNNs (Yang et al., 2016; Allamanis et al., 2016) to develop a label-wise attention framework where the most informative ngrams are extracted for each label in the dataset. Our attention mechanism extends their work to the zero-shot setting.

Few-Shot and Zero-Shot Learning. While neural networks are generally considered to need large datasets, they have been shown to work well on few-shot classification tasks. To handle infrequent labels, most NN methods use a k-NN-like approach. Siamese NNs (Koch et al., 2015) learn a nonlinear distance metric using a pairwise loss function. Matching networks (Vinyals et al., 2016) introduce an instance-level attention method to find relevant neighbors. Prototypical Networks (Snell et al., 2017) average all instances in each class to form "prototype label vectors" and train using a traditional cross-entropy loss. In our prior work (Rios and Kavuluru, 2018), we combine matching networks with a sophisticated thresholding strategy. However, in Rios and Kavuluru (2018) we did not explore the few- and zero-shot settings.

Zero-shot learning has not been widely explored in the large-scale multi-label classification scenario. Like neural few-shot methods, neural zero-shot methods use a matching framework. Instead of matching input instances with other instances, they are matched to predefined label vectors. For example, the Attributes and Animals Dataset (Xian et al., 2017) contains images of animals and the label vectors consist of features describing the types of animals (e.g., stripes: yes). When feature vectors for labels are not available, the average of the pretrained word embeddings of the class names have been used. The attribute label embedding method (Akata et al., 2016) uses a pairwise ranking loss to match zero-shot label vectors to instances. Romera-Paredes and Torr (2015) introduced the "embarrassingly simple zero-shot learning" (ESZSL) method which is trained using a mean squared error loss. A few zero-shot methods do not translate well to multi-label problems. CONSE (Mikolov et al., 2013) averages the embeddings for the top predicted supervised label vectors to match to zero-shot label vectors. CONSE assumes that both supervised and zero-shot labels cannot be assigned to the same instance. In this paper, we expand on the generalized zero-shot evaluation methodology introduced by Xian et al. (2017) to large-scale multi-label classification. Finally, it is important to note that zero-shot classification has been previously studied in the multi-label setting (Mensink et al., 2014). However, they focus on image classification and use datasets with around 300 labels.

Graph Convolutional Neural Networks. GCNNs generalize CNNs beyond 2d and 1d spaces. Defferrard et al. (2016) developed spectral methods to perform efficient graph convolutions. Kipf and Welling (2017) assume a graph structure is known over input instances and apply GCNNs for semi-supervised learning. GCNNs are applied to relational data (e.g., link prediction) by Schlichtkrull et al. (2018). GCNNs have also had success in other NLP tasks such as semantic role labeling (Marcheggiani and Titov, 2017), dependency parsing (Strubell and McCallum, 2017), and machine translation (Bastings et al., 2017).

There are three GCNN papers that share similarities with our work. (i) Peng et al. (2018) use a GCNN on a word co-occurrence graph for large-scale text classification where the GCNN operates on documents/words, while our GCNN operates on the labels. (ii) Chen et al. (2017) use GCNNs on structured label spaces. However, their

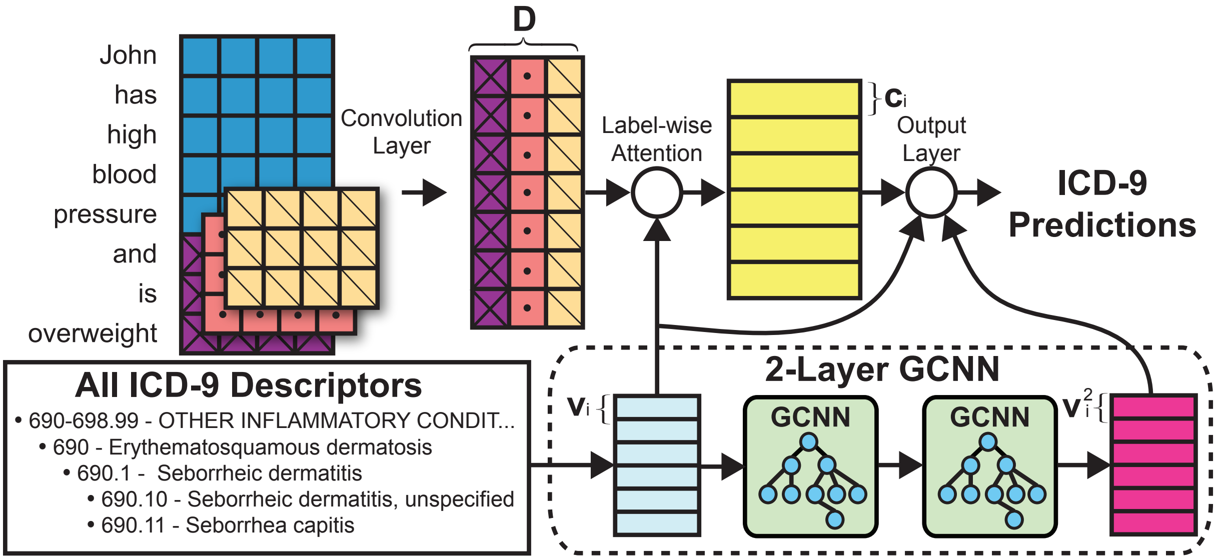

Figure 2: This figure provides a visual overview of our method. Intuitively, our method has two main components. The first component is a CNN that operates operates on the EMRs. The other component is a 2-layer GCNN which creates the label-specific attention vectors and label-vectors used for ranking using ICD-9 descriptions as input.

experiments focus on smaller label spaces and do not handle/assess zero-shot and few-shot labels. Also, their experiments for text classification do not incorporate attention and simply use an average of word vectors to represent each document. (iii) Wang et al. (2018) propose a zero-shot GCNN image classification method for structured multi--class problems. We believe their method may transfer to the multi-label text classification setting but exact modifications to affect that are not clear (i.e., their semi-supervised approach may not be directly applicable). Likewise, porting to text is nontrivial for long documents.

3 Method

Figure 2 shows the overall schematic of our architecture. Intuitively, we incorporate four main components. First, we assume we have the full English descriptor/gloss for each label we want to predict. We form a vector representation for each label by averaging the word embeddings for each word in its descriptor. Second, the label vectors formed from the descriptor are used as attention vectors (label-wise attention) to find the most informative ngrams in the document for each label. For each label, this will produce a separate vector representation of the input document. Third, the label vectors are passed through a two layer GCNN to incorporate hierarchical information about the label space. Finally, the vectors returned from the GCNN are matched to the document vectors to generate predictions.

Convolutional Neural Network. Contrary to prior CNN methods for text (Kim, 2014), instead of using a max-over-time pooling layer, we learn to find relevant ngrams in a document for each label via label-wise attention (Mullenbach et al., 2018). The CNN will return a document feature matrix $\mathbf{D} \in \mathbb{R}^{(n-s+1)\times u}$ where each column of $\mathbf{D}$ is a feature map, u is the total number of convolution filters, n is the number of words in the document, and s is the width of convolution filters.

Label Vectors. To be able to predict labels that were not in the training dataset, we avoid learning label specific parameters. We use the label descriptors to generate a feature vector for each label. First, to preprocess each descriptor, we lowercase all words and remove stop-words. Next, each label vector is formed by averaging the remaining words in the descriptor

$$\mathbf{v}_i = \frac{1}{|N|}\sum_{j\in N} \mathbf{w}_j, \qquad i = 1,\dots,L, \qquad (1)$$

where $\mathbf{v}_i \in \mathbb{R}^d$, L is the number of labels, and N is the index set of the words in the descriptor. Prior zero-shot work has focused on projecting input instances into the same semantic space as the label vectors (Sandouk and Chen, 2016). For zero-shot image classification, this is a non-trivial task. Because we work with textual data, we simply share the word embeddings between the convolutional layer and the label vector creation step to form $\mathbf{v}_i$.

Label-Wise Attention. Similar to the work by Mullenbach et al. (2018), we employ label-wise attention to avoid the needle in the haystack situation encountered with long documents. The issue with simply using a single attention vector or using max-pooling is that we assume a single vector can capture everything required to predict every label. For example, with a single attention, we would only look at one spot in the document and assume that spot contains the relevant information needed to predict all labels. In the multi-class setting, this assumption is plausible. However, for large multi-label problems, the relevant information for each label may be scattered throughout the document – the problem is worse when the documents are very long. Using label-wise attention, our model can focus on different sections. We also need to find relevant information for zero-shot classes. So we use the label vectors $\mathbf{v}_i$ rather than learning label specific attention parameters. First, we pass the document feature matrix $\mathbf{D}$ through a simple feed-forward neural network

$$\mathbf{D}^2 = \tanh(\mathbf{D}\,\mathbf{W}_b + \mathbf{b}_b)$$

where $\mathbf{W}_b \in \mathbb{R}^{u \times d}$ and $\mathbf{b}_b \in \mathbb{R}^d$. This mapping is important because the dimensionality of the ngram vectors (rows) in $\mathbf{D}$ depends on u, the number of scores we generate for each ngram. Given $\mathbf{D}^2$, we generate the label-wise attention vector

$$\mathbf{a}_i = softmax(\mathbf{D}^2\,\mathbf{v}_i), \quad i = 1, \ldots, L, \qquad (2)$$

where $\mathbf{a}_i \in \mathbb{R}^{n-s+1}$ measures how informative each ngram is for the i-th label. Finally, we use $\mathbf{D}$, and generate L label-specific document vector representations

$$\mathbf{c}_i = \mathbf{a}_i^T\,\mathbf{D}, \quad i = 1, \ldots, L,$$

such that $\mathbf{c}_i \in \mathbb{R}^u$. Intuitively, $\mathbf{c}_i$ is the weighted average of the rows in $\mathbf{D}$ forming a vector representation of the document for the i-th label.

GCNN Output Layer. Traditionally, the output layer of a CNN would learn label specific parameters optimized via a cross-entropy loss. Instead, our method attempts to match documents to their corresponding label vectors. In essence, this becomes a retrieval problem. Before using each document representation $\mathbf{c}_i$ to score its corresponding label, we take advantage of the structured knowledge we have over our label space using a 2-layer GCNN. For both the MIMIC II and MIMIC III datasets, this information is hierarchical. A snippet of the hierarchy can be found in Figure 2.

Starting with the label vectors $\mathbf{v}_i$, we combine the label vectors of the children and parents for the i-th label to form

$$\mathbf{v}_i^1 = f(\mathbf{W}^1\mathbf{v}_i + \sum_{j \in \mathcal{N}_p} \frac{\mathbf{W}_p^1\mathbf{v}_j}{|\mathcal{N}_p|} + \sum_{j \in \mathcal{N}_c} \frac{\mathbf{W}_c^1\mathbf{v}_j}{|\mathcal{N}_c|} + \mathbf{b}_g^1)$$

where $\mathbf{W}^1 \in \mathbb{R}^{q \times d}$, $\mathbf{W}_p^1 \in \mathbb{R}^{q \times d}$, $\mathbf{W}_c^1 \in \mathbb{R}^{q \times d}$, $\mathbf{b}_g^1 \in \mathbb{R}^q$, f is the rectified linear unit (Nair and Hinton, 2010) function, and $\mathcal{N}_c$ ($\mathcal{N}_p$) is the index set of the i-th label's children (parents). We use different parameters to distinguish each edge type. In this paper, given we only deal with hierarchies, the edge types include edges from parents, from children, and self edges. This can be adapted to arbitrary DAGs, where parent edges represent all incoming edges and the child edges represent all outgoing edges for each node.

The second layer follows the same formulation as the first layer with

$$\mathbf{v}_i^2 = f(\mathbf{W}^2\mathbf{v}_i^1 + \sum_{j \in \mathcal{N}_p} \frac{\mathbf{W}_p^2\mathbf{v}_j^1}{|\mathcal{N}_p|} + \sum_{j \in \mathcal{N}_c} \frac{\mathbf{W}_c^2\mathbf{v}_j^1}{|\mathcal{N}_c|} + \mathbf{b}_g^2)$$

where $\mathbf{W}^2 \in \mathbb{R}^{q \times q}$, $\mathbf{W}_p^2 \in \mathbb{R}^{q \times q}$, $\mathbf{W}_c^2 \in \mathbb{R}^{q \times q}$, and $\mathbf{b}_g^2 \in \mathbb{R}^q$. Next, we concatenate both the averaged description vector (from equation (1)) with the GCNN label vector to form

$$\mathbf{v}_i^3 = \mathbf{v}_i \mid\mid \mathbf{v}_i^2,$$

where $\mathbf{v}_i^3 \in \mathbb{R}^{d+q}$. Now, to compare the final label vector $\mathbf{v}_i^3$ with its document vector $\mathbf{c}_i$, we transform the document vector into

$$\mathbf{e}_i = ReLU(\mathbf{W}_o\mathbf{c}_i + \mathbf{b}_o), \quad i = 1, \ldots, L,$$

where $\mathbf{W}_o \in \mathbb{R}^{(q+d) \times u}$ and $\mathbf{b}_o \in \mathbb{R}^{q+d}$. This transformation is required to match the dimension to that of $\mathbf{v}_i^3$. Finally, the prediction for each label i is generated via

$$\hat{y}_i = sigmoid(\mathbf{e}_i^T\,\mathbf{v}_i^3), \quad i = 1, \ldots, L.$$

During experiments, we found that using either the output layer GCNN or a separate GCNN for the attention vectors (equation (2)) did not result in an improvement and severely slowed convergence.

Training. We train our model using a multi-label binary cross-entropy loss (Nam et al., 2014)

$$\mathcal{L} = \sum_{i=1}^{L} \big[- y_i \log(\hat{y}_i) - (1 - y_i) \log(1 - \hat{y}_i) \big],$$

where $y_i \in \{0, 1\}$ is the ground truth for the i-th label and $\hat{y}_i$ is our sigmoid score for the i-th label.

4 Experiments

In this paper, we use two medical datasets for evaluation purposes: MIMIC II (Jouhet et al., 2012) and MIMIC III (Johnson et al., 2016). Both datasets contain discharge summaries annotated with a set of ICD-9 diagnosis and procedure labels. Discharge summaries are textual documents consisting of, but not limited to, physician descriptions of procedures performed, diagnoses made, the patient's medical history, and discharge instructions. Following a generalized zero-shot learning evaluation methodology (Xian et al., 2017), we split the ICD-9 labels into three groups based on frequencies in the training dataset: The frequent group S that contains all labels that occur > 5 times, the few-shot group F that contains labels that occur between 1 and 5 times, and the zero-shot group Z of labels that never occur in the training dataset, but occur in the test/dev sets. The groups are only used for evaluation. That is, during training, systems are *optimized over all labels simultaneously*. Instances that do not contain few- or zero-shot classes are removed from their respective groups during evaluation. This grouping is important to assess how each model performs across labels grouped by label frequency. Our evaluation methodology differs from that of Xian et al. (2017) in two ways. First, because each instance is labeled with multiple labels, the same instance can appear in all groups — S, F, and Z. Second, instead of top-1 accuracy or HIT@k evaluation measures, we focus on R@k to handle multiple labels. At a high level, we want to examine whether a model can distinguish the correct few-shot (zero-shot) labels from the set of all few-shot (zero-shot) labels. Therefore, the R@k measures in Tables 2 and 3, and Figure 3 are computed relative to each group.

Evaluation Measures. The overall statistics for these two datasets are reported in Table 1. For reproducibility purposes, we use the same training/test splits of the MIMIC II as Perotte et al. (2013). Following the procedures in Perotte et al. (2013) and Vani et al. (2017), for each diagnosis and procedure label assigned to each medical report, we add its parents using the ICD-9 hierarchy. Each report in MIMIC II is annotated with nearly 37 labels on average using hierarchical label expansion.

			# Labels		
Dataset	# Train	# Test	S	F	Z
MIMIC II	18822	1711	3228	3459	355
MIMIC III	37016	1356	4403	4349	178

Table 1: Dataset statistics for MIMIC II and MIMIC III.

MIMIC III does not contain a standardized training/test split. Therefore, we create our own split that ensures the same patient does not appear in both the training and test datasets. Unlike the MIMIC II dataset, we do not augment the labels using the ICD-9 hierarchy. The ICD-9 hierarchy has three main levels. For MIMIC III, level 0 labels make up about 5% of all occurrences, level 1 labels make up about 62%, and level 2 (leaf level) labels make up about 33%. Also, each MIMIC III instance contains16 ICD-9 labels on average.

ICD-9 Structure and Descriptors. The International Classification of Diseases (ICD) contains alphanumeric diagnosis and procedure codes that are used by hospitals to standardize their billing practices. In the following experiments, we use the 9th edition of the ICD[1]. Each ICD-9 identifier contains between 3 to 5 alphanumeric characters of the form $abc.xy$. The alphanumeric structure defines a simple hierarchy over all ICD-9 codes. For example, "systolic heart failure" (428.2) and "diastolic heart failure" (428.3) are both children of the "heart failure" code 428. Furthermore, sequential codes are grouped together. For instance, numeric codes in the range 390-459 contain "Diseases of the Circulatory System". Furthermore, each code, including groups of codes (390-459), contain short descriptors, where the average descriptor length contains seven words[2]. In this work, we use both the group descriptors and in-

---

[1] The US transitioned from ICD-9 to ICD-10 in 2015. Unfortunately, at the time of publication, large publicly available ICD-10 EMR datasets are unavailable.

[2] The descriptors and hierarchy used in this paper can be found at `https://bioportal.bioontology.org/ontologies/ICD9CM`

dividual descriptors as input to the GCNN. At test time, we ignore the group codes.

Implementation Details. For the CNN component of our model, we use 300 convolution filters with a filter size of 10. We use 300 dimensional word embeddings pretrained on PubMed biomedical article titles and abstracts. To avoid overfitting, we use dropout directly after the embedding layer with a rate of 0.2. For training we use the ADAM (Kingma and Ba, 2015) optimizer with a minibatch size of 8 and a learning rate of 0.001. q, the GCNN hidden layer size, is set to 300. The code for our method is available at `https://github.com/bionlproc/multi-label-zero-shot`.

Thresholding has a large influence on traditional multi-label evaluation measures such as micro-F1 and macro-F1 (Tang et al., 2009). Hence, we report both recall at k (R@k) and precision at k (P@k) which do not require a specific threshold. R@k is preferred for few- and zero-shot labels, because P@k quickly goes to zero as k increases and gets bigger than the number of group specific labels assigned to each instance. Furthermore, for medical coding, these models are typically used as a recommendation engine to help coders. Unless a label appears at the top of the ranking, the annotator will not see it. Thus, ranking metrics better measure the usefulness of our systems.

Baseline Methods. For the frequent and few-shot labels we compare to state-of-the-art methods on the MIMIC II and MIMIC III datasets including ACNN (Mullenbach et al., 2018) and a CNN method introduced in Baumel et al. (2018). We also compare with the L1 regularized logistic regression model used in Vani et al. (2017). Finally, we compare against our prior EMR coding method, Match-CNN (Rios and Kavuluru, 2018).

	P@10	R@10	Macro-F1

ZAGCNN	0.587	0.439	0.038

Table 4: P@k, R@k, and macro-F1 results over all labels (the union of S, F, and Z).

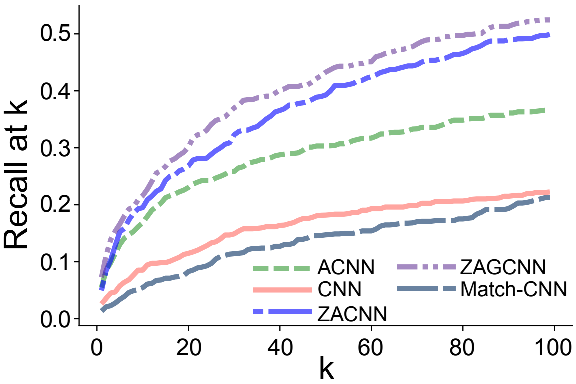

Figure 3: This graph plots the MIMIC III R@k for few-shot (F) labels at different k values.

For zero-shot learning, we compare our results with ESZSL (Romera-Paredes and Torr, 2015). To use ESZSL, we must specify feature vectors for each label. For zero-shot methods, the label vectors used are crucial regardless of the learning method used. Therefore, we evaluate ESZSL with three different sets of label vectors. We average 200 dimensional ICD-9 descriptor word embeddings generated by Pyysalo et al. (2013) which are pretrained on PubMed, Wikipedia, and PubMed Central (ESZSL + W2V). We lowercased descriptors and removed stop-words. We also compare with label vectors derived from our own 300 dimensional embeddings (ESZSL + W2V 2) pretrained on PubMed indexed titles and abstracts. Finally, we generate label vectors using the ICD-9 hierarchy. Specifically, let $\mathbf{Y} \in \mathbb{R}^{N \times L}$ be the document label matrix where N is the total number of documents. We factorize $\mathbf{Y}$ into two matrices $\mathbf{U} \in \mathbb{R}^{N \times 300}$ and $\mathbf{V} \in \mathbb{R}^{300 \times L}$ using graph regularized alternating least squares (GRALS) (Rao et al., 2015). Finally, we also report a baseline using a random ordering on labels, which is important for zero-shot labels — because the total number of such labels is small, the chance that the correct label is in the top k is higher compared to few-shot and frequent labels.

We compare two variants of our method: zero-shot attentive GCNN (ZAGCNN), which is the full method described in Section 3 and a simpler variant without the GCNN layers, zero-shot attentive CNN (ZACNN)[3].

Results. Table 2 shows the results for MIMIC II. Because the label set for each medical record is augmented using the ICD-9 hierarchy, we expect methods that use the hierarchy to have an advantage. Table 2 results do not rely on thresholding because we evaluate using the relative ranking of groups with similar frequencies. ACNN performs best on frequent labels. For few-shot labels, ZAGCNN outperforms ACNN by over 10% in R@10 and by 8% in R@5; compared to these R@k gains for few-shot labels, our loss on frequent labels is minimal (< 1%). We find that the word embedding derived label vectors work best for ESZSL on zero-shot labels. However, this setup is outperformed by GRALS derived label vectors on the frequent and few-shot labels. On zero-shot labels, ZAGCNN outperforms the best ESZSL variant by over 16% for both R@5 and R@10. Also, we find that the GCNN layers help both few- and zero-shot labels. Finally, similar to the setup in Xian et al. (2017), we also compute the harmonic average across all R@5 and all R@10 scores. The metric is only computed for methods that can predict zero-shot classes. We find that ZAGCNN outperforms ZACNN by 4% for R@10.

We report the MIMIC III results in Table 3. Unlike for MIMIC II, the label sets were not expanded using the ICD-9 hierarchy. Yet, we find substantial improvements on both few- and zero-shot labels using a GCNN. ZAGCNN outperforms ACNN by almost 5% and ZACNN by 1% in R@10 on few-shot classes. However, ACNN still outperforms all other methods on frequent labels, but by only 0.3% when compared with ZAGCNN. For zero-shot labels, ZAGCNN outperforms ZACNN by over 5% and outperforms the best ESZSL method by nearly 20% in R@10. We find that ZACNN slightly underperforms ZAGCNN on frequent labels with more prominent differences showing up for infrequent labels.

In Table 4 we compare the P@10, R@10, and

---

[3] We name our methods with the "zero-shot" prefix because they are primarily designed for such scenarios, although as we show later that these methods are effective for both few-shot and frequent labels

macro-F1 measures across all three groups (the union of S, F, and Z) on the MIMIC III dataset. We emphasize that the evaluation metrics are calculated over all labels and are not averages of the metrics computed independently for each group. We find that R@10 is nearly equivalent to the R@10 on the frequent group in Table 3. Furthermore, we find that ACNN outperforms ZAGCNN in P@10 by almost 4%. To compare all methods with respect to macro-F1, we simply threshold each label at 0.5. Both R@k and P@k give more weight to frequent labels, thus it is expected that ACNN outperforms ZAGCNN for frequent labels. However, we also find that ACNN outperforms our methods with respect to Macro-F1.

Given macro-F1 equally weights all labels, does the higher macro score mean ACNN performs better across infrequent labels? In Figure 3, we plot the MIMIC III R@k for the neural methods with k ranging from 1 to 100. We find as k increases, the differences between ZAGCNN and ACNN become more evident. Given Figure 3 and the scores in Table 3, it is clear that ACNN does not perform better than ZAGCNN with respect to few- and zero-shot labels. The improvement in macro-F1 for ACNN is because it performs better on frequent labels. In general, infrequent labels will have scores much less than 0.5. If we rank all labels ($S \cup F \cup Z$), we find that few-shot labels only occur among the top 16 ranked labels (average number of labels for MIMIC III) for 6% of the test documents that contain them. This suggests that many frequent irrelevant labels have higher scores than the correct few-shot label.

Why do the rankings among few- and zero-shot labels matter if they are rarely ranked above irrelevant frequent labels? If we can predict which instances contain infrequent labels (novelty detection), then we can help human coders by providing them with multiple recommendation lists — a list of frequent labels and a list of infrequent/zero-shot labels. Also, while we would ideally want a single method that performs best for both frequent and infrequent labels, currently we find that there is a trade-off between them. Hence it may be reasonable to use different methods in combination depending on label frequency.

5 Conclusion and Future Work

In this paper, we performed a fine-grained evaluation of few- and zero-shot label learning in the large-scale multi-label setting. We also introduced a neural architecture that incorporates label descriptors and the hierarchical structure of the label spaces for few- and zero-shot prediction. For these infrequent labels, previous evaluation methodologies do not provide a clear picture about what works. By evaluating power-law datasets using a generalized zero-shot learning methodology, we provide a staring point toward a better understanding. Our proposed architecture also provides large improvements on infrequent labels over state-of-the-art automatic medical coding methods.

We believe there are two important avenues for future work.

1. For medical coding, a wealth of unstructured domain expertise is available in biomedical research articles indexed by PubMed. These articles are annotated with medical subject headings (MeSH terms), which are organized in a hierarchy. Relationships between MeSH terms and ICD-9 codes are available in Unified Medical Language System (UMLS (Bodenreider, 2004)). If we can take advantage of all this structured and unstructured information via methods such as transfer learning or multi-task learning, then we may be able to predict infrequent labels better.

2. For our method to be useful for human coders, it is important to develop an accurate novelty detector. We plan to study methods for determining if an instance contains an infrequent label and if it does, how many infrequent labels it should be annotated with. In essence, this is an extension of the Meta-Labeler (Tang et al., 2009) methodology and open classification (Shu et al., 2017). If we can predict if an instance contains infrequent labels, then we can recommend few- and zero-shot labels only when necessary.

Acknowledgements

Thanks to the outstanding reviewers who provided invaluable insights to improve our manuscript. This research is supported by the U.S. National Library of Medicine through grant R21LM012274. We also gratefully acknowledge the support of the NVIDIA Corporation for its donation of the Titan X Pascal GPU used for this research.

Abstract

Poetry is one of the most beautiful forms of human language art. As a crucial step towards computer creativity, automatic poetry generation has drawn researchers' attention for decades. In recent years, some neural models have made remarkable progress in this task. However, they are all based on maximum likelihood estimation, which only learns common patterns of the corpus and results in loss-evaluation mismatch. Human experts evaluate poetry in terms of some specific criteria, instead of word-level likelihood. To handle this problem, we directly model the criteria and use them as explicit rewards to guide gradient update by reinforcement learning, so as to motivate the model to pursue higher scores. Besides, inspired by writing theories, we propose a novel mutual reinforcement learning schema. We simultaneously train two learners (generators) which learn not only from the teacher (rewarder) but also from each other to further improve performance. We experiment on Chinese poetry. Based on a strong basic model, our method achieves better results and outperforms the current state-of-the-art method.

1 Introduction

Language is one of the most important forms of human intelligence and poetry is a concise and graceful art of human language. Across different countries, nationalities and cultures, poetry is always popular, having far-reaching influence on the development of human society.

In this work, we concentrate on automatic poetry generation. Besides the long-term goal of building artificial intelligence, research on this task could become the auxiliary tool to better analyse poetry and understand the internal mechanism of human writing. In addition, these generation systems are also helpful for electronic entertainments and literary education.

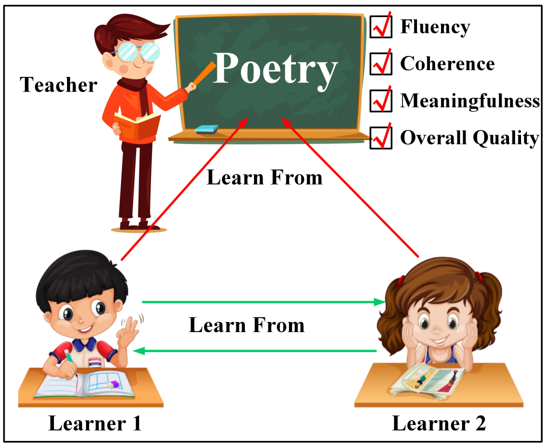

Figure 1: An artistic illustration of our mutual reinforcement learning method.

In recent years, neural networks have proven to be powerful on poetry generation. Some neural models are proposed and achieve significant improvement. However, existing models are all based on maximum likelihood estimation (MLE), which brings two substantial problems. First, MLE-based models tend to remember common patterns of the poetry corpus (Zhang et al., 2017), such as high-frequency bigrams and stop words, losing some diversity and innovation for generated poetry. Moreover, based on word-level likelihood, two kinds of loss-evaluation mismatch (Wiseman and Rush, 2016) arise. One is *evaluation granularity mismatch*. When evaluating, human experts usually focus on sequence level (a poem line) or discourse level (a whole poem), while MLE optimizes word-level loss, which fails to hold a wider view of generated poems. The other is *criteria mismatch*. Instead of the likelihood, humans usually evaluate poetry in terms of some criteria. In this work we focus on the main four criteria

Brussels, Belgium, October 31 - November 4, 2018.

(Manurung, 2003; Zhang and Lapata, 2014; Yan, 2016; Yi et al., 2017): **fluency** (are the lines fluent and well-formed?), **coherence** (is the poem as a whole coherent in meaning and theme?), **meaningfulness** (does the poem convey some certain messages?), **overall quality** (the reader's general impression on the poem). This mismatch may make the model lean towards optimizing easier criteria, e.g., fluency, and ignore other ones.

To tackle these problems, we directly model the four aforementioned human evaluation criteria and use them as explicit rewards to guide gradient update by reinforcement learning. This is a criterion-driven training process, which motivates the model to generate poems with higher scores on these criteria. Besides, in writing theories, writing requires observing other learners (Bandura, 2001). It is also shown that writing is supported as an activity in which writers will learn from more experienced writers, such as other students, teachers, or authors (Prior, 2006). Therefore it is necessary to equip generators with the ability of mutual learning and communication. Inspired by this, we propose a novel mutual reinforcement learning schema (Figure 1), where we simultaneously train two *learners* (generators). During the training process, one learner will learn not only from the *teacher* (rewarder) but also from the other. We will show this mutual learning-teaching process leads to better results.

In summary, our contributions are as follows:

- To the best of our knowledge, for the sake of tackling the loss-evaluation mismatch problem in poetry generation, we first utilize reinforcement learning to model and optimize human evaluation criteria.
- We propose a novel mutual reinforcement learning schema to further improve performance, which is **transparent** to model architectures. One can apply it to any poetry generation model.
- We experiment on Chinese quatrains. Both automatic and human evaluation results show that our method outperforms a strong basic method and the state-of-the-art model.

2 Related Work

As a desirable entry point of automatic analysing, understanding and generating literary text, the research on poetry generation has lasted for decades. In recent twenty years, the models can be categorized into two main paradigms.

The first one is based on statistical machine learning methods. Genetic algorithms (Manurung, 2003; Levy, 2001), Statistical Machine Translation (SMT) approaches (He et al., 2012; Jiang and Zhou, 2008) and Automatic Summarization approaches (Yan et al., 2013) are all adopted to generate poetry.

More recently, the second paradigm, neural network, has shown great advantages in this task, compared to statistical models. Recurrent Neural Network (RNN) is first used to generate Chinese quatrains by (Zhang and Lapata, 2014). To improve fluency and coherence, Zhang's model needs to be interpolated with extra SMT features as shown in their paper. Focusing on coherence, some works (Yi et al., 2017; Wang et al., 2016a) use sequence-to-sequence model with attention mechanism (Bahdanau et al., 2015) to generate poetry. Wang et al. (2016b) design a special Planning schema, which plans some sub-keywords in advance by a language model and then generates each line with the planned sub-keyword to improve coherence. Pursuing better overall quality, Yan (2016) proposes an iterative polishing schema to generate Chinese poetry, which refines the poem generated in one pass for several times. Aiming at enhancing meaningfulness, Ghazvininejad et al. (2016) extend user keywords to incorporate richer semantic information. Zhang et al. (2017) combine a neural memory, which saves hundreds of human-authored poems, with a sequence-to-sequence model to improve innovation of generated poems and achieve style transfer.

These neural structures have made some progress and improved different aspects of generated poetry. Nevertheless, as discussed in Section 1, the two essential problems, lack of diversity and loss-evaluation mismatch, are still challenging resulting from MLE. Compared to further adjusting model structures, we believe a better solution is to design more reasonable optimization objectives.

Deep Reinforcement Learning (DRL) first shows its magic power in automatic game playing, such as Atari electronic games (Mnih et al., 2013) and the game of Go (Silver et al., 2016). Soon, DRL is used to playing text games (Narasimhan et al., 2015; He et al., 2016) and then applied to dialogue generation (Li et al., 2016b).

From the perspective of poetry education, the teacher will judge student-created poems in terms of some specific criteria and guide the student to cover the shortage, which naturally accords with DRL process. Therefore we take advantage of DRL. We design four automatic rewarders for the criteria, which act as the teacher. Furthermore, we train two generators and make them learn from each other, which imitates the mutual learning of students, as a step towards multi-agent DRL in literary text generation.

3 Methods

3.1 Basic Generation Model

We apply our method to a basic poetry generation model, which is pre-trained with MLE. Therefore, we first formalize our task and introduce this model.

The inputs are user topics specified by K keywords, $\mathcal{W} = \{w_k\}_{k=1}^{K}$. The output is a poem consisting of n lines, $\mathcal{P} = L_1, L_2, \cdots, L_n$. Since we take the line-by-line generation process, the task can be converted to the generation of an i-th line given previous i-1 lines $L_{1:i-1}$ and $\mathcal{W}$.

We use GRU-based (Cho et al., 2014) sequence-to-sequence model. $\overrightarrow{h}_t$, $\overleftarrow{h}_t$ and s_t represent the forward encoder, backward encoder and decoder hidden states respectively. For each topic word $w_k = c_1, c_2, \cdots, c_{T_k}$, we feed characters into the encoder and get the keyword representation $v_k = [\overrightarrow{h}_{T_k}; \overleftarrow{h}_{T_k}]$, where [;] means concatenation. Then we get the topic representation by[1]:

$$o = f(\frac{1}{K}\sum_{t=1}^{K} v_k), \tag{1}$$

where f defines a non-linear layer.

Denote the generated i-th line in decoder, $Y = (y_1 y_2 \ldots y_{T_i})$. $e(y_t)$ is the word embedding of y_t. The probability distribution of each y_t to be generated in L_i is calculated by:

$$s_t = GRU(s_{t-1}, [e(y_{t-1}); o; g_{i-1}]), \tag{2}$$

$$P(y_t|y_{1:t-1}, L_{1:i-1}, \mathcal{W}) = softmax(W s_t), \tag{3}$$

where W is the projection parameter. g_{i-1} is a global history vector, which records what has been generated so far and provides global-level information for the model. Once L_i is generated, it is updated by a convolutional layer:

$$a_t = f([s_t; \cdots; s_{t+d-1}]), \tag{4}$$

$$g_i = f(g_{i-1}, \sum_t a_t), g_0 = \mathbf{0}, \tag{5}$$

where $\mathbf{0}$ is a vector with all 0-s and d is convolution window size. Then the basic model is pre-trained by minimizing standard MLE loss:

$$\mathcal{L}_{MLE}(\theta) = -\sum_{m=1}^{M} logP(\mathcal{P}^m|\mathcal{W}^m; \theta), \tag{6}$$

where M is data size and θ is the parameter set to be trained.

This basic model is a modified version of (Yan, 2016). The main differences are that we replace vanilla RNN with GRU unit, use convolution to calculate the line representation rather than directly use the last decoder hidden state, and we remove the polishing schema to better obverse the influence of DRL itself. We select this model as our basic framework since it achieves satisfactory performance and the author has done thorough comparisons with other models, such as (Yan et al., 2013) and (Zhang and Lapata, 2014).

3.2 Single-Learner Reinforcement Learning

Before presenting the single-learner version of our method (abbreviated as **SRL**), we first design corresponding automatic rewarders for the four human evaluation criteria.

Fluency Rewarder. We use a neural language model to measure fluency. Given a poem line L_i, higher probability $P_{lm}(L_i)$ indicates the line is more likely to exist in the corpus and thus may be more fluent and well-formed. However, it's inadvisable to directly use $P_{lm}(L_i)$ as the reward, since over high probability may damage diversity and innovation. We expect moderate probabilities which fall into a reasonable range, neither too high nor too low. Therefore, we define the fluency reward of a poem $\mathcal{P}$ as:

$$r(L_i) = max(|P_{lm}(L_i) - \mu| - \delta_1 * \sigma, 0), \tag{7}$$

$$R_1(\mathcal{P}) = \frac{1}{n}\sum_{i=1}^{n} exp(-r(L_i)), \tag{8}$$

where μ and σ are the mean value and standard deviation of P_{lm} calculated over all training sets. δ_1 is a hyper-parameter to control the range.

Coherence Rewarder. For poetry, good coherence means each line L_i should be coherent with

---

[1] For brevity, we omit biases in all equations.

previous lines in a poem. We use Mutual Information (MI) to measure the coherence of L_i and $L_{1:i-1}$. As shown in (Li et al., 2016a), MI of two sentences, S_1 and S_2, can be calculated by:

$$MI(S_1, S_2) = logP(S_2|S_1) - \lambda logP(S_2), \quad (9)$$

where λ is used to regulate the weight of generic sentences. Based on this, we calculate the coherence reward as:

$$\begin{aligned} MI(L_{1:i-1}, L_i) = & logP_{seq2seq}(L_i|L_{1:i-1}) \\ & - \lambda logP_{lm}(L_i), \end{aligned} \quad (10)$$

$$R_2(\mathcal{P}) = \frac{1}{n-1}\sum_{i=2}^{n} MI(L_{1:i-1}, L_i), \quad (11)$$

where $P_{seq2seq}$ is a GRU-based sequence-to-sequence model, which takes the concatenation of previous i-1 lines as input, and predicts L_i. A better choice is to use a dynamic λ instead of a static one. Here we directly set $\lambda = exp(-r(L_i)) + 1$, which gives smaller weights to lines with extreme language model probabilities.

Meaningfulness Rewarder. In dialogue generation task, neural models are prone to generate generic sentences such as "I don't know" (Li et al., 2016a; Serban et al., 2016). We observed similar issues in poetry generation. The basic model tends to generate some common and meaningless words, such as *bu zhi* (don't know), *he chu* (where), and *wu ren* (no one). It's quite intractable to quantify the meaningfulness of a whole poem, but we find that TF-IDF values of human-authored poems are significantly higher than values of generated ones (Figure 2). Consequently, we utilize TF-IDF to motivate the model to generate more meaningful words. This is a simple and rough attempt, but it makes generated poems more "meaningful" from the readers perspective.

Direct use of TF-IDF leads to serious out-of-vocabulary (OOV) problem and high variance, because we need to sample poems during the training process of DRL, which causes many OOV words. Therefore we use another neural network to smooth TF-IDF values. In detail, we have:

$$R_3(\mathcal{P}) = \frac{1}{n}\sum_{i=1}^{n} F(L_i), \quad (12)$$

where $F(L_i)$ is a neural network which takes a line as input and predicts its estimated TF-IDF value. For each line in training sets, we calculate standard TF-IDF values of all words and use the average as the line TF-IDF value. Then we use them to train $F(L_i)$ with Huber loss.

Overall Quality Rewarder. The three kinds of rewards above are all based on line-level. In fact, human experts will also focus on discourse-level to judge the overall quality of a poem, ignoring some minor defects. We train a neural classifier to classify a given poem (in terms of the concatenation of all lines) into three classes: computer-generated poetry (class 1), ordinary human-authored poetry (class 2) and masterpiece (class 3). Then we get the reward by:

$$R_4(\mathcal{P}) = \sum_{k=1}^{3} P_{cl}(k|\mathcal{P}) * k. \quad (13)$$

This classifier should be as reliable as possible. Due to the limited amount of masterpieces, normal classifiers don't work well. Therefore we use an adversarial training based classifier (Miyato et al., 2017), which achieves F-1 0.96, 0.73, 0.76 for the three classes respectively on the validation set.

Based on these rewarders, the total reward is:

$$R(\mathcal{P}) = \sum_{j=1}^{4} \alpha_j * \tilde{R}_j(\mathcal{P}), \quad (14)$$

where α_j is the weight and the symbol ˜ means the four rewards are re-scaled to the same magnitude. As (Gulcehre et al., 2018), we reduce the variance by:

$$R^{'}(\mathcal{P}) = \frac{R(\mathcal{P}) - b_u}{\sqrt{\sigma_u^2 + \epsilon}} - B(\mathcal{P}), \quad (15)$$

where b_u and σ_u are running average and standard deviation of R respectively. $B(\mathcal{P})$ is a neural network trained with Huber loss, which takes a poem as input and predicts its estimated reward.

DRL Process. For brevity, we use $P_g(\cdot|\mathcal{W};\theta)$ to represent a basic generator and use REINFORCE algorithm (Williams, 1992) to optimize the model, which minimizes:

$$\mathcal{L}_{DRL}(\theta) = -\sum_{m=1}^{M} \mathbb{E}_{\mathcal{P}\sim P_g(\cdot|\mathcal{W}^m;\theta)}(R^{'}(\mathcal{P})). \quad (16)$$

Training with solely Eq.(16) is unstable. Lacking of original MLE supervisory signals, the

```

model is easy to get lost and totally ignore the corresponding topics specified by $\mathcal{W}$, leading to explosive increase of MLE loss. We use two steps to alleviate this issue. The first one is the Teacher Forcing (Li et al., 2017). For each $\mathcal{W}$, we estimate $\mathbb{E}(R^{'}(\mathcal{P}))$ by n_s sampled poems, as well as the ground-truth $\mathcal{P}_g$ whose reward is set to $max(R^{'}(\mathcal{P}_g), 0)$. The second step is to combine MLE loss and DRL loss as:

$$\mathcal{L}(\theta) = (1 - \beta) * \mathcal{L}_{MLE}(\theta) + \beta * \tilde{\mathcal{L}}_{DRL}(\theta), \tag{17}$$

where ˜ means the DRL loss is re-scaled to the same magnitude with MLE loss. Ultimately, we use Eq.(17) to fine-tune the basic model.

3.3 Mutual Reinforcement Learning

As discussed in Section 1 & 2, to further improve the performance, we mimic the mutual writing learning activity by simultaneously training two generators defined as $P_g(\theta_1)$ and $P_g(\theta_2)$. The two learners (generators) learns not only from the teacher (rewarders) but also from each other.

From the perspective of machine learning, one generator may not explore the policy space sufficiently and thus is easy to get stuck in the local minima. Two generators can explore along different directions. Once one generator finds a better path (higher reward), it can communicate with the other and lead it towards this path. This process could also be considered as the ensemble of different generators during the training phase.

Models	$\tilde{R}_1$	$\tilde{R}_2$	$\tilde{R}_3$	$\tilde{R}_4$	R
Base	0.156	0.214	0.509	0.351	0.282

MRL	**0.207**	**0.268**	**0.613**	**0.494**	**0.369**

Table 1: Automatic rewards of different models and strategies. $\tilde{R}_1$: fluency, $\tilde{R}_2$: coherence, $\tilde{R}_3$: meaningfulness, $\tilde{R}_4$: overall quality, R: weighted-average reward. LMRL: local MRL, GMRL: global MRL.

We implement the Mutual Reinforcement Learning (abbreviated as **MRL**) by two methods.

Local MRL. The first one is a simple instance-based method. For the same input, suppose $\mathcal{P}_1$, $\mathcal{P}_2$ are generated by $P_g(\theta_1)$ and $P_g(\theta_2)$ respectively. If $R(\mathcal{P}_1) > R(\mathcal{P}_2) * (1 + \delta_2)$ and $\tilde{R}_j(\mathcal{P}_1) > \tilde{R}_j(\mathcal{P}_2)$ for all j, then $P_g(\theta_2)$ uses $\mathcal{P}_1$ instead of $\mathcal{P}_2$ to update itself in Eq.(16) and vice versa. That is, if a learner creates a significantly better poem, then the other learner will learn it. This process gives a generator more high-reward instances and allows it to explore larger space along a more proper direction so as to escape from the local minima.

Global MRL. During the training process, we need to sample poems from the generator, and hence local MRL may cause high variance. Instead of an instance, mutual learning can also be applied on the distribution level. We can pull the distribution of a generator towards that of the other by minimizing KL divergence of them. We detail this method in algorithm 1. The inner thought is that if learner 1 is generally better than learner 2, that is, during the creating history, learner 1 achieves higher average rewards, then learner 2 should directly learn from learner 1, rather than learn the poem itself. This process allows the generator to learn from long-period history and focus on a higher level.

In practice, we combine these two methods by simultaneously communicating high-reward samples and using KL loss, which leads to the best testing rewards (Table 1).

4 Experiments

4.1 Data and Setups

Our corpus consists of three sets: 117,392 Chinese quatrains (CQ), 10,000 Chinese regulated verses (CRV) and 10,000 Chinese iambics (CI). As men-

Models	Bigram Ratio	Jaccard
Base	0.126	0.214
Mem	**0.184**	0.183
MRL	0.181	**0.066**
GT	0.218	0.006
SRL	0.133	0.146
LMRL	0.178	0.085
GMRL	**0.186**	0.075
MRL	0.181	**0.066**

Table 2: Automatic evaluation results of diversity and innovation. The Jaccard values are multiplied by 10 for clearer observation. We expect higher bigram ratio and smaller Jaccard values.

tioned, we experiment on the generation of quatrain which is the most popular genre of Chinese poetry and accounts for the largest part of our corpus. From the three sets, we randomly select 10% for validation. From CQ, we select another 10% for testing. The rest are used for training.

For our model and baseline models, we run TextRank (Mihalcea and Tarau, 2004) on all training sets and then extract four keywords from each quatrain. Then we build four < keyword(s), poem > pairs for each quatrain using 1 to 4 keywords respectively, so as to enable the model to cope with different numbers of keywords.

For the models and rewarders, the sizes of word embedding and hidden state are 256 and 512 respectively. History vector size is 512 and convolution window size $d = 3$. The word embedding is initialized with pre-trained word2vec vectors. We use tanh as the activation function. For other more configurations of the basic model, we directly follow (Yan, 2016).

P_{lm} and $P_{seq2seq}$ are trained with the three sets. We train $F(L_i)$ and $B(\mathcal{P})$ with the CQ, CRV and 120,000 generated poems. There are 9,465 masterpieces in CQ. We use these poems, together with 10,000 generated poems and 10,000 ordinary human-authored poems to train the classifier P_{cl}. For training rewarders, half of the generated poems are sampled and the other half are generated with beam search (beam size 20). For testing, all models generate poems with beam search.

We use Adam (Kingma and Ba, 2015) with shuffled mini-batches. The batch size is 64 for MLE and 32 for DRL. For DRL, we random select batches to fine-tune the basic model. We set $\delta_1 = 0.5$, $\delta_2 = 0.1$, $\delta_3 = 0.001$, $\alpha_1 = 0.25$, $\alpha_2 = 0.31$, $\alpha_3 = 0.14$, $\alpha_4 = 0.30$, $n_s = 4$, and $\beta = 0.7$.

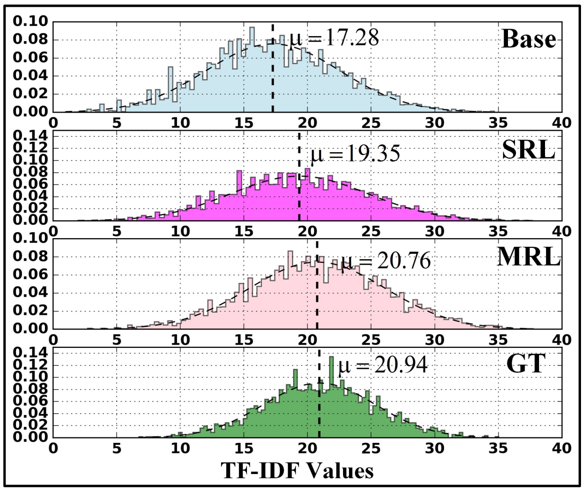

Figure 2: TF-IDF distributions of poems generated by different models. We show real TF-IDF, instead of the estimated $\tilde{R}_3$.

A key point for MRL is to give the two pretrained generators some diversity, which can be achieved by using different model structures or parameters. Here we simply initialize the generators differently and train one of them for more epoches.

4.2 Models for Comparisons

We compare **MRL**[2] (our model, with both local and global mutual learning), **GT** (ground-truth, namely human-authored poems), **Base** (the basic model described in Section 3.1) and **Mem** (Zhang et al., 2017). The Mem model is the current state-of-the-art model for Chinese quatrain generation, which also achieves the best innovation so far.

4.3 Automatic Evaluation

Some previous models (He et al., 2012; Zhang and Lapata, 2014; Yan, 2016) adopt BLEU and perplexity as automatic evaluation metrics. Nevertheless, as discussed in Section 1, word-level likelihood or n-gram matching will greatly diverge from human evaluation manner. Therefore we dispense with them and automatically evaluate generated poems as follows:

Rewarder Scores. The four rewarder scores are objective and model-irrelevant metrics which approximate corresponding human criteria. They

---

Models	Fluency	Coherence	Meaning	Overall Quality
Base	3.28	2.77	2.63	2.58
Mem	3.23	2.88	2.68	2.68
MRL	**4.05****	**3.81****	**3.68****	**3.60****
GT	4.14	4.11^{++}	4.16^{++}	3.97^{++}

Table 3: Human evaluation results. Diacritic ** ($p < 0.01$) indicates MRL significantly outperforms baselines; ++ ($p < 0.01$) indicates GT is significantly better than all models.

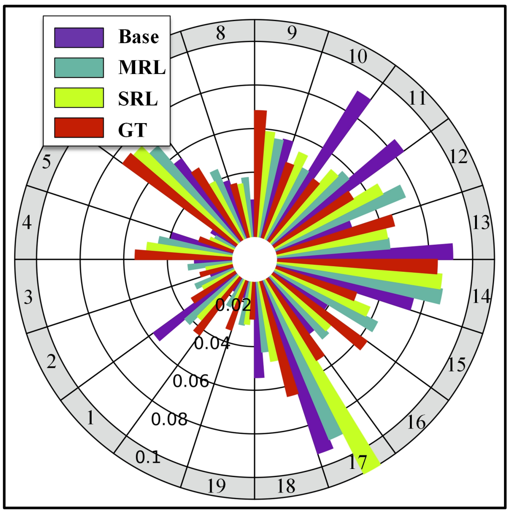

Figure 3: Topic Distributions of different models.

can reflect poetry quality to some extent. As shown in Table 1, on each criterion, GT gets much higher rewards than all these models. Compared to Base, MRL gets closer to GT and achieves 31% improvement on the weighted average reward. Mem outperforms Base on the criteria except for meaningfulness ($\tilde{R}_3$). This is mainly because Mem generates more distinct words (Table 2), but these words tend to concentrate on the high-frequency area, resulting in unsatisfactory TF-IDF reward. We also test different strategies of MRL. With naive single-learner RL, the improvement is limited, only 14%. With mutual RL, the improvement increases to 27%. Combining local MRL and global MRL leads to another 4% improvement. The results demonstrate our explicit optimization (RL) is more effective than the implicit ones and MRL gets higher scores than SRL.

Diversity and Innovation. Poetry is a kind of literature text with high requirements on diversity and innovation. Users don't expect the machine to always generate monotonous poems. We evaluate innovation of generated poems by distinct bigram ratio as (Li et al., 2016b). More novel generated bigrams can somewhat reflect higher innovation. The diversity is measured by bigram-based average Jaccard similarity of each two generated poems. Intuitively, a basic requirement for innovation is that, with different inputs, the generated poems should be different from each other.

As shown in Table 2, Mem gets the highest bigram ratio, close to GT, benefiting from its specially designed structure for innovation. Our MRL achieves 43% improvement over Base, comparable to Mem. We will show later this satisfactory performance may lie in the incorporation of TF-IDF (Figure 2). On Jaccard, MRL gets the best result due to the utilization of MI. MI brings richer context-related information which can enhance diversity as shown in (Li et al., 2016a). In fact, human-authored poems often contain strong diversity of personal emotion and experience. Therefore, despite prominent improvement, there is still a large gap between MRL and GT.

TF-IDF Distribution. As mentioned, the basic model tends to generate common and meaningless words. Consequently, we use TF-IDF as one of the rewards. Figure 2 shows the TF-IDF distributions. As we can see, Base generates poems with lower TF-IDF compared to GT, while MRL pulls the distribution towards that of GT, making the model generate more meaningful words and hence benefiting innovation and diversity.

Topic Distribution. We run LDA (Blei et al., 2003) with 20 topics on the whole corpus and then inference the topic of each generated poem. Figure 3 gives the topic distributions. Poems generated by Base center in a few topics, which again demonstrates the claim: MLE-based models tend to remember the common patterns. In contrast, human-authored poems spread on more topics. After fine-tuning by our MRL method, the topic distribution shows better diversity and balance.

4.4 Human Evaluation

From the testing set, we randomly select 80 sets of keywords to generate poems with these mod-

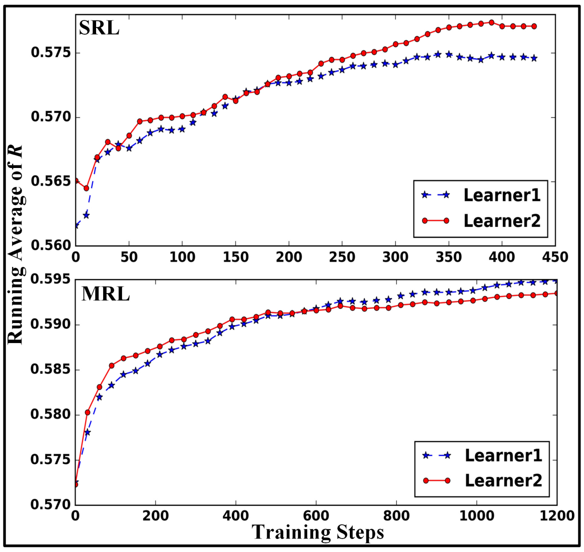

Figure 4: The learning curves of SRL and MRL. Learner (generator) 2 is pre-trained for more epoches to allow some diversity.

els. For GT, we select poems containing the given words. Therefore, we obtain 320 quatrains (80*4). We invite 12 experts on Chinese poetry to evaluate these poems in terms of the four criteria: fluency, coherence, meaningfulness and overall quality and each needs to be scored in a 5-point scale ranging from 1 to 5. Since it's tiring to evaluate all poems for one person, we randomly divide the 12 experts into three groups. Each group evaluates the randomly shuffled 320 poems (80 for each expert). Then for each model, each poem, we get 3 scores on each criterion and we use the average to alleviate individual preference.

Table 3 gives human evaluation results. MRL achieves better results than the other two models. Since fluency is quite easy to be optimized, our method gets close to human-authored poems on Fluency. The biggest gap between MRL and GT lies on Meaning. It's a complex criterion involving the use of words, topic, emotion expression and so on. The utilization of TF-IDF does ameliorate the use of words on diversity and innovation, hence improving Meaningfulness to some extent, but there are still lots to do.

4.5 Further Analyses and Discussions

In this section we give more discussions.

Learning Curve. We show the learning curves of SRL and MRL in Figure 4. As we can see, for SRL, the adequately pre-trained generator 2 always gets higher rewards than the other one during the DRL training process. With the increase of training steps, the gap between their rewards gets larger. After several hundred steps, rewards of the two generators converge.

For MRL, generator 2 gets higher rewards at the beginning, but it is exceeded by generator 1 since generator 1 learns from it and keeps chasing. Finally, the two generators converge to higher rewards compared to SRL.

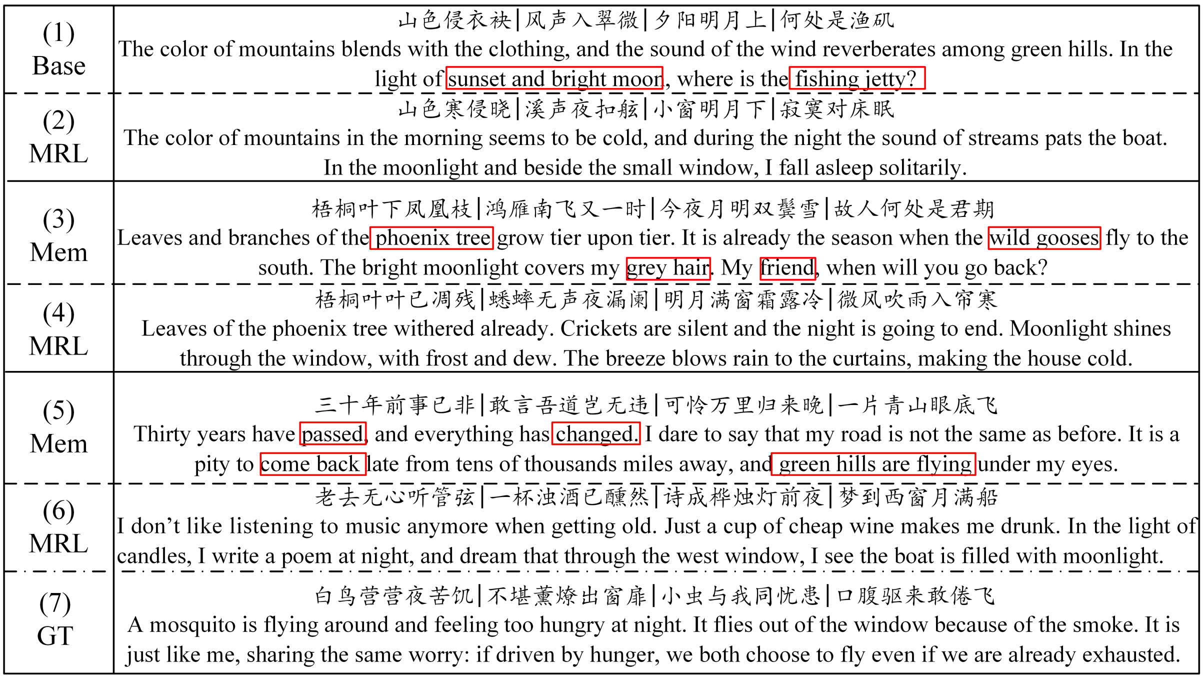
Case Study. We show some generated poems in Figure 5. The Base model generates two words, ‘sunset’ and ‘moon’ in poem (1), which appear together and thus cause the conflict of time. The word ‘fishing jetty’ is confusing without any necessary explanation in the context. In contrast, poem (2) describes a clearer scene and expresses some emotion: a lonely man takes a boat from morning till night and then falls asleep solitarily.

In poem (3), Mem generates some meaningful words, such as ‘phoenix tree’, ‘wild goose’ and ‘friend’. However, there isn't any clue to link them together, resulting in poor coherence. On the contrary, things in poem (4) are tightly connected. For example, ‘moonlight’ is related to ‘night’; ‘rain’, ‘frost’ and ‘dew’ are connected with ‘cold’.

Poem (5) expresses almost nothing. The first two lines seem to talk about the change of time. But the last two lines are almost unrelated to ‘time change’. Poem (6) talks about an old poet, with the description of cheap wine, poem and dream, expressing something about life and time. However, the human-authored poem (7) does much better. It seems to describe a mosquito, but in fact, it's a metaphor of the author himself.

5 Conclusion and Future Work

In this work, we address two substantial problems in automatic poetry generation: lack of diversity, and loss-evaluation mismatch, which are caused by MLE-based neural models. To this end, we directly model the four widely used human evaluation criteria and design corresponding automatic rewarders. We use these explicit rewards to guide gradient update by reinforcement learning. Furthermore, inspired by writing theories, we propose a novel mutual learning schema to further improve the performance. Mimicking the poetry learning activity, we simultaneously train two generators, which will not only be taught by the rewarders but also learn from each other. Experi-



(1) Base	山色侵衣袂|风声入翠微|夕阳明月上|何处是渔矶 The color of mountains blends with the clothing, and the sound of the wind reverberates among green hills. In the light of sunset and bright moon, where is the fishing jetty?
(2) MRL	山色寒侵晓|溪声夜扣舷|小窗明月下|寂寞对床眠 The color of mountains in the morning seems to be cold, and during the night the sound of streams pats the boat. In the moonlight and beside the small window, I fall asleep solitarily.
(3) Mem	梧桐叶下凤凰枝|鸿雁南飞又一时|今夜月明双鬓雪|故人何处是君期 Leaves and branches of the phoenix tree grow tier upon tier. It is already the season when the wild gooses fly to the south. The bright moonlight covers my grey hair. My friend, when will you go back?
(4) MRL	梧桐叶叶已凋残|蟋蟀无声夜漏阑|明月满窗霜露冷|微风吹雨入帘寒 Leaves of the phoenix tree withered already. Crickets are silent and the night is going to end. Moonlight shines through the window, with frost and dew. The breeze blows rain to the curtains, making the house cold.
(5) Mem	三十年前事已非|敢言吾道岂无违|可怜万里归来晚|一片青山眼底飞 Thirty years have passed, and everything has changed. I dare to say that my road is not the same as before. It is a pity to come back late from tens of thousands miles away, and green hills are flying under my eyes.
(6) MRL	老去无心听管弦|一杯浊酒已醺然|诗成桦烛灯前夜|梦到西窗月满船 I don't like listening to music anymore when getting old. Just a cup of cheap wine makes me drunk. In the light of candles, I write a poem at night, and dream that through the west window, I see the boat is filled with moonlight.
(7) GT	白鸟营营夜苦饥|不堪薰燎出窗扉|小虫与我同忧患|口腹驱来敢倦飞 A mosquito is flying around and feeling too hungry at night. It flies out of the window because of the smoke. It is just like me, sharing the same worry: if driven by hunger, we both choose to fly even if we are already exhausted.

Figure 5: Sampled poems generated by different models. Poems between two solid lines are generated with the same input keywords. Some defects are shown in red boxes.

mental results show our method achieves significant improvement both on automatic rewards and human evaluation scores, outperforming the current state-of-the-art model[3].

There are still lots to do. Can we better model the meaningfulness of a whole poem? Can we quantify some other intractable criteria, e.g, poeticness? Besides, we only tried two learners in this work. Would the collaboration of more learners lead to better results? How to design the methods of communication among many generators? We will explore these questions in the future.

Acknowledgments

We would like to thank Cheng Yang, Jiannan Liang, Zhipeng Guo, Huimin Chen and anonymous reviewers for their insightful comments. Abstract

Combining the virtues of probability graphic models and neural networks, Conditional Variational Auto-encoder (CVAE) has shown promising performance in many applications such as response generation. However, existing CVAE-based models often generate responses from a single latent variable which may not be sufficient to model high variability in responses. To solve this problem, we propose a novel model that sequentially introduces a series of latent variables to condition the generation of each word in the response sequence. In addition, the approximate posteriors of these latent variables are augmented with a backward Recurrent Neural Network (RNN), which allows the latent variables to capture long-term dependencies of future tokens in generation. To facilitate training, we supplement our model with an auxiliary objective that predicts the subsequent bag of words. Empirical experiments conducted on the OpenSubtitle and Reddit datasets show that the proposed model leads to significant improvements on both relevance and diversity over state-of-the-art baselines.

1 Introduction

Recently, variational Bayesian models have shown attractive merits from both theoretical and practical perspectives (Kingma and Welling, 2013). As one of the most successful variational Bayesian models, Conditional Variational Auto-Encoder (CVAE) (Kingma et al., 2014) was proposed to improve upon the traditional Sequence-to-Sequence (Seq2Seq) dialogue models. The CVAE based models incorporate stochastic latent variables into decoders in order to generate more relevant and diverse responses (Serban et al., 2017; Zhao et al., 2017; Shen et al., 2017). However, existing CVAE based models normally rely on the unimodal distribution with a single latent variable to provide the global guidance to response generation, which is not sufficient to capture the complex semantics and high variability of responses. As a result, the autoregressive decoders used in response generation always tend to ignore these oversimple latent variables and degrade the CVAE based model to the simple Seq2Seq model (aka. the *model collapse* problem).

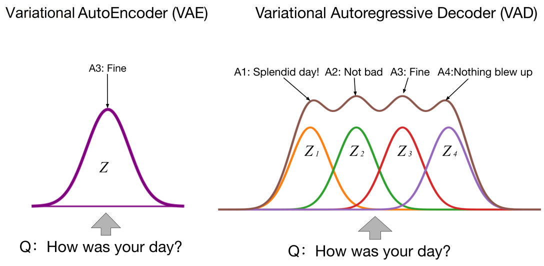

Figure 1: Distributions of latent variable

As illustrated in Figure 1, the unimodal latent variable z used in the conventional VAE usually captures simple unimodal pattern of responses. However, in open-domain conversations, an utterance may have various responses which form complex multimodal distributions. To overcome this problem and improve the quality of generated responses, we propose a novel model, named Variational Autoregressive Decoder (VAD) to iteratively incorporate a series of latent variables into the autoregressive decoder. In particular, a distinct latent variable sampled from CVAE is associated with each time step of the generation, and it is used to condition the next state of the autoregressive decoder (e.g., the hidden state of a RNN). These latent variables at different time steps are integrated by autoregressive decoder to model mutilmodal distribution of text sequences and capture variability of responses as depicted in Figure 1.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3154–3163
Brussels, Belgium, October 31 - November 4, 2018.

Partially inspired by the sequential VAE-based models adopted in speech generation (Goyal et al., 2017; Bayer and Osendorfer, 2014), in our VAD the approximate posterior of the latent variable at each time step is augmented by the corresponding hidden state of a backward RNN running through the remaining response sequence. Since the hidden states of the backward RNN contain the information of the succeeding words in the response, they can be used as the guidance for the latent variables to capture the long-term dependency on the future content.

It has been found that auxiliary losses that predict another task-related objective could help latent variables capture more information from different perspectives when training the VAE based models (Zhao et al., 2017). To enhance VAD, we propose a purposely designed auxiliary loss to use the latent variable at each time step to predict the Bag-Of-Words (BOW) of the succeeding subsequence. The proposed auxiliary loss could essentially help VAD to generate more coherent responses.

Experimental results show that the proposed VAD model outperforms the conventional response generation models when evaluated automatically and manually on the OpenSubtitle and Reddit datasets. The contributions in this work are two-fold:

- We propose a novel VAD model for response generation that can better capture the high variability of responses by sequentially associating latent variables to different time steps of autoregressive decoder and approximating the posterior of latent variables by augmenting the hidden states of a backward RNN.
- A BOW based auxiliary objective is proposed to help preserving the diversity of generated responses.

2 Related Work

2.1 Conversational Systems

As neural network based models dominate the research in natural language processing, Seq2Seq models have been widely used for response generation (Sordoni et al., 2015). However, Seq2seq models suffer from the problem of generating generic responses, such as *I don't know* (Li et al., 2016a). Various approaches have been proposed to address this problem, including adding additional information (Li et al., 2016b; Xing et al., 2017; Zhou et al., 2017b) and modifying the architecture of existing models (Li et al., 2016a; Xu et al., 2017; Zhou et al., 2017a).

Another solution to address this problem is to add stochastic latent variables in order to change the deterministic structure of Seq2Seq models. VAE (Kingma and Welling, 2013) is one of the most successful models (Serban et al., 2017; Zhao et al., 2017; Shen et al., 2017; Cao and Clark, 2017). However, VAE-based models only use a single latent variable to encode the whole response sequence, thus suffering from the ***model collapse*** problem (Bowman et al., 2016). To overcome this problem, we propose a novel model that based on the variational autoregressive decoder to better represent highly structural latent variables.

2.2 Variational Autoregressive Models

Recently, some works attempted to combine VAE with autoregressive models to better process input sequences. Broadly speaking, they can be categorized into two groups. Methods in the first group leverage autoregressive models to improve the inference of traditional VAEs. The most well-known model is Inverse Autoregressive Flow (IAF), which used a series of invertible transformations based on the autoregressive model to construct the latent variables (Kingma et al., 2016; Chen et al., 2017). Methods in the second group focus on improving autoregressive models like RNNs by adding variational inference (Bayer and Osendorfer, 2014; Chung et al., 2015; Fraccaro et al., 2016; Goyal et al., 2017). These models usually modeled continuous data such as images and audio signals. For dealing with discrete data such as text, (Li et al., 2017) applied variational recurrent neural networks (VRNN) for text summarization.

Our proposed framework is based on the second line of research, but is different from the previous research as it develops a new strategy of combining VAE with RNN for response generation.

3 Proposed VAD Model

As shown in Figure 2, we use the Seq2Seq model as the basic architecture. The Seq2Seq model is an encoder-decoder neural framework for mapping a source sequence to a target sequence (Sutskever et al., 2014). The input of Seq2seq response generation model is variable-length query sequence

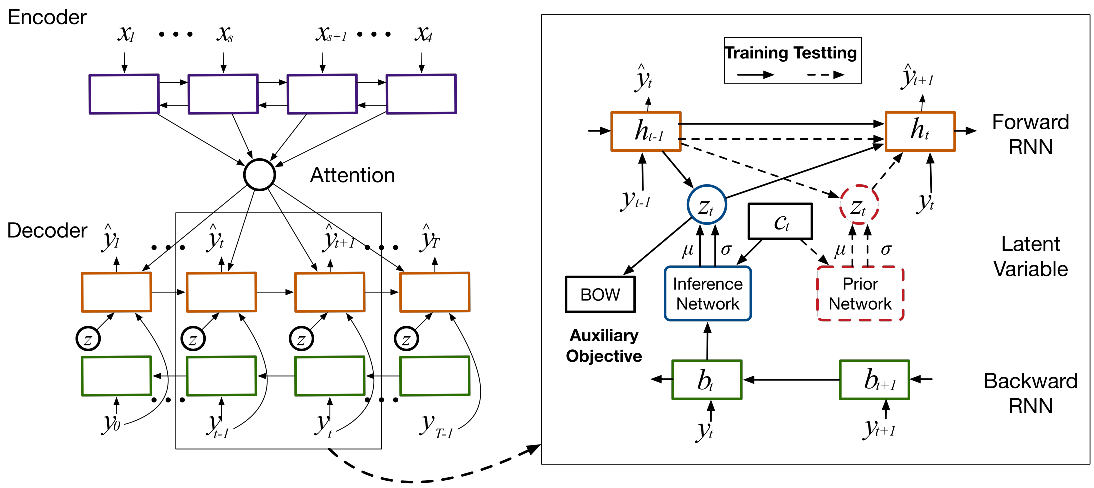

Figure 2: Sequence-to-sequence model using sequential variational decoder.

$\boldsymbol{x} = \{x_1, \ldots, x_m\}$, and the output is a response sequence $\boldsymbol{y} = \{y_1, \ldots, y_n\}$. Both the encoder and decoder are the Recurrent Neural Networks (RNN) with Gated Recurrent Units (GRU) (Chung et al., 2014).

The encoder is a bidirectional GRU that encodes the query sequence as the concatenation of the hidden states of a forward and a backward GRUs. The semantic of word t in the query sequence is represented by $h_t^e = [\overrightarrow{h_t^e}, \overleftarrow{h_t^e}]$, where

$$\begin{aligned} \overrightarrow{h_t^e} &= \overrightarrow{\text{GRU}}(x_t, \overrightarrow{h_{t-1}^e}) \\ \overleftarrow{h_t^e} &= \overleftarrow{\text{GRU}}(x_t, \overleftarrow{h_{t+1}^e}) \end{aligned} \qquad (1)$$

The decoder is a GRU with hidden state h_t^d at each step. The input at step t is the concatenation of previous word in response sequence y_{t-1} and the context vector c_t computed by a neural attention model. The context vector c_t is the weighted sum of the whole encoder's hidden states computed by:

$$\begin{aligned} \alpha_{s,t} &= f_{attention}([h_s^e, h_{t-1}^d]) \\ c_t &= \sum_{s=1}^{m} \alpha_{s,t} h_s^e \end{aligned} \qquad (2)$$

where $f_{attention}$ is a one-layer neural network that produces attention weights, $\alpha_{s,t}$ is the attention weight evaluating the correlation between encoder's hidden state h_s^e and hidden state of decoder h_{t-1}^d. The decoder predicts the next word $\hat{y}_t$ by jointly considering previous word y_{t-1}, attentional context c_t and previous hidden state h_{t-1}^d.

3.1 Conditional Variational Auto-Encoder

The decoder of VAD is based on the Conditional VAE (CVAE) framework (Kingma et al., 2014), which approximates the distribution of random variable $\boldsymbol{y}$ (response) conditioned on $\boldsymbol{x}$ (i.e., query) by incorporating an latent variable z. CVAE introduces a parameterized conditional posterior distribution $q_\theta(z|\boldsymbol{y}, \boldsymbol{x})$ to approximate true posterior distribution $p(z|\boldsymbol{y}, \boldsymbol{x})$. By injecting $q_\theta(z|\boldsymbol{y}, \boldsymbol{x})$, the conditional marginal distribution of $p(\boldsymbol{y}|\boldsymbol{x})$ can be maximized by approximating the Evidence Lower Bound (ELBO):

$$\log p_\phi(\boldsymbol{y}|\boldsymbol{x}) \geq \log p(\boldsymbol{y}|\boldsymbol{x}) - \text{KL}(q_\theta(z|\boldsymbol{y}, \boldsymbol{x}) || p(z|\boldsymbol{y}, \boldsymbol{x}))$$

where KL denotes the Kullback-Leibler divergence. ELBO can be rewritten as a regularized auto-encoder function:

$$\mathcal{L} = \mathbb{E}_{q_\theta(z|\boldsymbol{y},\boldsymbol{x})}\left[p_\phi(\boldsymbol{y}|z, \boldsymbol{x})\right] - \text{KL}(q_\theta(z|\boldsymbol{y}, \boldsymbol{x}) || p_\phi(z|\boldsymbol{x}))$$

where $p_\phi(\boldsymbol{y}|z, \boldsymbol{x})$ is the decoder that decodes $\boldsymbol{y}$ from the latent variable z and conditional variable $\boldsymbol{x}$, $q_\theta(z|\boldsymbol{y}, \boldsymbol{x})$ is the inference model that approximates the true posterior, $p_\phi(z|\boldsymbol{x})$ is the prior model that samples the latent variable from the prior distribution, θ, ϕ are the parameters of the inference and decoder models, respectively. All parameterized distributions are modeled by neural networks.

In the training phase, the latent variable z is sampled from both the inference model and the prior model. z from the inference model is then used to condition the generated distribution $p(\boldsymbol{y}|z, \boldsymbol{x})$. Meanwhile, CVAE minimizes the KL divergence between the latent variables from these two models. This process makes it possible for CVAE to samples z from the prior model only when decoding in the testing phase.

Different from the previous work on CVAE-based response generation that only relys on a single latent variable (Serban et al., 2017; Zhao et al., 2017; Shen et al., 2017), our proposed model incorporates a series of latent variables into the autoregressive decoder. Inspired by the work on variational recurrent neural networks (Goyal et al., 2017; Bayer and Osendorfer, 2014), our model sequentially decodes the response sequence conditioned on the latent variable z_t at each time step by $p_\phi(\boldsymbol{y}|\boldsymbol{z}, \boldsymbol{x}) = \prod_t p(y_t|\boldsymbol{y}_{<t}, \boldsymbol{z}_t, \boldsymbol{x})$.

3.2 Variational Autoregressive Decoder

Traditional CVAE-based models only use a single standard normal distribution to model the latent variable z. They are usually difficult to model the multi-modal distribution of responses $p(\boldsymbol{y}|z, \boldsymbol{x})$. To overcome this limitation, we propose a Variational Autoregressive Decoder (VAD) that decomposes $\boldsymbol{z}$ into sequential variables z_t at each time step t during response generation. Owing to the autoregressive structure of VAD, the hidden state of backward RNN $\overleftarrow{h^d_t}$ is used to condition the latent variable z_t, which can be seen as a long-term guidance to the generation. Moreover, we propose a novel auxiliary objective, which is specially designed for VAD, to avoid *model collapse*.

At each time step, the decoder uses a forward GRU to process the sequence and predicts the next token by a feed-forward network f_{output} with the softmax activation function. The input to GRU is the combination of the previous word's embedding y_{t-1}, the context vector produced by an attention model c_t and the latent variable z_t. The process is described by,

$$\overrightarrow{h^d_t} = \overrightarrow{\mathrm{GRU}}([y_{t-1}, c_t, z_t], \overrightarrow{h^d_{t-1}}) \tag{3}$$

$$p_\phi(y_t|\boldsymbol{y}_{<t}, \boldsymbol{z}_t, \boldsymbol{x}) = f_{\text{output}}([\overrightarrow{h^d_t}, c_t]) \tag{4}$$

where, $\overrightarrow{h^d_t}$ is the hidden state produced by the forward GRU at time step t. c_t is the attentional weighted sum of the encoder's output.

Inference Model We use the hidden states of the backward RNN running through the response sequence as an additional input to the inference model. The backward RNN processes the sequence by,

$$\overleftarrow{h^d_t} = \overleftarrow{\mathrm{GRU}}(y_{t+1}, \overleftarrow{h^d_{t+1}}) \tag{5}$$

The backward hidden state $\overleftarrow{h^d_t}$ contains the information of succeeding tokens, and it serves as a future plan for generation. By combining the information produced by the backward RNN, the inference model has a better capability of approximating the real posterior distribution.

Considering context variable c_t at each time step as a substitute of the condition variable $\boldsymbol{x}$ in (3.1), c_t is also fed to the inference model. The inference model is a feed-forward neural network f_{infer}. The approximated distribution $q(z_t|\boldsymbol{y}, \boldsymbol{x})$ is a normal distribution $\mathcal{N}(\mu^i, \sigma^i)$, which is parameterized by the output of f_{infer}:

$$[\mu^i, \sigma^i] = f_{\text{infer}}([\overrightarrow{h^d_{t-1}}, c_t, \overleftarrow{h^d_t}]) \tag{6}$$

$$q_\theta(z_t|\boldsymbol{y}, \boldsymbol{x}) = \mathcal{N}(\mu^i, \sigma^i) \tag{7}$$

where the sampling process of z_t is done by reparameterization (Kingma and Welling, 2013).

Prior Model The prior network can only use the observable variables in the testing phase to sample z_t. The observable variables include the previous hidden state $\overrightarrow{h^d_{t-1}}$ and the context variable c_t. The prior model is also modeled by a feed-forward network f_{prior} as follows.

$$[\mu^p, \sigma^p] = f_{\text{prior}}([\overrightarrow{h^d_{t-1}}, c_t]) \tag{8}$$

$$p_\phi(z_t|\boldsymbol{y}_{<t}, \boldsymbol{x}) = \mathcal{N}(\mu^p, \sigma^p) \tag{9}$$

where μ^p, σ^p are the parameters of prior normal distribution.

Auxiliary Objective As discussed in Section 1, the decoder based on the autoregressive model often ignores the latent variables and causes the model to collapse. One way to alleviate this problem is to add an auxiliary loss to the training objective (Zhao et al., 2017; Goyal et al., 2017). To allow the latent variables to capture the information from a different perspective, we use ***Sequential Bag of Word (SBOW)*** as the auxiliary objective for the proposed VAD model. The idea of the ***SBOW*** auxiliary objective is to sequentially predict the bag of succeeding words $\boldsymbol{y}_{bow(t+1,T)}$ in the response using the latent variable z_t at each time step. This auxiliary objective can be seen as the prediction of candidate words for future generation.

Our ***SBOW*** is specially designed for VAD. It is different from the Bag-of-Words (BOW) auxiliary loss used in the CVAE-based models (Zhao et al., 2017), which only uses the latent variable to predict the Bag-Of-Words of the whole sequence. VAD with ***SBOW*** sequentially produces the auxiliary loss for each time step of generation. The auxiliary loss at each time step is computed by

$$p_\xi(\boldsymbol{y}_{bow(t+1,T)}|z_{t:T}) = f_{\text{auxiliary}}(z_t) \tag{10}$$

where $\boldsymbol{y}_{bow(t+1,T)}$ is the bag-of-word vector of the words from $t+1$ to T in the response, and $f_{\text{auxiliary}}$ is a feed-forward neural network with the softmax output.

3.3 Learning

The loss function of our model is the sum of the losses at each time step, including the weighed sum of the ELBO loss $\mathcal{L}_{ELBO}(t)$ and the auxiliary loss $\mathcal{L}_{AUX}(t)$ where $\mathcal{L}_{ELBO}(t)$ can be further decomposed into a log-likelihood loss and the KL divergence:

$$\begin{aligned}\mathcal{L} &= \sum_t [\mathcal{L}_{ELBO}(t) + \alpha\mathcal{L}_{AUX}(t)] \\ &= \sum_t [(\mathcal{L}_{LL}(t) - \mathcal{L}_{KL}(t)) + \alpha\mathcal{L}_{AUX}(t)]\end{aligned} \tag{11}$$

Here, $\mathcal{L}_{LL}(t)$ denotes the log-likelihood loss when predicting y_t. $\mathcal{L}_{KL}(t)$ is the KL-divergence of the approximate posteriori q_θ and priori p_ϕ at time step t. $\mathcal{L}_{AUX}(t)$ is the auxiliary loss when predicting ***SBOW*** as described in Section 3.2. α is the weight controlling the auxiliary loss. The losses are computed by

$$\begin{aligned}\mathcal{L}_{LL}(t) &= \mathbb{E}_{q_\theta(z_t|\boldsymbol{y},\boldsymbol{z})}[\log p_\theta(y_t|\boldsymbol{y}_{<t}, z_t, x_t)] \\ \mathcal{L}_{KL}(t) &= \mathrm{KL}(q_\theta(z_t|\boldsymbol{y},\boldsymbol{x})||p_\phi(z_t|\boldsymbol{y}_{<t},\boldsymbol{x})) \\ \mathcal{L}_{AUX}(t) &= \mathbb{E}_{q_\theta(z_t|\boldsymbol{y},\boldsymbol{z})}\left[\log p_\xi(\boldsymbol{y}_{bow(t+1,T)}|z_t)\right]\end{aligned}$$

All the parameters are learned by optimizing Equation (11) and updated with back-propagation.

4 Experimental Setup

4.1 Datasets

We evaluate the proposed model on two datasets: **OpenSubtitles** and **Reddit**. The OpenSubtitles dataset contains subtitles for movies in various languages. Here, we only choose the English version of OpenSubtiles. The Reddit dataset is crawled from comments of Reddit[1] which is an American social news discussion website. We collected more than 10 million single-turn dialogues from 100 topics posted in 2017. For each dataset, we randomly select 6 million conversations for training, 10k for validation and 5k for testing. For every conversation, we remove the sentences whose length is shorter than 6 words and only keep the first 40 words for sentences longer than 40. We keep top 15k frequent words as the vocabulary for OpenSubtitles and 20k frequent words for Reddit.

4.2 Hyper-parameters and Training Setup

We use the pre-trained GloVe 300-dimensional word embeddings for both the encoder and the decoder. The encoder is a bidirectional RNN with GRU with the size of the hidden state set to 512. The size of the hidden states of GRU in the decoder is also set to 512. We apply Layer Normalization when training the decoder. The size of the latent variables is set to 400. The inference network and the prior network are all one-layer feed-forward network. All weights are initialized by the xavier method (Glorot and Bengio, 2010). The model is trained end-to-end by Adam optimizer (Kingma and Ba, 2014) with the learning rate set to 10^{-4} and gradient clipped at 1. When generating text, we adopt the greedy strategy and the KL-annealing strategy, with the temperature varying from 0 to 1 and increased by 10^{-5} after each iteration of batch update.

4.3 Baselines

We compare our proposed model with the following three baselines:

- **Seq2Seq**: Sequence-to-Sequence model with attention (Sordoni et al., 2015).
- **CVAE**: Conditional Variational Auto-Encoder for generating responses (Serban et al., 2017). Different from our model, CVAE uses a unimodal Gaussian distribution to model the whole response and append the output of VAE as an additional input to decoder. We also use the KL annealing strategy when training CVAE with the same parameter setting as in our model.

---

[1] `http://www.reddit.com`

- **CVAE+*BOW* loss**: CVAE model with the auxiliary bag-of-words loss (Zhao et al., 2017).

4.4 Metrics

We employ three types of commonly used automatic evaluation metrics and human evaluation in our experiments:

Embedding Similarity: Embedding-based metrics compute the cosine similarity between the sentence embedding of a ground-truth response and that of the generated one. There are various ways to derive the sentence-level embedding from the constituent word embeddings. In our experiments, we apply three most commonly used strategies to obtain the sentence-level embeddings. $\mathbf{EMB_A}$ calculates the average of word embeddings in a sentence. $\mathbf{EMB_E}$ takes the most extreme value among all words for each dimension of word embeddings in a sentence. $\mathbf{EMB_G}$ greedily calculates the maximum of cosine similarity of each token in two sentences and take the average of them to get the final matching score (Liu et al., 2016).

RUBER Score: RUBER (Referenced metric and Unreferenced metric Blended Evaluation Routine) is a newly proposed metric for evaluating the quality of response in conversations that show high correlation with human annotation (Tao et al., 2017). RUBER evaluates the generated responses by taking into account both the ground-truth responses and the given queries. For the *referenced* metric, RUBER calculates the embedding-based cosine similarity between a generated response and its corresponding ground-truth. For the *unreferenced* metric, RUBER firstly trains a neural network by a response retrieval task and evaluates the relatedness between a generated response and its query. Evaluating RUBER score can be treated as a rough simulation to the well-known *Turing Test*. For blending the two metrics, there are two strategies: taking the geometric mean ($\mathbf{RUB_G}$) or the arithmetic mean ($\mathbf{RUB_A}$). The RUBER score ranges between 0 and 1 and higher scores imply better relatedness.

Diversity: Diversity metrics evaluate the informativeness and diversity of generated responses. In our experiments, we use $\mathbf{Dist_1}$ and $\mathbf{Dist_2}$ (Li et al., 2016a) to evaluate the diversity and **Entropy** to measure the informativeness. $\mathbf{Dist_1}$ (or $\mathbf{Dist_2}$) calculates the ratio of the number of unique unigrams (or bigrams) against the total number of unigrams (or bigrams). Higher $\mathbf{Dist_1}$ (or $\mathbf{Dist_2}$) implies more diverse vocabularies used in responses. **Entropy** as a metric proposed by (Serban et al., 2017) calculates the average entropy in a generated response. According to information theory, it is known that low-frequent words have higher entropy and carries more information. Therefore, we use this **Entropy** to measure the informativeness and diversity of the generated responses. The unit of **Entropy** is *bit* and Higher **Entropy** correlates to more informative response.

Human Evaluation: In human evaluation, 10 research students are arranged to rate the generated responses generated by CVAE with *BOW* auxiliary loss and our model. We randomly selected 100 queries from the Reddit dataset[2] and used each model to generate the best responses. Each query with its ground-truth response and the two generated responses are simultaneously shown to the human evaluators. The evaluators are asked to rate the responses based on grammatical correctness, coherence and relevance to queries (tie is permitted).

5 Results

5.1 Quantitative Analysis

The experimental results evaluated by automatic metrics on the OpenSubtitles and the Reddit datasets are shown in Table 1 and 2, respectively. It is observed that both CVAE-based models and our proposed models outperform Seq2Seq by a large margin, showing the effectiveness of adding variational latent variable for response generation. However, using different structure of variational models leads to differences in performance on both plausibility and diversity. Our model with or without the SBOW auxiliary loss outperforms CVAE as observed by the significant boost in semantic relevance-oriented metrics (embedding similarities and RUBER score) and diversity-oriented metrics. This is mainly due to the different strategy employed for representing latent variables. CVAE only uses a unimodal latent variable as the semantic signal of the whole response sequence which limits its capability of capturing

---

[2] The reason of not conducting the human evaluation on the OpenSubtitles dataset is that query-response pairs in the OpenSubtitles dataset are extracted from movie scripts and hence are more difficult to evaluate without the context information.

variability of response sequences. By incorporating a series of time-varying latent variables into each step of autoregressive decoder, our model is able to model more complicated multimodal distributions of response sequences and capture more detailed semantic information.

Since adding the auxiliary loss could alleviate the *model collapse* problem, we found that CVAE model with the *BOW* auxiliary loss outperforms our basic model without auxiliary loss, especially on the diversity metrics. When adding the proposed *SBOW* auxiliary loss into our model, we found that our generated responses have shown better diversity compared to those generated by CVAE+*BOW* loss. The encouraging improvement is attributed to the autoregressive structure of our variational inferences, which makes it possible to gradually introduce additional information of *SBOW*. To better demonstrate the impact of *SBOW*, we calculate the average length of the generated responses of our model and CVAE with *BOW* loss and show the results in Table 3. It is observed that our model with *SBOW* can generate longer responses than CVAE+*BOW*. The results validate the effectiveness of adding the *SBOW* auxiliary objective into our model.

The evaluation results of human judgment is shown in Table 4. It is observed that the responses generated by our proposed VAD is more plausible than CVAE+*BOW* from human perspectives. We also conduct t-test to compare our model with CVAE+*BOW*. The results show that the improvement of VAD over CVAE+*BOW* is statistically significant ($p < 0.01$).

5.2 Qualitative Analysis

Case Study To empirically analyze the quality of the generated responses, we show some example responses generated by our model and two baselines (Seq2Seq and CVAE+*BOW*) in Table 5. It is observed that Seq2seq often generates generic responses that starting with '*I don't know*' or '*I am not sure*', since the deterministic structure of Seq2seq limits the diversity of generation. Injecting variational latent variables avoids dull responses as can be seen from the responses gen-

Dataset	Query	Seq2seq	CVAE+*BOW*	Ours
OpenSub	why he is not here ?	i do n't know where	he 's not present .	maybe he 's been caught in the rain too .
	that wasn ' t easy for him .	i ' m not so sure i know.	did he do good job and good job ?	it 's a tough job but it 's a great deal of money .

Reddit	he looks exactly like my australian uncle .	he is NUM NUM	lol , you know him , he is my uncle .	nope , he 's a young man and was born in LOC .
	why no windows ?	i ' m not so sure you 're right .	do you like windows NUM ?	cuz linux can be a great os .
	i hope the grand tour will make an episode .	i ca n't commit post though .	i 'm wondering getting it .	i would hope that it will be on netflix as well .

Table 5: Example responses generated by our model and two baselines (Seq2Seq and CVAE+*BOW*) from the OpenSubtitles and the Reddit Datasets.

erated by CVAE+*BOW* and our model. However, we found that CVAE+*BOW* tends to copy the given queries (the first and fourth example in Table 4) and repeatedly generate redundant tokens (the second example). The generated responses of our model are more fluent and relevant to queries. Also, our model generates longer responses compared to the baselines.

KL Divergence Visualization In order to demonstrate that our model is able to alleviate the ***model collapse*** problem of VAE, we visualize the KL divergence between the approximate posterior distribution $q_\theta(\boldsymbol{z}|\boldsymbol{y}, \boldsymbol{x})$ and priori $p_\phi(\boldsymbol{z}|\boldsymbol{x})$ during the training process of our models and CVAE with *BOW* loss in Figure 3. As we know, when variational models ignore the latent variable, the generated value $\boldsymbol{y}$ will be independent of the latent variable $\boldsymbol{z}$ which causes the KL divergence in Equation (3.1) to approach 0. The higher KL value during training means more dependence between $\boldsymbol{y}$ and $\boldsymbol{z}$. In this experiment, we use the same KL annealing strategies for our model and CVAE+*BOW* as described in Section 4.2. The KL divergence of the two models on the OpenSubtitles and the Reddit datasets during training is plotted in Figure 3. It is observed that the KL divergence of our model converges to a higher value compared to that of CVAE+*BOW*. It shows that our model could better alleviate the *model collapse* problem.

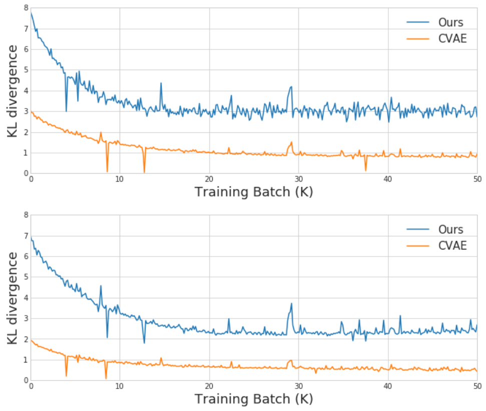

Figure 3: KL divergence during training.

6 Conclusion

In this paper, a novel variational autoregressive decoder is proposed to improve the performance of VAE-based models for open-domain response generation. By injecting the variational inference into the RNN-based decoder and applying carefully designed conditional variables and auxiliary objective for latent variables, the proposed model is expected to better modeling semantic information of text in conversations. Quantitative and qualitative experimental results show clear performance improvement of the proposed model over competitive baselines. In future works, we will explore the use of other attributes of responses such as Part-of-Speech (POS) tags and chunking sequences as additional conditions for better response generation.

Abstract

Sentence simplification aims to reduce the complexity of a sentence while retaining its original meaning. Current models for sentence simplification adopted ideas from machine translation studies and implicitly learned simplification mapping rules from normal-simple sentence pairs. In this paper, we explore a novel model based on a multi-layer and multi-head attention architecture and we propose two innovative approaches to integrate the Simple PPDB (A Paraphrase Database for Simplification), an external paraphrase knowledge base for simplification that covers a wide range of real-world simplification rules. The experiments show that the integration provides two major benefits: (1) the integrated model outperforms multiple state-of-the-art baseline models for sentence simplification in the literature (2) through analysis of the rule utilization, the model seeks to select more accurate simplification rules. The code and models used in the paper are available at https://github.com/Sanqiang/text_simplification.

1 Introduction

Sentence simplification aims to reduce the complexity of a sentence while retaining its original meaning. It can benefit individuals with low-literacy skills (Watanabe et al., 2009) including children, non-native speakers and individuals with language impairments such as dyslexia (Rello et al., 2013), aphasic (Carroll et al., 1999).

Most of the previous studies tackled this task in a way similar to machine translation (Xu et al., 2015a; Zhang and Lapata, 2017), in which models are trained on a large number of pairs of sentences, each consisting of a normal sentence and a simplified sentence. Statistical and neural network modeling are two major methods used for this task. The statistical models have the benefit of easily integrating with human-curated rules and features, thus they generally perform well even they are trained with a limited number of data. In contrast, neural network models could learn the simplifying rules automatically without the need for feature engineering, but at the cost of requiring a huge amount of training data. Even though models based on neural networks have outperformed the statistical methods in multiple Natural Language Processing (NLP) tasks, their performance in sentence simplification is still inferior to that of statistical models (Xu et al., 2015a; Zhang and Lapata, 2017). We speculate that current training datasets may not be large and broad enough to cover common simplification situations. However, human-created resources do exist which can provide abundant knowledge for simplification. This motivates us to investigate if it is possible to train neural network models with these types of resources.

Another limitation to using existing neural network models for sentence simplification is that they are only able to capture frequent transformations; they have difficulty in learning rules that are not frequently observed despite their significance. This may be due to nature of neural networks (Feng et al., 2017): during training, a neural network tunes its parameters to learn how to simplify different aspects of the sentence, which means that all the simplification rules are actually contained in the shared parameters. Therefore, if one simplification rule appears more frequently than others, the model will be trained to be more focused on it than the infrequent ones. Meanwhile, models tend to treat infrequent rules as noise if they are merely trained using sentence pairs. If we can leverage an additional memory component to maintain simplification rules individually, it would prevent the model from forgetting low-frequency rules as well as help it to distinguish real rules from noise. Therefore, we propose the Deep Memory Augmented Sentence Simplification (DMASS) model. For comparison pur-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3164–3173
Brussels, Belgium, October 31 - November 4, 2018.

pose, we also introduce another approach, Deep Critic Sentence Simplification (DCSS) model, to encourage applying the less frequently occurring rules by revising the loss function. It this way, simplification rules are encouraged to maintained internally in the shared parameters while avoiding the consumption of an unwieldy amount of additional memory.

In this study, we propose two improvements to the neural network models for sentence simplification. For the first improvement, we propose to use a multi-layer, multi-head attention architecture (Vaswani et al., 2017). Compared to RNN/LSTM (Recurrent Neural Network / Long Short-term Memory), the multi-layer, multi-head attention model would be able to selectively choose the correct words in the normal sentence and simplify them more accurately.

Secondly, we propose two new approaches to integrate neural networks with human-curated simplification rules. Note that previous studies rarely tried to incorporate explicit human language knowledge into the encoder-decoder model. Our first approach, DMASS, maintains additional memory to recognize the context and output of each simplification rules. Our second approach, DCSS, follows a more traditional approach to encode the context and output of each simplification rules into the shared parameters.

Our empirical study demonstrates that our model outperforms all the previous sentence simplification models. They achieve both a good coverage of rules to be applied (recall) and a high accuracy gained by applying the correct rules (precision).

2 Related Work

Sentence Simplification For statistical modeling, Zhu et al. (2010) proposed a tree-based sentence simplification model drawing inspiration from statistical machine translation. Woodsend and Lapata (2011) employed quasi-synchronous grammar and integer programming to score the simplification rules. Wubben et al. (2012) proposed a two-stage model PBMT-R, where a standard phrase-based machine translation (PBMT) model was trained on normal-simple aligned sentence pairs, and several best generations from PBMT were re-ranked based how dissimilar they were to a normal sentence. Hybrid, a model proposed by Narayan and Gardent (2014) was also a two-stage model combining a deep semantic analysis and machine translation framework. SBMT-SARI (Xu et al., 2016) achieved state-of-the-art performance by employing an external knowledge base to promote simplification. In terms of neural network models, Zhang and Lapata (2017) argued that the RNN/LSTM model generated sentences but it does not have the capability to simplify them. They proposed DRESS and DRESS-LS that employ reinforcement learning to reward simpler outputs. As they indicated, the performance is still inferior due to the lack of external knowledge. Our proposed model is designed to address the deficiency of current neural network models which are not able to integrate an external knowledge base.

Augmented Dynamic Memory Despite positive results obtained so far, a particular problem with the neural network approach is that it has a tendency towards favoring to frequent observations but overlooking special cases that are not frequently observed. This weakness with regard to infrequent cases has been noticed by a number of researchers who propose an augmented dynamic memory for multiple applications, such as language models (Daniluk et al., 2017; Grave et al., 2016), question answering (Miller et al., 2016), and machine translation (Feng et al., 2017; Tu et al., 2017). We find that current sentence simplification models suffer from a similar neglect of infrequent simplification rules, which inspires us to explore augmented dynamic memory.

3 Our Sentence Simplification Models

3.1 Multi-Layer, Multi-Head Attention

Our basic neural network-based sentence simplification model utilizes a multi-layer and multi-head attention architecture (Vaswani et al., 2017). As shown in Figure 1, our model based on the Transformer architecture works as follows: given a pair consisting a normal sentence I and a simple sentence O, the model learns the mapping from I to O.

The encoder part of the model (see the left part of Figure 1) encodes the normal sentence with a stack of L identical layers. Each layer has two sublayers: one layer is for multi-head self-attention and the other one is a fully connected feed-forward neural network for transformation. The multi-head self-attention layer encodes the output from the

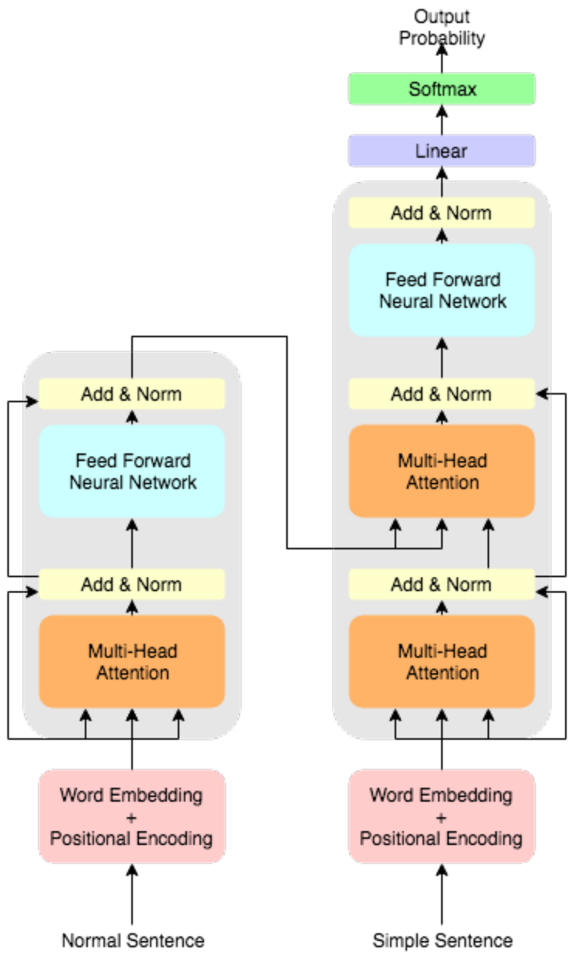

Figure 1: Diagram of the Transformer architecture

previous layer into hidden state $e_{(s,l)}$ (step s and layer l) as shown in Equation 1, where $\alpha^{enc}_{(s',l)}$ indicates the attention distribution over the step s' and layer l. Each hidden state summarizes the hidden states in the previous layer through the multi-head attention function $a()$ (Vaswani et al., 2017) where H refers to the number of heads.

The right part of Figure 1 denotes the decoder for generating the simplified sentence. The decoder also consists of a stack of L identical layers. In addition to the same two sub-layers as those in the encoder part, the decoder also inserts another multi-head attention layer aiming to attend on the encoder outputs. The bottom multi-head self-attention plays the same role as the one in the encoder, where the hidden state $d_{(s,l)}$ is computed in the Equation 2. The upper multi-head attention layer is used to seek relevant information from encoder outputs. Through the same mechanism, context vector $c_{(s,l)}$ (step s and layer l) is computed in the Equation 3.

$$e_{(s,l)} = \sum_{s'} \alpha^{enc}_{(s',l)} e_{(s',l-1)}, \quad \alpha^{enc}_{(s',l)} = a(e_{(s,l)}, e_{(s',l-1)}, H) \tag{1}$$
[1]

$$d_{(s,l)} = \sum_{s_\prime} \alpha^{dec}_{(s_\prime,l)} d_{(s_\prime,l-1)}, \quad \alpha^{dec}_{(s_\prime,l)} = a(d_{(s,l)}, c_{(s_\prime,l-1)}, H) \tag{2}$$
[2]

$$c_{(s,l)} = \sum_{s_\prime} \alpha^{dec2}_{(s_\prime,l)} e_{(s_\prime,L)}, \quad \alpha^{dec2}_{(s_\prime,l)} = a(d_{(s,l)}, e_{(s_\prime,L)}, H) \tag{3}$$

The model is trained to minimize the negative log-likelihood of the simple sentence, $L_{seq} = -logP(O|I,\theta)$ where θ represents all the parameters in the current model.

3.2 Integrating with Simple PPDB

A previous study (Xu et al., 2016) has demonstrated the benefits of using an external knowledge base in conjunction with a statistical simplification model. However, as far as we know, no efforts have been made to integrate neural network models with the knowledge base, and our study is the first to meet this goal.

Weight	Type	Rule
0.99623	[VP]	recipient → have receive
0.75530	[NN]	recipient → winner
0.58694	[NN]	recipient → receiver
0.46935	[NN]	recipient → host

Table 1: Examples from the Simple PPDB

Simple PPDB (Pavlick and Callison-Burch, 2016) refers to a paraphrase knowledge base for simplification. It is a refined version of another knowledge, PPDB (Ganitkevitch et al., 2013), which was originally designed to support paraphrase. Simple PPDB contains 4.5 million paraphrase rules, each of which provides the mapping from a normal phrase to a simplified phrase, the syntactic type of the normal phrase, and the simplification weight. Table 1 shows four examples, where "recipient" can be simplified to "winner" with a weight 0.75530 if "recipient" is a singular noun (NN).

3.2.1 Deep Critic Sentence Simplification Model (DCSS)

The Simple PPDB offers guidance about whether a word needs to be simplified and how it should

---

[1] The lowest hidden state $e_{(:,0)}$ is the word embedding.

[2] The lowest context vector $c_{(:,0)}$ is the word embedding.

be simplified. The Deep Critic Sentence Simplification (DCSS) model is designed to apply rules identified by the Simple PPDB by introducing a new loss function. Different from the standard loss function that minimizes the distance away from the ground truth, the new loss function aims to maximize the likelihood of applying simplification rules. It also reweights the probability of generating each word by its simplification weight in order to relieve the problem of overlooking infrequent simplification rules.

For example, given a normal sentence in the training set, "the recipient of the kate greenaway medal", the simplified sentence is "the winner of the kate greenaway medal.", where "recipient" is simplified to "winner", which is identified by Simple PPDB. The major goal of the loss functions is to support the model in generating the simplified word "winner" while deterring the model from generating the word "recipient". Specifically, for an applicable simplification rule, our new loss function maximizes the probability of generating the simplified form (word "winner") and meanwhile minimizes the probability of generating the original form (word "recipient"). As in Equation 4, where w_{rule} indicates the weight of the simplification rule provided by the Simple PPDB, once the model generates "recipient", the model is criticized to generate word "winner"; when model predicts correctly with "winner", the model is trained to minimize the probability of "recipient". In this way, the model avoids selecting normal words and instead becomes inclined to choose the simplified words.

$$L_{critic} = \begin{cases} -w_{rule} logP(winner|I, \theta) \\ \qquad\qquad \text{if model generates recipient} \\ w_{rule} logP(recipient|I, \theta) \\ \qquad\qquad \text{if model generates winner} \end{cases} \tag{4}$$

The L_{critic} merely focuses on the words identified by the Simple PPDB and L_{seq} focuses on the entire vocabulary. So, the model is trained in an end-to-end fashion by minimizing L_{seq} and L_{critic} alternately.

3.2.2 Deep Memory Augmented Sentence Simplification Model (DMASS)

DCSS, similar to the majority of neural network models, uses a piece of shared memory, i.e. the parameters, as the media to store the learned rules from the data. As a result, it still focuses much more on rules that are frequently observed and ignores the rules observed infrequently. However, infrequent rules are still important, particularly when the training data is limited.

In order to make full use of the rules in the knowledge base, we introduce the Deep Memory Augmented Sentence Simplification (DMASS) model. DMASS has an augmented dynamic memory to record multiple key-value pairs for each rule in the Simple PPDB. The key vector stores a context vector that is computed based on the weighted average of encoder hidden states and the current decoder hidden states. The value vector stores the output vector.

Our DMASS model is illustrated in Figure 2. Given the same example normal sentence " the recipient of kate greenaway medal", Simple PPDB determines that the word "recipient" should be simplified to "winner". The encoder represents the normal sentence as a list of hidden states, [$e_{(1,L)}$, $e_{(2,L)}$, ...] where L indicates the final layer of encoder hidden states. When predicting the next word in the simplified sentence, the decoder of layer j represents the previous words as hidden states [$d_{(1,j)}$, ...]. $c_{(1,j)}$ refers to the current context vector following attention layer, which is the weighted average of [$e_{(1,L)}$, $e_{(2,L)}$, ...] based on $d_{(1,j)}$. A feed-forward fully connected neural network (FFN) combines the output of the decoder and the output from memory read module into the final output r_{winner}. In addition to the word prediction, $c_{(1,j)}$ and r_{winner} will be sent to memory update module.

In the remainder of this section, we will introduce the two modules of DMASS mentioned above: Memory Read Module and Memory Update Module.

Memory Read Module The memory read module incorporates rules into prediction. As shown in Figure 2, current augmented memory contains three candidate rules for the word "recipient", which indicates that it can be simplified into "winner", "receiver" or "host", respectively. The current context vector $c_{(1,j)}$ is treated as a query to search for suitable rules by using Equation 5, where α_i^r denotes the weight for i^{th} rule, which is computed through the dot product between current context vector $c_{(1,j)}$ and c_i. Then using Equation 6, α_i^r weights each output vector to generate mem-

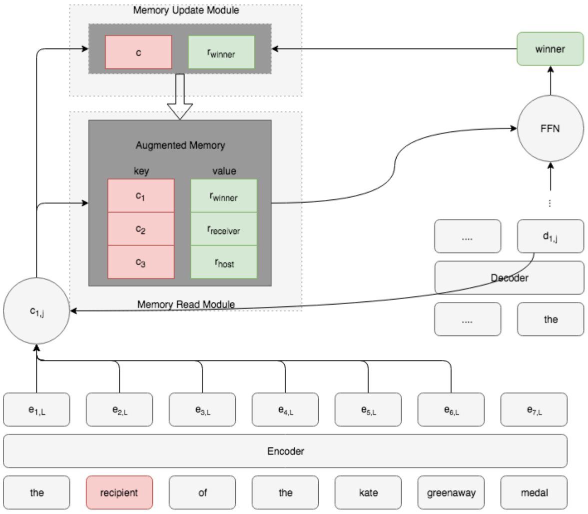

Figure 2: Diagram of DMASS Model

ory read output.

$$\alpha_i^r = \frac{e_i}{\sum_j e_j} \qquad e_i = exp(c_{(1,j)} \cdot c_i) \tag{5}$$

$$r_o = \sum \alpha_i^r r_r \qquad r_r \in [r_{winner}, r_{receiver}, r_{host}] \tag{6}$$

Memory Update Module The task of the memory update module is to update the key and value vectors in the augmented memory. Once the model predicts the output vector r_{winner}, both r_{winner} and the current context vector $c_{1,j}$ are sent to the memory update module. If the augmented memory does not contain the key-value pair for the rule, $c_{1,j}$ and r_{winner} are appended to the memory. If the augmented memory contains the key-value pair, the key vector is updated as the mean of current key vector and $c_{1,j}$. Similarly, the value vector is also updated as the mean of current value vector and r_{winner}.

4 Experiments

Dataset We utilize the dataset *WikiLarge* (Zhang and Lapata, 2017) for training. It is the largest Wikipedia corpus, constructed by merging previously created simplification corpora. Specifically, the training dataset contains 296,402 normal-simple sentence pairs gathered from (Zhu et al., 2010; Woodsend and Lapata, 2011; Kauchak, 2013). For validation and testing, we use the dataset *Turk* created by (Xu et al., 2016). In this dataset, eight simplified reference sentences for each normal sentence are used as the ground-truth, all of which are generated by Amazon Mechanical Turk workers. The *Turk* dataset contains 2,000 data samples for validation and 356 samples for testing. We consider the *Turk* to be the most reliable data set because (1) it is human-generated and (2) it contains multiple simplification references for each normal sentence due to the existence of multiple equally good simplifications of each sentence. We also include the second test set *Newsela*, a corpus introduced by (Xu et al., 2015b) who argue that only using normal-simple sentence pairs from Wikipedia is suboptimal due to the automatic sentence alignment which unavoidably introduces errors, and the uniform writing style which leads to systems that generalize poorly. The test set contains 1,419 normal-simple sentence pairs[3]. To demonstrate that our models are able to perform well on a different style of corpus, we report the results of *Newsela* test set by using the models trained/tuned on *Turk* dataset. Following Zhang and Lapata (2017)'s way, we tag and anonymize name entities with a special token in the format of **NE@N**, where NE includes $\{PER, LOC, ORG\}$ and N indicates the N^{th} distinct NE type of entity. We also replace those tokens occurring three times or less in the training set with a mark "UNK" as mentioned in (Zhang and Lapata, 2017).

Evaluation Metrics We report the results of the experiment with two metrics that are widely used in the literature: SARI (Xu et al., 2016) and FKGL (Kincaid et al., 1975). FKGL computes the sentence length and word length as a way to measure the simplicity of a sentence. The lower value of FKGL indicates simpler sentence. FKGL measures the simplicity of a sentence without considering the ground truth simplification references and it correlates little with human judgment (Xu et al., 2016), so we also use another metric, SARI. SARI, which stands for "System output Against References and against the normal sentence", computes the arithmetic mean of N-grams (N includes 1,2,3 and 4) F1-score of three rewrite operations: addition, deletion, and keeping. Specifically, it rewards addition operations where a word in the generated simplified sentence does not appear in the normal sentence but is mentioned in the reference sentences. It also rewards words kept or deleted in both the simplified sentence and the reference sentences. In our experiment, we also present the F1-score of three rewrite

---

[3] Because the earlier publications don't provide preprocess details, we use our own script to pre-process the articles into sentence pairs.

operations: addition, deletion, and keeping. Xu et al. (2016) demonstrated that SARI correlates most closely to human judgments in sentence simplification tasks. Thus, we treated SARI as the most important measurement in our study.

Because SARI rewards deleting and adding separately, we also include another metric to measure the correctness of lexical transformation, namely word simplification, verified by Simple PPDB. By comparing the normal sentence and ground truth simplified references, we collect rules that are correct to be used for simplifying each normal sentence. Then we calculate the precision, recall, and F1 score for using the correct rules. As a result, the recall expresses the coverage of rules to be applied, and the precision implies the accuracy gained by applying the correct rules.

Training Details We initialized the encoder and decoder word embedding lookup matrices with 300-dimensional Glove vectors(Pennington et al., 2014). The word embedding dimensionality and the number of hidden units are set to 300. During the training, we regularize all layers with a dropout rate of 0.2 (Srivastava et al., 2014). For multi-layer and multi-head architecture, 4 encoder and decoder layers (set L as 4) and 5 multi-attention heads (set H as 5) are used. We will discuss the trade-off between different layers and different heads in Sections 4.1. For DMASS, we use the context vector based on the first layer of the decoder (set j as 1). For optimization, we use Adagrad (Duchi et al., 2011) with the learning rate set to 0.1. The gradient is truncated by 4 (Pascanu et al., 2013).

4.1 Impacts of Multi-Layer, Multi-Head Attention Architecture

The reason to employ the Transformer architecture in the sentence simplification task is that we believe that its multi-layer, multi-head attention provides a better capability of modeling both the overall context and the important cues for sentence simplification. In this section, we examine the applicability of multi-layer, multi-head attention architecture to the sentence simplification task. We compare our results against the RNN/LSTM-based sentence simplification models. Note that the results of our models presented here have not been integrated with the Simple PPDB.

Table 2 shows the experiment results where LxHy indicates a run with Transformer using x layers and y heads. When compared with results of RNN/LSTM, our Transformer-based model performed better in terms of SARI and FKGL values. In addition, with the increased number of layers or heads, the values of SARI and FKGL improve accordingly. In the remainder of this section, we analyze the insights of these results in detail.

In our tasks, FKGL measures the sentence length and the word length as two factors for evaluating a simplified sentence. Therefore, we include *Wlen(Word Length)* and *Slen(Sentence Length)* into our analysis. As shown in Table 2, models with higher numbers of layers and/or heads do generally reduce the average word length and the average sentence length, which indicates that the higher number of layers and/or heads in the model leads to simpler outcomes.

It has been found that SARI correlates most closely to human judgment (Xu et al., 2016). To further analyze the effects of SARI, we study the impacts of three rewrite operations in SARI: add, delete, and keep. As shown in Table 2, we find that the improvement mostly results from correctly adding simplified words and deleting normal words, but not from keeping words. By analyzing the outputs, the increased number of layers or heads results in better capability to simplify the words. Specifically, models with the greater number of layers or heads tend to remove the normal words and add simplified words. However, they may introduce inaccurate simplified words, thereby driving down the F1 score for keeping words. We believe the Simple PPDB, which offers guidance about whether words need to be simplified and how they should be simplified, provides an ideal method to alleviate this issue.

4.2 Impacts of Integrating the Simple PPDB

In order to make comprehensive comparisons with the state-of-the-art models, we include multiple baselines from the literature, including PBMT-R (Wubben et al., 2012), Hybrid (Narayan and Gardent, 2014), and SBMT-SARI (Xu et al., 2016). We also include several strong baselines based on neural networks such as RNN/LSTM, DRESS, DRESS-LS (Zhang and Lapata, 2017) as shown in Tables 3 and 4 We developed three models for this experiment. They are DMASS, DCSS, and DMASS+DCSS, where DMASS+DCSS indicates the combination of DMASS and DCSS. The

Table 4: Performance of baselines and proposed models on the Newsela dataset.

subscript *beam* indicates the size of beam search.

Results with FKGL Metric As shown in Tables 3 and 4, Hybrid achieves the lowest (thus the best) FKGL score, and DRESS and DRESS-LS have the second best FKGL scores. All the other models including ours do not perform as well as these two. But FKGL measures the simplicity of a sentence without considering the ground truth simplification references, so high FKGL may be at the cost of losing information and readability.

To further analyze the FKGL results, we examine the average sentence length and word length of the outcomes of the models and they are listed as WLen (Word Length) and SLen (Sentence Length) in Tables 3 and 4. Hybrid, DRESS, and DRESS-LS are good at generating shorter sentences, but they are not as good at choosing shorter words. In contrast, SBMT-SARI, DCSS, and DMASS all generate shorter words. Therefore, we believe that, by optimizing language model as a goal for the reinforcement learning, DRESS and DRESS-LS are tuned to simplify sentences by shortening the sentence lengths. In contrast, with the help of an integrated external knowledge base, SBMT-SARI and our models have more capability to generate shorter words in order to simplify sentences. Therefore, these two sets of models complete sentence simplification tasks via different routes, and perhaps there should be an exploration of combining these two routes for even more successful sentence simplification.

Another interesting finding is that the larger beam search size increases average word length slightly. This is because the larger beam search size mitigates the issue of the inaccurate simplification so that fewer words are simplified. To measure the correctness of simplification, we analyze the SARI metric and Rule Utilization.

Results with SARI Metric SARI is the most reliable metric for the sentence simplification task (Xu et al., 2016), therefore we would like to present more detailed discussion regarding the SARI results. As shown in Tables 3 and 4, DMASS+DCSS achieves the best SARI score, which demonstrates the effectiveness of integrating the knowledge base Simple PPDB for sentence simplification.

To further examine the impacts of the F1 scores for three operations in calculating the SARI scores, as shown in Tables 3 and 4, DMASS+DCSS, as well as other models with high SARI performance benefit greatly by correctly adding and deleting words. We believe these benefits mostly result from the integration with the knowledge base, which provides reliable guidance about which words to modify. SBMT-SARI, which represents a previous state-of-the-art model that also integrates with knowledge bases, performs best in correctly adding new words but performs inferiorly in deleting/keeping words. By analyzing the outputs, SBMT-SARI acts aggressively to simplify as many words as possible. But it also results in incorrect simplification. DRESS and DRESS-LS are inclined to generate the shorter sentence, which leads to high F1 scores for deleting words, but it lags behind other models in adding/keeping words.

DMASS leverages an additional memory component to maintain the simplification rules; DCSS uses internal memory to store those rules. A large number of simplification rules might confuse the model with limited internal memory. This might be the reason why DMASS works better than DCSS. By taking a two-way advantage of both models, DMASS+DCSS takes a two-fisted approach to store the simplification rules in both additional and internal memory. As a result, DMASS+DCSS achieves the best performance in SARI.

Results with Rule Utilization In this section, we evaluate the models' capabilities for word transformation. The majority of previous approaches, except for the SBMT-SARI, perform poorly in recall. We believe the knowledge base Simple PPDB will reduce uncertainty in the word selection.

As before, SBMT-SARI acts aggressively to simplify every word in the sentence. Such an aggressive action leads to relatively high performance in recall. However, it does not achieve a strong performance in precision. DMASS performs better in terms of rule utilization as compared to DCSS by leveraging an additional memory. DMASS+DCSS takes advantage of both approaches that store the simplification rules in additional and internal memory. This combined model is guaranteed to apply more accurate rules.

As compared to the loose relationship between SARI and beam search size, we find that that beam search size correlates strongly with the performance in rule utilization. Thus, we believe larger beam search size contributes to good coverage of rules to be applied as well as accuracy in applying rules.

5 Conclusion

In this paper, we propose two innovative approaches for sentence simplification based on neural networks. Both approaches are based on multi-layer and multi-head attention architecture and integrated with the Simple PPDB, an external sentence simplification knowledge base, in different ways. By conducting a set of experiments, we demonstrate that the proposed models perform better than existing methods and achieve new state-of-the-art in sentence simplification. Our experiments firstly prove that the multi-layer and multi-head attention architecture has an excellent capability to understand the text by accurately selecting specific words in a normal sentence and then choosing right simplified words. Secondly, by integrating with the knowledge base, our models outperform multiple state-of-the-art baselines for sentence simplification. Compared to previous models which integrated with the knowledge base, our models, especially, DMASS+DCSS, provide both good coverage of rules to be applied and accuracy in applying the correct rules. In future, we would like to investigate deeper into the different effects of additional memory and internal memory.

Learning Neural Templates for Text Generation

Sam Wiseman **Stuart M. Shieber** **Alexander M. Rush**

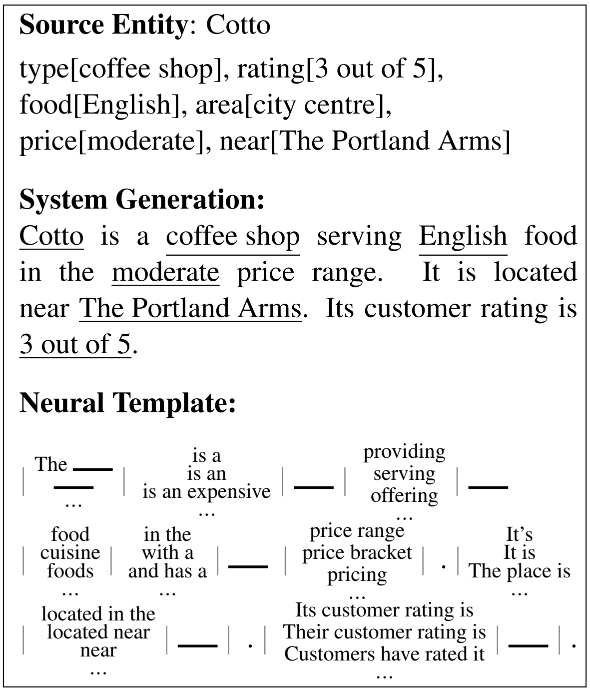
Abstract

While neural, encoder-decoder models have had significant empirical success in text generation, there remain several unaddressed problems with this style of generation. Encoder-decoder models are largely (a) uninterpretable, and (b) difficult to control in terms of their phrasing or content. This work proposes a neural generation system using a hidden semi-markov model (HSMM) decoder, which learns latent, discrete templates jointly with learning to generate. We show that this model learns useful templates, and that these templates make generation both more interpretable and controllable. Furthermore, we show that this approach scales to real data sets and achieves strong performance nearing that of encoder-decoder text generation models.

1 Introduction

With the continued success of encoder-decoder models for machine translation and related tasks, there has been great interest in extending these methods to build general-purpose, data-driven natural language generation (NLG) systems (Mei et al., 2016; Dušek and Jurcıcek, 2016; Lebret et al., 2016; Chisholm et al., 2017; Wiseman et al., 2017). These encoder-decoder models (Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2015) use a neural encoder model to represent a source knowledge base, and a decoder model to emit a textual description word-by-word, conditioned on the source encoding. This style of generation contrasts with the more traditional division of labor in NLG, which famously emphasizes addressing the two questions of "what to say" and "how to say it" separately, and which leads to systems with explicit content selection, macro- and micro-planning, and surface realization components (Reiter and Dale, 1997; Jurafsky and Martin, 2014).



Source Entity: Cotto

type[coffee shop], rating[3 out of 5], food[English], area[city centre], price[moderate], near[The Portland Arms]

System Generation:

Cotto is a coffee shop serving English food in the moderate price range. It is located near The Portland Arms. Its customer rating is 3 out of 5.

Neural Template:

Figure 1: An example template-like generation from the E2E Generation dataset (Novikova et al., 2017). Knowledge base x (top) contains 6 records, and $\hat{y}$ (middle) is a system generation; records are shown as `type[value]`. An induced neural template (bottom) is learned by the system and employed in generating $\hat{y}$. Each cell represents a segment in the learned segmentation, and "blanks" show where slots are filled through copy attention during generation.

Encoder-decoder generation systems appear to have increased the fluency of NLG outputs, while reducing the manual effort required. However, due to the black-box nature of generic encoder-decoder models, these systems have also largely sacrificed two important desiderata that are often found in more traditional systems, namely (a) interpretable outputs that (b) can be easily controlled in terms of form and content.

This work considers building interpretable and controllable neural generation systems, and proposes a specific first step: a new data-driven generation model for learning discrete, *template-like*

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3174–3187
Brussels, Belgium, October 31 - November 4, 2018.

structures for conditional text generation. The core system uses a novel, neural hidden semi-markov model (HSMM) decoder, which provides a principled approach to template-like text generation. We further describe efficient methods for training this model in an entirely data-driven way by backpropagation through inference. Generating with the template-like structures induced by the neural HSMM allows for the explicit representation of what the system intends to say (in the form of a learned template) and how it is attempting to say it (in the form of an instantiated template).

We show that we can achieve performance competitive with other neural NLG approaches, while making progress satisfying the above two desiderata. Concretely, our experiments indicate that we can induce explicit templates (as shown in Figure 1) while achieving competitive automatic scores, and that we can control and interpret our generations by manipulating these templates. Finally, while our experiments focus on the data-to-text regime, we believe the proposed methodology represents a compelling approach to learning discrete, latent-variable representations of conditional text.

2 Related Work

A core task of NLG is to generate textual descriptions of knowledge base records. A common approach is to use hand-engineered templates (Kukich, 1983; McKeown, 1992; McRoy et al., 2000), but there has also been interest in creating templates in an automated manner. For instance, many authors induce templates by clustering sentences and then abstracting templated fields with hand-engineered rules (Angeli et al., 2010; Kondadadi et al., 2013; Howald et al., 2013), or with a pipeline of other automatic approaches (Wang and Cardie, 2013).

There has also been work in incorporating probabilistic notions of templates into generation models (Liang et al., 2009; Konstas and Lapata, 2013), which is similar to our approach. However, these approaches have always been conjoined with discriminative classifiers or rerankers in order to actually accomplish the generation (Angeli et al., 2010; Konstas and Lapata, 2013). In addition, these models explicitly model knowledge base field selection, whereas the model we present is fundamentally an end-to-end model over generation segments.

Recently, a new paradigm has emerged around neural text generation systems based on machine translation (Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2015). Most of this work has used unconstrained black-box encoder-decoder approaches. There has been some work on discrete variables in this context, including extracting representations (Shen et al., 2018), incorporating discrete latent variables in text modeling (Yang et al., 2018), and using non-HSMM segmental models for machine translation or summarization (Yu et al., 2016; Wang et al., 2017; Huang et al., 2018). Dai et al. (2017) develop an approximate inference scheme for a neural HSMM using RNNs for continuous emissions; in contrast we maximize the exact log-marginal, and use RNNs to parameterize a discrete emission distribution. Finally, there has also been much recent interest in segmental RNN models for non-generative tasks in NLP (Tang et al., 2016; Kong et al., 2016; Lu et al., 2016).

The neural text generation community has also recently been interested in "controllable" text generation (Hu et al., 2017), where various aspects of the text (often sentiment) are manipulated or transferred (Shen et al., 2017; Zhao et al., 2018; Li et al., 2018). In contrast, here we focus on controlling either the content of a generation or the way it is expressed by manipulating the (latent) template used in realizing the generation.

3 Overview: Data-Driven NLG

Our focus is on generating a textual description of a knowledge base or meaning representation. Following standard notation (Liang et al., 2009; Wiseman et al., 2017), let $x = \{r_1 \dots r_J\}$ be a collection of records. A record is made up of a *type* ($r.t$), an *entity* ($r.e$), and a *value* ($r.m$). For example, a knowledge base of restaurants might have a record with $r.t$ = `Cuisine`, $r.e$ = `Denny's`, and $r.m$ = `American`. The aim is to generate an adequate and fluent text description $\hat{y}_{1:T} = \hat{y}_1, \dots, \hat{y}_T$ of x. Concretely, we consider the E2E Dataset (Novikova et al., 2017) and the WikiBio Dataset (Lebret et al., 2016). We show an example E2E knowledge base x in the top of Figure 1. The top of Figure 2 shows an example knowledge base x from the WikiBio dataset, where it is paired with a *reference* text $y = y_{1:T}$ at the bottom.

The dominant approach in neural NLG has been

Author abbrev. (botany)	Park.-Rhodes

Frederick Parker-Rhodes (21 March 1914 - 21 November 1987) was an English linguist, plant pathologist, computer scientist, mathematician, mystic, and mycologist.

Figure 2: An example from the WikiBio dataset (Lebret et al., 2016), with a database x (top) for Frederick Parker-Rhodes and corresponding reference generation y (bottom).

to use an encoder network over x and then a conditional decoder network to generate y, training the whole system in an end-to-end manner. To generate a description for a given example, a black-box network (such as an RNN) is used to produce a distribution over the next word, from which a choice is made and fed back into the system. The entire distribution is driven by the internal states of the neural network.

While effective, relying on a neural decoder makes it difficult to understand what aspects of x are correlated with a particular system output. This leads to problems both in controlling fine-grained aspects of the generation process and in interpreting model mistakes.

As an example of why controllability is important, consider the records in Figure 1. Given these inputs an end-user might want to generate an output meeting specific constraints, such as not mentioning any information relating to customer rating. Under a standard encoder-decoder style model, one could filter out this information either from the encoder or decoder, but in practice this would lead to unexpected changes in output that might propagate through the whole system.

As an example of the difficulty of interpreting mistakes, consider the following actual generation from an encoder-decoder style system for the records in Figure 2: ”frederick parker-rhodes (21 november 1914 - 2 march 1987) was an english mycology and plant pathology, mathematics at the university of uk.” In addition to not being fluent, it is unclear what the end of this sentence is even attempting to convey: it may be attempting to convey a fact not actually in the knowledge base (e.g., where Parker-Rhodes studied), or perhaps it is simply failing to fluently realize information that *is* in the knowledge base (e.g., Parker-Rhodes's country of residence).

Traditional NLG systems (Kukich, 1983; McKeown, 1992; Belz, 2008; Gatt and Reiter, 2009), in contrast, largely avoid these problems. Since they typically employ an explicit planning component, which decides which knowledge base records to focus on, and a surface realization component, which realizes the chosen records, the intent of the system is always explicit, and it may be modified to meet constraints.

The goal of this work is to propose an approach to neural NLG that addresses these issues in a principled way. We target this goal by proposing a new model that generates with template-like objects induced by a neural HSMM (see Figure 1). Templates are useful here because they represent a fixed plan for the generation's content, and because they make it clear what part of the generation is associated with which record in the knowledge base.

4 Background: Semi-Markov Models

What does it mean to learn a template? It is natural to think of a template as a sequence of typed text-segments, perhaps with some segments acting as the template's "backbone" (Wang and Cardie, 2013), and the remaining segments filled in from the knowledge base.

A natural probabilistic model conforming with this intuition is the hidden semi-markov model (HSMM) (Gales and Young, 1993; Ostendorf et al., 1996), which models latent segmentations in an output sequence. Informally, an HSMM is much like an HMM, except emissions may last multiple time-steps, and multi-step emissions need not be independent of each other conditioned on the state.

We briefly review HSMMs following Murphy (2002). Assume we have a sequence of observed tokens $y_1 \dots y_T$ and a discrete, latent state $z_t \in \{1, \dots, K\}$ for each timestep. We additionally use two per-timestep variables to model multi-step segments: a length variable $l_t \in \{1, \ldots, L\}$ specifying the length of the current segment, and a deterministic binary variable f_t indicating whether a segment finishes at time t. We will consider in particular *conditional* HSMMs, which condition on a source x, essentially giving us an HSMM decoder.

An HSMM specifies a joint distribution on the observations and latent segmentations. Letting θ denote all the parameters of the model, and using the variables introduced above, we can write the corresponding joint-likelihood as follows

$$p(y, z, l, f \mid x; \theta) = \prod_{t=0}^{T-1} p(z_{t+1}, l_{t+1} \mid z_t, l_t, x)^{f_t} \times \prod_{t=1}^{T} p(y_{t-l_t+1:t} \mid z_t, l_t, x)^{f_t},$$

where we take z_0 to be a distinguished start-state, and the deterministic f_t variables are used for excluding non-segment log probabilities. We further assume $p(z_{t+1}, l_{t+1} \mid z_t, l_t, x)$ factors as $p(z_{t+1} \mid z_t, x) \times p(l_{t+1} \mid z_{t+1})$. Thus, the likelihood is given by the product of the probabilities of each discrete state transition made, the probability of the length of each segment given its discrete state, and the probability of the observations in each segment, given its state and length.

5 A Neural HSMM Decoder

We use a novel, neural parameterization of an HSMM to specify the probabilities in the likelihood above. This full model, sketched out in Figure 3, allows us to incorporate the modeling components, such as LSTMs and attention, that make neural text generation effective, while maintaining the HSMM structure.

5.1 Parameterization

Since our model must condition on x, let $\boldsymbol{r}_j \in \mathbb{R}^d$ represent a real embedding of record $r_j \in x$, and let $\boldsymbol{x}_a \in \mathbb{R}^d$ represent a real embedding of the entire knowledge base x, obtained by max-pooling coordinate-wise over all the $\boldsymbol{r}_j$. It is also useful to have a representation of just the unique *types* of records that appear in x, and so we also define $\boldsymbol{x}_u \in \mathbb{R}^d$ to be the sum of the embeddings of the unique types appearing in x, plus a bias vector and followed by a ReLU nonlinearity.

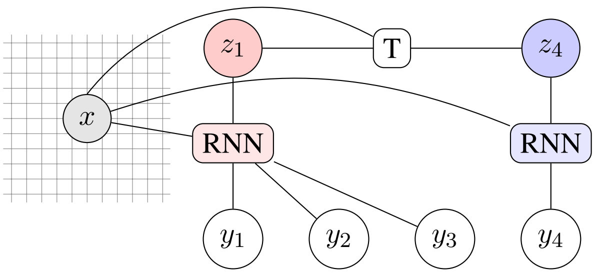

Figure 3: HSMM factor graph (under a known segmentation) to illustrate parameters. Here we assume z_1 is in the "red" state (out of K possibilities), and transitions to the "blue" state after emitting three words. The transition model, shown as T, is a function of the two states and the neural encoded source x. The emission model is a function of a "red" RNN model (with copy attention over x) that generates words 1, 2 and 3. After transitioning, the next word y_4 is generated by the "blue" RNN, but independently of the previous words.

Transition Distribution The transition distribution $p(z_{t+1} \mid z_t, x)$ may be viewed as a $K \times K$ matrix of probabilities, where each row sums to 1. We define this matrix to be

$$p(z_{t+1} \mid z_t, x) \propto \boldsymbol{A}\boldsymbol{B} + \boldsymbol{C}(\boldsymbol{x}_u)\boldsymbol{D}(\boldsymbol{x}_u),$$

where $\boldsymbol{A} \in \mathbb{R}^{K \times m_1}$, $\boldsymbol{B} \in \mathbb{R}^{m_1 \times K}$ are state embeddings, and where $\boldsymbol{C} : \mathbb{R}^d \rightarrow \mathbb{R}^{K \times m_2}$ and $\boldsymbol{D} : \mathbb{R}^d \rightarrow \mathbb{R}^{m_2 \times K}$ are parameterized non-linear functions of $\boldsymbol{x}_u$. We apply a row-wise $\mathrm{softmax}$ to the resulting matrix to obtain the desired probabilities.

Length Distribution We simply fix all length probabilities $p(l_{t+1} \mid z_{t+1})$ to be uniform up to a maximum length L.[1]

Emission Distribution The emission model models the generation of a text segment conditioned on a latent state and source information, and so requires a richer parameterization. Inspired by the models used for neural NLG, we base this model on an RNN decoder, and write a segment's probability as a product over token-level probabilities,

$$p(y_{t-l_t+1:t} \mid z_t = k, l_t = l, x) = \prod_{i=1}^{l_t} p(y_{t-l_t+i} \mid y_{t-l_t+1:t-l_t+i-1}, z_t = k, x) \times p(\text{</seg>} \mid y_{t-l_t+1:t}, z_t = k, x) \times \mathbf{1}_{\{l_t = l\}},$$

---

[1] We experimented with parameterizing the length distribution, but found that it led to inferior performance. Forcing the length probabilities to be uniform encourages the model to cluster together functionally similar emissions of different lengths, while parameterizing them can lead to states that specialize to specific emission lengths.

where </seg> is an end of segment token. The RNN decoder uses attention and copy-attention over the embedded records $\boldsymbol{r}_j$, and is conditioned on $z_t = k$ by concatenating an embedding corresponding to the k'th latent state to the RNN's input; the RNN is also conditioned on the entire x by initializing its hidden state with $\boldsymbol{x}_a$.

More concretely, let $\boldsymbol{h}^k_{i-1} \in \mathbb{R}^d$ be the state of an RNN conditioned on x and $z_t = k$ (as above) run over the sequence $y_{t-l_t+1:t-l_t+i-1}$. We let the model attend over records $\boldsymbol{r}_j$ using $\boldsymbol{h}^k_{i-1}$ (in the style of Luong et al. (2015)), producing a context vector $\boldsymbol{c}^k_{i-1}$. We may then obtain scores $\boldsymbol{v}_{i-1}$ for each word in the output vocabulary,

$$\boldsymbol{v}_{i-1} = \boldsymbol{W} \tanh(\boldsymbol{g}^k_1 \circ [\boldsymbol{h}^k_{i-1}, \boldsymbol{c}^k_{i-1}]),$$

with parameters $\boldsymbol{g}^k_1 \in \mathbb{R}^{2d}$ and $\boldsymbol{W} \in \mathbb{R}^{V \times 2d}$. Note that there is a $\boldsymbol{g}^k_1$ vector for each of K discrete states. To additionally implement a kind of slot filling, we allow emissions to be directly copied from the value portion of the records r_j using copy attention (Gülçehre et al., 2016; Gu et al., 2016; Yang et al., 2016). Define copy scores,

$$\rho_j = \boldsymbol{r}_j^{\mathsf{T}} \tanh(\boldsymbol{g}^k_2 \circ \boldsymbol{h}^k_{i-1}),$$

where $\boldsymbol{g}^k_2 \in \mathbb{R}^d$. We then normalize the output-vocabulary and copy scores together, to arrive at

$$\widetilde{\boldsymbol{v}}_{i-1} = \mathrm{softmax}([\boldsymbol{v}_{i-1}, \rho_1, \ldots, \rho_J]),$$

and thus

$$p(y_{t-l_t+i} = w \mid y_{t-l_t+1:t-l_t+i-1}, z_t = k, x) = \widetilde{\boldsymbol{v}}_{i-1,w} + \sum_{j: r_j.m = w} \widetilde{\boldsymbol{v}}_{i-1,V+j}.$$

An Autoregressive Variant The model as specified assumes segments are independent conditioned on the associated latent state and x. While this assumption still allows for reasonable performance, we can tractably allow interdependence between tokens (but not segments) by having each next-token distribution depend on all the previously generated tokens, giving us an autoregressive HSMM. For this model, we will in fact use $p(y_{t-l_t+i} = w \mid y_{1:t-l_t+i-1}, z_t = k, x)$ in defining our emission model, which is easily implemented by using an additional RNN run over all the preceding tokens. We will report scores for both non-autoregressive and autoregressive HSMM decoders below.

5.2 Learning

The model requires fitting a large set of neural network parameters. Since we assume z, l, and f are unobserved, we marginalize over these variables to maximize the log marginal-likelihood of the observed tokens y given x. The HSMM marginal-likelihood calculation can be carried out efficiently with a dynamic program analogous to either the forward- or backward-algorithm familiar from HMMs (Rabiner, 1989).

It is actually more convenient to use the backward-algorithm formulation when using RNNs to parameterize the emission distributions, and we briefly review the backward recurrences here, again following Murphy (2002). We have:

$$\begin{aligned}
\beta_t(j) &= p(y_{t+1:T} \mid z_t = j, f_t = 1, x) \\
&= \sum_{k=1}^{K} \beta^*_t(k)\, p(z_{t+1} = k \mid z_t = j) \\
\beta^*_t(k) &= p(y_{t+1:T} \mid z_{t+1} = k, f_t = 1, x) \\
&= \sum_{l=1}^{L} \Big[\beta_{t+l}(k)\, p(l_{t+1} = l \mid z_{t+1} = k) \\
&\qquad p(y_{t+1:t+l} \mid z_{t+1} = k, l_{t+1} = l) \Big],
\end{aligned}$$

with base case $\beta_T(j) = 1$. We can now obtain the marginal probability of y as $p(y \mid x) = \sum_{k=1}^{K} \beta^*_0(k)\, p(z_1 = k)$, where we have used the fact that f_0 must be 1, and we therefore train to maximize the log-marginal likelihood of the observed y:

$$\ln p(y \mid x; \theta) = \ln \sum_{k=1}^{K} \beta^*_0(k)\, p(z_1 = k). \tag{1}$$

Since the quantities in (1) are obtained from a dynamic program, which is itself differentiable, we may simply maximize with respect to the parameters θ by back-propagating through the dynamic program; this is easily accomplished with automatic differentiation packages, and we use `pytorch` (Paszke et al., 2017) in all experiments.

5.3 Extracting Templates and Generating

After training, we could simply condition on a new database and generate with beam search, as is standard with encoder-decoder models. However, the structured approach we have developed allows us to generate in a more template-like way, giving us more interpretable and controllable generations.

[The Golden Palace]$_{55}$ [is a]$_{59}$ [coffee shop]$_{12}$ [providing]$_{3}$ [Indian]$_{50}$ [food]$_{1}$ [in the]$_{17}$ [£20-25]$_{26}$ [price range]$_{16}$ [.]$_{2}$ [It is]$_{8}$ [located in the]$_{25}$ [riverside]$_{40}$ [.]$_{53}$ [Its customer rating is]$_{19}$ [high]$_{23}$ [.]$_{2}$

Figure 4: A sample Viterbi segmentation of a training text; subscripted numbers indicate the corresponding latent state. From this we can extract a template with $S = 17$ segments; compare with the template used at the bottom of Figure 1.

First, note that given a database x and reference generation y we can obtain the MAP assignment to the variables z, l, and f with a dynamic program similar to the Viterbi algorithm familiar from HMMs. These assignments will give us a typed segmentation of y, and we show an example Viterbi segmentation of some training text in Figure 4. Computing MAP segmentations allows us to associate text-segments (i.e., phrases) with the discrete labels z_t that frequently generate them. These MAP segmentations can be used in an exploratory way, as a sort of dimensionality reduction of the generations in the corpus. More importantly for us, however, they can also be used to guide generation.

In particular, since each MAP segmentation implies a sequence of hidden states z, we may run a *template extraction* step, where we collect the most common "templates" (i.e., sequences of hidden states) seen in the training data. Each "template" $z^{(i)}$ consists of a sequence of latent states, with $z^{(i)} = z_1^{(i)}, \ldots z_S^{(i)}$ representing the S distinct segments in the i'th extracted template (recall that we will technically have a z_t for each time-step, and so $z^{(i)}$ is obtained by collapsing adjacent z_t's with the same value); see Figure 4 for an example template (with $S = 17$) that can be extracted from the E2E corpus. The bottom of Figure 1 shows a visualization of this extracted template, where discrete states are replaced by the phrases they frequently generate in the training data.

With our templates $z^{(i)}$ in hand, we can then restrict the model to using (one of) them during generation. In particular, given a new input x, we may generate by computing

$$\hat{y}^{(i)} = \arg\max_{y'} p(y', z^{(i)} \mid x), \qquad (2)$$

which gives us a generation $\hat{y}^{(i)}$ for each extracted template $z^{(i)}$. For example, the generation in Figure 1 is obtained by maximizing (2) with x set to the database in Figure 1 and $z^{(i)}$ set to the template extracted in Figure 4. In practice, the $\arg\max$ in (2) will be intractable to calculate exactly due to the use of RNNs in defining the emission distribution, and so we approximate it with a constrained beam search. This beam search looks very similar to that typically used with RNN decoders, except the search occurs only over a segment, for a particular latent state k.

5.4 Discussion

Returning to the discussion of controllability and interpretability, we note that with the proposed model (a) it is possible to explicitly force the generation to use a chosen template $z^{(i)}$, which is itself automatically learned from training data, and (b) that every *segment* in the generated $\hat{y}^{(i)}$ is typed by its corresponding latent variable. We explore these issues empirically in Section 7.1.

We also note that these properties may be useful for other text applications, and that they offer an additional perspective on how to approach latent variable modeling for text. Whereas there has been much recent interest in learning continuous latent variable representations for text (see Section 2), it has been somewhat unclear what the latent variables to be learned are intended to capture. On the other hand, the latent, template-like structures we induce here represent a plausible, probabilistic latent variable story, and allow for a more controllable method of generation.

Finally, we highlight one significant possible issue with this model – the assumption that segments are independent of each other given the corresponding latent variable and x. Here we note that the fact that we are allowed to condition on x is quite powerful. Indeed, a clever encoder could capture much of the necessary interdependence between the segments to be generated (e.g., the correct determiner for an upcoming noun phrase) in its encoding, allowing the segments themselves to be decoded more or less independently, given x.

6 Data and Methods

Our experiments apply the approach outlined above to two recent, data-driven NLG tasks.

6.1 Datasets

Experiments use the E2E (Novikova et al., 2017) and WikiBio (Lebret et al., 2016) datasets, examples of which are shown in Figures 1 and 2, respectively. The former dataset, used for the

2018 E2E-Gen Shared Task, contains approximately 50K total examples, and uses 945 distinct word types, and the latter dataset contains approximately 500K examples and uses approximately 400K word types. Because our emission model uses a word-level copy mechanism, any record with a phrase consisting of n words as its value is replaced with n positional records having a single word value, following the preprocessing of Lebret et al. (2016). For example, "type[coffee shop]" in Figure 1 becomes "type-1[coffee]" and "type-2[shop]."

For both datasets we compare with published encoder-decoder models, as well as with direct template-style baselines. The E2E task is evaluated in terms of BLEU (Papineni et al., 2002), NIST (Belz and Reiter, 2006), ROUGE (Lin, 2004), CIDEr (Vedantam et al., 2015), and METEOR (Banerjee and Lavie, 2005).[2] The benchmark system for the task is an encoder-decoder style system followed by a reranker, proposed by Dušek and Jurcıcek (2016). We compare to this baseline, as well as to a simple but competitive non-parametric template-like baseline ("SUB" in tables), which selects a training sentence with records that maximally overlap (without including extraneous records) the unseen set of records we wish to generate from; ties are broken at random. Then, word-spans in the chosen training sentence are aligned with records by string-match, and replaced with the corresponding fields of the new set of records.[3]

The WikiBio dataset is evaluated in terms of BLEU, NIST, and ROUGE, and we compare with the systems and baselines implemented by Lebret et al. (2016), which include two neural, encoder-decoder style models, as well as a Kneser-Ney, templated baseline.

6.2 Model and Training Details

We first emphasize two additional methodological details important for obtaining good performance.

Constraining Learning We were able to learn more plausible segmentations of y by constraining the model to respect word spans $y_{t+1:t+l}$ that appear in some record $r_j \in x$. We accomplish this by giving zero probability (within the backward recurrences in Section 5) to any segmentation that splits up a sequence $y_{t+1:t+l}$ that appears in some r_j, or that includes $y_{t+1:t+l}$ as a subsequence of another sequence. Thus, we maximize (1) subject to these hard constraints.

Increasing the Number of Hidden States While a larger K allows for a more expressive latent model, computing K emission distributions over the vocabulary can be prohibitively expensive. We therefore tie the emission distribution between multiple states, while allowing them to have a different transition distributions.

We give additional architectural details of our model in the Supplemental Material; here we note that we use an MLP to embed $\boldsymbol{r}_j \in \mathbb{R}^d$, and a 1-layer LSTM (Hochreiter and Schmidhuber, 1997) in defining our emission distributions. In order to reduce the amount of memory used, we restrict our output vocabulary (and thus the height of the matrix $\boldsymbol{W}$ in Section 5) to only contain words in y that are *not* present in x; any word in y present in x is assumed to be copied. In the case where a word y_t appears in a record r_j (and could therefore have been copied), the input to the LSTM at time $t+1$ is computed using information from r_j; if there are multiple r_j from which y_t could have been copied, the computed representations are simply averaged.

For all experiments, we set $d=300$ and $L=4$. At generation time, we select the 100 most common templates $z^{(i)}$, perform beam search with a beam of size 5, and select the generation with the highest overall joint probability.

For our E2E experiments, our best non-autoregressive model has 55 "base" states, duplicated 5 times, for a total of $K=275$ states, and our best autoregressive model uses $K=60$ states, without any duplication. For our WikiBio experiments, both our best non-autoregressive and autoregressive models uses 45 base states duplicated 3 times, for a total of $K=135$ states. In all cases, K was chosen based on BLEU performance on held-out validation data. Code implementing our models is available at `https://github.com/harvardnlp/neural-template-gen`.

7 Results

Our results on automatic metrics are shown in Tables 1 and 2. In general, we find that the templated baselines underperform neural models, whereas our proposed model is fairly competitive with neural models, and sometimes even out-

---

[2] We use the official E2E NLG Challenge scoring scripts at `https://github.com/tuetschek/e2e-metrics`.

[3] For categorical records, like "familyFriendly", which cannot easily be aligned with a phrase, we simply select only candidate training sentences with the same categorical value.

Table 3: Impact of varying the template $z^{(i)}$ for a single x from the E2E validation data; generations are annotated with the segmentations of the chosen $z^{(i)}$. Results were obtained using the NTemp+AR model from Table 1.

performs them. On the E2E data, for example, we see in Table 1 that the SUB baseline, despite having fairly impressive performance for a non-parametric model, fares the worst. The neural HSMM models are largely competitive with the encoder-decoder system on the validation data, despite offering the benefits of interpretability and controllability; however, the gap increases on test.

Table 2 evaluates our system's performance on the test portion of the WikiBio dataset, comparing with the systems and baselines implemented by Lebret et al. (2016). Again for this dataset we see that their templated Kneser-Ney model underperforms on the automatic metrics, and that neural models improve on these results. Here the HSMMs are competitive with the best model of Lebret et al. (2016), and even outperform it on ROUGE. We emphasize, however, that recent, sophisticated approaches to encoder-decoder style database-to-text generation have since surpassed the results of Lebret et al. (2016) and our own, and we show the recent seq2seq style results of Liu et al. (2018), who use a somewhat larger model, at the bottom of Table 2.

7.1 Qualitative Evaluation

We now qualitatively demonstrate that our generations are controllable and interpretable.

Controllable Diversity One of the powerful aspects of the proposed approach to generation is that we can manipulate the template $z^{(i)}$ while leaving the database x constant, which allows for easily controlling aspects of the generation. In Table 3 we show the generations produced by our model for five different neural template sequences $z^{(i)}$, while fixing x. There, the segments in each generation are annotated with the latent states determined by the corresponding $z^{(i)}$. We see that these templates can be used to affect the word-ordering, as well as which fields are mentioned in the generated text. Moreover, because the discrete states align with particular fields (see below), it is generally simple to automatically infer to which fields particular latent states correspond, allowing users to choose which template best meets their requirements. We emphasize that this level of controllability is much harder to obtain for encoder-decoder models, since, at best, a large amount of sampling would be required to avoid generating around a particular mode in the conditional distribution, and even then it would be difficult to control the sort of generations obtained.

Table 4: Impact of varying the template $z^{(i)}$ for a single x from the WikiBio validation data; generations are annotated with the segmentations of the chosen $z^{(i)}$. Results were obtained using the NTemp model from Table 2.

Interpretable States Discrete states also provide a method for interpreting the generations produced by the system, since each segment is explicitly typed by the current hidden state of the model. Table 4 shows the impact of varying the template $z^{(i)}$ for a single x from the WikiBio dataset. While there is in general surprisingly little stylistic variation in the WikiBio data itself, there is variation in the information discussed, and the templates capture this. Moreover, we see that particular discrete states correspond in a consistent way to particular pieces of information, allowing us to align states with particular field types. For instance, birth names have the same hidden state (132), as do names (117), nationalities (82), birth dates (101), and occupations (20).

To demonstrate empirically that the learned states indeed align with field types, we calculate the average purity of the discrete states learned for both datasets in Table 5. In particular, for each discrete state for which the majority of its generated words appear in some r_j, the *purity* of a state's record type alignment is calculated as the percentage of the state's words that come from the most frequent record type the state represents. This calculation was carried out over training examples that belonged to one of the top 100 most frequent templates. Table 5 indicates that discrete states learned on the E2E data are quite pure. Discrete states learned on the WikiBio data are less pure, though still rather impressive given that there are approximately 1700 record types represented in the WikiBio data, and we limit the number of states to 135. Unsurprisingly, adding autoregressiveness to the model decreases purity on both datasets, since the model may rely on the autoregressive RNN for typing, in addition to the state's identity.

WikiBio	43.2 (19.7)	39.9 (17.9)

Table 5: Empirical analysis of the average purity of discrete states learned on the E2E and WikiBio datasets, for the NTemp and NTemp+AR models. Average purities are given as percents, and standard deviations follow in parentheses. See the text for full description of this calculation.

8 Conclusion and Future Work

We have developed a neural, template-like generation model based on an HSMM decoder, which can be learned tractably by backpropagating through a dynamic program. The method allows us to extract template-like latent objects in a principled way in the form of state sequences, and then generate with them. This approach scales to large-scale text datasets and is nearly competitive with encoder-decoder models. More importantly, this approach allows for controlling the diversity of generation and for producing interpretable states during generation. We view this work both as the first step towards learning discrete latent variable template models for more difficult generation tasks, as well as a different perspective on learning latent variable text models in general. Future work will examine encouraging the model to learn maximally different (or minimal) templates, which our objective does not explicitly encourage, templates of larger textual phenomena, such as paragraphs and documents, and hierarchical templates.

A Supplemental Material

A.1 Additional Model and Training Details

Computing $\boldsymbol{r}_j$ A record r_j is represented by embedding a feature for its type, its position, and its word value in $\mathbb{R}^d$, and applying an MLP with ReLU nonlinearity (Nair and Hinton, 2010) to form $\boldsymbol{r}_j \in \mathbb{R}^d$, similar to Yang et al. (2016) and Wiseman et al. (2017).

LSTM Details The initial cell and hidden-state values for the decoder LSTM are given by $\boldsymbol{Q}_1 \boldsymbol{x}_a$ and $\tanh(\boldsymbol{Q}_2 \boldsymbol{x}_a)$, respectively, where $\boldsymbol{Q}_1, \boldsymbol{Q}_2 \in \mathbb{R}^{d \times d}$.

When a word y_t appears in a record r_j, the input to the LSTM at time $t+1$ is computed using an MLP with ReLU nonlinearity over the concatenation of the embeddings for r_j's record type, word value, position, and a feature for whether it is the final position for the type. If there are multiple r_j from which y_t could have been copied, the computed representations are averaged. At test time, we use the MAP r_j to compute the input, even if there are multiple matches. For y_t which could not have been copied, the input to the LSTM at time $t+1$ is computed using the same MLP over y_t and three dummy features.

For the autoregressive HSMM, an additional 1-layer LSTM with d hidden units is used. We experimented with having the autoregressive HSMM consume either tokens $y_{1:t}$ in predicting y_{t+1}, or the average embedding of the field *types* corresponding to copied tokens in $y_{1:t}$. The former worked slightly better for the WikiBio dataset (where field types are more ambiguous), while the latter worked slightly better for the E2E dataset.

Transition Distribution The function $\boldsymbol{C}(\boldsymbol{x}_u)$, which produces hidden state embeddings conditional on the source, is defined as $\boldsymbol{C}(\boldsymbol{x}_u) = \boldsymbol{U}_2(\mathrm{ReLU}(\boldsymbol{U}_1 \boldsymbol{x}_u))$, where $\boldsymbol{U}_1 \in \mathbb{R}^{m_3 \times d}$ and $\boldsymbol{U}_2 \in \mathbb{R}^{K \times m_2 \times m_3}$; $\boldsymbol{D}(x)$ is defined analogously. For all experiments, $m_1 = 64$, $m_2 = 32$, and $m_3 = 64$.

Optimization We train with SGD, using a learning rate of 0.5 and decaying by 0.5 each epoch after the first epoch in which validation log-likelihood fails to increase. When using an autoregressive HSMM, the additional LSTM is optimized only after the learning rate has been decayed. We regularize with Dropout (Srivastava et al., 2014).

A.2 Additional Learned Templates

In Tables 6 and 7 we show visualizations of additional templates learned on the E2E and WikiBio data, respectively, by both the non-autoregressive and autoregressive HSMM models presented in the paper. For each model, we select a set of five dissimilar templates in an iterative way by greedily selecting the next template (out of the 200 most frequent) that has the highest percentage of states that do not appear in the previously selected templates; ties are broken randomly. Individual states within a template are visualized using the three most common segments they generate.

Multi-Reference Training with Pseudo-References for Neural Translation and Text Generation

Renjie Zheng [1] **Mingbo Ma** [1,2] **Liang Huang** [1,2]

Abstract

Neural text generation, including neural machine translation, image captioning, and summarization, has been quite successful recently. However, during training time, typically only one reference is considered for each example, even though there are often multiple references available, e.g., 4 references in NIST MT evaluations, and 5 references in image captioning data. We first investigate several different ways of utilizing multiple human references during training. But more importantly, we then propose an algorithm to generate exponentially many pseudo-references by first compressing existing human references into lattices and then traversing them to generate new pseudo-references. These approaches lead to substantial improvements over strong baselines in both machine translation (+1.5 BLEU) and image captioning (+3.1 BLEU / +11.7 CIDEr).

1 Introduction

Neural text generation has attracted much attention in recent years thanks to its impressive generation accuracy and wide applicability. In addition to demonstrating compelling results for machine translation (MT) (Sutskever et al., 2014; Bahdanau et al., 2014), by simple adaptation, practically very same or similar models have also proven to be successful for summarization (Rush et al., 2015; Nallapati et al., 2016) and image or video captioning (Venugopalan et al., 2015; Xu et al., 2015a).

The most common neural text generation model is based on the encoder-decoder framework (Sutskever et al., 2014) which generates a variable-length output sequence using an RNN-based decoder with attention mechanisms (Bahdanau et al., 2014; Xu et al., 2015b). There are many recent efforts in improving the generation accuracy, e.g., ConvS2S (Gehring et al., 2017) and Transformer (Vaswani et al., 2017). However, all these efforts are limited to training with a single reference even when multiple references are available.

Multiple references are essential for evaluation due to the non-uniqueness of translation and generation unlike classification tasks. In MT, even though the training sets are usually with single reference (bitext), the evaluation sets often come with multiple references. For example, the NIST Chinese-to-English and Arabic-to-English MT evaluation datasets (2003–2008) have in total around 10,000 Chinese sentences and 10,000 Arabic sentences each with 4 different English translations. On the other hand, for image captioning datasets, multiple references are more common not only for evaluation, but also for training, e.g., the MSCOCO (Lin et al., 2014) dataset provides 5 references per image and PASCAL-50S and ABSTRACT-50S (Vedantam et al., 2015) even provide 50 references per image. Can we use the extra references during training? How much can we benefit from training with multiple references?

We therefore first investigate several different ways of utilizing existing human-annotated references, which include Sample One (Karpathy and Fei-Fei, 2015), Uniform, and Shuffle methods (explained in Sec. 2). Although Sample One has been explored in image captioning, to the best of our knowledge, this is the first time that an MT system is trained with multiple references.

Actually, four or five references still cover only a tiny fraction of the exponentially large space of potential references (Dreyer and Marcu, 2012). More importantly, encouraged by the success of training with multiple human references, we further propose a framework to generate many more pseudo-references automatically. In particular, we design a neural multiple-sequence alignment algo-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3188–3197
Brussels, Belgium, October 31 - November 4, 2018.

rithm to compress all existing human references into a lattice by merging similar words across different references (see examples in Fig. 1); this can be viewed as a modern, neural version of paraphrasing with multiple-sequence alignment (Barzilay and Lee, 2003, 2002). We can then generate theoretically exponentially more references from the lattice.

We make the following main contributions:

- Firstly, we investigate three different methods for multi-reference training on both MT and image captioning tasks (Section 2).
- Secondly, we propose a novel neural network-based multiple sequence alignment model to compress the existing references into lattices. By traversing these lattices, we generate exponentially many new pseudo-references (Section 3).
- We report substantial improvements over strong baselines in both MT (+1.5 BLEU) and image captioning (+3.1 BLEU / +11.7 CIDEr) by training on the newly generated pseudo-references (Section 4).

2 Using Multiple References

In order to make the multiple reference training easy to adapt to any frameworks, we do not change anything from the existing models itself. Our multiple reference training is achieved by converting a multiple reference dataset to a single reference dataset without losing any information.

Considering a multiple reference dataset D, where the i^{th} training example, $(\mathbf{x}_i, Y_i)$, includes one source input $\mathbf{x}_i$, which is a source sentence in MT or image vector in image captioning, and a reference set $Y_i = \{\mathbf{y}_i^1, \mathbf{y}_i^2, ...\mathbf{y}_i^K\}$ of K references. We have the following methods to convert the multiple reference dataset to a single reference dataset D' (note that the following $D'_{\text{sample one}}$, D'_{uniform} and D'_{shuffle} are ordered sets):

Sample One: The most straightforward way is to use a different reference in different epochs during training to explore the variances between references. For each example, we randomly pick one of the K references in each training epoch (note that the random function will be used in each epoch). This method is commonly used in existing image captioning literatures, such as (Karpathy and Fei-Fei, 2015), but never used in MT. This approach can be formalized as:

$$D'_{\text{sample one}} = \bigcup_{i=1}^{|D|} \{(\mathbf{x}_i, \mathbf{y}_i^{k_i})\}, k_i = \text{rand}(1, ..., K)$$

Uniform: Although all references are accessible by using Sample One, it is not guaranteed that all references are used during training. So we introduce **Uniform** which basically copies $\mathbf{x}_i$ training example K times and each time with a different reference. This approach can be formalized as:

$$D'_{\text{uniform}} = \bigcup_{i=1}^{|D|} \bigcup_{k=1}^{K} \{(\mathbf{x}_i, \mathbf{y}_i^k)\}$$

Shuffle is based on Uniform, but shuffles all the source and reference pairs in random order before each epoch. So, formally it is:

$$D'_{\text{shuffle}} = \text{Shuffle}(D'_{\text{uniform}})$$

Sample One is supervised by different training signals in different epochs while both Uniform and Shuffle include all the references at one time. Note that we use mini-batch during training. When we set the batch size equal to the entire training set size in both Uniform and Shuffle, they become equivalent.

3 Pseudo-References Generation

In text generation tasks, the given multiple references are only a small portion in the whole space of potential references. To cover a larger number of references during training, we want to generate more pseudo-references which is similar to existing ones.

Our basic idea is to compress different references $\mathbf{y}_0, \mathbf{y}_1, ..., \mathbf{y}_K$ into a lattice. We achieve this by merging similar words in the references. Finally, we generate more pseudo-references by simply traversing the compressed lattice and select those with high quality according to its BLEU score.

Take the following three references from the NIST Chinese-to-English machine translation dataset as an example:

1. `Indonesia reiterated its opposition to foreign military presence`
2. `Indonesia repeats its opposition against station of foreign troops in Indonesia`
3. `Indonesia reiterates opposition to garrisoning foreign armies`

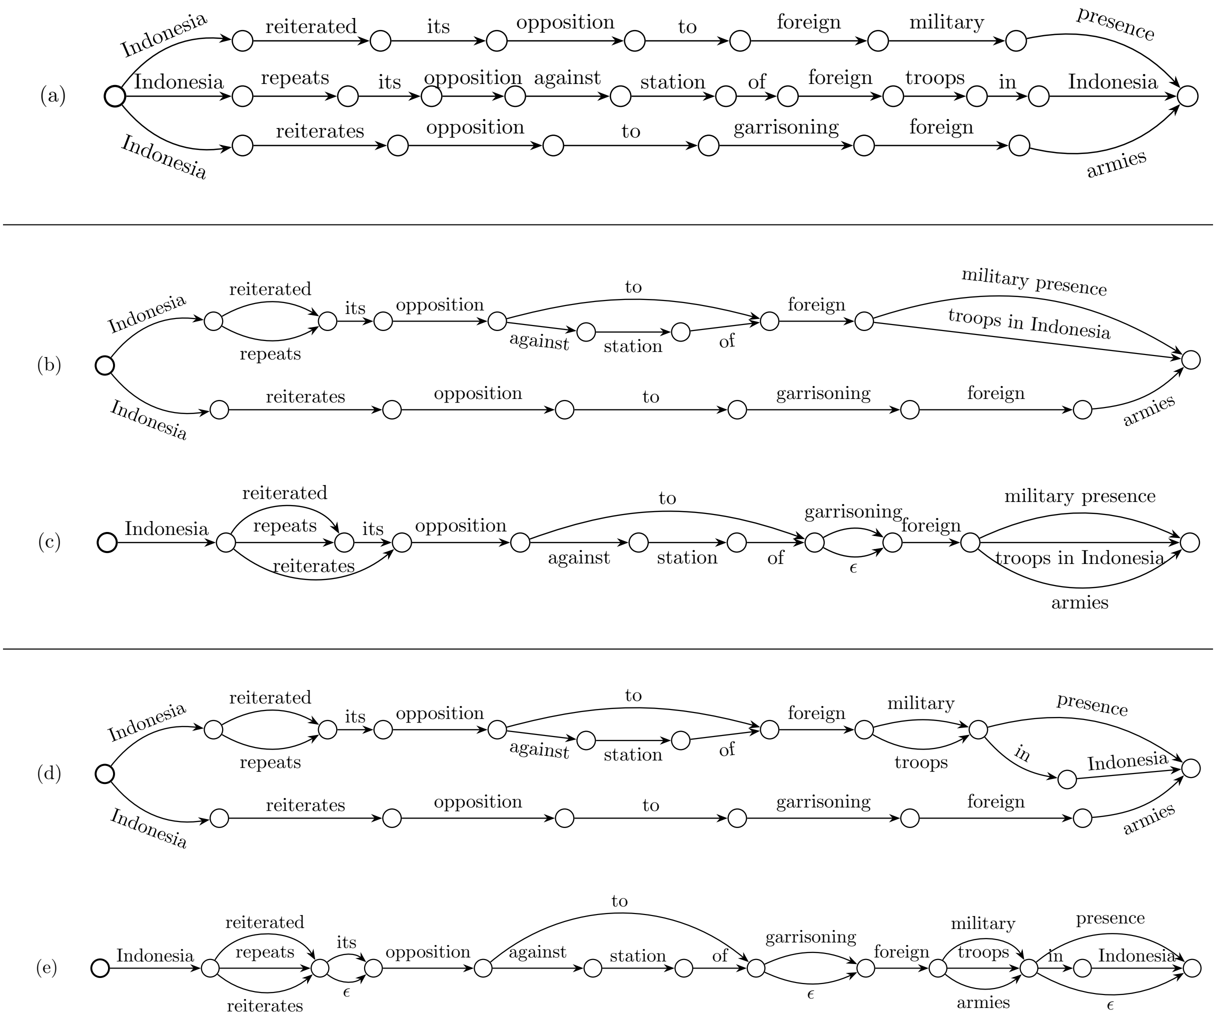

Figure 1: Lattice construction with word alignment. (b-c) is hard word alignment and 33 pseudo-references can be generated. (d-e) is soft word alignment, 213 pseudo-references can be generated.

3.1 Naive Idea: Hard Word Alignment

The simplest way to compress different references into a lattice is to do pairwise reference compression iteratively. At each time, we select two references and merge the same words in them.

Considering the previous example, we can derive an initial lattice from the three references as shown in Fig. 1(a). Assume that we first do a pairwise reference compression on first two references, we can merge at four sharing words: `Indonesia`, `its`, `opposition` and `foreign`, and the lattice will turn to Fig. 1(b). If we further compress the first and third references, we can merge at `Indonesia`, `opposition`, `to` and `foreign`, which gives the lattice Fig. 1(c). By simply traversing the final lattice, 33 new pseudo-references can be generated. For example:

1. `Indonesia reiterated its opposition to garrisoning foreign armies`
2. `Indonesia repeats its opposition to foreign military presence`
3. `Indonesia reiterates opposition to foreign troops in Indonesia`
4. ...

However, this simple hard alignment method (only identical words can be aligned) suffers from two problems:

1. Different words may have similar meanings and need to be merged together. For example, in the previous example, `reiterated`, `repeats` and `reiterates` should be merged together. Similarly, `military`, `troops` and `armies` also have similar meanings. If the

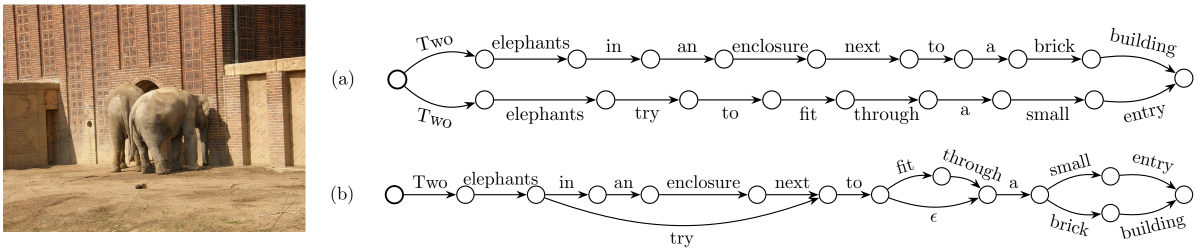

Figure 2: Mistakes from hard word alignment by merging at "`to`".

lattice can align these words, we can generate the lattice shown in Fig. 1(e) which can generate 213 pseudo-references.

2. Identical words may have different meaning in different contexts and should not be merged. Considering the following two references from the COCO image captioning dataset (corresponding picture is shown in Fig. 2):

1. `Two elephants in an enclosure next to a brick building`
2. `Two elephants try to fit through a small entry`

Following the previously described algorithm, we can merge the two references at "`two elephants`", at "`to`" and at "`a`". However, "`to`" in the two references are very different (it is a preposition in the first reference and an infinitive in the second) and should not be merged. Thus, the lattice in Fig. 2(b) will generate the following wrong pseudo-references:

1. `Two elephants try to a small entry`
2. `Two elephants in an enclosure next to fit through a brick building`

Therefore, we need to investigate a better method to compress the lattice.

3.2 Measuring Word Similarity in Context

To tackle the above listed two problems of hard alignment, we need to identify synonyms and words with similar meanings. Barzilay and Lee (2002) utilize an external synonyms dictionary to get the similarity score between words. However, this method ignores the given context of each word. For example, in Fig. 1(a), there are two `Indonesia`'s in the second path of reference. If we use a synonyms dictionary, both `Indonesia` tokens will be aligned to the `Indonesia` in the first or third sentence with the same score. This incorrect alignment would lead to meaningless lattice.

Thus, we introduce the semantic substitution matrix which measures the semantic similarity of each word pairs in context. Formally, given a sentence pair $\mathbf{y}_i$ and $\mathbf{y}_j$, we build a semantic substitution matrix $M = \mathbb{R}^{|\mathbf{y}_i| \times |\mathbf{y}_j|}$, whose cell $M_{u,v}$ represents the similarity score between word $\mathbf{y}_{i,u}$ and word $\mathbf{y}_{j,v}$.

We propose a new neural network-based multiple sequence alignment algorithm to take context into consideration. We first build a language model (LM) to obtain the semantic representation of each word, then these word representations are used to construct the semantic substitution matrix between sentences.

Fig. 3 shows the architecture of the bidirectional LM (Mousa and Schuller, 2017). The optimization goal of our LM is to minimize the i^{th} word's prediction error given the surrounding word's hidden state:

$$p(w_i \mid \overrightarrow{\mathbf{h}_{i-1}} \oplus \overleftarrow{\mathbf{h}_{i+1}}) \qquad (1)$$

For any new given sentences, we concatenate both forward and backward hidden states to represent each word $\mathbf{y}_{i,u}$ in a sentence $\mathbf{y}_i$. We then calculate the normalized *cosine* similarity score of word $\mathbf{y}_{i,u}$ and $\mathbf{y}_{j,v}$ as:

$$M_{u,v} = cosine(\overrightarrow{\mathbf{h}_u} \oplus \overleftarrow{\mathbf{h}_u}, \overrightarrow{\mathbf{h}_v} \oplus \overleftarrow{\mathbf{h}_v}) \qquad (2)$$

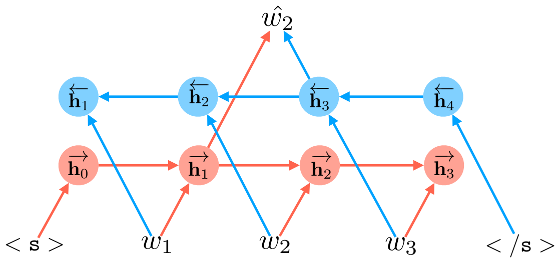

Figure 3: Bidirectional Language Model

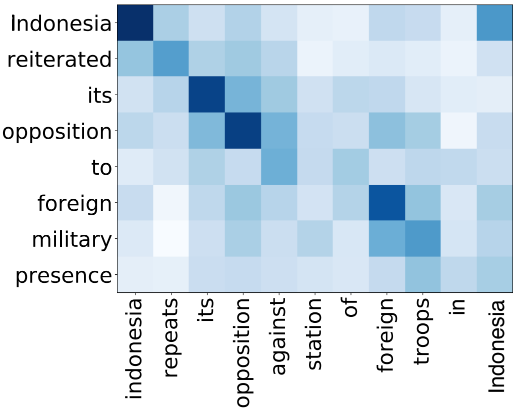

Figure 4: Semantic Substitution Matrix

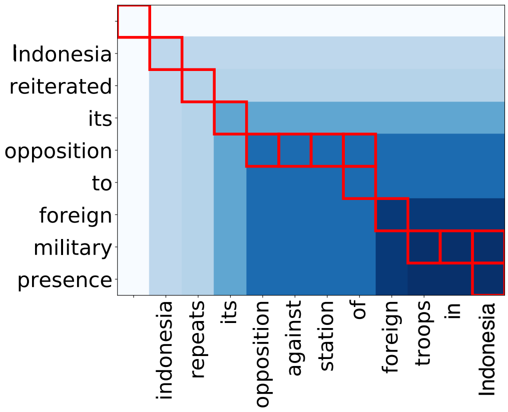

Figure 5: Dynamic Programming on Semantic Substitution Matrix

Fig. 4 shows an example of the semantic substitution matrix of first two sentences in example references of Fig. 1(a).

3.3 Iterative Pairwise Word Alignment using Dynamic Programming

With the help of semantic substitution matrix $M_{u,v}$ which measures pairwise word similarity, we need to find the optimal word alignment to compress references into a lattice.

Unfortunately, this computation is exponential in the number of sequences. Thus, we use iterative pairwise alignment which greedily merges sentence pairs (Durbin et al., 1998).

Based on pairwise substitution matrix we can define an optimal pairwise sequence alignment as an optimal path from $M_{0,0}$ to $M_{|\mathbf{y}_i|,|\mathbf{y}_j|}$. This is a dynamic programming problem with the state transition function described in Equation (3). Fig. 5 shows the optimal path according to the semantic substitution matrix in Fig. 4. There is a gap if the continuous step goes vertical or horizontal, and an alignment if it goes diagonal.

$$opt(u,v) = \begin{cases} opt(u-1,v-1)+M_{u,v} \\ opt(u-1,v) \\ opt(u,v-1) \end{cases} \quad (3)$$

What order should we follow to do the iterative pairwise word alignment? Intuitively, we need to compress the most similar reference pair first, since this compression will lead to more aligned words. Following this intuition, we order reference pairs by the maximum alignment score $opt(|\mathbf{y}_i|,|\mathbf{y}_j|)$ (i.e. the score of bottom-right cell in Fig. 5) which is the sum of all aligned words. Using this order, we can iteratively merge each sentence pair in descending order, unless both the sentences have already been merged (this will prevent generating a cyclic lattice).

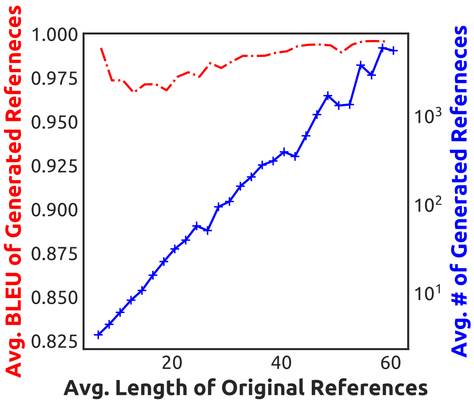
Since the semantic substitution matrix $M_{u,v}$, defined as a normalized cosine similarity, scales in $(0, 1)$, it's very likely for the DP algorithm to align unrelated words. To tackle this problem, we deduct a global penalty p from each cell of $M_{u,v}$. With the global penalty p, the DP algorithm will not align a word pair $(\mathbf{y}_{i,u}, \mathbf{y}_{i,v})$ unless $M_{u,v} \geq p$.

After the pairwise references alignment, we merge those aligned words. For example, in Fig. 1, after we generate an initial lattice as shown in Fig. 1(a), we then calculate the maximum alignment score of all sentence pairs. After that, the lattice turns into Fig. 1(d) by merging the first two references (assuming they have the highest score) according to pairwise alignment shown in Fig. 5. Then we pick the sentence pair with next highest alignment score (assuming it's the last two sentences). Similar to the previous step, we find alignments according to the dynamic programming and merge to the final lattice (see Fig. 1(e)).

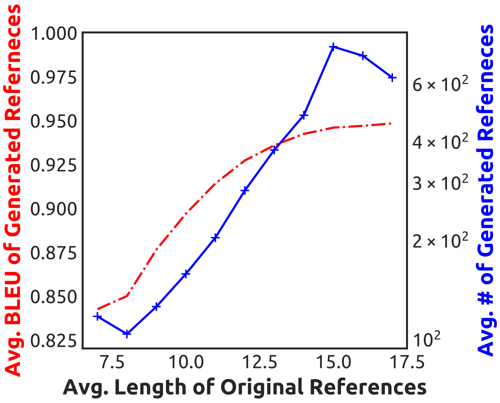
3.4 Traverse Lattice and Pseudo-References Selection by BLEU

We generate pseudo-references by simply traversing the generated lattice. For example, if we traverse the final lattice shown in Fig. 1(e), we can generate 213 pseudo-refrences in total.

Then, we can put those generated pseudo-references to expand the training dataset. To balance the number of generated pseudo-references for each example, we force the total number of pseudo-references from each example to be



(a) Machine Translation Dataset



(b) Image Captioning Dataset

Figure 6: Analysis of generated references

K'. For those examples generating k pseudo-references and $k > K'$, we calculate all pseudo-references' BLEU scores based on gold references, and only keep top $K' - k$ pseudo-references with highest BLEU score.

4 Experiments

To investigate the empirical performances of our proposed algorithm, we conduct experiments on machine translation and image captioning.

4.1 Machine Translation

We evaluate our approach on NIST Chinese-to-English translation dataset which consists of 1M pairs of single reference data and 5974 pairs of 4 reference data (NIST 2002, 2003, 2004, 2005, 2006, 2008). Table 1 shows the statistics of this dataset. We first pre-train our model on a 1M pairs single reference dataset and then train on the NIST 2002, 2003, 2004, 2005. We use the NIST 2006 dataset as validation set and NIST 2008 as test sets.

Fig. 6(a) analyzes the number and quality of generated references using our proposed approach. We set the global penalty as 0.9 and only calculate the top 50 generated references for the average BLEU analysis. From the figure, we can see that when the sentence length grows, the number of generated references grows exponentially. To generate enough references for the following experiments, we set an initial global penalty as 0.9 and gradually decrease it by 0.05 until we collect no less than 100 references. We train a bidirectional language model on the pre-training dataset and training dataset with Glove (Pennington et al., 2014) word embedding size of 300 dimension, for 20 epochs to minimize the perplexity

We employ byte-pair encoding (BPE) (Sennrich et al., 2015) which reduces the source and target language vocabulary sizes to 18k and 10k. We adopt length reward (Huang et al., 2017) to find optimal sentence length. We use a two layer bidirectional LSTM as the encoder and a two layer LSTM as the decoder. We perform pre-training for 20 epochs to minimize perplexity on the 1M dataset, with a batch size of 64, word embedding size of 500, beam size of 15, learning rate of 0.1, learning rate decay of 0.5 and dropout rate of 0.3. We then train the model in 30 epochs and use the best batch size among 100, 200, 400 for each update method. These batch sizes are multiple of the number of references used in experiments, so it is guaranteed that all the references of one single example are in one batch for the Uniform method. The learning rate is set as 0.01 and learning rate decay as 0.75. We do each experiment three times and report the average result.

Table 2 shows the translation quality on the dev-set of machine translation task. Besides the original 4 references in the training set, we generate another four dataset with 10, 20, 50 and 100 references including pseudo-references using hard word alignment and soft word alignment. We compare the three update methods (Sample One, Uniform, Shuffle) with always using the first reference (First). All results of soft word alignment are better than corresponding hard word alignment results and the best result is achieved with 50 references using Uniform and soft word alignment. According to Table 3, Shuffle with original 4 references has +0.7 BLEU improvement and Uniform

with 50 references has +1.5 BLEU improvement. From Fig. 7(b), we can see that using the Sample One method, the translation quality drops dramatically with more than 10 references. This may be due to the higher variance of used reference in each epoch.

4.2 Image Captioning

For the image captioning task, we use the widely-used MSCOCO image captioning dataset. Following prior work, we use the Kapathy split (Karpathy and Fei-Fei, 2015). Table 1 shows the statistics of this dataset. We use Resnet (He et al., 2016) to extract image feature of 2048 feature size and simple fully connected layer of size 512 to an LSTM decoder. We train every model for 100 epochs and calculate the BLEU score on validation set and select the best model. For every update method, we find the optimal batch size among 50, 250, 500, 1000 and we use a beam size of 5.

Fig. 6(b) analyzes the correlation between average references length with the number and quality of generated references. We set global penalty as 0.6 (which is also adopted for the generated references in the following experiments) and calculate the top 50 generated references for the average BLEU analysis. Since the length of original references is much shorter than the previous machine translation dataset, it has worse quality and fewer generated references.

Table 4 shows that the best result is achieved with 20 references using Shuffle. This result is

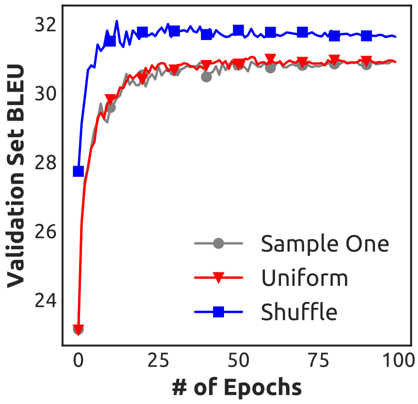
(b) MT with different number of references

Figure 7: Translation quality of machine translation task on dev-set with soft alignment

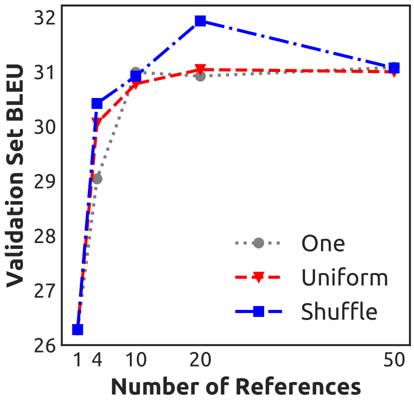
different from the result of machine translation task where Uniform method is the best. This may be because the references in image captioning dataset are much more diverse than those in machine translation dataset. Different captions of one image could even talk about different aspects. When using the Uniform method, the high variance of references in one batch may harm the model and lead to worse text generation quality. Table 5 shows that it outperforms Sample One with 4 original references, which is adopted in previous work (Karpathy and Fei-Fei, 2015), +3.1 BLEU score and +11.7 CIDEr.

4.3 Case Study

Fig. 6 shows a training example in the COCO dataset and its corresponding generated lattice and pseudo-references which is sorted according to its BLEU score. Our proposed algorithm generates 73724 pseudo-references in total. All the top 50 pseudo-references' BLEU scores are above 97.1 and the top three even achieve 100.0 BLEU score though they are not identical to any original references. Although the BLEU of last two sentences is 0.0, they are still valid to describe this picture.



(a) Learning curve of different methods with 20 References



(b) Image captioning with different number of references

Figure 8: Text generation quality of image captioning task on validation set with soft alignment

5 Conclusions

We introduce several multiple-reference training methods and a neural-based lattice compression framework, which can generate more training references based on existing ones. Our proposed framework outperforms the baseline models on both MT and image captioning tasks.

Abstract

The rapid development of knowledge graphs (KGs), such as Freebase and WordNet, has changed the paradigm for AI-related applications. However, even though these KGs are impressively large, most of them are suffering from incompleteness, which leads to performance degradation of AI applications. Most existing researches are focusing on knowledge graph embedding (KGE) models. Nevertheless, those models simply embed entities and relations into latent vectors without leveraging the rich information from the relation structure. Indeed, relations in KGs conform to a three-layer hierarchical relation structure (HRS), i.e., semantically similar relations can make up relation clusters and some relations can be further split into several fine-grained sub-relations. Relation clusters, relations and sub-relations can fit in the top, the middle and the bottom layer of three-layer HRS respectively. To this end, in this paper, we extend existing KGE models TransE, TransH and DistMult, to learn knowledge representations by leveraging the information from the HRS. Particularly, our approach is capable to extend other KGE models. Finally, the experiment results clearly validate the effectiveness of the proposed approach against baselines.

1 Introduction

Knowledge Graphs (KGs) are extremely useful resources for many AI-related applications, such as question answering, information retrieval and query expansion. Indeed, KGs are multi-relational directed graphs composed of entities as nodes and relations as edges. They represent information about real-world entities and relations in the form of knowledge triples, which is denoted as (h, r, t), where h and t correspond to the head and tail entities and r denotes the relation between them, e.g., $(Donald\ Trump, presidentOf, USA)$. Large scale, collaboratively created KGs , such as Freebase (Bollacker et al., 2008), WordNet (Miller, 1994), Yago (Suchanek et al., 2007), Gene Ontology (Sherlock, 2009), NELL (Carlson et al., 2010) and Google's KG[1], have recently become available. However, despite the impressively large sizes, the coverage of most existing KGs are far from complete. This has motivated research in knowledge base completion task, which includes KGE methods aiming to embed entities and relations in KGs into low-dimensional embeddings.

In the literature, there are a number of studies about KGE models. These models embed entities and relations into latent vectors and complete KGs based on these vectors, such as TransE (Bordes et al., 2013), TransH (Wang et al., 2014) and TransR (Lin et al., 2015b). However, most of the existing works simply embed relations into vectors. Less efforts have been made for investigating the rich information from the relation structure. Indeed, in this research, we define a three-layer hierarchical relation structure (HRS), which can be conformed by relation clusters, relations and sub-relations in KGs.

- **Relation clusters**: Semantically similar relations are often observed in Large-scales KGs. For example, the relation *'producerOf'* and *'directorOf'* may be semantically related if both of them describe a relation between a person and a film. These semantically similar relations can make up relation clusters. We believe the information from semantically similar relations is of great value, and relations in the same group can be trained in a collective way to facilitate the knowledge sharing when learning the embeddings of related relations.

- **Relations**: A relation connects the head and

---

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3198–3207
Brussels, Belgium, October 31 - November 4, 2018.

tail entities in a knowledge triple, denoted as (h, r, t), where h and t correspond to the head and tail entities and r denotes the relation between them.

- **Sub-relations**: There are relations that have multiple semantic meanings and can be split into several sub-relations. For example, the relation $partOf$ has at least two semantics: location-related as $(New\ York$, $partOf$, $USA)$ and composition-related as $(monitor$, $partOf$, $television)$. We believe the sub-relations can give fine-grained descriptions for each relation.

The relation clusters, relations and sub-relations correspond to the top, middle and bottom layer of the three-layer HRS.

In this paper, we extend state-of-the-art models TransE (Bordes et al., 2013), TransH (Wang et al., 2014) and DistMult (Yang et al., 2015) to learn knowledge representations by leveraging the rich information from the HRS. Moreover, the same technique can easily be used to extend other state-of-the-art models and utilize the HRS information. In the proposed models, for each knowledge triple (h, r, t), the embedding of r is the sum of three embedding vectors, which correspond to the three layers of the HRS respectively and therefore, the information from the HRS is leveraged. Particularly, instead of using additional information like text or paths, our model simply use the knowledge triples in KGs and the rich information from the HRS. Extensive experiments on popular benchmark data sets demonstrate the effectiveness of our models.

In summary, we highlight our key contributions as follows,

1. We propose a technique by making use of the HRS information to conduct the KGE task, and extend three state-of-the-art models to utilize this technique. The technique can be easily applied to other KGE models.

2. Our proposed models don't use additional information like text or paths, instead, we only use the knowledge triples in KGs and take advantage of the rich information from the HRS.

3. We evaluate our models on popular benchmark data sets, and the results show that our extended models achieve substantial improvements against the original models as well as other state-of-the-art baselines.

2 Preliminaries and Related Work

We extend three popular KGE models by leveraging the HRS information in this study. Therefore, in this section, we first introduce the three existing models TransE (Bordes et al., 2013), TransH (Wang et al., 2014) and DistMult (Yang et al., 2015) in detail. Then, we further summarize other state-of-the-art models on the topic of KGE.

2.1 TransE, TransH and DistMult

Recently, a number of KGE models have been proposed. These methods learn low-dimensional vector representations for entities and relations (Bordes et al., 2013; Wang et al., 2014; Lin et al., 2015b).

TransE (Bordes et al., 2013) is one of the most widely used model, which views relations as translations from a head entity to a tail entity on the same low-dimensional hyperplane, i.e, $\mathbf{h} + \mathbf{r} \approx \mathbf{t}$ when (h, r, t) holds. This indicates that $\mathbf{t}$ should be the nearest neighbor of $\mathbf{h} + \mathbf{r}$. In this case, the score function of TransE is defined as

$$f_r(h, t) = \|\mathbf{h} + \mathbf{r} - \mathbf{t}\|_{L_n}, \quad (1)$$

which can be measured by L_1 or L_2 norm. Positive triples are supposed to have lower scores than negative ones.

TransH (Wang et al., 2014) introduces a mechanism of projecting entities into relation-specific hyperplanes that enables different roles of an entity in different relations. TransH models the relation as a vector $\mathbf{r}$ on a hyperplane $\mathbf{w}_r$ and assumes that $\mathbf{h}_\perp + \mathbf{r} \approx \mathbf{t}_\perp$ when (h, r, t) holds, where $\mathbf{h}_\perp$ and $\mathbf{t}_\perp$ are the projection of $\mathbf{h}$ and $\mathbf{t}$ in the relation-specific hyperplane. The score function of TransH is defined as

$$f_r(h, t) = \|\mathbf{h}_\perp + \mathbf{r} - \mathbf{t}_\perp\|_2^2, \quad (2)$$

where $\mathbf{h}_\perp = \mathbf{h} - \mathbf{w}_r^\top \mathbf{h} \mathbf{w}_r$, $\mathbf{t}_\perp = \mathbf{t} - \mathbf{w}_r^\top \mathbf{t} \mathbf{w}_r$ and $\|\mathbf{w}_r\|_2 = 1$. Like triples in TransE, positive triples in TransH should have lower scores than negative ones.

DistMult (Yang et al., 2015) adopts a bilinear score function to compute the scores given (h, r, t) triples. The score function is defined as

$$f_r(h, t) = \mathbf{h}\mathbf{M}_r\mathbf{t}, \quad (3)$$

where $\mathbf{M}_r$ is a relation-specific diagonal matrix, which represents the characteristics of a relation. Different from TransE and TransH, positive triples should have larger scores than negative ones.

2.2 Other KGE Models

Besides TransE, TransH and DistMult, there are also many models on the topic of KGE. TransR (Lin et al., 2015b) embeds entities and relations into separate entity space and relation-specific spaces. ComplEx (Welbl et al., 2016) extends DistMult to embed entities and relations into complex vectors instead of real-valued ones. HolE (Nickel et al., 2016) employs circular correlations to create compositional representations. ProjE (Shi and Weninger, 2017) adopts a two-layer network to embed entities and relations. Other KGE models also try to embeds entities and relations in various ways, such as Unstructured Model (Bordes et al., 2012a, 2014), Structured Embedding (Bordes et al., 2012b), Single Layer Model (Socher et al., 2013), Semantic Matching Energy (Bordes et al., 2012a, 2014), NTN Model (Socher et al., 2013), etc.

Many efforts have been devoted to building models using additional information like paths or text. For instance, PTransE (Lin et al., 2015a) and R-GCN (Schlichtkrull et al., 2017) use paths as additional information, while DKRL (Xie et al., 2016) and SSP (Xiao et al., 2017) adopt text to assist the embedding task.

Some KGE works focus on making use of the information from relations. CTransR (Lin et al., 2015b), TransD (Ji et al., 2015) and TransG (Xiao et al., 2016) try to find fine-grained representations for each relation. However, these works didn't utilize the information from semantically similar relations and the HRS is also not exploited. Different from the above studies, we believe semantically similar relations can make up relation clusters, and some relations may have multiple semantic meanings and can be split into fine-grained sub-relations. In this paper, we take advantage of the three-layer HRS and conduct the KGE task by extending three widely used models.

3 Methodology

In this section, we provide the technical details of how to extend existing KGE models by leveraging the HRS information. We first formally define the HRS and its integration with existing models.Then we introduce the new loss functions of extended models TransE-HRS, TransH-HRS and DistMult-HRS. Finally, two variants of the HRS models and implementation details are provided.

3.1 Hierarchical Relation Structure

Given a KG $\mathcal{G} = \{(h, r, t)\} \subseteq \mathcal{E} \times \mathcal{R} \times \mathcal{E}$, where $\mathcal{E}$ and $\mathcal{R}$ are the entity (node) set and relation (edge) set respectively. We believe the relations in KGs can make up relation clusters as well as be split into fine-grained sub-relations. On the one hand, large scale KGs always have semantically related relations. The information from semantically similar relations is of great value and these relations should be trained in a collective way. In this way, meaningful associations among related relations can be utilized and less frequent relations can be enriched with more training data. On the other hand, some relations may have multiple semantic meanings and can be split into several sub-relations, which can provide fine-grained descriptions for each relation. In general, relations in KGs conform to a three-layer HRS, as shown in Figure 1. The HRS include a relation cluster layer, a relation layer and a sub-relation layer, which are denoted in yellow, green and blue in Figure 1 respectively.

For a triple (h, r, t) in the HRS model, the embedding of r is comprised of three parts: the relation cluster embedding $\mathbf{r}_c$, relation-specific embedding $\mathbf{r}'$ and sub-relation embedding $\mathbf{r}_s$, which is denotes as

$$\mathbf{r} = \mathbf{r}_c + \mathbf{r}' + \mathbf{r}_s. \tag{4}$$

According to the above equation, the embedding of each relation can leverage the information from the three-layer HRS. The relation clusters and sub-relations are determined by k-means algorithm based on the results of TransE:

- **Relation clusters**. We first run TransE on a given data set and obtain the embeddings of relations $\mathbf{r}_1$, $\mathbf{r}_2$, $\mathbf{r}_3$, ..., $\mathbf{r}_{|\mathcal{R}|}$, where $|\mathcal{R}|$ is the number of relations. Then, the k-means algorithm is applied on these embeddings. In this way, we get relation clusters $\mathcal{C}_1$, $\mathcal{C}_2$, $\mathcal{C}_3$, ..., $\mathcal{C}_{|\mathcal{C}|}$, where $\mathcal{C}$ is the set of relation clusters. Previous studies have shown that the embeddings of semantically similar relations locate near each other in the latent space (Yang et al., 2015). In this way, we are able to find relation clusters composed of semantically related relations.

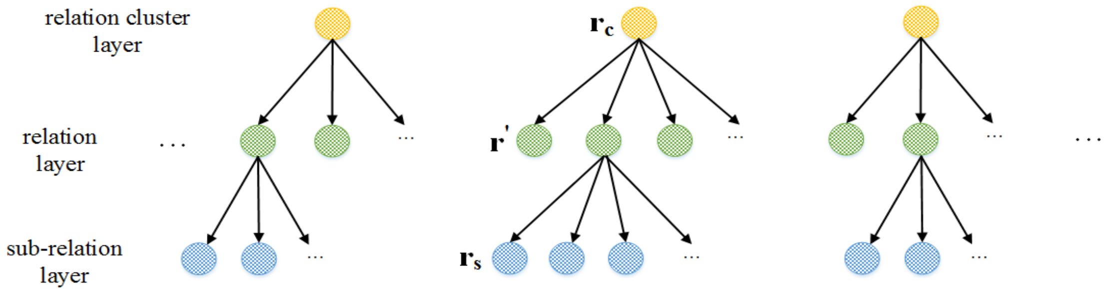

Figure 1: Hierarchical Relation Structure

- **Sub-relations**. TransE assumes that $\mathbf{t} - \mathbf{h} \approx \mathbf{r}$ when (h, r, t) holds. For each triple (h, r, t), we define that $\widehat{\mathbf{r}} = \mathbf{t} - \mathbf{h}$, where $\mathbf{h}$ and $\mathbf{t}$ are obtained from the results of TransE. For each relation, we collect all the $\widehat{\mathbf{r}}$ and adopt the k-means algorithm to cluster these vectors into several groups $\mathcal{S}_1^r$, $\mathcal{S}_2^r$, $\mathcal{S}_3^r$, ..., $\mathcal{S}_{n_r}^r$, where n_r is the number of sub-relations for relation r. Each group corresponds to a fine-grained sub-relation.

3.2 Loss Function

The loss of the extended HRS model is comprised of two parts, as is shown in Equation (5),

$$L_{Total} = L_{Orig} + L_{HRS}, \tag{5}$$

where L_{Orig} is the loss function of the original model, while L_{HRS} is the loss function for the HRS information.

We know that TransE, TransH and DistMult all adopt a margin-based ranking loss. Taking TransE as an example, the loss function of TransE for the first part L_{Orig} is shown as Equation (6),

$$L_{Orig} = \sum_{c=1}^{|\mathcal{C}|} \sum_{r \in \mathcal{C}_c} \sum_{(h,r,t) \in \triangle_r} \sum_{(h',r,t') \in \triangle'_r} [\gamma + f_r(h,t) - f_r(h',t')]_+, \tag{6}$$

where $[x]_+ = max(0, x)$, $\triangle_r$ denotes the set of positive triples for relation r and $\triangle'_r = \{(h', r, t) | h' \in \mathcal{E}\} \cup \{(h, r, t') | t' \in \mathcal{E}\}$ is the set of negative ones for relation r. γ is the margin separating the positive triples from the negative ones. $f_r(h, t)$ is the score function as shown in Equation (7),

$$f_r(h,t) = \left\| \mathbf{h} + \mathbf{r}_c + \mathbf{r}' + \mathbf{r}_s - \mathbf{t} \right\|_{L_n}, \tag{7}$$

which can be measured by L_1 or L_2 norm. Positive triples are supposed to have lower scores than negative ones.

The second part, L_{HRS}, is composed of three regularized terms, which is shown in Equation (8),

$$L_{HRS} = \lambda_1 \sum_{\mathbf{r}_c \in \mathcal{C}} \|\mathbf{r}_c\|_2^2 + \lambda_2 \sum_{\mathbf{r}' \in \mathcal{R}} \|\mathbf{r}'\|_2^2 + \lambda_3 \sum_{\mathbf{r}_s \in \mathcal{S}} \|\mathbf{r}_s\|_2^2, \tag{8}$$

where $\mathcal{C} = \{\mathcal{C}_1, \mathcal{C}_2, ..., \mathcal{C}_{|\mathcal{C}|}\}$ is the set of relation clusters, $\mathcal{S} = \{\mathcal{S}_1^r, \mathcal{S}_2^r, \mathcal{S}_3^r, ..., \mathcal{S}_{n_r}^r | r \in \mathcal{R}\}$ is the set of fine-grained sub-relations, n_r is the number of sub-relations for relation r. λ_1, λ_2 and λ_3 are trade-off parameters. Large value of λ_1 will result in the separate training of each relation, while large value of λ_2 will lead to all relations in the same relation cluster sharing the same embedding vector. λ_3 should be larger than λ_1 and λ_2 to restrict $\mathbf{r}_s$ to be a small value, i.e., the sub-relations from the same relation should be close.

3.3 Variants of the HRS Model and Implementation details

Additionally, we introduce two variants of the HRS model: the top-middle model and the middle-bottom model. The top-middle model only uses the HRS by leveraging the information from the top to the middle layer. For this model, the relation embedding and the loss for HRS is defined as Equation (9) and (10).

$$\mathbf{r} = \mathbf{r}_c + \mathbf{r}', \tag{9}$$

$$L_{HRS} = \lambda_1 \sum_{\mathbf{r}_c \in \mathcal{C}} \|\mathbf{r}_c\|_2^2 + \lambda_2 \sum_{\mathbf{r}' \in \mathcal{R}} \|\mathbf{r}'\|_2^2. \tag{10}$$

While the middle-bottom model only utilizes the information from the middle to the bottom layer. The relation embedding and HRS loss are defined as Equation (11) and (12).

$$\mathbf{r} = \mathbf{r}' + \mathbf{r}_s, \tag{11}$$

$$L_{HRS} = \lambda_2 \sum_{\mathbf{r}' \in \mathcal{R}} \|\mathbf{r}'\|_2^2 + \lambda_3 \sum_{\mathbf{r}_s \in \mathcal{S}} \|\mathbf{r}_s\|_2^2 . \quad (12)$$

The learning process of the extended models is carried out by using the Adam (Kingma and Ba, 2014) optimizer. For the extended models of TransE, all the entity and relation embedding parameters are initialized with a uniform distribution $U\left[-\frac{6}{\sqrt{k}}, \frac{6}{\sqrt{k}}\right]$ following TransE, where k is the dimension of the embedding space. For the extended models of TransH and DistMult, we initialize these parameters with the results of TransE. For the relation cluster embeddings and sub-relation embeddings, we initialize all the parameters with the value of zero.

4 Experiments

4.1 Data Sets

In this research, we evaluate the performances of our extended models on popular benchmarks FB15k (Bordes et al., 2013), FB15k-237 (Toutanova and Chen, 2015), FB13(Socher et al., 2013), WN18 (Bordes et al., 2013) and WN11 (Socher et al., 2013). FB15k, FB15k-237 and FB13 are extracted from Freebase (Bollacker et al., 2008), which provides general facts of the world. WN18 and WN11 are obtained from WordNet (Miller, 1994), which provides semantic knowledge of words. FB15k-237 and WN18 are used for the task of link prediction, FB13 and WN11 are used for the triple classification task, while FB15k is used for both tasks. The statistics of the five data sets are summarized in Table 1.

Table 1: Statistics of the Five Datasets.

Dataset	$\|\mathcal{E}\|$	$\|\mathcal{R}\|$	#triples in Train/Valid/Test
FB15k	14,951	1,345	483,142 / 50,000 / 59,071
FB15k-237	14,541	237	272,115 / 17,535 / 20,466
FB13	75,043	13	316,232 / 5,908 / 23,733
WN18	40,943	18	141,442 / 5,000 / 5,000
WN11	38,696	11	112,581 / 2,609 / 10,544

4.2 Baselines

To demonstrate the effectiveness of our models, we compare results with the following baselines.

- TransE (Bordes et al., 2013): one of the most widely used KGE models.
- TransH (Wang et al., 2014): a KGE model which adopts relation-specific hyperplanes to lay entities and relations.
- DistMult (Yang et al., 2015): a state of the art model which uses a bilinear score function to compute scores of knowledge triples.
- CTransR (Lin et al., 2015b): a pioneering KGE model which exploits fine-grained sub-relations for each relation.
- TransD (Ji et al., 2015): an improvement of CTransR, which embeds KGs using dynamic mapping matrices.
- TransG (Xiao et al., 2016): the first generative KGE model that uses a non-parametric bayesian model to embed KGs.

4.3 Link Prediction

Link prediction, a.k.a. knowledge graph completion, aims to fill the missing values into incomplete knowledge triples. More formally, the goal of link prediction is to predict either the head entity in a given query $(?, r, t)$ or the tail entity in a given query $(h, r, ?)$.

4.3.1 Experimental Settings

All the parameters are set by some preliminary test. For TransE-HRS, TransE-top-middle and TransE-middle-bottom, λ_1, λ_2, λ_3 and the margin γ are set as $\lambda_1 = 1e-5, \lambda_2 = 1e-4, \lambda_3 = 1e-3, \gamma = 2$. For the extended models of TransH, we set the parameters as $\lambda_1 = 1e-5, \lambda_2 = 1e-5, \lambda_3 = 1e-3, \gamma = 1$. For the extended models of DistMult, the parameters are set as $\lambda_1 = 1e-5, \lambda_2 = 1e-4, \lambda_3 = 1e-3, \gamma = 1$. For all the above models, the learning rate ς, batch size b and embedding size k are set as $\varsigma = 1e-3, b = 4096, k = 100$. The L_1 norm is adopted by the score function of TransE and its extended models. The number of relation clusters are set as 300, 120 and 10 for FB15k, FB15k-237 and WN18 respectively. For all the data sets, we generate 3 sub-relations for relations that have more than 500 occurrences in the training set. For all the extended models and baselines, we produce negative triples following the "bern" sampling strategy which was introduced in TransH (Wang et al., 2014). For baselines TransE, TransH and DistMult, the embedding parameters of entities and relations are initialized the same way as the extended models for a fair comparison.

In the test phase, we replace the head and tail entities with all the entities in KG in turn for each triple in the test set. Then we compute a score for each corrupted triple. Note that for each corrupted triple (h', r, t'), the sub-relation is determined by $\mathbf{t}' - \mathbf{h}'$, i.e., the k-means model is adopted to assign $\mathbf{t}' - \mathbf{h}'$ to a specific sub-relation of r. We rank all the candidate entities according to the scores. Specifically, positive candidates are supposed to precede negative ones. Finally, the rank of the correct entity is stored. We compare our models with baselines using the following metrics: (1) Mean Rank (MR, the mean of all the predicted ranks); (2) Mean Reciprocal Rank (MRR, the mean of all the reciprocals of predicted ranks); (3) Hits@n (Hn, the proportion of ranks not larger than n). Lower values of MR and larger values of MRR and Hn indicate better performance. All the results are reported in the "filtered" setting (Bordes et al., 2013).

4.3.2 Experimental Results

Evaluation results are shown in Table 2. We divide all the results into 4 groups. The second, third and forth group are results of TransE, TransH, DistMult and their extended models respectively, while the first group are results of other state-of-the-art competitors. Results in bold font are the best results in the group and the underlined results denote the best results in the column. From Table 1, we have the following findings: (1) Our extended models outperform the original models, which indicates that the information learned from the HRS is valuable; (2) For WN18, the results from 'top-middle' models of TransE, TransH and DistMult are worse than the original models, and HRS models can't outperform middle-bottom ones. We conjecture the reason lies as follows: WN18 has only 18 relations and the semantic correlation among relations is small. In this case, the information learned from the top to the middle layer of the HRS may lead to worse results since for each relation, even though the information learned from semantically similar relations are useful, the information learned from unrelated relations may damage the results. The results indicate that HRS models are especially useful for KGs with dense semantic distributions over relations; (3) For WN18, TransE-middle-bottom and DistMult-middle-bottom achieve the best results on MRR, Hits@10, Hits@3 and Hits@1 while failing to get the best results on MR in the same group. Further analysis shows that in the results of TransE-middle-bottom, 56 test triples get ranks more than 10000, leading to more than 110 MR loss. While in the results of DistMult-middle-bottom, there exist 37 test triples whose ranks are more than 7000, which would lead to about 50 MR loss. Indeed, MR is sensitive to these high ranks, which lead to worse results on the metric of MR; (4) From all the results, based on the good basic model DistMult, the extended models of DistMult can achieve the best performance compared with other state-of-the-art baselines CTransR, TransD and TransG.

We also provide some case studies on relation clusters and sub-relations. Table 3 shows some relation clusters of FB15k. Cluster 1 to 3 are Olympics-related, basketball-related and software-related relations respectively. From Table 3 we can see that semantically related relations can join the same cluster. Table 4 shows some (head, tail) pairs for the sub-relations of *'/educational_institution/education/degree'*. Sub-relation 1 to 3 are about the degree of Doctor, Master and Bachelor respectively. Table 5 gives some (head, tail) pairs for the sub-relations of *'/music/artist/genre'*. Sub-relation 1 and 2 are about rock music and pop music respectively while sub-cluster 3 is about other kinds of music. From Table 4 and 5, we can see that different sub-relations give fine-grained descriptions for each relation.

4.3.3 Parameter Study

In this section, we study the performance affected by the number of relation clusters $\mathcal{N}_1$ as well as the number of sub-relations for each relation $\mathcal{N}_2$. The results in Figure 2 and 3 clearly show that there exists an optimal value of $\mathcal{N}_1$ and $\mathcal{N}_2$ for each dataset. All three models keep achieving better results as we increase the number of clusters from 0 to the optimal value. Then, after $\mathcal{N}_1$ and $\mathcal{N}_2$ exceed the optimal point, the performance starts falling down. The reason lies as: (1) Smaller value of $\mathcal{N}_1$ leads to large-sized relation clusters. Some unrelated relations may join in the same large-sized cluster and degrade the performance of our models. Larger value of $\mathcal{N}_1$ leads to small-sized relation clusters, thus less information can be leveraged by each relation, leading to the unsatisfying performance; (2) Smaller value of $\mathcal{N}_2$ can't provide sufficient representations for each relation and degrade the performance of our models. Larger value of $\mathcal{N}_2$ may lead to lacking of training data for each sub-relation and also result in the unsatisfying performance.

Table 2: Link prediction results on FB15k, FB15k-237 and WN18. We implement TransE, TransH, DistMult and their extended models by ourselves. The code of CTransR, TransD and TransG are taken from https://github.com/thunlp/TensorFlow-TransX, https://github.com/thunlp/KB2E and https://github.com/BookmanHan/Embedding respectively.

4.4 Triple Classification

In order to testify the discriminative capability of our models, we conduct a triple classification task aiming to predict the label (True or False) of a given triple (h, r, t).

4.4.1 Experimental Settings

In this paper, we use three datasets WN11, FB13 and FB15k to evaluate our models. The data sets WN11 and FB13 released by NTN (Socher et al., 2013) already have negative triples. The test set of FB15k only contains correct triples, which requires us to construct negative triples. In this study, we construct negative triples following the same setting used for FB13 (Socher et al., 2013). For the extended models of TransE, λ_1, λ_2, λ_3 and γ are set as $\lambda_1 = 1e-5$, $\lambda_2 = 1e-5$, $\lambda_3 = 1e-3$ and $\gamma = 4$. For the extended models of TransH, we set $\lambda_1 = 1e-5$, $\lambda_2 = 1e-4$, $\lambda_3 = 1e-3$ and $\gamma = 5$. While for the extended models of DistMult, parameters are set as $\lambda_1 = 1e-5$, $\lambda_2 = 1e-4$, $\lambda_3 = 1e-2$ and $\gamma = 4$. For WN11 and FB13, we generate 2 sub-relations for each relation. For FB15k, we generate 3 sub-relations for

Figure 3: The Change of Hits@10 with The Value of $\mathcal{N}_2$ Increasing.

relations that have more than 500 occurrences in the training set. Other parameters are set as introduced in Section 4.3.1. We follow the same decision process as NTN (Socher et al., 2013): for TransE and TransH, a triple is predicted to be positive if $f_r(h,t)$ is below a threshold, while for DistMult, a triple is regarded as a positive one if $f_r(h,t)$ is above a threshold; otherwise negative. The thresholds are determined on the validation set. We adopt accuracy as our evaluation metric.

4.4.2 Experimental Results

Finally, the evaluation results in Table 6 lead to the following findings: (1) Our models outperform other baselines on WN11 and FB15k, and obtain comparable results with baselines on FB13, which validate the effectiveness of our models; (2) The extended models TransE-HRS, TransH-HRS and DistMult-HRS achieve substantial improvements against the original models. On WN11, TransE-HRS outperforms TransE with a margin as large as 10.9%. These improvements indicates the technique of utilizing the HRS information is capable to be extended to different KGE models. Figure 4

Table 6: Triple Classification Results. The results of baselines on WN11 and FB13 are directly taken from the original paper except DistMult. We obtain other results by ourselves.

Model	WN11	FB13	FB15k	Avg
CTransR	85.7	-	84.4	-
TransD	86.4	89.1	88.2	87.9
TransG	87.4	87.3	88.5	87.7
TransE	75.9	81.5	78.7	78.7
TransH	78.8	83.3	81.1	81.1
DistMult	87.1	86.2	86.3	86.5
TransE-HRS	86.8	88.4	87.6	87.6
TransH-HRS	**87.6**	88.9	**88.7**	**88.4**
DistMult-HRS	**88.9**	89.0	**89.1**	**89.0**

shows the classification accuracy of different relations on WN11. We can see that extended models significantly improve the original models in each relation classification task, which again validate the effectiveness of our models.

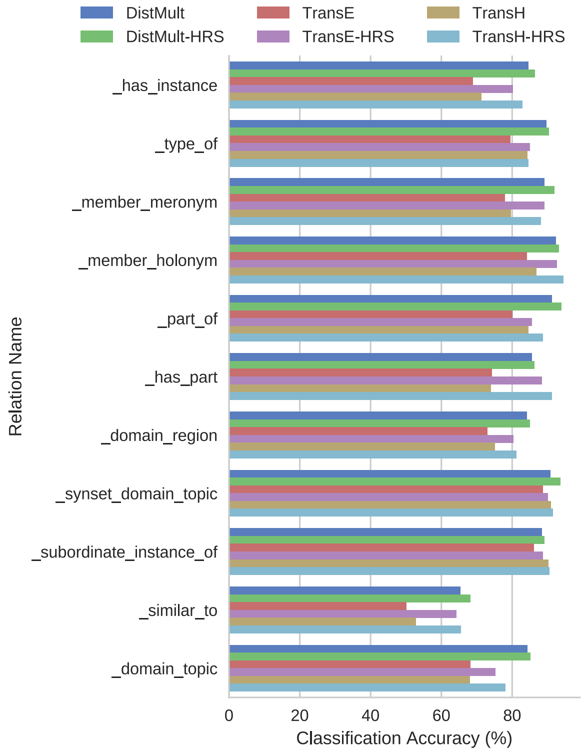

Figure 4: Classification Accuracies of Different Relations on WN11

5 Conclusion

In this paper, we found that relations in KGs conform to a three-layer HRS. This HRS model provides a critical capacity for embedding entities and relations, and along this line we extended three state-of-the-art models to leverage the HRS information. The technique we used can be easily applied to extend other KGE models. Moreover, our proposed models don't need additional information like text or paths, instead, we made full use of the knowledge triples in KGs and the rich information from the HRS. We evaluate our model on the link prediction task and triple classification task. The results show that our extended models achieve substantial improvements against the original models as well as other baseline competitors.

In the future, we will utilize more sophisticated models to leverage the HRS information, e.g, (1) utilize the embeddings of the three layers in a more sophisticated way instead of sum them together; (2) determine the number of relation clusters and sub-relations automatically instead of manually.

Abstract

Representing entities and relations in an embedding space is a well-studied approach for machine learning on relational data. Existing approaches, however, primarily focus on simple link structure between a finite set of entities, ignoring the variety of data types that are often used in knowledge bases, such as text, images, and numerical values. In this paper, we propose multimodal knowledge base embeddings (MKBE) that use different neural encoders for this variety of observed data, and combine them with existing relational models to learn embeddings of the entities and multimodal data. Further, using these learned embedings and different neural *decoders*, we introduce a novel multimodal imputation model to generate missing multimodal values, like text and images, from information in the knowledge base. We enrich existing relational datasets to create two novel benchmarks that contain additional information such as textual descriptions and images of the original entities. We demonstrate that our models utilize this additional information effectively to provide more accurate link prediction, achieving state-of-the-art results with a considerable gap of 5-7% over existing methods. Further, we evaluate the quality of our generated multimodal values via a user study. We have release the datasets and the open-source implementation of our models at https://github.com/pouyapez/mkbe.

1 Introduction

Knowledge bases (KB) are an essential part of many computational systems with applications in search, structured data management, recommendations, question answering, and information retrieval. However, KBs often suffer from incompleteness, noise in their entries, and inefficient inference under uncertainty. To address these issues, learning relational knowledge representations has been a focus of active research (Bordes et al., 2011, 2013; Yang et al., 2015; Nickel et al., 2016; Trouillon et al., 2016; Dettmers et al., 2018). These approaches represent relational triples, that consist of a subject entity, relation, and an object entity, by learning fixed, low-dimensional representations for each entity and relation from observations, encoding the uncertainty and inferring missing facts accurately and efficiently. The subject and the object entities come from a fixed, enumerable set of entities that appear in the knowledge base.

Knowledge bases in the real world, however, contain a wide variety of data types beyond these direct links. Apart from relations to a fixed set of entities, KBs often not only include numerical attributes (such as ages, dates, financial, and geoinformation), but also textual attributes (such as names, descriptions, and titles/designations) and images (profile photos, flags, posters, etc.). These different types of data can play a crucial role as extra pieces of evidence for knowledge base completion. For example the textual descriptions and images might provide evidence for a person's age, profession, and designation. In the multimodal KB shown in Figure 1 for example, the image can be helpful in predicting of Carles Puyol's occupation, while the description contains his nationality. Incorporating this information into existing approaches as entities, unfortunately, is challenging as they assign each entity a distinct vector and predict missing links (or attributes) by enumerating over the possible values, both of which are only possible if the entities come from a small, enumerable set. There is thus a crucial need for relational modeling that goes beyond just the link-based view of KB completion, by not only utilizing multimodal information for better link prediction between existing entities, but also being able to generate missing multimodal values.

In this paper, we introduce *multimodal knowl-*

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3208–3218
Brussels, Belgium, October 31 - November 4, 2018.

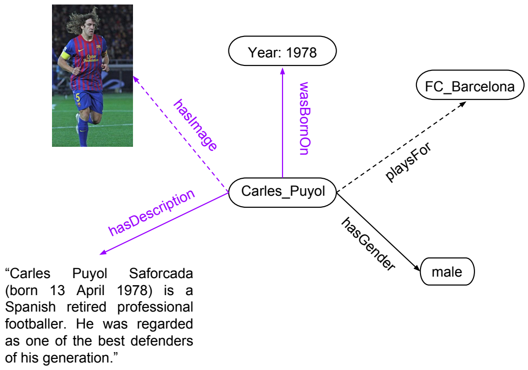

Figure 1: **Example of a Multimodal KB.** Graph representation of (a part of) a KB that consists of regular links (in black) and multimodal ones (in purple) that we support in this work.

edge base embeddings (MKBE) for modeling knowledge bases that contain a variety of data types, such as links, text, images, numerical, and categorical values. We propose neural encoders and decoders to replace initial layers of any embedding-based relational model; we apply them to DistMult (Yang et al., 2015) and ConvE (Dettmers et al., 2018) here. Specifically, instead of learning a distinct vector for each entity and using enumeration to predict links, MKBE includes the following extensions: (1) introduce additional neural encoders to embed multimodal evidence types that the relational model uses to predict links, and (2) introduce neural decoders that use an entity's embedding to generate its multimodal attributes (like image and text). For example, when the object of a triple is an image, we encode it into a fixed-length vector using a CNN, while textual objects are encoded using RNN-based sequence encoders. The scoring module remains identical to the underlying relational model; given the vector representations of the subject, relation, and object of a triple, we produce a score indicating the probability that the triple is correct using DistMult or ConvE. After learning the KB representation, neural decoders use entity embeddings to generate missing multimodal attributes, for example, generating the description of a person from their structured information in the KB. This unified framework allows for flow of the information across the different relation types (multimodal or otherwise), providing a more accurate modeling of relational data.

We provide an evaluation of our proposed approach on two relational KBs. Since we are introducing the multimodal KB completion setting, we provide two benchmarks, created by extending the existing YAGO-10 and MovieLens-100k datasets to include additional relations such as textual descriptions, numerical attributes, and images of the entities. We demonstrate that MKBE utilizes the additional information effectively to provide gains in link-prediction accuracy, achieving state-of-the-art results on these datasets for both the DistMult and the ConvE scoring functions. We evaluate the quality of multimodal attributes generated by the decoders via user studies that demonstrate their realism and information content, along with presenting examples of such generated text and images.

2 Multimodal KB Completion

As described earlier, KBs often contain different types of information about entities including links, textual descriptions, categorical attributes, numerical values, and images. In this section, we briefly introduce existing relational embedding approaches that focus on modeling the linked data using distinct, dense vectors. We then describe MKBE that extends these approaches to the multimodal setting, i.e., modeling the KB using all the different information to predict the missing links and impute the missing attributes.

2.1 Background on Link Prediction

Factual statements in a knowledge base are represented using a triple of subject, relation, and object, $\langle s, r, o\rangle$, where $s, o \in \xi$, a set of entities, and $r \in \mathcal{R}$, a set of relations. Respectively, we consider two goals for relational modeling, (1) to train a machine learning model that can score the *truth* value of any factual statement, and (2) to predict missing links between the entities. In existing approaches, a scoring function $\psi : \xi \times \mathcal{R} \times \xi \rightarrow \mathbb{R}$ (or sometimes, $[0, 1]$) is learned to evaluate whether any given fact is true, as per the model. For predicting links between the entities, since the set ξ is small enough to be enumerated, missing links of the form $\langle s, r, ?\rangle$ are identified by enumerating all the objects and scoring the triples using ψ (i.e. assume the resulting entity comes from a known set). For example, in Figure 1, the goal is to predict that Carles Puyol plays for Barcelona.

Many of the recent advances in link prediction use an embedding-based approach; each entity in ξ and relation in $\mathcal{R}$ are assigned distinct, dense vectors, which are then used by ψ to compute the score. In DistMult (Yang et al., 2015), for example, each entity i is mapped to a d-dimensional dense vector

($\mathbf{e}_i \in \mathbb{R}^d$) and each relation r to a diagonal matrix $\mathbf{R}_r \in \mathbb{R}^{d\times d}$, and consequently, the score for any triple $\langle s, r, o\rangle$ is computed as $\psi(s, r, o) = \mathbf{e}_s^T \mathbf{R}_r \mathbf{e}_o$. Along similar lines, ConvE (Dettmers et al., 2018) uses vectors to represent the entities and the relations, $\mathbf{e}_s, \mathbf{e}_o, \mathbf{r}_r \in \mathbb{R}^{d\times 1}$, then, after applying a CNN layer on $\mathbf{e}_s$ and $\mathbf{r}_r$, combines it with $\mathbf{e}_o$ to score a triplet, i.e. the scoring function $\psi(s, r, o)$ is $f(\text{vec}(f([\bar{\mathbf{e}_s}; \bar{\mathbf{r}_r} * w]))W)\mathbf{e}_o$. Other relational embedding approaches primarily vary in their design of the scoring function (Bordes et al., 2013; Yang et al., 2015; Nickel et al., 2016; Trouillon et al., 2016), but share the shortcoming of assigning distinct vectors to every entity, and assuming that the possible object entities can be enumerated. In this work we focus on DistMult because of its simplicity, popularity, and high accuracy, and ConvE because of its state-of-the-art results.

2.2 Problem Setup

When faced with additional triples in form of multimodal data, the setup of link prediction is slightly different. Consider a set of all potential multimodal objects, $\mathcal{M}$, i.e. possible images, text, numerical, and categorical values, and multimodal evidence triples, $\langle s, r, o\rangle$, where $s \in \xi$, $r \in \mathcal{R}$, and $o \in \mathcal{M}$. Our goals with incorporating multimodal information into KB remain the same: we want to be able to score the truth of any triple $\langle s, r, o\rangle$, where o is from ξ (link data) or from $\mathcal{M}$ (multimodal data), and to be able to predict missing value $\langle s, r, ?\rangle$ that may be from ξ or $\mathcal{M}$ (depending on r). For the example in Figure 1, in addition to predicting that Carles Puyol plays for Barcelona from multimodal evidence, we are also interested in generating an image for Carles Puyol, if it is missing.

Existing approaches to this problem assume that the subjects and the objects are from a fixed set of entities ξ, and thus are treated as indices into that set, which fails for the multimodal setting primarily for two reasons. First, learning distinct vectors for each object entity does not apply to multimodal values as they will ignore the actual content of the multimodal attribute. For example, there will be no way to generalize vectors learned during training to unseen values that might appear in the test; this is not a problem for the standard setup due to the assumption that all entities have been observed during training. Second, in order to predict a missing *multimodal* value, $\langle s, r, ?\rangle$, enumeration is not possible as the search space is potentially infinite (or at least intractable to search).

2.3 Multimodal KB Embeddings (MKBE)

To incorporate such multimodal *objects* into the existing relational models like DistMult and ConvE, we propose to learn embeddings for these types of data as well. We utilize recent advances in deep learning to construct *encoders* for these objects to represent them, essentially providing an embedding $\mathbf{e}_o$ for any object value.

The overall goal remains the same: the model needs to utilize all the observed subjects, objects, and relations, across different data types, in order to estimate whether any fact $\langle s, r, o\rangle$ holds. We present an example of an instantiation of MKBE for a knowledge base containing YAGO entities in Figure 2a. For any triple $\langle s, r, o\rangle$, we embed the subject (*Carles Puyol*) and the relation (such as playsFor, wasBornOn, or playsFor) using a direct lookup. For the object, depending on the domain (indexed, string, numerical, or image, respectively), we use approrpiate encoders to compute its embedding $\mathbf{e}_o$. As in DistMult and ConvE, these embeddings are used to compute the score of the triple.

Via these neural encoders, the model can use the information content of multimodal objects to predict missing links where the objects are from ξ, however, learning embeddings for objects in $\mathcal{M}$ is not sufficient to generate missing multimodal values, i.e. $\langle s, r, ?\rangle$ where the object is in $\mathcal{M}$. Consequently, we introduce a set of neural decoders $D : \xi \times \mathcal{R} \rightarrow \mathcal{M}$ that use entity embeddings to *generate* multimodal values. An outline of our model for imputing missing values is depicted in Figure 2b. We will describe these decoders in Section 2.5.

2.4 Encoding Multimodal Data

Here we describe the encoders we use for multimodal objects. A simple example of MKBE is provided in Figure 2a. As it shows, we use different encoder to embed each specific data type.

Structured Knowledge Consider a triplet of information in the form of $\langle s, r, o\rangle$. To represent the subject entity s and the relation r as independent embedding vectors (as in previous work), we pass their one-hot encoding through a dense layer. Furthermore, for the case that the object entity is categorical, we embed it through a dense layer with a recently introduced selu activation (Klambauer et al., 2017), with the same number of nodes as the

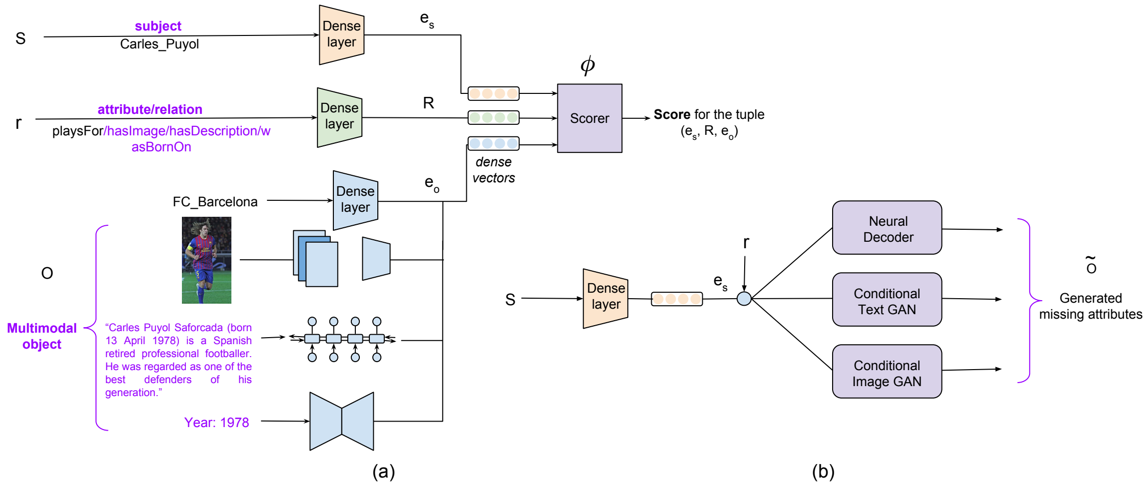

Figure 2: **Multimodal KB Embeddings (MKBE):** (a) Proposed architecture that, given any entity and its relations, uses domain-specific encoders to embed each object. The embeddings of entities, and the relation are then used to score the *truth* value of the triple by the *Scorer*. (b) Architecture of the proposed work for multimodal attributes recovery. Given an entity, we use its learned embeddings from (a) as the context for attribute-specific decoders to generate the missing values.

embedding space dimension.

Numerical Objects in the form of real numbers can provide a useful source of information and are often quite readily available. We use a feed forward layer, after standardizing the input, in order to *embed* the numbers (in fact, we are projecting them to a higher-dimensional space, from $\mathbb{R} \rightarrow \mathbb{R}^d$). It is worth noting that existing methods treat numbers as distinct *entities*, e.g., learn independent vectors for numbers 39 and 40, relying on data to learn that these values are similar to each other.

Text Since text can be used to store a wide variety of different types of information, for example names versus paragraph-long descriptions, we create different encoders depending on the lengths of the strings involved. For attributes that are fairly short, such as names and titles, we use character-based stacked, bidirectional GRUs to encode them, similar to Verga et al. (2016), using the final output of the top layer as the representation of the string. For strings that are much longer, such as detailed descriptions of entities consisting of multiple sentences, we treat them as a sequence of words, and use a CNN over the word embeddings, similar to Francis-Landau et al. (2016), in order to learn the embedding of such values. These two encoders provide a fixed length encoding that has been shown to be an accurate semantic representation of strings for multiple tasks (Dos Santos and Gatti, 2014).

Images Images can also provide useful evidence for modeling entities. For example, we can extract person's details such as gender, age, job, etc., from image of the person (Levi and Hassner, 2015), or location information such as its approximate coordinates, neighboring locations, and size from map images (Weyand et al., 2016). A variety of models have been used to compactly represent the semantic information in the images, and have been successfully applied to tasks such as image classification, captioning (Karpathy and Fei-Fei, 2015), and question-answering (Yang et al., 2016). To embed images such that the encoding represents such semantic information, we use the last hidden layer of VGG pretrained network on Imagenet (Simonyan and Zisserman, 2015), followed by compact bilinear pooling (Gao et al., 2016), to obtain the embedding of the images.

Training We follow the setup from Dettmers et al. (2018) that consists of binary cross-entropy loss without negative sampling for both ConvE and DisMult scoring. In particular, for a given subject-relation pair (s, r), we use a binary *label* vector $\mathbf{t}^{s,r}$ over all entities, indicating whether $\langle s, r, o\rangle$ is observed during training. Further, we denote the model's probability of truth for any triple $\langle s, r, o\rangle$ by $p_o^{s,r}$, computed using a sigmoid over $\psi(s, r, o)$. The binary cross-entropy loss is thus defined as:

$$\sum_{(s,r)} \sum_{o} t_o^{s,r} \log(p_o^{s,r}) + (1 - t_o^{s,r}) \log(1 - p_o^{s,r}).$$

We use the same loss for multimodal triples as well, except that the summation is restricted to the objects of the same modality, i.e. for an entity s

and its text description, $\mathbf{t}^{s,r}$ is a one-hot vector over all descriptions observed during training.

2.5 Decoding Multimodal Data

Here we describe the decoders we use to generate multimodal values for entities from their embeddings. The multimodal imputing model is shown in Figure 2b, which uses different neural decoders to generate missing attributes (more details are provided in supplementary materials).

Numerical and Categorical data To recover the missing numerical and categorical data such as dates, gender, and occupation, we use a simple feed-forward network on the entity embedding to predict the missing attributes. In other words, we are asking the model, if the actual birth date of an entity is not in the KB, what will be the most likely date, given the rest of the relational information. These decoders are trained with embeddings from Section 2.4, with appropriate losses (RMSE for numerical and cross-entropy for categories).

Text A number of methods have considered generative adversarial networks (GANs) to generate grammatical and linguistically coherent sentences (Yu et al., 2017; Rajeswar et al., 2017; Guo et al., 2017). In this work, we use the adversarially regularized autoencoder (ARAE) (Zhao et al., 2017) to train generators that decodes text from continuous codes, however, instead of using the random noise vector z, we condition the generator on the entity embeddings.

Images Similar to text recovery, to find the missing images we use conditional GAN structure. Specifically, we combine the BE-GAN (Berthelot et al., 2017) structure with pix2pix-GAN (Isola et al., 2017) model to generate high-quality images, conditioning the generator on the entity embeddings in the knowledge base representation.

3 Related Work

There is a rich literature on modeling knowledge bases using low-dimensional representations, differing in the operator used to score the triples. In particular, they use matrix and tensor multiplication (Nickel et al., 2011; Yang et al., 2015; Socher et al., 2013), Euclidean distance (Bordes et al., 2013; Wang et al., 2014; Lin et al., 2015), circular correlation (Nickel et al., 2016), or the Hermitian dot product (Trouillon et al., 2016) as scoring function. However, the *objects* for all of these approaches are a fixed set of entities, i.e., they only embed the structured links between the entities. Here, we use different types of information (text, numerical values, images, etc.) in the encoding component by treating them as relational triples.

Table 1: **Data Statistics** of the two benchmark datasets we are using. The numbers in bold are our contributions to the datasets.

	MovieLens	**YAGO-10**
#Link Types	13	45
#Entities	2,625	123,182
#Link Triples	100,000	1,079,040
#Numerical Attributes	2,625	**111,406**
#Image Attributes	**1,651**	**61,246**
#Text Attributes	1,682	**107,326**

A number of methods utilize an extra type of information as the observed features for entities, by either merging, concatenating, or averaging the entity and its features to compute its embeddings, such as numerical values (Garcia-Duran and Niepert, 2017) (we use KBLN from this work to compare it with our approach using only numerical as extra attributes), images (Xie et al., 2017; Oñoro-Rubio et al., 2017) (we use IKRL from the first work to compare it with our approach using only images as extra attributes), text (McAuley and Leskovec, 2013; Zhong et al., 2015; Toutanova et al., 2015, 2016; Xie et al., 2016; Tu et al., 2017), and a combination of text and image (Sergieh et al., 2018). Further, Verga et al. (2016) address the multilingual relation extraction task to attain a universal schema by considering raw text with no annotation as extra feature and using matrix factorization to jointly embed KB and textual relations (Riedel et al., 2013). In addition to treating the extra information as features, graph embedding approaches (Schlichtkrull et al., 2017; Kipf and Welling, 2016) consider observed attributes while encoding to achieve more accurate embeddings.

The difference between MKBE and these mentioned approaches is three-fold: (1) we are the first to use different types of information in a unified model, (2) we treat these different types of information (numerical, text, image) as relational triples of structured knowledge instead of predetermined features, i.e., first-class citizens of the KB, and not auxiliary features, and (3) our model represents uncertainty in them, supporting the missing values and facilitating recovery of missing values.

Table 2: **Rating Prediction in MovieLens.** Results for models that use: rating information (R), movie-attribute (M), user-attribute (U), movies' title text (T), and poster images (P).

	Models	MRR	Hits@1	Hits@2	RMSE

	R+M+U+T+P	0.726	0.512	0.84	**1.09**

4 Evaluation Benchmarks

To evaluate the performance of our multimodal relational embeddings approach, we provide two new benchmarks by extending existing datasets. Table 1 provides the statistics of these datasets.

MovieLens-100k dataset (Harper and Konstan, 2016) is a popular benchmark in recommendation systems to predict user ratings with contextual features, containing around 1000 users on 1700 movies. MovieLens already contains rich relational data about occupation, gender, zip code, and age for users and genre, release date, and the titles for movies. We augment this data with movie posters collected from TMDB (https://www.themoviedb.org/). We treat the 5-point ratings as five different relations in KB triple format, i.e., $\langle \text{user}, r = 5, \text{movie} \rangle$, and evaluate the rating predictions as other relations are introduced.

YAGO-10 Even though MovieLens has a variety of data types, it is still quite small, and is over a specialized domain. We also consider a second dataset that is much more appropriate for knowledge graph completion and is popular for link prediction, the YAGO3-10 knowledge graph (Suchanek et al., 2007; Nickel et al., 2012). This graph consists of around 120,000 entities, such as people, locations, and organizations, and 37 relations, such as kinship, employment, and residency, and thus much closer to the traditional information extraction goals. We extend this dataset with the textual description (as an additional relation) and the images associated with each entity (for half of the entities), provided by *DBpedia* (Lehmann et al., 2015). We also include additional relations such as `wasBornOnDate` that have dates as values.

Table 3: **Link Prediction in YAGO-10.** Results shown for models using: structured information (S), textual description of the entities (D), dates as numerical information (N), and images (I). Published refers to Dettmers et al. (2018).

5 Experiment Results

In this section, we first evaluate the ability of MKBE to utilize the multimodal information by comparing to DistMult and ConvE through a variety of tasks. Then, by considering the recovery of missing multimodal values (text, images, and numerical) as the motivation, we examine the capability of our models in generation. Details of the hyperparameters and model configurations is provided in the supplementary material, and the source code and the datasets to reproduce the results is available at https://github.com/pouyapez/mkbe.

5.1 Link Prediction

In this section, we evaluate the capability of MKBE in the link prediction task. The goal is to calculate MRR and Hits@ metric (ranking evaluations) of recovering the missing entities from triples in the test dataset, performed by ranking all the entities and computing the rank of the correct entity. Similar to previous work, here we focus on providing the results in a filtered setting, that is we only rank triples in the test data against the ones that never appear in either train or test datasets.

MovieLens-100k We train the model using `Rating` as the relation between users and movies. We use a character-level GRU for the movie titles, a separate feed-forward network for age, zip code, and release date, and finally, we use a VGG network on the posters (for every other relation we use a dense layer). Table 2 shows the link (rating) prediction

Table 4: **Per-Relation Breakdown** showing performance of each model on different relations.

Relation	**Links Only**		**+Numbers**		**+Description**		**+Images**	
	MRR	Hits@1	MRR	Hits@1	MRR	Hits@1	MRR	Hits@1
isAffiliatedTo	0.524	0.401	0.551	0.467	**0.572**	**0.481**	0.569	0.478
playsFor	0.528	0.413	0.554	0.471	**0.574**	**0.486**	0.566	0.476
hasGender	0.798	0.596	0.799	0.599	0.813	0.627	**0.842**	**0.683**
isConnectedTo	0.482	0.367	**0.497**	0.379	0.492	**0.384**	0.484	0.372
isMarriedTo	0.365	0.207	0.387	0.221	0.404	0.296	**0.413**	**0.326**

evaluation on MovieLens when test data is consisting only of rating triples. We calculate our metrics by ranking the five relations that represent ratings instead of object entities. We label models that use ratings as R, movie-attributes as M, user-attributes as U, movie titles as T, and posters as P. As shown, the model R+M+U+T outperforms others with a considerable gap demonstrating the importance of incorporating extra information. Hits@1 for the baseline is *40%*, matching existing recommendation systems (Guimerà et al., 2012). From these results, we see that the models benefit more from titles as compared to the posters.

YAGO-10 The result of link prediction on our YAGO dataset is provided in Table 3. We label models using structured information as S, entity-description as D, numerical information as N, and entity-image as I. We see that the model that encodes all type of information consistently performs better than other models, indicating that the model is effective in utilizing the extra information. On the other hand, the model that uses only text performs the second best, suggesting the entity descriptions contain more information than others. It is notable that model S is outperformed by all other models, demonstrating the importance of using different data types for attaining higher accuracy. This observation is consistent across both DistMult and ConvE, and the results obtained on ConvE are the new state-of-art for this dataset (as compared to Dettmers et al. (2018)). Furthermore, we implement KBLN (Garcia-Duran and Niepert, 2017) and IKRL (Xie et al., 2017) to compare them with our S+N and S+I models. Our models outperform these approaches, in part because both of these methods require same multimodal attributes for both of the subject and object in each triple.

Relation Breakdown We perform additional analysis on the YAGO dataset to gain a deeper understanding of the performance of our model using ConvE method. Table 4 compares our models on some of the most frequent relations. As shown, the model that includes textual description significantly benefits isAffiliatedTo, and playsFor relations, as this information often appears in text. Moreover, images are useful for hasGender and isMarriedTo, while for the relation isConnectedTo, numerical (dates) are more effective than images.

Table 5: **Predicting Numbers and Categories** for YAGO (dates) and MovieLens (genres), using models with access with different information.

Models	**Search**	**Decoding**
S+N	62.49	58.7
S+N+D	59.42	56.2
S+N+I	59.86	55.8
All Info	**57.62**	**54.1**

Models	**Accuracy**
R+M	71.82
R+M+U	71.98
R+M+U+T	73.01
R+M+U+P	73.77
All Info	**75.89**

(b) Genres in MovieLens

5.2 Imputing Multimodal Attributes

Here we present an evaluation on imputing multimodal attributes (text, image and numerical).

Numerical and Categorical Table 5a shows performance of predicting missing numerical attributes in the data, evaluated via holding out 10% of the data. We only consider numerical values (dates) that are more recent than $1000AD$ to focus on more relevant entities. In addition to the neural decoder, we train a search-based decoder as well by considering all 1017 choices in the interval $[1000, 2017]$, and for each triple in the test data, finding the number that the model scores the highest; we use this value to compute the RMSE. As we can see, *all info* outperform other methods on both datasets, demonstrating MKBE is able to utilize different multimodal values for modeling numerical information. Further, the neural decoder performs better than the search-based one, showing the importance of proper decoder, even for finite, enumerable sets. Along the same line, Table 5b shows genre prediction accuracy on 10% of held-

Table 6: **Evaluating Generated Titles** for MovieLens using movies embeddings conditioned on just the ratings (R) and all the information. We present the accuracy of the users in guessing whether the generated title for a movie was real (yes/no), and genre of the movie (4 choices).

Models	Real vs Fake	Genre
R	63	27.2
R+M+U+T+P	73	41.6
Reference	90	68

Table 7: **Evaluating Generated Text and Images** for YAGO using entity embeddings conditioned on just the links (S) or all information. We present the accuracy of the users in guessing whether the generated text/image for a person was real (yes/no), gender of the person, age (<35, or ≥35), and occupation (3 choices).

	Models	Real	Gender	Age	Occup.
descrip.	S	57.1	72.1	59	71.4
	S+N+D+I	59.2	77.2	63.4	78.6
	Reference	67.8	83.2	69.5	90.4
images	S	60	67	53	43
	S+N+D+I	67	77	53	52
	Reference	96	1.0	83	82

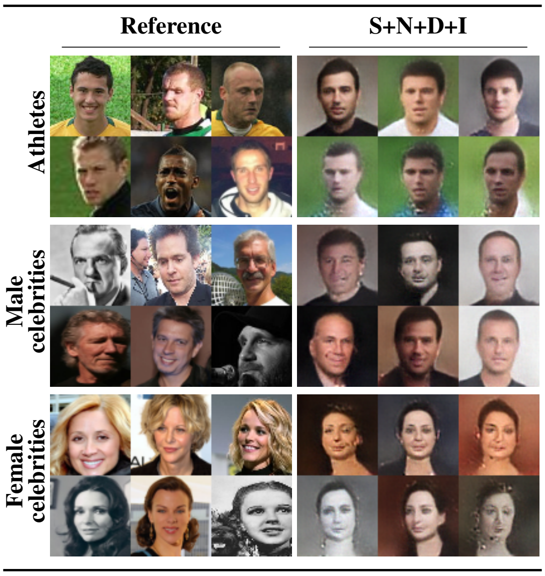
out MovieLens dataset. Again, the model that uses all the information outperforms other methods.

MovieLens Titles For generating movie titles, we randomly consider 200 of them as test, 100 as validation, and the remaining ones as training data. The goal here is to generate titles for movies in the test data using the previously mentioned GAN structure. To evaluate our results we conduct a human experiment on Amazon Mechanical Turk (AMT) asking participant two questions: (1) whether they find the movie title real, and (2) which of the four genres is most appropriate for the given title. We consider 30 movies each as reference titles, fake titles generated from only ratings as conditional data, and fake titles conditioned on all the information. Further, each question was asked for 3 participants, and the results computed over the majority choice are shown in Table 6. Fake titles generated with all the information are more similar to reference movie titles, demonstrating that the embeddings that have access to more information effectively generate higher-quality titles.

Table 8: **Generated Descriptions** for "Carles Puyol" (and the corresponding reference from the DBpedia) by embeddings trained from just the links (S) and all of the information (S+N+D+I).

Model	Generated Descriptions
Reference	⟨subject⟩ (born 13 April 1978) is a Spanish retired professional footballer.
Only S	⟨subject⟩ (born 25 January 1949) is a Georgian football coach and former professional player.
S+N+D+I	⟨subject⟩ (born 22 April 1967) is an English former football player.

Table 9: **Generated Images** for YAGO. We consider athletes, and male and female celebrities, and compare their reference images with corresponding ones generated from all the information.



YAGO Descriptions The goal here is to generate descriptive text for entities from their embeddings. Since the original descriptions can be quite long, we consider first sentences that are less than 30 tokens, resulting in 96,405 sentences. We randomly consider 3000 of them as test, 3000 as validation, and the remaining as training data for the decoder. To evaluate the quality of the generated descriptions, and whether they are appropriate for the entity, we conduct a user study asking participants if they can guess the realness of sentences and the occupation (*entertainer*, *sportsman*, or *politician*), gender, and age (above or below 35) of the subject entity from the description. We provide 30 examples for each model asking each question from 3 participants and calculate the accuracy of the majority vote. The results presented in Table 7 show that the models are fairly competent in informing the users of the entity information, and further, descriptions generated from embeddings that had access to more information outperforms the model with only structured data. Examples of generated descriptions are provided in Table 8 (in addition to screenshots of user study, more examples of generated descriptions, and MovieLens titles are provided in supplementary materials).

YAGO Images Here, we evaluate the quality of images generated from entity embeddings by humans ($31,520$, split into train/text). Similar to descriptions, we conduct a study asking users to guess the realness of images and the occupation, gender, and age of the subject. We provide 30 examples for each model asking each question from 3 participants, and use the majority choice.

The results in Table 7 indicate that the images generated with embeddings based on all the information are more accurate for gender and occupation. Guessing age from the images is difficult since the image on DBpedia may not correspond to the age of the person, i.e. some of the older celebrities had photos from their youth. Examples of generated images are shown in Table 9.

6 Discussion and Limitations

An important concern regarding KB embedding approaches is their scalability. While large KBs are a problem for all embedding-based link prediction techniques, MKBE is not significantly worse than existing ones because we treat multimodal information as additional triples. Specifically, although multimodal encoders/decoders are more expensive to train than existing relational models, the cost is still additive as we are effectively increasing the size of the training dataset.

In addition to scalability, there are few other challenges when working with multimodal attributes. Although multimodal evidence provides more information, it is not at all obvious which parts of this additional data are informative for predicting the relational structure of the KB, and the models are prone to overfitting. MKBE builds upon the design of neural encoders and decoders that have been effective for specific modalities, and the results demonstrate that it is able to utilize the information effectively. However, there is still a need to further study models that capture multimodal attributes in a more efficient and accurate manner.

Since our imputing multimodal attributes model is based on GAN structure and the embeddings learned from KB representation, the generated attributes are directly limited by the power of GAN models and the amount of information in the embedding vectors. Although our generated attributes convey several aspects of corresponding entities, their quality is far from ideal due to the size of our datasets (both of our image and text datasets are order of magnitude smaller than common datasets in the existing text/image genration literature) and the amount of information captured by embedding vectors (the knowledge graphs are sparse). In future, we would like to (1) expand multimodal datasets to have more attributes (use many more entities from YAGO), and (2) instead of using learned embeddings to generate missing attributes, utilize the knowledge graph directly for generation.

7 Conclusion

Motivated by the need to utilize multiple sources of information, such as text and images, to achieve more accurate link prediction, we present a novel neural approach to multimodal relational learning. We introduce MKBE, a link prediction model that consists of (1) a compositional encoding component to jointly learn the entity and multimodal embeddings to encode the information available for each entity, and (2) adversarially trained decoding component that use these entity embeddings to impute missing multimodal values. We enrich two existing datasets, YAGO-10 and MovieLens-100k, with multimodal information to introduce benchmarks. We show that MKBE, in comparison to existing link predictors DistMult and ConvE, can achieve higher accuracy on link prediction by utilizing the multimodal evidence. Further, we show that MKBE effectively incorporates relational information to generate high-quality multimodal attributes like images and text. We have release the datasets and the open-source implementation of our models at https://github.com/pouyapez/mkbe.

Multi-Task Identification of Entities, Relations, and Coreference for Scientific Knowledge Graph Construction

Yi Luan   Luheng He   Mari Ostendorf   Hannaneh Hajishirzi
University of Washington
{luanyi, luheng, ostendor, hannaneh}@uw.edu

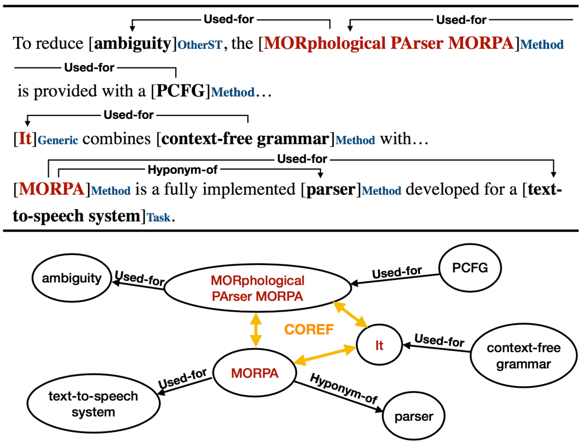
Abstract

We introduce a multi-task setup of identifying and classifying entities, relations, and coreference clusters in scientific articles. We create SciERC, a dataset that includes annotations for all three tasks and develop a unified framework called Scientific Information Extractor (SciIE) for with shared span representations. The multi-task setup reduces cascading errors between tasks and leverages cross-sentence relations through coreference links. Experiments show that our multi-task model outperforms previous models in scientific information extraction without using any domain-specific features. We further show that the framework supports construction of a scientific knowledge graph, which we use to analyze information in scientific literature.[1]

1 Introduction

As scientific communities grow and evolve, new tasks, methods, and datasets are introduced and different methods are compared with each other. Despite advances in search engines, it is still hard to identify new technologies and their relationships with what existed before. To help researchers more quickly identify opportunities for new combinations of tasks, methods and data, it is important to design intelligent algorithms that can extract and organize scientific information from a large collection of documents.

Organizing scientific information into structured knowledge bases requires information extraction (IE) about scientific entities and their relationships. However, the challenges associated with scientific IE are greater than for a general domain. First, annotation of scientific text requires domain expertise which makes annotation costly and limits resources.



To reduce **[ambiguity]**OtherST, the **[MORphological PArser MORPA]**Method is provided with a **[PCFG]**Method…

[It]Generic combines **[context-free grammar]**Method with…

[MORPA]Method is a fully implemented **[parser]**Method developed for a **[text-to-speech system]**Task.

Figure 1: Example annotation: phrases that refer to the same scientific concept are annotated into the same coreference cluster, such as *MORphological PAser MORPA*, *it* and *MORPA* (marked as red).

In addition, most relation extraction systems are designed for within-sentence relations. However, extracting information from scientific articles requires extracting relations across sentences. Figure 1 illustrates this problem. The cross-sentence relations between some entities can only be connected by entities that refer to the same scientific concept, including generic terms (such as the pronoun *it*, or phrases like *our method*) that are not informative by themselves. With co-reference, *context-free grammar* can be connected to *MORPA* through the intermediate co-referred pronoun *it*. Applying existing IE systems to this data, without co-reference, will result in much lower relation coverage (and a sparse knowledge base).

In this paper, we develop a unified learning model for extracting scientific entities, relations, and coreference resolution. This is different from previous work (Luan et al., 2017b; Gupta and Manning, 2011; Tsai et al., 2013; Gábor et al., 2018) which often addresses these tasks as independent

---

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3219–3232
Brussels, Belgium, October 31 - November 4, 2018.

components of a pipeline. Our unified model is a multi-task setup that shares parameters across low-level tasks, making predictions by leveraging context across the document through coreference links. Specifically, we extend prior work for learning span representations and coreference resolution (Lee et al., 2017; He et al., 2018). Different from a standard tagging system, our system enumerates all possible spans during decoding and can effectively detect overlapped spans. It avoids cascading errors between tasks by jointly modeling all spans and span-span relations.

To explore this problem, we create a dataset SCIERC for scientific information extraction, which includes annotations of scientific terms, relation categories and co-reference links. Our experiments show that the unified model is better at predicting span boundaries, and it outperforms previous state-of-the-art scientific IE systems on entity and relation extraction (Luan et al., 2017b; Augenstein et al., 2017). In addition, we build a scientific knowledge graph integrating terms and relations extracted from each article. Human evaluation shows that propagating coreference can significantly improve the quality of the automatic constructed knowledge graph.

In summary we make the following contributions. We create a dataset for scientific information extraction by jointly annotating scientific entities, relations, and coreference links. Extending a previous end-to-end coreference resolution system, we develop a multi-task learning framework that can detect scientific entities, relations, and coreference clusters without hand-engineered features. We use our unified framework to build a scientific knowledge graph from a large collection of documents and analyze information in scientific literature.

2 Related Work

There has been growing interest in research on automatic methods for information extraction from scientific articles. Past research in scientific IE addressed analyzing citations (Athar and Teufel, 2012b,a; Kas, 2011; Gabor et al., 2016; Sim et al., 2012; Do et al., 2013; Jaidka et al., 2014; Abu-Jbara and Radev, 2011), analyzing research community (Vogel and Jurafsky, 2012; Anderson et al., 2012), and unsupervised methods for extracting scientific entities and relations (Gupta and Manning, 2011; Tsai et al., 2013; Gábor et al., 2016).

More recently, two datasets in SemEval 2017 and 2018 have been introduced, which facilitate research on supervised and semi-supervised learning for scientific information extraction. SemEval 17 (Augenstein et al., 2017) includes 500 paragraphs from articles in the domains of computer science, physics, and material science. It includes three types of entities (called keyphrases): Tasks, Methods, and Materials and two relation types: hyponym-of and synonym-of. SemEval 18 (Gábor et al., 2018) is focused on predicting relations between entities within a sentence. It consists of six relation types. Using these datasets, neural models (Ammar et al., 2017, 2018; Luan et al., 2017b; Augenstein and Søgaard, 2017) are introduced for extracting scientific information. We extend these datasets by increasing relation coverage, adding cross-sentence coreference linking, and removing some annotation constraints. Different from most previous IE systems for scientific literature and general domains (Miwa and Bansal, 2016; Xu et al., 2016; Peng et al., 2017; Quirk and Poon, 2017; Luan et al., 2018; Adel and Schütze, 2017), which use preprocessed syntactic, discourse or coreference features as input, our unified framework does not rely on any pipeline processing and is able to model overlapping spans.

While Singh et al. (2013) show improvements by jointly modeling entities, relations, and coreference links, most recent neural models for these tasks focus on single tasks (Clark and Manning, 2016; Wiseman et al., 2016; Lee et al., 2017; Lample et al., 2016; Peng et al., 2017) or joint entity and relation extraction (Katiyar and Cardie, 2017; Zhang et al., 2017; Adel and Schütze, 2017; Zheng et al., 2017). Among those studies, many papers assume the entity boundaries are given, such as (Clark and Manning, 2016), Adel and Schütze (2017) and Peng et al. (2017). Our work relaxes this constraint and predicts entity boundaries by optimizing over all possible spans. Our model draws from recent end-to-end span-based models for coreference resolution (Lee et al., 2017, 2018) and semantic role labeling (He et al., 2018) and extends them for the multi-task framework involving the three tasks of identification of entity, relation and coreference.

Neural multi-task learning has been applied to a range of NLP tasks. Most of these models share word-level representations (Collobert and Weston, 2008; Klerke et al., 2016; Luan et al., 2016, 2017a; Rei, 2017), while Peng et al. (2017) uses high-order cross-task factors. Our model instead propagates cross-task information via span representations, which is related to Swayamdipta et al. (2017).

3 Dataset

Our dataset (called SciERC) includes annotations for scientific entities, their relations, and coreference clusters for 500 scientific abstracts. These abstracts are taken from 12 AI conference/workshop proceedings in four AI communities from the Semantic Scholar Corpus[2]. SciERC extends previous datasets in scientific articles SemEval 2017 Task 10 (SemEval 17) (Augenstein et al., 2017) and SemEval 2018 Task 7 (SemEval 18) (Gábor et al., 2018) by extending entity types, relation types, relation coverage, and adding cross-sentence relations using coreference links. Our dataset is publicly available at: `http://nlp.cs.washington.edu/sciIE/`. Table 1 shows the statistics of SciERC.

Annotation Scheme We define six types for annotating scientific entities (Task, Method, Metric, Material, Other-ScientificTerm and Generic) and seven relation types (Compare, Part-of, Conjunction, Evaluate-for, Feature-of, Used-for, Hyponym-Of). Directionality is taken into account except for the two symmetric relation types (Conjunction and Compare). Coreference links are annotated between identical scientific entities. A Generic entity is annotated only when the entity is involved in a relation or is coreferred with another entity. Annotation guidelines can be found in Appendix A. Figure 1 shows an annotated example.

Following annotation guidelines from QasemiZadeh and Schumann (2016) and using the BRAT interface (Stenetorp et al., 2012), our annotators perform a greedy annotation for spans and always prefer the longer span whenever ambiguity occurs. Nested spans are allowed when a subspan has a relation/coreference link with another term outside the span.

Human Agreements One domain expert annotated all the documents in the dataset; 12% of the data is dually annotated by 4 other domain experts to evaluate the user agreements. The kappa score for annotating entities is 76.9%, relation extraction is 67.8% and coreference is 63.8%.

Statistics	SciERC	SemEval 17	SemEval 18
#Entities	8089	9946	7483
#Relations	4716	672	1595
#Relations/Doc	9.4	1.3	3.2
#Coref links	2752	-	-
#Coref clusters	1023	-	-

Table 1: Dataset statistics for our dataset SciERC and two previous datasets on scientific information extraction. All datasets annotate 500 documents.

Comparison with previous datasets SciERC is focused on annotating cross-sentence relations and has more relation coverage than SemEval 17 and SemEval 18, as shown in Table 1. SemEval 17 is mostly designed for entity recognition and only covers two relation types. The task in SemEval 18 is to classify a relation between a pair of entities given entity boundaries, but only intra-sentence relations are annotated and each entity only appears in one relation, resulting in sparser relation coverage than our dataset (3.2 vs. 9.4 relations per abstract). SciERC extends these datasets by adding more relation types and coreference clusters, which allows representing cross-sentence relations, and removing annotation constraints. Table 1 gives a comparison of statistics among the three datasets. In addition, SciERC aims at including broader coverage of general AI communities.

4 Model

We develop a unified framework (called SciIE) to identify and classify scientific entities, relations, and coreference resolution across sentences. SciIE is a multi-task learning setup that extends previous span-based models for coreference resolution (Lee et al., 2017) and semantic role labeling (He et al., 2018). All three tasks of entity recognition, relation extraction, and coreference resolution are treated as multinomial classification problems with shared span representations. SciIE benefits from expressive contextualized span representations as classifier features. By sharing span representations, sentence-level tasks can benefit from information propagated from coreference resolution across sentences, without increasing the complexity of inference. Figure 2 shows a high-level overview of the SciIE multi-task framework.

4.1 Problem Definition

The input is a document represented as a sequence of words $D = \{w_1, \dots, w_n\}$, from which we derive $S = \{s_1, \dots, s_N\}$, the set of all possible

---

[2] These conferences include general AI (AAAI, IJCAI), NLP (ACL, EMNLP, IJCNLP), speech (ICASSP, Interspeech), machine learning (NIPS, ICML), and computer vision (CVPR, ICCV, ECCV) at `http://labs.semanticscholar.org/corpus/`

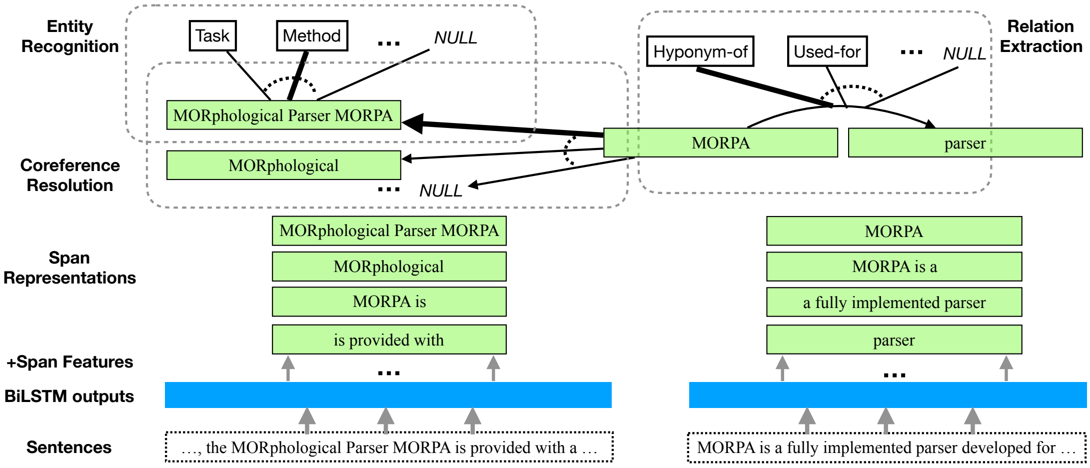

Figure 2: Overview of the multitask setup, where all three tasks are treated as classification problems on top of shared span representations. Dotted arcs indicate the normalization space for each task.

within-sentence word sequence spans (up to a reasonable length) in the document. The output contains three structures: the entity types E for all spans S, the relations R for all pair of spans $S \times S$, and the coreference links C for all spans in S. The output structures are represented with a set of discrete random variables indexed by spans or pairs of spans. Specifically, the output structures are defined as follows.

Entity recognition is to predict the best entity type for every candidate span. Let L_{E} represent the set of all possible entity types including the null-type ϵ. The output structure E is a set of random variables indexed by spans: $e_i \in L_{\mathrm{E}}$ for $i = 1, \ldots, N$.

Relation extraction is to predict the best relation type given an ordered pair of spans (s_i, s_j). Let L_{R} be the set of all possible relation types including the null-type ϵ. The output structure R is a set of random variables indexed over pairs of spans (i, j) that belong to the same sentence: $r_{ij} \in L_{\mathrm{R}}$ for $i, j = 1, \ldots, N$.

Coreference resolution is to predict the best antecedent (including a special null antecedent) given a span, which is the same mention-ranking model used in Lee et al. (2017). The output structure C is a set of random variables defined as: $c_i \in \{1, \ldots, i-1, \epsilon\}$ for $i = 1, \ldots, N$.

4.2 Model Definition

We formulate the multi-task learning setup as learning the conditional probability distribution $P(E, R, C|D)$. For efficient training and inference, we decompose $P(E, R, C|D)$ assuming spans are conditionally independent given D:

$$P(E, R, C \mid D) = P(E, R, C, S \mid D) \qquad (1)$$
$$= \prod_{i=1}^{N} P(e_i \mid D) P(c_i \mid D) \prod_{j=1}^{N} P(r_{ij} \mid D),$$

where the conditional probabilities of each random variable are independently normalized:

$$P(e_i = e \mid D) = \frac{\exp(\Phi_{\mathrm{E}}(e, s_i))}{\sum_{e' \in L_{\mathrm{E}}} \exp(\Phi_{\mathrm{E}}(e', s_i))} \qquad (2)$$
$$P(r_{ij} = r \mid D) = \frac{\exp(\Phi_{\mathrm{R}}(r, s_i, s_j))}{\sum_{r' \in L_{\mathrm{R}}} \exp(\Phi_{\mathrm{R}}(r', s_i, s_j))}$$
$$P(c_i = j \mid D) = \frac{\exp(\Phi_{\mathrm{C}}(s_i, s_j))}{\sum_{j' \in \{1, \ldots, i-1, \epsilon\}} \exp(\Phi_{\mathrm{C}}(s_i, s_{j'}))},$$

where Φ_{E} denotes the unnormalized model score for an entity type e and a span s_i, Φ_{R} denotes the score for a relation type r and span pairs s_i, s_j, and Φ_{C} denotes the score for a binary coreference link between s_i and s_j. These Φ scores are further decomposed into span and pairwise span scores computed from feed-forward networks, as will be explained in Section 4.3.

For simplicity, we omit D from the Φ functions and S from the observation.

Objective Given a set of all documents $\mathcal{D}$, the model loss function is defined as a weighted sum of the negative log-likelihood loss of all three tasks:

$$-\sum_{(D, R^*, E^*, C^*) \in \mathcal{D}} \Big\{ \lambda_{\mathrm{E}} \log P(E^* \mid D) \qquad (3)$$
$$+ \lambda_{\mathrm{R}} \log P(R^* \mid D) + \lambda_{\mathrm{C}} \log P(C^* \mid D) \Big\}$$

where E^*, R^*, and C^* are gold structures of the entity types, relations, and coreference, respectively. The task weights λ_{E}, λ_{R}, and λ_{C} are introduced as hyper-parameters to control the importance of each task.

For entity recognition and relation extraction, $P(E^* \mid D)$ and $P(R^* \mid D)$ are computed with the definition in Equation (2). For coreference resolution, we use the marginalized loss following Lee et al. (2017) since each mention can have multiple correct antecedents. Let C_i^* be the set of all correct antecedents for span i, we have: $\log P(C^* \mid D) = \sum_{i=1..N} \log \sum_{c \in C_i^*} P(c \mid D)$.

4.3 Scoring Architecture

We use feedforward neural networks (FFNNs) over *shared span representations* $\mathbf{g}$ to compute a set of span and pairwise span scores. For the span scores, $\phi_e(s_i)$ measures how likely a span s_i has an entity type e, and $\phi_{\text{mr}}(s_i)$ and $\phi_{\text{mc}}(s_i)$ measure how likely a span s_i is a mention in a relation or a coreference link, respectively. The pairwise scores $\phi_r(s_i, s_j)$ and $\phi_{\text{c}}(s_i, s_j)$ measure how likely two spans are associated in a relation r or a coreference link, respectively. Let $\mathbf{g}_i$ be the fixed-length vector representation for span s_i. For different tasks, the span scores $\phi_{\text{x}}(s_i)$ for x $\in \{e, \text{mc}, \text{mr}\}$ and pairwise span scores $\phi_{\text{y}}(s_i, s_j)$ for y $\in \{r, \text{c}\}$ are computed as follows:

$$\begin{aligned} \phi_{\text{x}}(s_i) &= \mathbf{w}_{\text{x}} \cdot \text{FFNN}_{\text{x}}(\mathbf{g}_i) \\ \phi_{\text{y}}(s_i, s_j) &= \mathbf{w}_{\text{y}} \cdot \text{FFNN}_{\text{y}}([\mathbf{g}_i, \mathbf{g}_j, \mathbf{g}_i \odot \mathbf{g}_j]), \end{aligned}$$

where $\odot$ is element-wise multiplication, and $\{\mathbf{w}_{\text{x}}, \mathbf{w}_{\text{y}}\}$ are neural network parameters to be learned.

We use these scores to compute the different Φ:

$$\begin{aligned} \Phi_{\text{E}}(e, s_i) &= \phi_e(s_i) \qquad (4) \\ \Phi_{\text{R}}(r, s_i, s_j) &= \phi_{\text{mr}}(s_i) + \phi_{\text{mr}}(s_j) + \phi_r(s_i, s_j) \\ \Phi_{\text{C}}(s_i, s_j) &= \phi_{\text{mc}}(s_i) + \phi_{\text{mc}}(s_j) + \phi_{\text{c}}(s_i, s_j) \end{aligned}$$

The scores in Equation (4) are defined for entity types, relations, and antecedents that are not the null-type ϵ. Scores involving the null label are set to a constant 0: $\Phi_{\text{E}}(\epsilon, s_i) = \Phi_{\text{R}}(\epsilon, s_i, s_j) = \Phi_{\text{C}}(s_i, \epsilon) = 0$.

We use the same span representations $\mathbf{g}$ from (Lee et al., 2017) and share them across the three tasks. We start by building bi-directional LSTMs (Hochreiter and Schmidhuber, 1997) from word, character and ELMo (Peters et al., 2018) embeddings.

For a span s_i, its vector representation $\mathbf{g}_i$ is constructed by concatenating s_i's left and right end points from the BiLSTM outputs, an attention-based soft "headword," and embedded span width features. Hyperparameters and other implementation details will be described in Section 6.

4.4 Inference and Pruning

Following previous work, we use beam pruning to reduce the number of pairwise span factors from $O(n^4)$ to $O(n^2)$ at both training and test time, where n is the number of words in the document. We define two separate beams: B_{C} to prune spans for the coreference resolution task, and B_{R} for relation extraction. The spans in the beams are sorted by their span scores ϕ_{mc} and ϕ_{mr} respectively, and the sizes of the beams are limited by $\lambda_{\text{C}} n$ and $\lambda_{\text{R}} n$. We also limit the maximum width of spans to a fixed number W, which further reduces the number of span factors to $O(n)$.

5 Knowledge Graph Construction

We construct a scientific knowledge graph from a large corpus of scientific articles. The corpus includes all abstracts (110k in total) from 12 AI conference proceedings from the Semantic Scholar Corpus. Nodes in the knowledge graph correspond to scientific entities. Edges correspond to scientific relations between pairs of entities. The edges are typed according to the relation types defined in Section 3. Figure 4 shows a part of a knowledge graph created by our method. For example, *Statistical Machine Translation (SMT)* and *grammatical error correction* are nodes in the graph, and they are connected through a *Used-for* relation type. In order to construct the knowledge graph for the whole corpus, we first apply the SciIE model over single documents and then integrate the entities and relations across multiple documents (Figure 3).

Extracting nodes (entities) The SciIE model extracts entities, their relations, and coreference

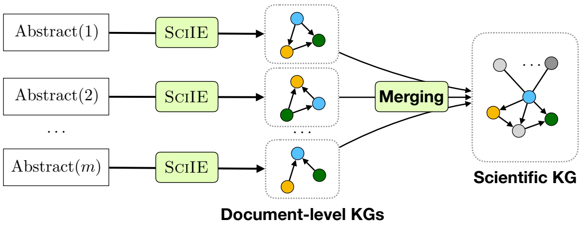

Figure 3: Knowledge graph construction process.

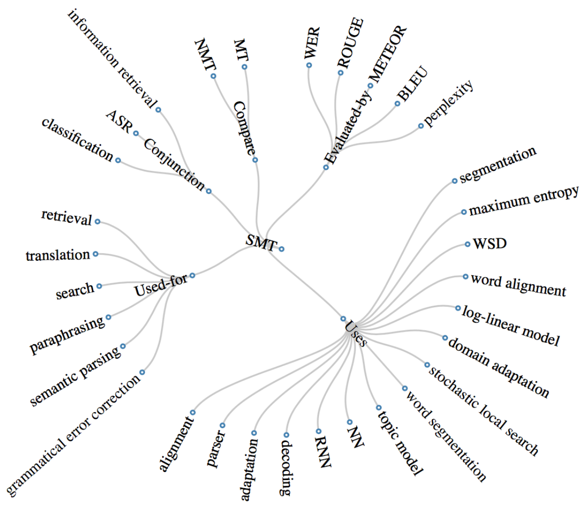

Figure 4: A part of an automatically constructed scientific knowledge graph with the most frequent neighbors of the scientific term *statistical machine translation (SMT)* on the graph. For simplicity we denote *Used-for (Reverse)* as *Uses*, *Evaluated-for (Reverse)* as *Evaluated-by*, and replace common terms with their acronyms. The original graph and more examples are given Figure 10 in Appendix B.

clusters within one document. Phrases are heuristically normalized (described in Section 6) using entities and coreference links. In particular, we link all entities that belong to the same coreference cluster to replace generic terms with any other non-generic term in the cluster. Moreover, we replace all the entities in the cluster with the entity that has the longest string. Our qualitative analysis shows that there are fewer ambiguous phrases using coreference links (Figure 5). We calculate the frequency counts of all entities that appear in the whole corpus. We assign nodes in the knowledge graph by selecting the most frequent entities (with counts $> k$) in the corpus, and merge in any remaining entities for which a frequent entity is a substring.

Assigning edges (relations) A pair of entities may appear in different contexts, resulting in different relation types between those entities (Figure 6). For every pair of entities in the graph, we calculate the frequency of different relation types across the whole corpus.We assign edges between entities by selecting the most frequent relation type.

6 Experimental Setup

We evaluate our unified framework SciIE on SciERC and SemEval 17. The knowledge graph for scientific community analysis is built using the Semantic Scholar Corpus (110k abstracts in total).

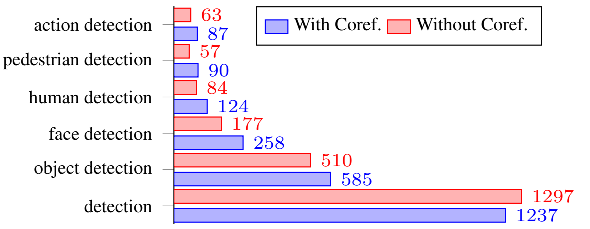

Figure 5: Frequency of detected entities with and without coreferece resolution: using coreference reduces the frequency of the generic phrase *detection* while significantly increasing the frequency of specific phrases. Linking entities through coreference helps disambiguate phrases when generating the knowledge graph.

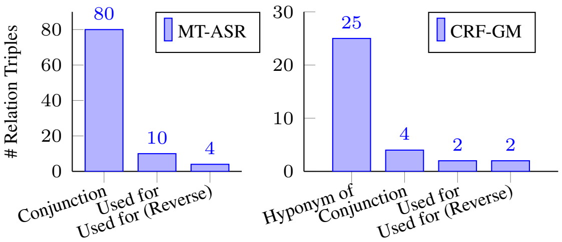

Figure 6: Frequency of relation types between pairs of entities: (*left*) automatic speech recognition (ASR) and machine translation (MT), (*right*) conditional random field (CRF) and graphical model (GM). We use the most frequent relation between pairs of entities in the knowledge graph.

6.1 Baselines

We compare our model with the following baselines on SciERCdataset:

- **LSTM+CRF** The state-of-the-art NER system (Lample et al., 2016), which applies CRF on top of LSTM for named entity tagging, the approach has also been used in scientific term extraction (Luan et al., 2017b).
- **LSTM+CRF+ELMo** LSTM+CRF with ELMo as an additional input feature.
- **E2E Rel** State-of-the-art joint entity and relation extraction system (Miwa and Bansal, 2016) that has also been used in scientific literature (Peters et al., 2017; Augenstein et al., 2017). This system uses syntactic features such as part-of-speech tagging and dependency parsing.

- **E2E Rel(Pipeline)** Pipeline setting of E2E Rel. Extract entities first and use entity results as input to relation extraction task.

- **E2E Rel+ELMo** E2E Rel with ELMo as an additional input feature.

- **E2E Coref** State-of-the-art coreference system Lee et al. (2017) combined with ELMo. Our system SciIE extends E2E Coref with multi-task learning.

In the SemEval task, we compare our model SciIE with the best reported system in the SemEval leaderboard (Peters et al., 2017), which extends E2E Rel with several in-domain features such as gazetteers extracted from existing knowledge bases and model ensembles. We also compare with the state of the art on keyphrase extraction (Luan et al., 2017b), which applies semi-supervised methods to a neural tagging model.[3]

6.2 Implementation details

Our system extends the implementation and hyper-parameters from Lee et al. (2017) with the following adjustments. We use a 1 layer BiLSTM with 200-dimensional hidden layers. All the FFNNs have 2 hidden layers of 150 dimensions each. We use 0.4 variational dropout (Gal and Ghahramani, 2016) for the LSTMs, 0.4 dropout for the FFNNs, and 0.5 dropout for the input embeddings. We model spans up to 8 words. For beam pruning, we use $\lambda_{\text{C}} = 0.3$ for coreference resolution and $\lambda_{\text{R}} = 0.4$ for relation extraction. For constructing the knowledge graph, we use the following heuristics to normalize the entity phrases. We replace all acronyms with their corresponding full name and normalize all the plural terms with their singular counterparts.

7 Experimental Results

We evaluate SciIE on SciERC and SemEval 17 datasets. We provide qualitative results and human evaluation of the constructed knowledge graph.

7.1 IE Results

	Dev			Test

SciIE	61.5	54.8	**58.0**	52.0	44.9	**48.2**

(c) Coreference resolution.

Table 2: Comparison with previous systems on the development and test set for our three tasks. For coreference resolution, we report the average P/R/F1 of MUC, B^3, and CEAF_{ϕ_4} scores.

Results on SciERC Table 2 compares the result of our model with baselines on the three tasks: entity recognition (Table 2a), relation extraction (Table 2b), and coreference resolution (Table 2c). As evidenced by the table, our unified multi-task setup SciIE outperforms all the baselines. For entity recognition, our model achieves 1.3% and 2.4% relative improvement over LSTM+CRF with and without ELMo, respectively. Moreover, it achieves 1.8% and 2.7% relative improvement over E2E Rel with and without ELMo, respectively. For relation extraction, we observe more significant improvement with 13.1% relative improvement over E2E Rel and 7.4% improvement over E2E Rel with ELMo. For coreference resolution, SciIE outperforms E2E Coref with 4.5% relative improvement. We still observe a large gap between human-level performance and a machine learning system. We invite the community to address this challenging task.

Ablations We evaluate the effect of multi-task learning in each of the three tasks defined in our dataset. Table 3 reports the results for individual tasks when additional tasks are included in the learning objective function. We observe that performance improves with each added task in the objective. For example, Entity recognition (65.7) benefits from both coreference resolution (67.5) and relation extraction (66.8). Relation extrac-

---

[3] We compare with the inductive setting results.

Task	Entity Rec.	Relation	Coref.
Multi Task (SciIE)	68.1	39.5	58.0
Single Task	65.7	37.9	55.3
+Entity Rec.	-	38.9	57.1

tion (37.9) significantly benefits when multi-tasked with coreference resolution (7.1% relative improvement). Coreference resolution benefits when multi-tasked with relation extraction, with 4.9% relative improvement.

Results on SemEval 17 Table 4 compares the results of our model with the state of the art on the SemEval 17 dataset for tasks of span identification, keyphrase extraction and relation extraction as well as the overall score. Span identification aims at identifying spans of entities. Keyphrase classification and relation extraction has the same setting with the entity and relation extraction in SciERC. Our model outperforms all the previous models that use hand-designed features. We observe more significant improvement in span identification than keyphrase classification. This confirms the benefit of our model in enumerating spans (rather than BIO tagging in state-of-the-art systems). Moreover, we have competitive results compared to the previous state of the art in relation extraction. We observe less gain compared to the SciERC dataset mainly because there are no coference links, and the relation types are not comprehensive.

7.2 Knowledge Graph Analysis

We provide qualitative analysis and human evaluations on the constructed knowledge graph.

Scientific trend analysis Figure 7 shows the historical trend analysis (from 1996 to 2016) of the most popular applications of the phrase *neural network*, selected according to the statistics of the extracted relation triples with the 'Used-for' relation type from speech, computer vision, and NLP conference papers. We observe that, before 2000, *neural network* has been applied to a greater percentage of speech applications compared to the NLP and computer vision papers. In NLP, neural networks first gain popularity in language modeling and then extend to other tasks such as POS Tagging and Machine Translation. In computer vision, the application of neural networks gains popularity in *object recognition* earlier (around 2010) than the other two more complex tasks of *object detection* and *image segmentation* (hardest and also the latest).

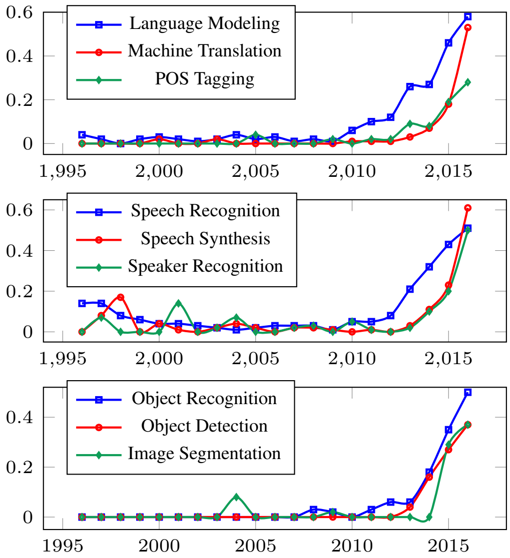

Figure 7: Historical trend for top applications of the keyphrase *neural network* in NLP, speech, and CV conference papers we collected. y-axis indicates the ratio of papers that use *neural network* in the task to the number of papers that is about the task.

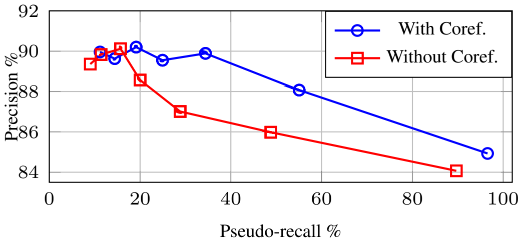

Figure 8: Precision/pseudo-recall curves for human evaluation by varying cut-off thresholds. The AUC is 0.751 with coreference, and 0.695 without.

Knowledge Graph Evaluation Figure 8 shows the human evaluation of the constructed knowledge graph, comparing the quality of automatically generated knowledge graphs with and without the coreference links. We randomly select 10 frequent scientific entities and extract all the relation triples that include one of the selected entities leading to 1.5k relation triples from both systems. We ask four domain experts to annotate each of these ex-

	Span Indentification			Keyphrase Extraction			Relation Extraction			Overall

SciIE	62.2	55.4	**58.6**	48.5	43.8	**46.0**	40.4	21.2	27.8	48.1	41.8	**44.7**

Table 4: Results for scientific keyphrase extraction and extraction on SemEval 2017 Task 10, comparing with previous best systems.

tracted relations to define ground truth labels. Each domain expert is assigned 2 or 3 entities and all of the corresponding relations. Figure 8 shows precision/recall curves for both systems. Since it is not feasible to compute the actual recall of the systems, we compute the pseudo-recall (Zhang et al., 2015) based on the output of both systems. We observe that the knowledge graph curve with coreference linking is mostly above the curve without coreference linking. The precision of both systems is high (above 84% for both systems), but the system with coreference links has significantly higher recall.

8 Conclusion

In this paper, we create a new dataset and develop a multi-task model for identifying entities, relations, and coreference clusters in scientific articles. By sharing span representations and leveraging cross-sentence information, our multi-task setup effectively improves performance across all tasks. Moreover, we show that our multi-task model is better at predicting span boundaries and outperforms previous state-of-the-art scientific IE systems on entity and relation extraction, without using any hand-engineered features or pipeline processing. Using our model, we are able to automatically organize the extracted information from a large collection of scientific articles into a knowledge graph. Our analysis shows the importance of coreference links in making a dense, useful graph.

We still observe a large gap between the performance of our model and human performance, confirming the challenges of scientific IE. Future work includes improving the performance using semi-supervised techniques and providing in-domain features. We also plan to extend our multi-task framework to information extraction tasks in other domains.

A Annotation Guideline

A.1 Entity Category

- **Task**: Applications, problems to solve, systems to construct.

  E.g. information extraction, machine reading system, image segmentation, etc.

- **Method**: Methods , models, systems to use, or tools, components of a system, frameworks.

  E.g. language model, CORENLP, POS parser, kernel method, etc.

- **Evaluation Metric**: Metrics, measures, or entities that can express quality of a system/method.

  E.g. F1, BLEU, Precision, Recall, ROC curve, mean reciprocal rank, mean-squared error, robustness, time complexity, etc.

- **Material**: Data, datasets, resources, Corpus, Knowledge base.

  E.g. image data, speech data, stereo images, bilingual dictionary, paraphrased questions, CoNLL, Panntreebank, WordNet, Wikipedia, etc.

- **Evaluation Metric**: Metric measure or term that can express quality of a system/method.

  E.g. F1, BLEU, Precision, Recall, ROC curve, mean reciprocal rank, mean-squared error,robustness, compile time, time complexity...

- **Generic**: General terms or pronouns that may refer to a entity but are not themselves informative, often used as connection words.

  E.g model, approach, prior knowledge, them, it...

A.2 Relation Category

Relation link can not go beyond sentence boundary. We define 4 asymmetric relation types (*Used-for*, *Feature-of*, *Hyponym-of*, *Part-of*), together with 2 symmetric relation types (*Compare*, *Conjunction*). B always points to A for asymmetric relations

- **Used-for**: B is used for A, B models A, A is trained on B, B exploits A, A is based on B. E.g.

  > The TISPER system has been designed to enable many text applications.
  >
  > Our method models user proficiency.
  >
  > Our algorithms exploits local soothness.

- **Feature-of**: B belongs to A, B is a feature of A, B is under A domain. E.g.

  > prior knowledge of the model
  >
  > genre-specific regularities of discourse structure
  >
  > English text in science domain

- **Hyponym-of**: B is a hyponym of A, B is a type of A. E.g.

  > TUIT is a software library
  >
  > NLP applications such as machine translation and language generation

- **Part-of**: B is a part of A... E.g.

  > The system includes two models: speech recognition and natural language understanding
  >
  > We incorporate NLU module to the system.

- **Compare**: Symmetric relation (use blue to denote entity). Opposite of conjunction, compare two models/methods, or listing two opposing entities. E.g.

  > Unlike the quantitative prior, the qualitative prior is often ignored...
  >
  > We compare our system with previous sequential tagging systems...

- **Conjunction**: Symmetric relation (use blue to denote entity). Function as similar role or use/incorporate with. E.g.

  > obtained from human expert or knowledge base
  >
  > NLP applications such as machine translation and language generation

A.3 Coreference

Two Entities that points to the same concept.

- **Anaphora and Cataphora**:

  > We introduce a machine reading system... The system...
  >
  > The prior knowledge include...Such knowledge can be applied to...

- **Coreferring noun phrase**:

  > We develop a part-of-speech tagging system...The POS tagger...

A.4 Notes

1. Entity boundary annotation follows the ACL RD-TEC Annotation Guideline (QasemiZadeh and Schumann, 2016), with the extention that spans can be embedded in longer spans, only if the shorter span is involved in a relation.

2. Do not include determinators (such as the, a), or adjective pronouns (such as this,its, these, such) to the span. If generic phrases are not involved in a relation, do not tag them.

3. Do not tag relation if one entity is:

    - Variable bound:
      We introduce a neural based approach.. *Its* benefit is...
    - The word *which*:
      We introduce a neural based approach, *which* is a...

4. Do not tag coreference if the entity is

    - Generically-used Other-ScientificTerm:
      ...advantage gained from *local smoothness* which... We present algorithms exploiting *local smoothness* in more aggressive ways...
    - Same scientific term but refer to different examples:
      We use a *data structure*, we also use another *data structure*...

5. Do not label negative relations:

    X is not used in Y or X is hard to be applied in Y

Abstract

The 20 Questions (Q20) game is a well known game which encourages deductive reasoning and creativity. In the game, the answerer first thinks of an object such as a famous person or a kind of animal. Then the questioner tries to guess the object by asking 20 questions. In a Q20 game system, the user is considered as the answerer while the system itself acts as the questioner which requires a good strategy of question selection to figure out the correct object and win the game. However, the optimal policy of question selection is hard to be derived due to the complexity and volatility of the game environment. In this paper, we propose a novel policy-based Reinforcement Learning (RL) method, which enables the questioner agent to learn the optimal policy of question selection through continuous interactions with users. To facilitate training, we also propose to use a reward network to estimate the more informative reward. Compared to previous methods, our RL method is robust to noisy answers and does not rely on the Knowledge Base of objects. Experimental results show that our RL method clearly outperforms an entropy-based engineering system and has competitive performance in a noisy-free simulation environment.

1 Introduction

The 20 Question Game (Q20 Game) is a classic game that requires deductive reasoning and creativity. At the beginning of the game, the ***answerer*** thinks of a target object and keeps it concealed. Then the ***questioner*** tries to figure out the target object by asking questions about it, and the answerer answers each question with a simple “Yes”, “No” or “Unknown”, honestly. The questioner wins the game if the target object is found within 20 questions. In a Q20 game system, the user is considered as the answerer while the system itself acts as the questioner which requires a good question selection strategy to win the game.

As a game with the hype *read your mind*, Q20 has been played since the 19th century, and was brought to screen in the 1950s by the TV show *Twenty Questions*. Burgener’s program (Burgener, 2006) further popularized Q20 as an electronic game in 1988, and modern virtual assistants like Microsoft XiaoIce and Amazon Alexa also incorporate this game into their system to demonstrate their intelligence.

However, it is not easy to design the algorithm to construct a Q20 game system. Although the decision tree based method seems like a natural fit to the Q20 game, it typically require a well defined Knowledge Base (KB) that contains enough information about each object, which is usually not available in practice. Burgener (2006) instead uses a object-question relevance table as the pivot for question and object selection, which does not depend on an existing KB. Wu et al. (2018) further improve the relevance table with a lot of engineering tricks. Since these table-based methods greedily select questions and the model parameters are only updated by rules, their models are very sensitive to noisy answers from users, which is common in the real-world Q20 games. Zhao and Maxine (2016) utilizes a value-based Reinforcement Learning (RL) model to improve the generalization ability but still relies on the existing KB.

In this paper, we formulate the process of question selction in the game as a Markov Decision Process (MDP), and further propose a novel policy-based RL framework to learn the optimal policy of question selection in the Q20 game. Our questioner agent maintains a probability distribution over all objects to model the confidence of the target object, and updates the confidence based on answers from the user. At each time-step. the agent uses a policy network $\pi_\theta(a|\boldsymbol{s})$ to take in

Brussels, Belgium, October 31 - November 4, 2018.

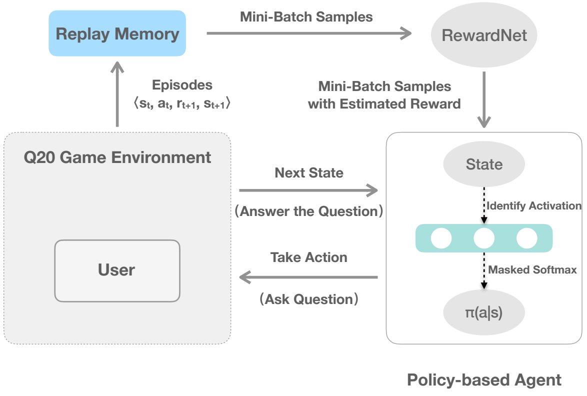

Figure 1: The overview of our RL framework.

the confidence vector and output a question distribution for selecting the next question. To solve the problem that there is no immediate reward for each selected question, we also propose to employ a RewardNet to estimate the appropriate immediate reward at each time-step, which is further used to calculate the long-term return to train our RL model. Our RL framework makes the agent robust to noisy answers since the model parameters are fully learnable and the question distribution from $\pi_\theta(a|\boldsymbol{s})$ provides us with a principled way to sample questions, which enables the agent to jump out of the local optimum caused by incorrect answers and also introduces more randomness during training to improve the model generalization ability. Furthermore, the ability to sample questions, compared to greedy selection, also improves the diversity of the questions asked by our agent, which is crucial for user experience.

Our contributions can be summarized as follows: (1) We propose a novel RL framework to learn the optimal policy of question selection in the Q20 game without any dependencies on the existing KBs of target objects. Our trained agent is robust to noisy answers and has a good diversity in its selected questions. (2) To make the reward more meaningful, we also propose a novel neural network on reward function approximation to deliver the appropriate immediate rewards at each time-step. (3) Extensive experiments show that our RL method clearly outperforms a highly engineered baseline in the real-world Q20 games where noisy answers are common. Besides, our RL method is also competitive to that baseline on a noise-free simulation environment.

2 Method

In this section, we first describe our RL framework for playing the Q20 game, which is shown in the Fig. 1. The user in our system is the answerer who thinks of a target object o_{tgt} in the object set $\mathcal{O}$ at the beginning of the game. Our policy-based agent acts as the questioner that can ask 20 questions to figure out what exactly o_{tgt} is. Specifically, an internal state vector $\boldsymbol{s}$ is maintained by our agent, which describes the confidence about o_{tgt}. At each time-step t, the agent picks up the promising action (select a question) according to the policy $\pi_\theta(a|\boldsymbol{s}_t)$, and transits from the state $\boldsymbol{s_t}$ to the next state $\boldsymbol{s_{t+1}}$ after receiving the answer ("Yes"/"No"/"Unknown") from the user. The historical trajectories $\langle s_t, a_t, r_{t+1}, s_{t+1}\rangle$ are stored in a *replay memory* which enables the agent to be trained on previously observed data by sampling from it. Note that only when a guess is made about o_{tgt} at the end of game can the agent receive a reward signal, which makes it unable to distinguish the importance of each selected question. Therefore, we design a RewardNet to learn the more informative reward at each time-step and thus lead the agent to achieve the better performance.

In the rest of this section, we first describe how to formulate the Q20 game into a RL framework, and then introduce the RewardNet. Finally, we will demonstrate our training procedure in detail.

2.1 Modeling of the Q20 Game

In the Q20 game, the goal of our agent is to figure out the object o_{tgt} that the user thinks of at the beginning of game by asking 20 questions. We formulate the process of question selection as a finite Markov Decision Process (MDP) which can be solved with RL. A tuple $\langle \mathcal{S}, \mathcal{A}, \mathcal{P}, \mathcal{R}, \gamma\rangle$ is defined to represent the MDP, where $\mathcal{S}$ is the continuous state space, $\mathcal{A} = \{a_1, a_2, \cdots, a_m\}$ is the set of all available actions, $\mathcal{P}(S_{t+1} = s' | S_t = s, A_t = a)$ is the transition probability matrix, $\mathcal{R}(s, a)$ is the reward function and $\gamma \in [0, 1]$ is the discount factor used to calculate the long-time return. In the RL framework, at each time-step t, the agent takes an action a_t under the state s_t according to the policy $\pi_\theta(a|s_t)$. After interacting with the environment, the agent receives a reward scalar r_{t+1} and transits to the next state s_{t+1}, then another time-step begins. All these trajectories $\langle s_t, a_t, r_{t+1}, s_{t+1}\rangle$ in a game constitute an episode which is an instance of the finite MDP. The long-time return G_t of the time-step t is calculated as follows:

$$G_t = \sum_{k=0}^{T} \gamma^k r_{t+k+1} \tag{1}$$

In the following parts, we describe each component of RL corresponding to the Q20 game.

Environment. The major component of our environment is the user in the Q20 game who decides the target object o_{tgt} and answers questions from the agent. Besides, the environment also needs to deliver the reward based on the outcome of the game and store historical data into the replay memory (see Fig. 1).

Action. Since the agent interacts with the user by asking questions, the action $a_t \in \mathcal{A}$ taken by our agent refers to selecting the question q_{a_t} at time-step t, and $\mathcal{A}$ is the set of the indices to all available questions in the Q20 game.

State. In our method, we use the state $\boldsymbol{s}_t$ to keep track of the current confidence of target object o_{tgt}. Specifically $\boldsymbol{s}_t \in \mathbb{R}^{|\mathcal{O}|}$ and $\sum_{i=1}^{n} s_{t,i} = 1$, where $\mathcal{O} = \{o_1, o_2, \cdots, o_n\}$ represents the set of all the objects that can be chosen by the user. Therefore, the state $\boldsymbol{s}_t$ is a probability distribution over all the objects and $s_{t,i}$ is the confidence that the object o_i is the target object o_{tgt} at time-step t.

The initial state $\boldsymbol{s}_0$ can either be a uniform distribution or initialized by the prior knowledge. We observe that users typically prefer to choose popular objects which are more concerned by the public. For example, the founder of Tesla Inc. and the designer of SpaceX, "Elon Musk", is more likely to be chosen compared to a CEO of a new startup. Motivated by this, we could use the yearly retrieval frequency $C(o_i)$ of object o_i on a commercial search engine to calculate the initial state $\boldsymbol{s}_0$, where $s_{0,i} = C(o_i) \;/\; \sum_{j=1}^{n} C(o_j)$.

Transition Dynamics. In our method, the transition dynamics is deterministic. Given the object set $\mathcal{O}$ and the question set $\mathcal{A}$, we collect the normalized probabilities of the answer over "Yes", "No" and "Unknown" for each object-question pair. And the rule of state transition is define as:

$$\boldsymbol{s}_{t+1} = \boldsymbol{s}_t \odot \boldsymbol{\alpha} \tag{2}$$

where $\boldsymbol{\alpha}$ depends on the answer x_t to the question q_{a_t} which is selected by the agent at the step t:

$$\alpha = \begin{cases} [R(1, a_t), \dots, R(|\mathcal{O}|, a_t)], & x_t = Yes \\ [W(1, a_t), \dots, W(|\mathcal{O}|, a_t)], & x_t = No \\ [U(1, a_t), \dots, U(|\mathcal{O}|, a_t)], & x_t = Unk \end{cases} \tag{3}$$

where $\mathcal{O}$ is the object set and for each object-question pair (o_i, q_j), $R(i, j)$ and $W(i, j)$ are calculated as follows:

$$\begin{aligned} R(i,j) &= \frac{C_{yes}(i,j) + \delta}{C_{yes}(i,j) + C_{no}(i,j) + C_{unk}(i,j) + \lambda} \\ W(i,j) &= \frac{C_{no}(i,j) + \delta}{C_{yes}(i,j) + C_{no}(i,j) + C_{unk}(i,j) + \lambda} \end{aligned} \tag{4}$$

$R(i, j)$ and $W(i, j)$ are probabilities of answering "Yes" and "No" to question q_j with respect to the object o_i respectively. $C_{yes}(i, j)$, $C_{no}(i, j)$ and $C_{unk}(i, j)$ are frequencies of answering "Yes", "No" and "Unknown" to question q_j with respect to the object o_i. δ and λ are smoothing parameters. Then the probability of answering "Unknown" to question q_j with respect to the object o_i is:

$$U(i, j) = 1 - R(i, j) - W(i, j) \tag{5}$$

In this way, the confidence $s_{t,i}$ that the object o_i is the target object o_{tgt} is updated following the user's answer x_t to the selected question q_{a_t} at the time-step t.

Policy Network. We directly parameterize the policy $\pi_\theta(a|\boldsymbol{s_t})$ with a neural network which maps the state $\boldsymbol{s_t}$ to a probability distribution over all available actions: $\pi_\theta(a|\boldsymbol{s_t}) = \mathbb{P}[a|\boldsymbol{s_t}; \theta]$. The parameters θ are updated to maximize the expected return which is received from the environment. Instead of learning a greedy policy in value-based methods like DQN, the policy network is able to learn a stochastic policy which can increase the diversity of questions asked by our agent and potentially make the agent more robust to noisy answers in the real-world Q20 game. The policy $\pi_\theta(a|\boldsymbol{s})$ is modeled by a Multi-Layer Perceptron (MLP) and the output layer is normalized by using a masked softmax function to avoid selecting the question that has been asked before. Because asking the same question twice does not provide extra information about o_{tgt} in a game.

2.2 Problem of Direct Reward

For most reinforcement learning applications, it is always a critical part to design reward functions, especially when the agent needs to precisely take actions in a complex task. A good reward function can improve the learning efficiency and help the agent achieve better performances.

In the Q20 game, however, the immediate reward r_t of selecting question q_{a_t} is unknown at the time-step t ($t < T$) because each selected question is just answered with a simple "Yes", "No" or

"Unknown" and there is no extra information provided by user. Only when the game ends $(t = T)$ can the agent receive a reward signal of win or loss. So we intuitively consider the ***direct reward***: $r_T = 30$ and -30 for the win and loss respectively while $r_t = 0$ for all $t < T$. Unfortunately, the direct reward is not discriminative because the agent receives the same immediate reward $r_t = 0\,(t < T)$ for selecting both good and bad questions. For example, if the o_{tgt} is "Donald Trump", then selecting question (a) "Is your role the American president?" should receive more immediate reward r_t than selecting question (b) "Has your role been married?". The reason is that as for the o_{tgt}, question (a) is more relevant and can narrow down the searching space to a greater extent.

Therefore, it is necessary to design a better reward function to estimate a non-zero immediate reward r_t, and make the long-time return $G_t = \sum_{k=0}^{T} \gamma^k r_{t+k+1}$ more informative.

2.3 Reward Function Approximation by Neural Network

To solve the problem of the direct reward, we propose a reward function which employs a neural network to estimate a non-zero immediate reward r_t at each time-step. So that G_t can be more informative, which thus leads to a better trained questioner agent.

The reward function takes the state-action pair (s_t, a_t) as input and outputs the corresponding immediate reward r_{t+1}. In our method, we use a MLP with sigmoid output to learn the appropriate immediate reward during training, and this network is referred as ***RewardNet***. In each episode, the long-term return G_t is used as a surrogate indicator of r_{t+1} to train our RewardNet with the following loss function:

$$L_1(\sigma) = (R(s_t, a_t; \sigma) - \text{sigmoid}(G_t))^2 \quad (6)$$

where σ is the network parameters. Here we apply the sigmoid function on G_t so as to prevent G_t from growing too large. Besides, we also use the replay memory to store both old and recent experiences, and then train the network by sampling mini-batches from it. The training process based on the experience replay technique can decorrelate the sample data and thus make the training of the RewardNet more efficient.

Furthermore, since the target object o_{tgt} can be obtained at the end of each episode, we can use the extra information provided by o_{tgt} to estimate a better immediate reward r_t. To capture the relevance between the selected questions and o_{tgt} in an episode, we further propose a ***object-aware RewardNet*** which takes the $\langle s_t, a_t, o_{tgt}\rangle$ tuple as input and produces corresponding r_{t+1} as output. The detailed training algorithm is shown in Algo. 1.

Algorithm 1: Training Object-Aware RewardNet

```
Initialize replay memory $\mathcal{D}_1$ to capacity $N_1$
Initialize RewardNet with random weights $\sigma$
for episode $i \leftarrow 1$ to $Z$ do
    User chooses object $o_i$ from $\mathcal{O}$
    Initialize temporary set $S_1$ and $S_2$
    Play with policy $\pi_\theta(a_t|s_t)$, and store $(s_t, a_t)$ in $S_1$, where $t \in [0, T]$
    $r_T \leftarrow 30$ or $-30$ for a win or loss
    for $(s_t, a_t)$ in $S_1$ do
        Get $r_{t+1}$ from RewardNet
        Store $(s_t, a_t, r_{t+1})$ tuple in $S_2$
    for $(s_t, a_t, r_{t+1})$ in $S_2$ do
        $G_t \leftarrow \sum_{k=0}^{T} \gamma^k r_{t+k+1}$
        $r'_{t+1} \leftarrow sigmoid(G_t)$
        Store $(s_t, a_t, o_i, r'_{t+1})$ in $\mathcal{D}_1$
        if $len(\mathcal{D}_1) > K_1$ then
            Sample mini-batch from $\mathcal{D}_1$
            Update $\sigma$ with loss $L_1(\sigma)$ in Eq. 6
```

2.4 Training the Policy-Based Agent

We train the policy network using REINFORCE (Williams, 1992) algorithm and the corresponding loss function is defined as follows:

$$L_2(\theta) = -\mathbb{E}_{\pi_\theta}[\log \pi_\theta(a_t|s_t)(G_t - b_t)] \quad (7)$$

where the baseline b_t is a estimated value of the expected future reward at the state s_t, which is produced by a value network $\mathcal{V}_\eta(s_t)$. Similarly, the value network $\mathcal{V}_\eta(s_t)$ is modeled as a MLP which takes the state s_t as input and outputs a real value as the expected return. By introducing the baseline b_t for the policy gradient, we can reduce the variance of gradients and thus make the training process of policy network more stable. The network parameters η are updated by minimizing the loss function below:

$$L_3(\eta) = (\mathcal{V}_\eta(s_t) - G_t)^2 \quad (8)$$

Note that, in our method, both the RewardNet and the value network $\mathcal{V}_\eta(s_t)$ approximate the reward during training. But the difference lies in that the RewardNet is designed to estimate a appropriate non-zero reward r_t and further derive the more informative return G_t while $\mathcal{V}_\eta(s_t)$ aims to learn a baseline b_t to reduce the variance of policy gradients. We combine both of two networks to improve the gradients for our policy network and thus lead to a better agent. The training procedure is described in Algo. 2.

Algorithm 2: Training the Agent

```
Initialize replay memory $\mathcal{D}_2$ to capacity $N_2$
Initialize policy net $\pi$ with random weights $\theta$
Initialize value net $\mathcal{V}$ with random weights $\eta$
Initialize RewardNet with random weights $\sigma$
for $episode\ i \leftarrow 1$ to $Z$ do
    Rollout, collect rewards, and save the
      history in $S_2$ (4-10 in Algo. 1)
    for $(s_t, a_t, r_{t+1})$ in $S_2$ do
        $G_t \leftarrow \sum_{k=0}^{T} \gamma^k r_{t+k+1}$
        Update RewardNet (13-17 in
          Algo. 1)
        Store $(s_t, a_t, G_t)$ in $\mathcal{D}_2$
        if $len(\mathcal{D}_2) > K_2$ then
            Sample mini-batch from $\mathcal{D}_2$
            Update $\eta$ with loss $L_3$ in Eq. 8
            Update $\theta$ with loss $L_2$ in Eq. 7
```

3 Experimental Setup

We use a user simulator to train our questioner agent and test the agent with the simulated answerer and real users. Specifically, our experiments answer three questions: (1) Is our method more robust in real-world Q20 games, compared to the methods based on relevance table? (Section. 4.2) And how does it perform in the simulation environment? (Section. 4.1) (2) Does our RewardNet help in the training process? (Section. 4.3) (3) How the winning rate grows with the number of questions, and whether it is possible to stop earlier? (Section. 4.4)

3.1 User Simulator

Training the RL agent is challenging because the agent needs to continuously interact with the environment. To speed up the training process of the proposed RL model, we construct a user simulator which has enough prior knowledge to choose objects and answer questions selected by the agent.

We collect 1,000 famous people and 500 questions for them. Besides, for every person-question pair in our dataset, a prior frequency distribution over "Yes", "No" and "Unknown" is also collected from thousands of real users. For example, as for "Donald Trump", question (a) "Is your role the American president?" is answered with "Yes" for 9,500 times, "No" for 50 times and "Unknown" for 450 times. We use Eq.4 and 5 to construct three matrices $R, W, U \in \mathbb{R}^{|\mathcal{O}|*|\mathcal{A}|}$ ($|\mathcal{O}| = 1000, |\mathcal{A}| = 500$) which are used for state transition in the Section. 2.1. Then given the object o_i and question q_j, the user simulator answers "Yes", "No" and "Unknown" when $R(i,j)$, $W(i,j)$, and $U(i,j)$ has the max value among them respectively.

Constructed by the prior knowledge, the simulator can give noise-free answer in most cases. Because the prior frequency distribution for each person-question pair is collected from thousands of users with the assumption that most of them do not lie when answering questions in the Q20 game.

In an episode, the simulator randomly samples a person following the object distribution s_0, which is generated from the object popularity (see the state part of Section. 2.1), as the target object. Then the agent gives a guess when the number of selected questions reaches 20. After that, the simulator check the agent's answer and return a reward signal of win or loss. There is only one chance for the agent to guess in an episode. The win and loss reward are 30 and -30 respectively.

3.2 Implementation Details

While the architectures of the policy network, RewardNet and value network can vary in different scenarios, in this paper, we simply use the MLP with one hidden layer of size 1,000 for all of them, but with different parameters. These networks take in the state vector directly, which is a probability distribution over all objects. The RewardNet further takes in the one-hot vector of action a_t. Based on the input of RewardNet, the object-aware RewardNet takes one more target object o_{tgt} as the feature which is also a one-hot vector.

We use the ADAM optimizer (Kingma and Ba, 2014) with the learning rate 1e-3 for policy network and 1e-2 for both RewardNet and value network. The discounted factor γ for calculating the long-term return is 0.99. The model was trained up

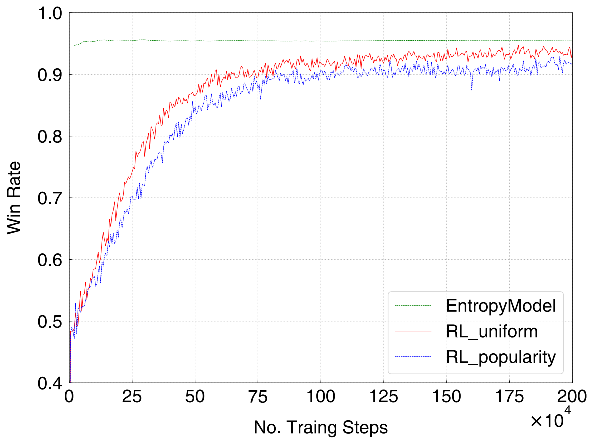

Figure 2: Win Rate Curves in Simulation Environment.

to 2,000,000 steps (2,00,000 games) and the policy network was evaluated every 5,000 steps. Each evaluation records the agent's performance with a greedy policy for 2,000 independent episodes. The 2,000 target objects for these 2,000 episodes are randomly selected following the distribution s_0, which is generated from the object popularity and kept the same for all the training settings.

3.3 Competitor

We compare our RL method with the entropy-based model proposed by Wu et al. (2018), which utilizes the real-world answers to each object-question pair to calculate an object-question relevance matrix with the entropy-based method. The relevance matrix is then used for question ranking and object ranking via carefully designed formulas and engineering tricks. Since this method is shown to be effective in their production environment, we consider it to be a strong baseline to our proposed RL model.

4 Experimental Results

4.1 Simulated Evaluation

We first evaluate our agent and the entropy-based baseline (referred to as `EntropyModel`, see Section. 3.3) by using the simulated user (Section. 3.1). To investigate which initialization strategy of the state s_0 is better (see the state part of Section. 2.1), we further evaluate two variants of our model: the agent with uniform distribution s_0 (`RL_uniform`) and the agent with the distribution s_0 initialized by the prior knowledge on the object popularity (`RL_popularity`).

Fig. 2 shows the curves on the win rate of these methods evaluated on 2,000 independent episodes with respect to the number of training steps. Note that, the `EntropyModel` only needs to update its statistics during training and has already accumulated a significant number of data since it has been run for over a year in their production environment. Therefore, only a small fraction of its statistics can be changed, which leads to a small rise at the beginning of training, and its win rate remains at around 95% afterwards.

On the other hand, both our RL models continuously improve the win rate with the growing number of interactions with the user simulator, and they achieve 50% win rate after around 20,000 steps. As we can see, although the s_0 initialized with the prior knowledge of object popularity keeps consistent with the object selection strategy of the simulator, the agent with uniform distribution s_0 (`RL_uniform`) still performs clearly better than the agent with s_0 based on the prior knowledge (`RL_popularity`). The reason is that the former can explore the Q20 game environment more fully. The prior knowledge based s_0 helps the agent narrow down the candidate space more quickly when the target object is a popular object. However, it also becomes misleading when the target object is not popular and makes the agent even harder to correct the confidence of the target object. On the contrary, the uniform distribution s_0 makes the agent keep track of the target object only based on the user's answers. And the superior performance of the `RL_uniform` indicates that our question selection policy is highly effective, which means it is not necessary to use the `RL_popularity` to increase the win rate of hot objects in the game.

As shown in Fig. 2, `RL_uniform` achieves win rate 94% which is very close to `EntropyModel`. Compared to our RL method, `EntropyModel` needs more user data to calculate their entropy-based relevance matrix and involves many engineering tricks. The fact that `RL_uniform` is competitive to `EntropyModel` in the noise-free simulation environment indicates that our RL method is very cost-effective: it makes use of user data more efficiently and is easier to implement.

4.2 Human Evaluation

To further investigate the performance of our RL method in the real-world Q20 game where noisy answers are common, we also conduct an human evaluation experiment. Specifically, we let real

	Win Rate
`EntropyModel`	71.3%
`RL_uniform`	75.9%

Table 1: Win Rate on Human Evaluation.

users to play the game with `EntropyModel` and `RL_uniform` for 1,000 times respectively. In the real-world Q20 game, users sometimes make mistakes when they answer the questions during the game. For example, as for the target object "Donald Trump", question (a) "Is your role the American president?" is sometimes answered with "No" or "Unknown" by real users. On the contrary, the simulator hardly makes such mistakes since we have provided it with enough prior knowledge. As shown in Table. 1, `RL_uniform` outperforms `EntropyModel` by about 4.5% on win rate in the real-world Q20 games. It shows that our RL method is more robust to noisy answers than `EntropyModel`. Specifically, the robustness of our RL method to the noise is shown in the following two aspects. First, compared to the rule-based statistics update in `EntropyModel`, our RL model can be trained by modern neural network optimizers in a principled way, which results in the better generalization ability of our model. Secondly, different from the `EntropyModel` selecting the top-ranked question at each time-step, `RL_uniform` samples a question following its question probability distribution $\pi_\theta(a|\boldsymbol{s})$, which enables our agent to jump out of the local optimum caused by incorrect answers from users. And since more randomness is introduced by sampling from the question probability distribution during training, it also improves the tolerance of our model towards the unexpected question sequences.

Besides, we also find some interesting cases during human evaluation. Sometimes, the RL agent selects a few strange questions which seems to be not that much relevant to the chosen object, but it can still find the correct answer at the end of game. This situation is caused by the fact that our method samples questions based on the output of policy net, rather than greedy selection during training. We find that this phenomenon increases the user experience since it makes the agent more unpredictable to the users.

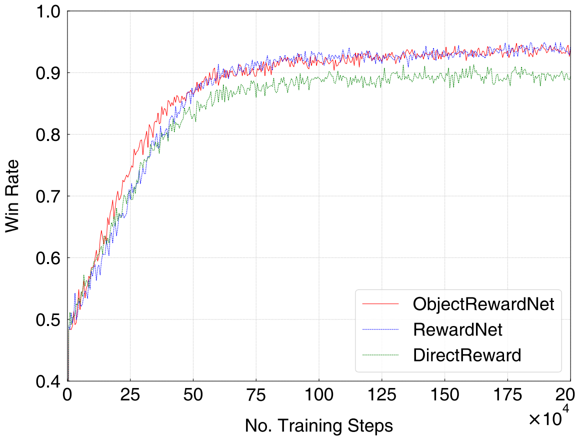

Figure 3: Effectiveness of RewardNet.

4.3 The Effectiveness of RewardNet

To investigate the effectiveness of our RewardNet (Section. 2.3), we further evaluate three variants of our model in the simulation environment: the model trained with with direct reward, RewardNet, and object-aware RewardNet, which are referred to as `DirectReward`, `RewardNet`, and `ObjectRewardNet` respectively. They are all trained with the uniform distribution $\boldsymbol{s}_0$.

As shown in Fig. 3, `DirectReward` converges in the early steps and has a relatively poor performance with the win rate 89%. Both `RewardNet` and `ObjectRewardNet` achieve the better performance with a win rate of 94% after convergence. This clear improvement shows that the more informative long-term return, calculated with the immediate reward delivered by our RewardNet method, significantly helps the training of the agent.

Furthermore, as shown in Fig. 3, we can also see that `ObjectRewardNet` learns faster than `RewardNet` in the early steps. This indicates that `ObjectRewardNet` can estimate the immediate reward more quickly with the extra information provided by the target object, which leads to the faster convergence of the agent.

4.4 Win Rate Regarding Question Numbers

In this section, we investigate how the win rate grows with the number of asked questions and whether a early-stop strategy can be adopted in the game. We use the user simulator to play the game with the `RL_uniform` agent and two settings are taken into account: the simulator samples the target object following the uniform object distribution (`UnifSimulator`), and samples following

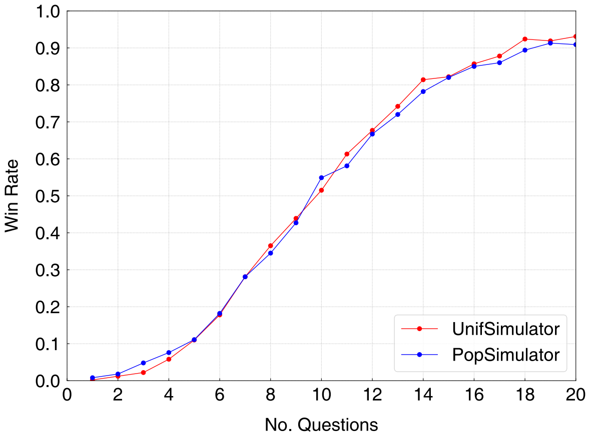

Figure 4: Win Rate Regarding Numbers of Questions.

the prior object distribution based on the object popularity (`PopSimulator`). We perform 1,000 simulations for each number of questions, and the win rate curve is shown in Fig. 4.

As we can see that `UnifSimulator` achieves the win rate of 80% with only 14 questions in both settings. And the flat curves in the region after 18 questions indicate that the game can be early stopped with the almost same win rate at step 18. Since a lower win rate is acceptable sometimes, other early-stop strategies can also be derived for the better user experience with the trade-off between the win rate and game steps.

Besides, the fact that `RL_uniform` performs similarly under both settings actually shows that our RL method is robust to different objects. It also performs well on infrequent objects where we may have the limited user data for constructing a well-tuned state transition dynamics.

4.5 Case Study

When our agent is playing the game with real users, we select two cases from records. In the first case, the person that the user chooses is Cristiano Ronaldo, the famous football player. As we can see in Tab. 2, our agent can still figure out the target person while No.17 and No.19 questions are answered wrong by the user, which indicates our agent is robust to noisy answers. In the second case, the chosen person is Napoleon Bonaparte who was the French Emperor. Although there are some other candidates satisfied the constraints, the target person can be figured out because of the people popularity, which is shown in Tab. 3.

5 Related Work

Q20. The Q20 game is popularized as an electronic game by the program of Robin Burgener in 1988 (Burgener, 2006), which uses a object-question relevance table to rank questions and target objects. Wu et al. (Wu et al., 2018) improves the relevance table with entropy-based metrics, and uses complicated engineering tricks to make it perform quite well in their production environment. These table-based methods use rules to update parameters, which makes them easily affected by noisy answers. Besides, Zhao and Maxine (2016) also explores Q20 in their dialogue state tracking research. However, they only use a small toy Q20 setting where the designed questions are about 6 person attributes in the Knowledge Base (KB). Since their method relies on the KB for narrowing down the scope of target object, it is not applicable to real-world Q20 games where a well-defined object KB is often unavailable. Compared to previous approaches, our RL method is robust to the answer noise and does not rely on the KB.

Deep Reinforcement Learning. DRL has witnessed great success in playing complex games like Atari games (Mnih et al., 2015) , Go (Silver et al., 2016), and etc. In the natural language processing (NLP), DRL is also used to play text-based games (Narasimhan et al., 2015), and used to handle fundamental NLP tasks like machine translation (He et al., 2016) and machine comprehension (Hu et al., 2017) as well. Our Q20 game lies in the intersection of the field of game and NLP. In this work, we propose a policy-based RL model that acts as the questioner in the Q20 game, and it exhibits the superior performance in our human evaluation.

Natural Language Games. In the literature, there are some works focusing on solving and generating English riddles (De Palma and Weiner, 1992; Binsted, 1996) and Chinese character riddles (Tan et al., 2016). Compared to riddles, the Q20 game is a sequential decision process which requires careful modeling of this property.

6 Conclusions

In this paper, we propose a policy-based RL method to solve the question selection problem in the Q20 Game. Instead of using the direct reward, we further propose an object-aware RewardNet to estimate the appropriate non-zero reward and thus make the long-time return more informative. Compared to previous approaches, our RL method is more robust to the answer noise which is common in the real-world Q20 game. Besides, our RL agent can also ask various questions and does not require the existing KB and complicated engineering tricks. The experiments on a noisy-free simulation environment show that our RL method is competitive to an entropy-based engineering system, and clearly outperforms it on the human evaluation where noisy answers are common.

As for the future work, we plan to explore methods to use machine reading to automatically construct the state transition dynamics from corpora like Wikipedia. In this way, we can further build an end-to-end framework for the large-scale Q20 games in the real world.

Multi-Hop Knowledge Graph Reasoning with Reward Shaping

Xi Victoria Lin **Richard Socher** **Caiming Xiong**
Salesforce Research
{xilin,rsocher,cxiong}@salesforce.com

Abstract

Multi-hop reasoning is an effective approach for query answering (QA) over incomplete knowledge graphs (KGs). The problem can be formulated in a reinforcement learning (RL) setup, where a policy-based agent sequentially extends its inference path until it reaches a target. However, in an incomplete KG environment, the agent receives low-quality rewards corrupted by false negatives in the training data, which harms generalization at test time. Furthermore, since no golden action sequence is used for training, the agent can be misled by spurious search trajectories that incidentally lead to the correct answer. We propose two modeling advances to address both issues: (1) we reduce the impact of false negative supervision by adopting a pretrained one-hop embedding model to estimate the reward of unobserved facts; (2) we counter the sensitivity to spurious paths of on-policy RL by forcing the agent to explore a diverse set of paths using randomly generated edge masks. Our approach significantly improves over existing path-based KGQA models on several benchmark datasets and is comparable or better than embedding-based models.

1 Introduction

Large-scale knowledge graphs (KGs) support a variety of downstream NLP applications such as semantic search (Berant et al., 2013) and dialogue generation (He et al., 2017). Whether curated automatically or manually, practical KGs often fail to include many relevant facts. A popular approach for modeling incomplete KGs is knowledge graph embeddings, which map both entities and relations in the KG to a vector space and learn a truth value function for any potential KG triple parameterized by the entity and relation vectors (Yang et al., 2014; Dettmers et al., 2018).

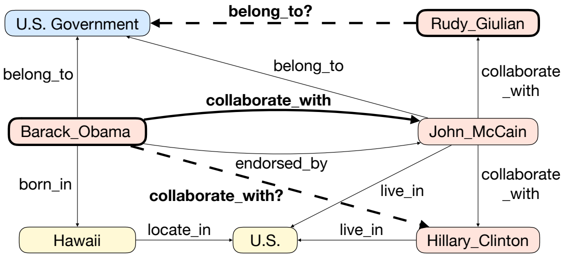

Figure 1: Example of an incomplete knowledge graph which contains missing links (dashed lines) that can possibly be inferred from existing facts (solid lines).

Embedding based approaches ignore the symbolic compositionality of KG relations, which limit their application in more complex reasoning tasks. An alternative solution for KG reasoning is to infer missing facts by synthesizing information from multi-hop paths, e.g. *bornIn(Obama, Hawaii)* $\wedge$ *locatedIn(Hawaii, US)* $\Rightarrow$ *bornIn(Obama, US)*, as shown in Figure 1. Path-based reasoning offers logical insights of the underlying KG and are more directly interpretable. Early work treats it as a link prediction problem and perform maximum-likelihood classification over either discrete path features (Lao et al., 2011, 2012; Gardner et al., 2013) or their hidden representations in a vector space (Guu et al., 2015; Toutanova et al., 2016; McCallum et al., 2017).

More recent work formulates multi-hop reasoning as a sequential decision problem, and leverages reinforcement learning (RL) to perform effective path search (Xiong et al., 2017; Das et al., 2018; Shen et al., 2018; Chen et al., 2018). In particular, MINERVA (Das et al., 2018) uses the REINFORCE algorithm (Williams, 1992) to train an end-to-end model for multi-hop KG query answering: given a query relation and a source entity, the trained agent searches over the KG starting from the source and arrives at the candidate answers without access to any pre-computed paths.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3243–3253
Brussels, Belgium, October 31 - November 4, 2018.

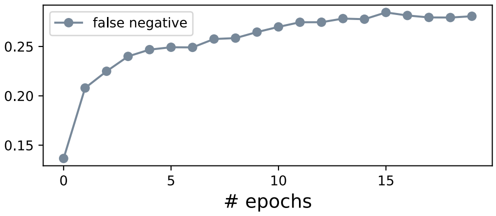

Figure 2: Percentage of false negatives hit (where the model predicted an answer that exists in the full KG but cannot be identified by the training subset) in the first 20 epochs of walk-based QA training on the UMLS knowledge graph (Kok and Domingos, 2007).

We refer to the RL formulation adopted by MINERVA as "learning to walk towards the answer" or "walk-based query-answering (QA)". Walk-based QA eliminates the need to precompute path features, yet this setup poses several challenges for training. First, because practical KGs are intrinsically incomplete, the agent may arrive at a correct answer whose link to the source entity is missing from the training graph without receiving any reward (false negative targets, Figure 2). Second, since no ground truth path is available for training, the agent may traverse spurious paths that lead to a correct answer only incidentally (false positive paths). Because REINFORCE (Williams, 1992) is an on-policy RL algorithm (Sutton and Barto, 1998) which encourages past actions with high reward, it can bias the policy toward spurious paths found early in training (Guu et al., 2017).

We propose two modeling advances for RL approaches in the walk-based QA framework to address the aforementioned problems. First, instead of using a binary reward based on whether the agent has reached a correct answer or not, we adopt pre-trained state-of-the-art embedding-based models (Dettmers et al., 2018; Trouillon et al., 2016) to estimate a ***soft reward*** for target entities whose correctness cannot be determined. As embedding-based models capture link semantics well, unobserved but correct answers would receive a higher reward score compared to a true negative entity using a well-trained model. Second, we perform ***action dropout*** which randomly blocks some outgoing edges of the agent at each training step so as to enforce effective exploration of a diverse set of paths and dilute the negative impact of the spurious ones. Empirically, our overall model significantly improves over state-of-the-art multi-hop reasoning approaches on four out of five benchmark KG datasets (UMLS, Kinship, FB15k-237, WN18RR). It is also the first path-based model that achieves consistently comparable or better performance than embedding-based models. We perform a thorough ablation study and result analysis, demonstrating the effect of each modeling innovation.

2 Approach

In this section, we first review the walk-based QA framework (§2.2) and the on-policy reinforcement learning approach proposed by Das et al. (2018) (§2.3,§2.4). Then we describe our proposed solutions to the false negative reward and spurious path problems: knowledge-based reward shaping (§2.5) and action dropout (§2.6).

2.1 Formal Problem Definition

We formally represent a knowledge graph as $\mathcal{G} = (\mathcal{E}, \mathcal{R})$, where $\mathcal{E}$ is the set of entities and $\mathcal{R}$ is the set of relations. Each directed link in the knowledge graph $l = (e_s, r, e_o) \in \mathcal{G}$ represents a fact (also called a triple).

Given a query $(e_s, r_q, ?)$, where e_s is the source entity and r_q is the relation of interest, the goal is to perform an efficient search over $\mathcal{G}$ and collect the set of possible answers $E_o = \{e_o\}$ where $(e_s, r_q, e_o) \notin \mathcal{G}$ due to incompleteness.

2.2 Reinforcement Learning Formulation

The search can be formulated as a Markov Decision Process (MDP) (Sutton and Barto, 1998): starting from e_s, the agent sequentially selects an outgoing edge l and traverses to a new entity until it arrives at a target. Specifically, the MDP consists of the following components (Das et al., 2018).

States Each state $s_t = (e_t, (e_s, r_q)) \in \mathcal{S}$ is a tuple where e_t is the entity visited at step t and (e_s, r_q) are the source entity and query relation. e_t can be viewed as the state-dependent information while (e_s, r_q) are the global context shared by all states.

Actions The set of possible actions $A_t \in \mathcal{A}$ at step t consists of the outgoing edges of e_t in $\mathcal{G}$, i.e., $A_t = \{(r', e') | (e_t, r', e') \in \mathcal{G}\}$. To give the agent the option to terminat a search, a self-loop edge is added to every A_t. When search is unrolled for a fixed number of steps T, the self-loop acts similarly to a "stop" action.

Transition A transition function $\delta : \mathcal{S} \times \mathcal{A} \rightarrow \mathcal{S}$ is defined by $\delta(s_t, A_t) = \delta(e_t, (e_s, r_q), A_t)$. In walk-based QA, the transition is determined by $\mathcal{G}$.

Rewards In the default formulation, the agent receives a terminal reward of 1 if it arrives at a correct target entity when search ends and 0 otherwise.

$$R_b(s_T) = \mathbb{1}\{(e_s, r_q, e_T) \in \mathcal{G}\}. \tag{1}$$

2.3 Policy Network

The search policy is parameterized using state information and global context, plus the search history (Das et al., 2018).

Specifically, every entity and relation in $\mathcal{G}$ is assigned a dense vector embedding $\mathbf{e} \in \mathbb{R}^d$ and $\mathbf{r} \in \mathbb{R}^d$. A particular action $a_t = (r_{t+1}, e_{t+1}) \in A_t$ is represented as the concatenation of the relation embedding and the end node embedding $\mathbf{a}_t = [\mathbf{r}; \mathbf{e}'_t]$.

The search history $h_t = (e_s, r_1, e_1, \ldots, r_t, e_t) \in \mathcal{H}$ consists of the sequence of actions taken up to step t, and can be encoded using an LSTM:

$$\mathbf{h}_0 = \text{LSTM}(\mathbf{0}, [\mathbf{r}_0; \mathbf{e}_s]) \tag{2}$$

$$\mathbf{h}_t = \text{LSTM}(\mathbf{h}_{t-1}, \mathbf{a}_{t-1}),\ t > 0, \tag{3}$$

where r_0 is a special start relation introduced to form a start action with e_s.

The action space A_t is encoded by stacking the embeddings of all actions in it: $\mathbf{A}_t \in \mathbb{R}^{|A_t| \times 2d}$. And the policy network π is defined as:

$$\pi_\theta(a_t|s_t) = \sigma(\mathbf{A}_t \times W_2 \,\text{ReLU}(W_1[\mathbf{e}_t; \mathbf{h}_t; \mathbf{r}_q])), \tag{4}$$

where σ is the softmax operator.

2.4 Optimization

The policy network is trained by maximizing the expected reward over all queries in $\mathcal{G}$:

$$J(\theta) = \mathbb{E}_{(e_s, r, e_o) \in \mathcal{G}}[\mathbb{E}_{a_1, \ldots, a_T \sim \pi_\theta}[R(s_T|e_s, r)]]. \tag{5}$$

The optimization is done using the REINFORCE (Williams, 1992) algorithm, which iterates through all (e_s, r, e_o) triples in $\mathcal{G}$[1] and updates θ with the following stochastic gradient:

$$\nabla_\theta J(\theta) \approx \nabla_\theta \sum_{t=1}^{T} R(s_T|e_s, r) \log \pi_\theta(a_t|s_t). \tag{6}$$

2.5 Knowledge-Based Reward Shaping

According to Equation 1, the agent receives a binary reward based solely on the observed answers in $\mathcal{G}$. However, $\mathcal{G}$ is intrinsically incomplete and this approach penalizes the false negative search attempts identically to true negatives. To alleviate this problem, we adopt existing KG embedding models designed for the purpose of KG completion (Trouillon et al., 2016; Dettmers et al., 2018) to estimate a soft reward for target entities whose correctness is unknown.

Formally, the embedding models map $\mathcal{E}$ and $\mathcal{R}$ to a vector space, and estimate the likelihood of each fact $l = (e_s, r, e_t) \in \mathcal{G}$ using $f(e_s, r, e_t)$, a composition function of the entity and relation embeddings. f is trained by maximizing the likelihood of all facts in $\mathcal{G}$. We propose the following reward shaping strategy (Ng et al., 1999):

$$R(s_T) = R_b(s_T) + (1 - R_b(s_T))f(e_s, r_q, e_T). \tag{7}$$

Namely, if the destination e_T is a correct answer according to $\mathcal{G}$, the agent receives reward 1. Otherwise the agent receives a fact score estimated by $f(e_s, r_q, e_T)$, which is pre-trained. Here we keep f in its general form and it can be replaced by any state-of-the-art model (Trouillon et al., 2016; Dettmers et al., 2018) or ensemble thereof.

2.6 Action Dropout

The REINFORCE training algorithm performs on-policy sampling according to $\pi_\theta(a_t|s_t)$, and updates θ stochastically using Equation 6. Because the agent does not have access to any oracle path, it is possible for it to arrive at a correct answer e_o via a path irrelevant to the query relation. As shown in Figure 1, the path *Obama —endorsedBy→ McCain —liveIn→ U.S. ←locatedIn— Hawaii* does not infer the fact $bornIn(Obama, Hawaii)$.

Discriminating paths of different qualities is non-trivial, and existing RL approaches for walk-based KGQA largely rely on the terminal reward to bias the search. Since there are usually more spurious paths than correct ones, spurious paths are often found first, and following exploration can be increasingly biased towards them (Equation 6).

---

[1] This training strategy treats a query with $n > 1$ answers as n single-answer queries. In particular, given a query $(e_s, r_q, ?)$ with multiple answers $\{e_{t_1}, \ldots e_{t_n}\}$, when training w.r.t. the example (e_s, r_q, e_{t_i}), MINERVA removes all $\{e_{t_j} | j \neq i\}$ observed in the training data from the possible set of target entities in the last search step so as to force the agent to walk towards e_{t_i}. We adopt the same technique in our training.

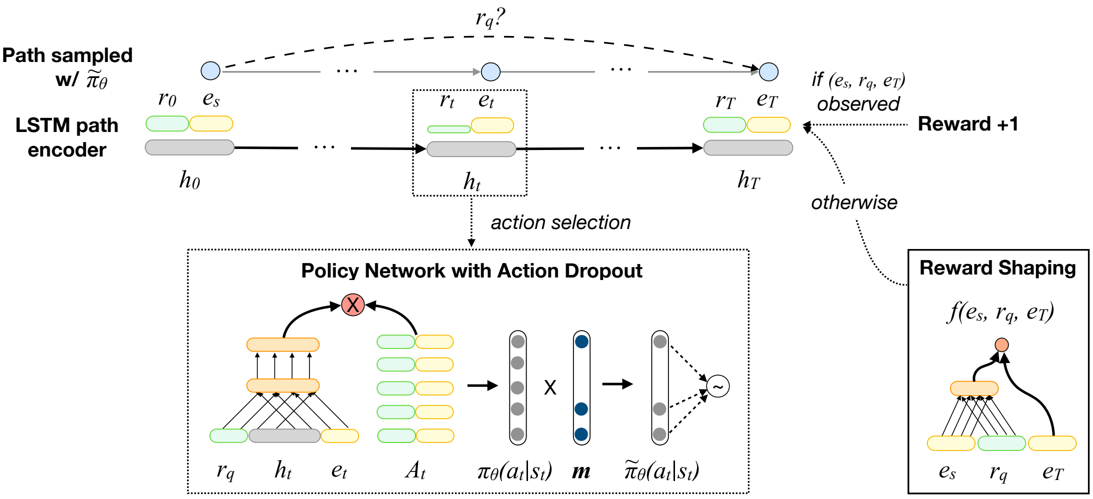

Figure 3: Overall training approach. At each time step t, the agent samples an outgoing link according to $\tilde{\pi}_\theta(a_t|s_t)$, which is the stochastic REINFORCE policy $\pi_\theta(a_t|s_t)$ perturbed by a random binary mask $\mathbf{m}$. The agent receives reward 1 if stopped at an observed answer of the query $(e_s, r_q, ?)$; otherwise, it receives reward $f(e_s, r_q, e_T)$ estimated by the reward shaping (RS) network. The RS network is pre-trained and doesn't receive gradient updates.

Entities with larger fan-in (in-degree) and fan-out (out-degree) often exacerbate this problem.

Guu et al. (2017) identified a similar issue in RL-based semantic parsing with weak supervision, where programs that do not semantically match the user utterance frequently pass the tests. To solve this problem, Guu et al. (2017) proposed randomized beam search combined with a meritocratic update rule to ensure all trajectories that obtain rewards are up-weighted roughly equally.

Here we propose the action dropout technique which achieves similar effect as randomized search and is simpler to implement over graphs. Action dropout randomly masks some outgoing edges for the agent in the sampling step of REINFORCE. The agent then performs sampling[2] according to the adjusted action distribution

$$\tilde{\pi}_\theta(a_t|s_t) \propto (\pi_\theta(a_t|s_t) \cdot \mathbf{m} + \epsilon) \tag{8}$$

$$m_i \sim Bernoulli(1-\alpha), i = 1, \dots |A_t|, \tag{9}$$

where each entry of $\mathbf{m} \in \{0,1\}^{|A_t|}$ is a binary variable sampled from the Bernoulli distribution with parameter $1-\alpha$. A small value ϵ is used to smooth the distribution in case $\mathbf{m} = \mathbf{0}$, where $\tilde{\pi}_\theta(a_t|s_t)$ becomes uniform.

Our overall approach is illustrated in Figure 3.

3 Related Work

In this section, we summarize the related work and discuss their connections to our approach.

3.1 Knowledge Graph Embeddings

KG embeddings (Bordes et al., 2013; Socher et al., 2013; Yang et al., 2014; Trouillon et al., 2016; Dettmers et al., 2018) are one-hop KG modeling approaches which learn a scoring function $f(e_s, r, e_o)$ to define a fuzzy truth value of a triple in the embedding space. These models can be adapted for query answering by simply return the e_o's with the highest $f(e_s, r, e_o)$ scores. Despite their simplicity, embedding-based models achieved state-of-the-art performance on KGQA (Das et al., 2018). However, such models ignore the symbolic compositionality of KG relations, which limits their usage in more complex reasoning tasks. The reward shaping (RS) strategy we proposed is a step to combine their capability in modeling triple semantics with the symbolic reasoning capability of the path-based approach.

3.2 Multi-Hop Reasoning

Multi-hop reasoning focus on learning symbolic inference rules from relational paths in the KG and has been formulated as sequential decision problems in recent works (Xiong et al., 2017; Das et al., 2018; Shen et al., 2018; Chen et al., 2018). In particular, DeepPath (Xiong et al., 2017) first adopted REINFORCE to search for generic representative paths between pairs of entities. DIVA (Chen et al., 2018) also performs generic path search between entities using RL and its variational objective can be interpreted as model-based reward assignment. MINERVA (Das et al., 2018) first introduced RL

---

[2] We only modify the sampling distribution and still use $\pi_\theta(a_t|s_t)$ to compute the gradient update in equation 6.

to search for answer entities of a particular KG query end-to-end. MINERVA uses entropy regularization to softly encourage the policy to sample diverse paths, and we show that hard action dropout is more effective in this setup. ReinforceWalk (Shen et al., 2018) further proposed to solve the reward sparsity problem in walk-based QA using off-policy learning. ReinforceWalk scores the search targets with a value function which is updated based on the search history cached through epochs. In comparison, we leveraged existing embedding-based models for reward shaping, which is much more efficient during training.

3.3 Reinforcement Learning

Recently, RL has seen a variety of applications in NLP including machine translation (Ranzato et al., 2015), summarization (Paulus et al., 2017), and semantic parsing (Guu et al., 2017). Compared to the domain of gaming (Mnih et al., 2013) where RL is mostly applied for, RL formulations in NLP often have a large discrete action space. For example, in machine translation, the space of possible actions is the entire vocabulary of a language. Walk-based QA also suffers from this problem, as some entities may have thousands of neighbors (e.g. $U.S.$). Since often there is no golden path available for a KG reasoning problem, we cannot leverage supervised pre-training to initialize the path search following the common practice in RL-based natural language generation (Ranzato et al., 2015). On the other hand, the inference paths being studied in a KG are often much shorter (usually containing 2-5 steps) compared to the target sentences in the NL generation problems (often containing 20-30 words), which simplifies the training to some extent.

4 Experiment Setup

We evaluate our modeling contributions on five KGs from different domains and exhibiting different graph properties (§ 4.1). We compare with two classes of state-of-the-art KG models: multi-hop neural symbolic approaches and KG embeddings (§4.2). In this section, we describe the datasets and our experiment setup in detail.

4.1 Dataset

We adopt five benchmark KG datasets for query answering: (1) Alyawarra Kinship, (2) Unified Medical Language Systems (Kok and Domingos, 2007), (3) FB15k-237 (Toutanova et al., 2015), (4) WN18RR (Dettmers et al., 2018), and (5) NELL-995 (Xiong et al., 2017). The statistics of the datasets are shown in Table 1.

Dataset	**#Ent**	**#Rel**	**#Fact**	**#degree**	
				mean	**median**
Kinship	104	25	8,544	85.15	82
UMLS	135	46	5,216	38.63	28
FB15k-237	14,505	237	272,115	19.74	14
WN18RR	40,945	11	86,835	2.19	2
NELL-995	75,492	200	154,213	4.07	1

Table 1: KGs used in the experiments sorted by increasing sparsity level.

4.2 Baselines and Model Variations

We compare with three embedding based models: DistMult (Yang et al., 2014), ComplEx (Trouillon et al., 2016) and ConvE (Dettmers et al., 2018). We also compare with three multi-hop neural symbolic models: (a) NTP-λ, an improved version of Neural Theorem Prover (Rocktäschel and Riedel, 2017), (b) Neural Logical Programming (NeuralLP) (Yang et al., 2017) and (c) MINERVA. For our own approach, we include two model variations that use ComplEx and ConvE as the reward shaping modules respectively, denoted as Ours(ComplEx) and Ours(ConvE). We quote the results of NeuralLP, NTP-λ and MINERVA reported in Das et al. (2018), and replicated the embedding based systems.[3]

4.3 Implementation Details

Beam Search Decoding We perform beam search decoding to obtain a list of *unique* entity predictions. Because multiple paths may lead to the same target entity, we compute the list of unique entities reached in the final search step and assign each of them the maximum score of all paths that led to it. We then output the top-ranked unique entities. We find this approach to improve over directly taking the entities ranked at the beam top, as many of them are repetitions.

KG Setup Following previous work, we treat every KG link as bidirectional and augment the graph with the reversed (e_o, r^{-1}, e_s) links. We use the same train, dev, and test set splits as Das et al. (2018). We exclude any link from the dev and

---

[3] Das et al. (2018) reported MINERVA results with the entity embedding usage as an extra hyperparameter – the quoted performance of MINERVA in Table 2 on UMLS and Kinship were obtained with entity embeddings setting to zero. In contrast, our system always uses trained entity embeddings.

Table 2: Query answering performance compared to state-of-the-art embedding based approaches (top part) and multi-hop reasoning approaches (bottom part). The @1, @10 and MRR metrics were multiplied by 100. We highlight the best approach in each category.

test set (and its reversed link) from the train set. Following Das et al. (2018), we cut the maximum number of outgoing edges of an entity by threshold η to prevent GPU memory overflow: for each entity we keep its top-η neighbors with the highest PageRank scores (Page et al., 1999) in the graph.

Hyperparameters We set the entity and relation embedding size to 200 for all models. We use Xavier initialization (Glorot and Bengio, 2010) for the embeddings and the NN layers. For ConvE, we use the same convolution layer and label smoothing hyperparameters as Dettmers et al. (2018). For path-based models, we use a three-layer LSTM as the path encoder and set its hidden dimension to 200. We perform grid search on the reasoning path length $(2, 3)$, the node fan-out threshold η (256-512) and the action dropout rate α (0.1-0.9). Following Das et al. (2018), we add an entropy regularization term in the objective and tune the weight parameter β within 0-0.1. We use Adam optimization (Kingma and Ba, 2014) and search the learning rate (0.001-0.003) and mini-batch size (128-512).[4] For all models we apply dropout to the entity and relation embeddings and all feed-forward layers, and search the dropout rates within 0-0.5. We use a decoding beam size of 512 for NELL-995 and 128 for the other datasets.

Evaluation Protocol We convert each triple (e_s, r, e_o) in the test set into a query and compute ranking-based evaluation metrics. The models take e_s, r as the input and output a list of candidate answers $E_o = [e^1, \ldots, e^L]$ ranked in decreasing order of confidence score. We compute r_{e_o}, the rank of e_o among E_o, after removing the other correct answers from E_o and use it to compute two types of metrics: (1) Hits@k which is the percentage of examples where $r_{e_o} \leq k$ and (2) mean reciprocal rank (MRR) which is the mean of $1/r_{e_o}$ for all examples in the test set. We use the entire test set for evaluation, with the exception of NELL-995, where test triples with unseen entities are removed following Das et al. (2018).

Our Pytorch implementation of all experiments is released at `https://github.com/salesforce/MultiHopKG`.

5 Results

5.1 Model Comparison

Table 2 shows the evaluation results of our proposed approach and the baselines. The top part presents embedding based approaches and the bottom part presents multi-hop reasoning approaches.[5]

We find embedding based models perform strongly on several datasets, achieving overall best evaluation metrics on UMLS, Kinship, FB15K-237 and NELL-995 despite their simplicity. While previous path based approaches achieve comparable performance on some of the datasets (WN18RR, NELL-995, and UMLS), they perform significantly worse than the embedding based models on the other datasets (9.1 and 14.2 absolute points lower on Kinship and FB15k-237 respectively). A possible reason for this is that embedding based methods map every link in the KG into the same embedding space, which implicitly encodes the connectivity of the whole graph. In contrast, path based models use the discrete represen-

---

[4] On some datasets, we found larger batch size to continue improving the performance but had to stop at 512 due to memory constraints.

[5] We report the model robustness measurements in § A.1.

Model	UMLS	Kinship	FB15k237	WN18RR	NELL995
Ours(ConvE)	**73.0**	**75.0**	**38.2**	43.8	**78.8**

−AD	61.3	65.4	31.0	39.1	76.1

Table 3: Comparison of dev set MRR of Ours(ConvE) and models without reward shaping and action dropout.

tation of a KG as input, and therefore have to leave out a significant proportion of the combinatorial path space by selection. For some path based approaches, computation cost is a bottleneck. In particular, NeuralLP and NTP-λ failed to scale to the larger datasets and their results are omitted from the table, as Das et al. (2018) reported.

Ours is the first multi-hop reasoning approach which is consistently comparable or better than embedding based approaches on all five datasets. The best single model, Ours(ConvE), improves the SOTA performance of path-based models on three datasets (UMLS, Kinship, and FB15k-237) by 4%, 9%, and 39% respectively. On NELL-995, our approach did not significantly improve over existing SOTA. The NELL-995 dataset consists of only 12 relations in the test set and, as we further detail in the analysis (§ 5.3.3), our approach is less effective for those relation types.

The model variations using different reward shaping modules perform similarly. While a better reward shaping module typically results in a better overall model, an exception is WN18RR, where ComplEx performs slightly worse on its own but is more helpful for reward shaping. We left the study of the relationship between the reward shaping module accuracy and the overall model performance as future work.

5.2 Ablation Study

We perform an ablation study where we remove reward shaping (−RS) and action dropout (−AD) from Ours(ConvE) and compare their MRRs to the whole model on the dev sets.[6] As shown in Table 3, on most datasets, removing each component results in a significant performance drop. The exception is WN18RR, where removing the ConvE reward shaping module improves the performance.[7] Removing reward shaping on NELL-995 does not change the results significantly. In general, removing action dropout has a greater impact, suggesting that thorough exploration of the path space is important across datasets.

5.3 Analysis

5.3.1 Convergence Rate

We are interested in studying the impact of each proposed enhancement on the training convergence rate. In particular, we expect reward shaping to accelerate the convergence of RL (to a better performance level) as it propagates prior knowledge about the underlying KG to the agent. On the other hand, a fair concern for action dropout is that it can be slower to train, as the agent is forced to explore a more diverse set of paths. Figure 4 eliminates this concern.

The first row of Figure 4 shows the changes in dev set MRR of Ours(ConvE) (green $*$) and the two ablated models w.r.t. # epochs. In general, the proposed approach is able to converge to a higher accuracy level much faster than either of the ablated models and the performance gap often persists until the end of training (on UMLS, Kinship, and FB15k-237). Particularly, on FB15k-237, our approach still shows improvement even after the two ablated models start to overfit, with −AD beginning to overfit sooner. On WN18RR, introducing reward shaping hurt dev set performance from the beginning, as discussed in § 5.2. On NELL-995, Ours(ConvE) performs significantly better in the beginning, but −RS gradually reaches a comparable performance level.

It is especially interesting that introducing action dropout immediately improves the model performance on all datasets. A possible explanation for this is that by exploring a more diverse set of paths the agent learns search policies that generalize better.

5.3.2 Path Diversity

We also compute the total number of unique paths the agent explores during training and visualize its change w.r.t. # training epochs in the second row of Figure 4. When counting a unique path, we include both the edge label and intermediate entity.

---

[6] According to Table 3 and Table 2, the dev and test set evaluation metrics differ significantly on several datasets. We discuss the cause of this in § A.2.

[7] A possible explanation for this is that as path-based models tend to outperform the embedding based approaches on WN18RR, ConvE may be supplying more noise than useful information about the KG. Yet counter-intuitively, we found that adding the ComplEx reward shaping module helps, despite the fact that ComplEx performs slightly worse than ConvE on this dataset. This indicates that dev set accuracy is not the only factor which determines the effectiveness of reward shaping.

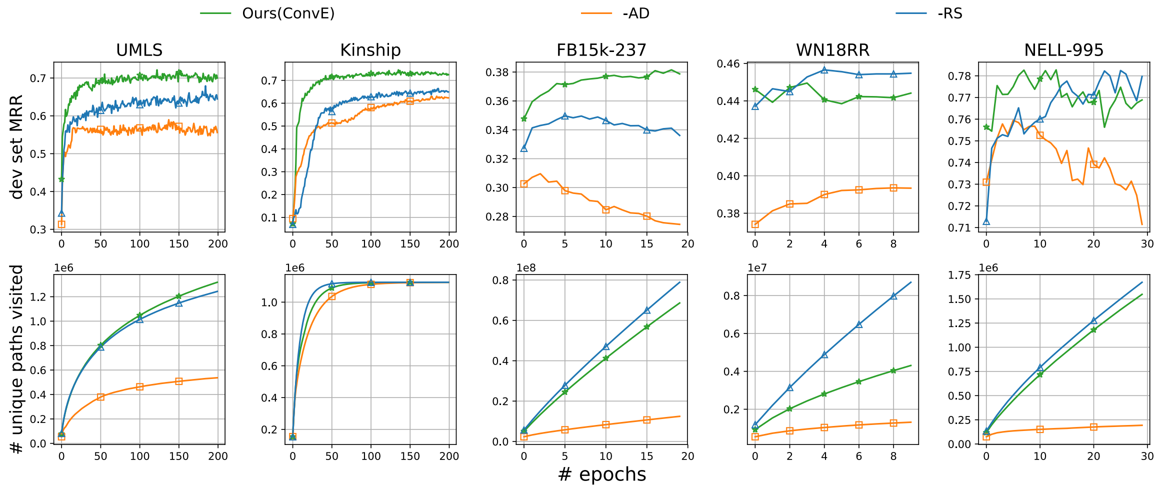

Figure 4: Illustration of convergence rate and path exploration efficiency. The three curves in each subplot represents Ours(ConvE) (green $*$) and the two ablated models: $-$RS (blue $\triangle$) and $-$AD (orange $\square$). The top row shows the change of dev set MRR and the bottom row shows the growth of # unique paths explored w.r.t. # epochs.

Dataset	**To-many**				**To-one**			
	%	Ours(ConvE)	$-$RS	$-$AD	%	Ours(ConvE)	$-$RS	$-$AD
UMLS	99.1	73.1	67.9 (**-7**%)	61.3 (**-16**%)	0.9	62.5	55.5 (**-11**%)	54.4 (**-13**%)
Kinship	100	75	66.5 (**-11**%)	65.4 (**-13**%)	0	–	–	–
FB15k-237	76.6	28.3	24.5 (**-13**%)	20.9 (**-26**%)	23.4	72	69.8 (**-3**%)	63.9 (**-11**%)
WN18RR	52.8	65	65.7 (+1%)	57.9 (**-11**%)	47.2	20.1	23.2 (+16%)	18.1 (**-10**%)
NELL-995	12.9	55.7	62.1 (+12%)	56.9 (+2%)	87.1	81.4	80.7 (**-1**%)	80.5 (**-1**%)

Table 4: MRR evaluation of different relation types (to-many vs. to-one) on five datasets. The % columns show the percentage of examples of each relation type found in the development split of the corresponding dataset. In general, our proposed techniques improve the prediction results for to-many relations more significantly.

First we observe that, on all datasets, the agent explores a large number of paths before reaching a good performance level. The speed of path discovery slowly decreases as training progresses. On smaller KGs (UMLS and Kinship), the rate of encountering new paths is significantly lower after a certain number of epochs, and the dev set accuracy plateaus correspondingly. On much larger KGs (FB15k-237, WN18RR, and NELL-995), we did not observe a significant slowdown before severe overfitting occurs and the dev set performance starts to drop. A possible reason for this is that the larger KGs are more sparsely connected compared to the smaller KGs (Table 1), therefore it is less efficient to gain generalizable knowledge from the KG by exploring a limited proportion of the path space through sampling.

Second, while removing action dropout significantly lowers the effectiveness of path exploration (orange $\square$ vs. green $*$), we observe that removing reward shaping (blue $\triangle$) slightly increases the # paths visited if the action dropout rate is kept the same. This indicates that the correlation between # paths explored and dev set performance is not strictly positive. The best performing model is not always the model that explored the largest # paths. It also demonstrates the role of reward shaping as a regularizer which guides the agent to avoid noisy paths with its prior knowledge.

5.3.3 Performance w.r.t. Relation Types

We investigate the behaviors of our proposed approach w.r.t different relation types. For each KG, we classify its set of relations into two categories based on the answer set cardinality. Specifically, we define the metric ξ_r as the average answer set cardinality of all queries with topic relation r. We count r as a "to-many" relation if $\xi_r > 1.5$, which indicates that most queries in relation r has more than 1 correct answer; we count r as a "to-one" relation otherwise, meaning most queries of this relation have only 1 correct answer.

Table 4 shows the percentage of examples of to-many and to-one relations on each dev dataset and the MRR evaluation metrics of previously studied models computed on the examples of each relation

Dataset	**Seen Queries**				**Unseen Queries**			
	%	Ours(ConvE)	−RS	−AD	%	Ours(ConvE)	−RS	−AD
UMLS	97.2	73.1	67.9 (**-7**%)	61.4 (**-16**%)	2.8	68.5	61.5 (**-10**%)	58.7 (**-14**%)
Kinship	96.8	75.1	66.5 (**-11**%)	65.8 (**-12**%)	3.2	73.6	64.3 (**-13**%)	53.3 (**-27**%)
FB15k-237	76.1	28.3	24.3 (**-14**%)	20.6 (**-27**%)	23.9	70.9	69.1 (**-2**%)	63.9 (**-10**%)
WN18RR	41.8	60.8	62.0 (+2%)	53.4 (**-12**%)	58.2	31.5	33.9 (+7%)	28.8 (**-9**%)
NELL-995	15.3	40.4	45.9 (+14%)	42.5 (+5%)	84.7	85.5	84.7 (**-1**%)	84.3 (**-1**%)

Table 5: MRR evaluation of seen queries vs. unseen queries on five datasets. The % columns show the percentage of examples of seen/unseen queries found in the development split of the corresponding dataset.

type. Since UMLS and Kinship are densely connected, they almost exclusively contain to-many relations. FB15k-237 mostly contains to-many relations. In Figure 4, we observe the biggest relative gains from the ablated models on these three datasets. WN18RR is more balanced and consists of slightly more to-many relations than to-one relations. The NELL-995 dev set is a unique one which almost exclusively consists of to-one relations. There is no common performance pattern over the two relation types across datasets: on some datasets all models perform better on to-many relations (UMLS, WN18RR) while others show the opposite trend (FB15k-237, NELL-995). We leave the study of these discrepancies to future work.

We show the relative performance change of the ablated models −RS and −AD w.r.t. Ours(ConvE) in parentheses. We observe that in general our proposed enhancements are effective in improving query-answering over both relation types (more effective for to-many relations). However, adding the ConvE reward shaping module on WN18RR hurts the performance over both to-many and to-one relations (more for to-one relations). On NELL-995, both techniques hurt the performance over to-many relations.

5.3.4 Performance w.r.t. Seen Queries vs. Unseen Queries

Since most benchmark datasets randomly split the KG triples into train, dev and test sets, the queries that have multiple answers may fall into multiple splits. As a result, some of the test queries $(e_s, r_q, ?)$ are seen in the training set (with a different set of answers) while the others are not. We investigate the behaviors of our proposed approach w.r.t. seen and unseen queries.

Table 5 shows the percentage of examples associated with seen and unseen queries on each dev dataset and the corresponding MRR evaluation metrics of previously studied models. On most datasets, the ratio of seen vs. unseen queries is similar to that of to-many vs. to-one relations (Table 4) as a result of random data split, with the exception of WN18RR. On some datasets, all models perform better on seen queries (UMLS, Kinship, WN18RR) while others reveal the opposite trend. We leave the study of these model behaviors to future work. On NELL-995 both of our proposed enhancements are not effective over the seen queries. In most cases, our proposed enhancements improve the performance over unseen queries, with AD being more effective.

6 Conclusions

We propose two modeling advances for end-to-end RL-based knowledge graph query answering: (1) reward shaping via graph completion and (2) action dropout. Our approach improves over state-of-the-art multi-hop reasoning models consistently on several benchmark KGs. A detailed analysis indicates that the access to a more accurate environment representation (reward shaping) and a more thorough exploration of the search space (action dropout) are important to the performance boost.

On the other hand, the performance gap between RL-based approaches and the embedding-based approaches for KGQA remains. In future work, we would like to investigate learnable reward shaping and action dropout schemes and apply model-based RL to this domain.

Acknowledgements

We thank Mark O. Riedl, Yingbo Zhou, James Bradbury and Vena Jia Li for their feedback on early draft of the paper, and Mark O. Riedl for helpful conversations on reward shaping. We thank the anonymous reviewers and the Salesforce research team members for their thoughtful comments and discussions. We thank Fréderic Godin for pointing out an error in Equation 8 in an early version of the paper.

Abstract

Neural state-of-the-art sequence-to-sequence (seq2seq) models often do not perform well for small training sets. We address paradigm completion, the morphological task of, given a partial paradigm, generating all missing forms. We propose two new methods for the minimal-resource setting: (i) *Paradigm transduction*: Since we assume only few paradigms available for training, neural seq2seq models are able to capture relationships between paradigm cells, but are tied to the idiosyncracies of the training set. Paradigm transduction mitigates this problem by exploiting the input subset of inflected forms at test time. (ii) *Source selection with high precision (SHIP)*: Multi-source models which learn to automatically select one or multiple sources to predict a target inflection do not perform well in the minimal-resource setting. SHIP is an alternative to identify a reliable source if training data is limited. On a 52-language benchmark dataset, we outperform the previous state of the art by up to 9.71% absolute accuracy.

1 Introduction

Morphological generation of previously unencountered word forms is a crucial problem in many areas of natural language processing (NLP). High performance can lead to better systems for downstream tasks, e.g., machine translation (Tamchyna et al., 2017). Since existing lexicons have limited coverage, learning morphological inflection patterns from labeled data is an important mission and has recently been the subject of multiple shared tasks (Cotterell et al., 2016, 2017a).

In morphologically rich languages, words inflect, i.e., they change their surface form in oder to express certain properties, e.g., number or tense. A word's canonical form, which can be found in a dictionary, is called the lemma, and the set of all inflected forms is referred to as the lemma's paradigm.

	Singular	Plural
NOM	*Schneemann*	*Schneemänner*
GEN	**Schneemannes**	*Schneemänner*
DAT	*Schneemann*	**Schneemännern**
ACC	*Schneemann*	*Schneemänner*
LEMMA	Schneemann	

Figure 1: The paradigm of the German noun "Schneemann" ("snowman"). In this running example, the input subset is bold, the output subset italic.

In this work, we address paradigm completion (PC), the morphological task of, given a partial paradigm of a lemma, generating all of its missing forms. For the partial paradigm represented by the input subset {("Schneemannes", GEN;SG), ("Schneemännern", DAT;PL)} of the German noun "Schneemann" shown in Figure 1, the goal of PC is to generate the output subset consisting of the six remaining forms.

Neural seq2seq models define the state of the art for morphological generation if training sets are large; however, they have been less successful in the low-resource setting (Cotterell et al., 2017a). In this paper, we address an even more extreme *minimal-resource* setting: for some of our experiments, our training sets only contain $k \approx 10$ paradigms. Each paradigm has multiple cells, so the number of *forms* (as opposed to the number of *paradigms*) is not necessarily minimal. However, we will see that generalizing from paradigm to paradigm is a key challenge, making the number of paradigms a good measure of the effective training set size.

We propose two PC methods for the minimal-resource setting: *paradigm transduction* and *source selection with high precision (SHIP)*. We define a learning algorithm as *transductive*[1] if its goal is to generalize from specific training examples to specific test examples (Vapnik, 1998). In contrast, in-

---

[1] In order to avoid ambiguity, "transduction" is never used in the sense of string-to-string transduction in this paper.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3254–3264
Brussels, Belgium, October 31 - November 4, 2018.

ductive inference learns a general model that is independent of any test set. Predictions of transductive inference for the same item are different for different test sets. There is no such dependence in inductive inference. Our motivation for transduction is that, in the minimal-resource setting, neural seq2seq models capture relationships between paradigm cells like affix substitution and umlauting, but are tied to the idiosyncracies of the k training paradigms. For example, if all source forms in the training set start with "b" or "d", a purely inductive model may then be unable to generate targets with different initials. By transductive inference on the information available in the input subset at test time, i.e., the given partial paradigm, our model can learn idiosyncracies. For example, if the input subset sources start with "p", we can learn to generate output subset targets that start with "p". Thus, we exploit the input subset for learning idiosyncracies at test time and then generate the output subset using a modified model. This setup employs standard inductive training (on the training set) for learning general rules of inflectional morphology and transductive inference (on the test set) for learning idiosyncracies. Our use of transduction is innovative in that most previous work has addressed unstructured problems whereas our problem is structured: we complete a paradigm, a complex structure of forms, each of them labeled with a morphological tag. Thus, the test set contains labels, whereas, in transduction for unstructured problems, the test set is a flat set of unlabeled instances. We view our work as an extension of transduction to the structured case, even though not all elements of the theory developed by Vapnik (1998) carry over.

The motivation for our second PC method for limited training data, SHIP, is as follows. Multi-source models can learn which combination of sources most reliably predicts the target in the high-resource, but less well in the minimal-resource setting. SHIP models the relationship between paradigm slots using edit trees (Chrupała et al., 2008), in order to measure how deterministic each transformation is. Then, it identifies the most deterministic source slot for the generation of each target inflection.

Paradigm transduction and SHIP can be employed separately or in combination. Our experiments show that, in an extreme minimal-resource setting, a combination of SHIP and a non-neural approach is most effective; for slightly more data, a combination of a neural model, paradigm transduction and SHIP obtains the best results.

Contributions. (i) We introduce neural paradigm transduction, which exploits the structure of the PC task to mitigate the negative effect of limited training data. (ii) We propose SHIP, a new algorithm for picking a single reliable source for PC in the minimal-resource setting. (iii) On average over all languages of a 52-language benchmark dataset, our approaches outperform state-of-the-art baselines by up to 9.71% absolute accuracy.

2 Paradigm Completion

In this section, we formally define our task, developing the notation for the rest of the paper.

Given the set of morphological tags $T(w)$ of a lemma w, we define the paradigm of w as the set of tuples of inflected form f_k and tag t_k:

$$\pi(w) = \big\{ \big(f_k[w], t_k\big) \big\}_{t_k \in T(w)} \tag{1}$$

The example in Figure 1 thus corresponds to: π(Schneemann) = $\big\{\big($"Schneemann", NOM;SG$\big)$ ... $\big($"Schneemänner", ACC;PL$\big)\big\}$.

A training set in our setup consists of complete paradigms, i.e., all inflected forms of each lemma are available. This simulates a setting in which a linguist annotates complete paradigms, as done, e.g., in Sylak-Glassman et al. (2016). In contrast, each element of the test set is a partial paradigm, which we refer to as the *input subset*. This simulates a setting in which we collect all forms of a lemma occurring in a (manually or automatically) annotated input corpus; this set will generally not be complete. The PC task consists of generating the *output subset* of the paradigm, i.e., the forms belonging to form-tag pairs which are missing from the collected subset.

3 Method

Our approach for PC is based on MED (*Morphological Encoder-Decoder*), a state-of-the-art model for morphological generation in the high-resource case, which was developed by Kann and Schütze (2016b). In this section, we first cover required background on MED and then introduce our new approaches.

3.1 MED

Input and output format. MED converts one inflected form of a paradigm into another, given the two respective tags. Thus, the input of MED is a sequence of subtags of the source and the target form (e.g., NOM and SG are subtags of NOM;SG), as well as the characters of the source form. All elements are represented by embeddings, which are trained together with the model. The output of MED is the character sequence of the target inflected form.

An example from the paradigm in Figure 1 is:

INPUT: DAT^S PL^S GEN^T SG^T Schneemännern
OUTPUT: Schneemannes

Encoder. The model's encoder consists of a bidirectional gated recurrent neural network (GRU) with a single hidden layer. It reads an input vector sequence $x = (x_1,...,x_{X_t})$ and encodes it from two opposite directions into two hidden representations $\overrightarrow{h_t}$ and $\overleftarrow{h_t}$ as

$$\overrightarrow{h_t} = \text{GRU}(x_t, \overrightarrow{h_{t-1}}) \tag{2}$$

$$\overleftarrow{h_t} = \text{GRU}(x_t, \overleftarrow{h_{t+1}}) \tag{3}$$

which are concatenated to

$$h_t = \left[\overrightarrow{h_t}; \overleftarrow{h_t}\right] \tag{4}$$

Decoder. The decoder, another GRU with a single hidden layer, defines a probability distribution over the output vocabulary, which, for paradigm completion, consists of the characters in the language, as

$$p(y) = \prod_{t=1}^{T_y} \text{GRU}(y_{t-1}, s_{t-1}, c_t) \tag{5}$$

s_t denotes the state of the decoder at step t, and c_t is the sum of the hidden representations of the encoder, weighted by an attention mechanism.

Additional background on the general model architecture is given in Bahdanau et al. (2015); details on MED can be found in Kann and Schütze (2016b).

3.2 Semi-supervised MED

In order to make use of unlabeled data with MED, Kann and Schütze (2017) defined an auxiliary autoencoding task and proposed a multi-task learning approach.

For this extension, an additional symbol is added to the input vocabulary. Each input is then of the form $(\mathbf{A} \mid M^+)\,\Sigma^+$, with $\mathbf{A}$ being a novel tag for autoencoding, Σ being the alphabet of the language, and M being the set of morphological subtags of the source and the target. As for the basic MED model, all parts of the input are represented by embeddings.

The training objective is to maximize the joint likelihood for the tasks of paradigm completion and autoencoding:

$$\begin{aligned}\mathcal{L}(\boldsymbol{\theta}) = \; & \textstyle\sum_{(s,t^S,t^T,w)\in\mathcal{D}} && \log p_{\boldsymbol{\theta}}(w \mid e_\theta(t^S,t^T,s)) \\ & +\textstyle\sum_{a\in\mathcal{A}} && \log p_{\boldsymbol{\theta}}(a \mid e_\theta(a))\end{aligned}$$

where $\mathcal{A}$ is a set of autoencoding examples, e_θ is the encoder, and $\mathcal{D}$ is a labeled training set of tuples of source s, morphological source tag t^S, morphological target tag t^T, and target w.

3.3 MED for Paradigm Completion

MED was originally developed for morphological reinflection. Thus, it operates on pairs consisting of a single source and a single target form. In order to use it for paradigm completion, where multiple source forms are given, and multiple target forms are expected, we convert the given data into a suitable format in the way described in the following.

For a lemma w, let $J(w)$ be the set of tags in the input subset. Recall that $J(w)$ is a subset of $T(w)$, the set of all tags, at test time, but that training paradigms are complete, i.e., $J(w) = T(w)$ for the training set.

For both training of the inductive model and paradigm transduction, we generate $|J(w)|(|J(w)|-1)$ training examples

$$(t_i, t_j, f_i[w]) \mapsto f_j[w]$$

one for each pair of different tags in $J(w)$. We also generate autoencoding training examples for all tags in $J(w)$ (removing duplicates):

$$\big(\mathbf{A}, f_i[w]\big) \mapsto f_i[w]$$

For the German lemma "Schneemann", assume:

$J(\text{Schneemann}) = \{\text{GEN;SG,DAT;PL}\}$

at test time. We then produce the following training examples for paradigm transduction:

(DAT^S PL^S GEN^T SG^T Schneemännern) ↦ Schneemannes
(GEN^S SG^S DAT^T PL^T Schneemannes) ↦ Schneemännern
(**A** Schneemannes) ↦ Schneemannes
(**A** Schneemännern) ↦ Schneemännern

For completing a partial paradigm, we then select one source form per target slot (the lemma, unless stated otherwise) and create all forms corresponding to the tags in $J(w) \setminus T(w)$ one by one.

3.4 Paradigm Transduction

Motivation. In the minimal-resource setting, parameter estimates are tied to the idiosyncracies of the lemmas seen in training, due to overfitting. Our example in §1 is that the model has difficulties producing initial letters not seen during training. However, within each paradigm, forms are generally similar; thus, input subset sources contain valuable information about how to generate output

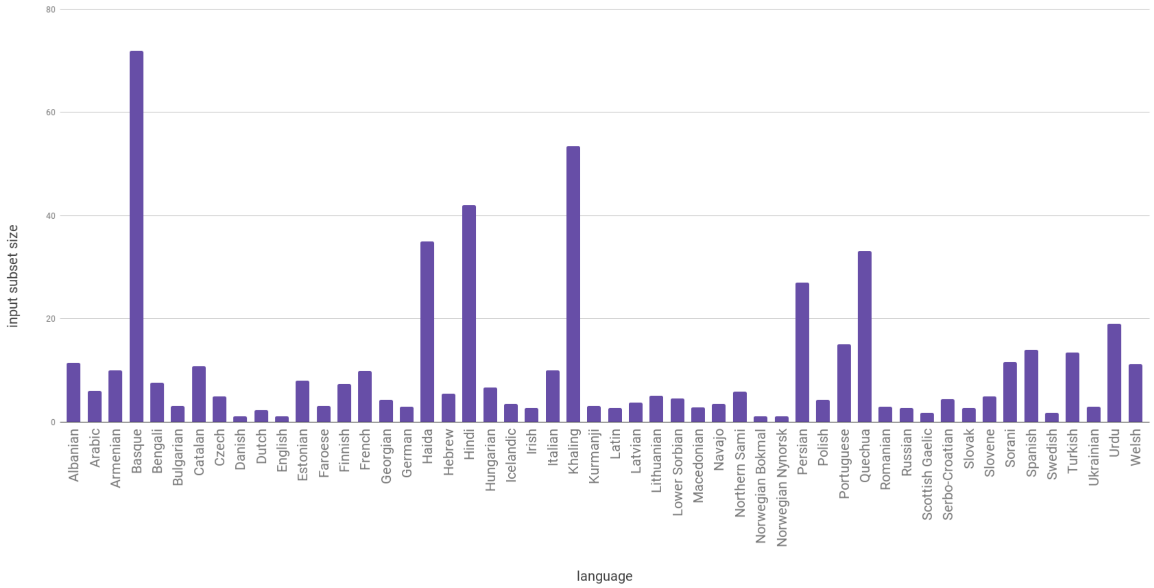

Figure 2: Average amount of sources in the input subset for paradigm transduction, per language.

subset targets. Based on this observation, we solve the problem of overfitting by transduction: we teach the model test idiosyncracies by training it on the input subset before generating the output subset.

Method description. We first train a general model on the training set in the standard supervised learning setup, i.e., the setup which is called inductive inference by Vapnik (1998). At test time, we take the general model as initialization and continue training on examples generated from the input subset as described in §3.3. We do this separately for each lemma, satisfying the defining criterion of transductive inference that predictions depend on the test data. Also, different input subsets (i.e., different subsets of the same paradigm) can in general make different predictions on an output subset target.

Paradigm transduction is expected to perform best in a setting in which many forms of each paradigm are given as input, i.e., when $|J(w)|$ is big. In Figure 2 we show the average sizes of the input subsets for all languages in our experiments.

3.5 Source Selection with High Precision

During PC, some sources contain more information relevant to generating certain targets than others. For instance, the nominative singular and accusative singular in German are generally identical (cf. Figure 1); thus, for generating the accusative singular, we should use the nominative singular as source if it is available—rather than, say, the dative plural.

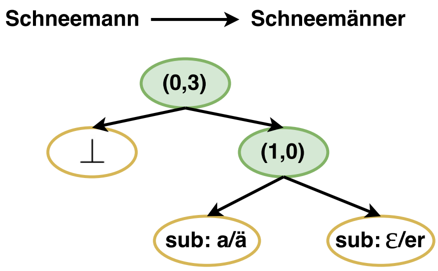

Figure 3: Edit tree example. Each node gives lengths of the parts before/after LCS, e.g., the root has LCS "Schneem", before part ϵ and after part "ann", thus the lengths are "(0,3)". "sub" = "substitution".

In fact, for many languages, the entire paradigm of most lemmas is deterministic if the right source forms are known and used for the right targets. A set of forms that determines all other inflected forms is called *principal parts* (Finkel and Stump, 2007). Based on this theory, Cotterell et al. (2017b) induce topologies and jointly decode entire paradigms, thus making use of all available forms. However, their method is only applicable if good estimates of the probabilities $p(f_j[w]|f_i[w])$ for source $f_i[w]$ and target $f_j[w]$ can be obtained, and they train on hundreds of paradigms per part of speech (POS) and language, which are not available in our setup.

We propose an alternative for the minimal-resource setting: SHIP, which selects a single best source for each target and is based on edit trees. An edit tree $e(f_i[w], f_j[w])$ is a transformation from a source $f_i[w]$ to a target $f_j[w]$ (Chrupała et al., 2008); see Figure 3. It is constructed by first determining

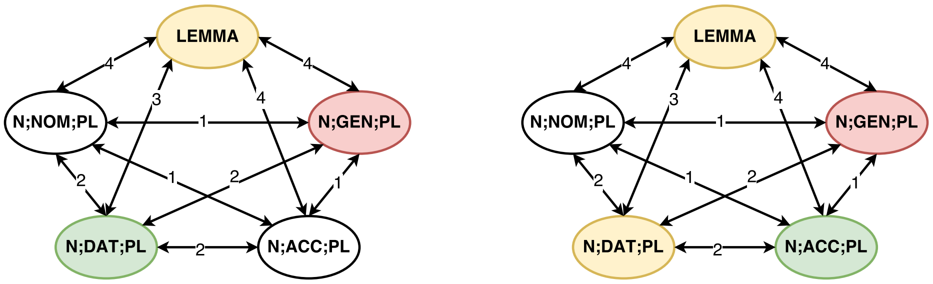

Figure 4: SHIP example for German plural forms (SET1). For the graph constructed in training (see §3.5), subgraphs are extracted in testing for input subset sizes two (left) and three (right). Input subset: yellow and green. Output subset: white and red. For generation of the target shown in red, SHIP selects the source shown in green.

the longest common substring (LCS) (Gusfield, 1997) of $f_i[w]$ and $f_j[w]$ and then modeling the prefix and suffix pairs of the LCS recursively. In the case of an empty LCS, $e(f_i[w], f_j[w])$ is the substitution operation that replaces $f_i[w]$ with $f_j[w]$.

We construct edit trees for each pair $(f_i[w], f_j[w])$ in the training set, count the number n_{ij} of different edit trees for $t_i \mapsto t_j$, and construct a fully connected graph. The tags are nodes of the graph, and the counts n_{ij} are weights. Edges are undirected, since edit trees are bijections (cf. Figure 4). We then interpret the weight of an edge as a measure of the (un)reliability of the corresponding two source-target relationships. Our intuition is that the fewer different edit trees relate source and target, the more reliable the source is for generating the target.

At test time, we find for each target t_j a source t_k such that $n_{kj} \leq n_{ij} \forall i \in J(w)$. We then use $f_k[w]$ to generate $f_j[w]$. Again, Figure 4 shows examples.

4 Experiments

4.1 Data

We run experiments on the datasets from task 2 of the CoNLL–SIGMORPHON 2017 shared task, which have been created using UniMorph (Kirov et al., 2018). We give a short overview here; see (Cotterell et al., 2017a) for details. The dataset contains, for each of 52 languages, a development set of 50 partial paradigms, a test set of 50 partial paradigms, and three training sets of complete paradigms. Training set sizes are 10 (SET1), 50 (SET2), and 200 (SET3). Recall that we view the number of paradigms (not the number of forms) as the best measure of the amount of training data available. Even for SET3, there are only 200 lemmas per language in the training set, which are additionally distributed over multiple POS tags, compared to >600 lemmas per POS used by Cotterell et al. (2017b). We, thus, want to emphasize that all settings—SET1, SET2, and SET3—can be considered low-resource.

We produce training sets for our encoder-decoder as described in §3.3, but limit the total number of training examples to 200,000.

4.2 Hyperparameters

With our hyperparameters, we follow Kann and Schütze (2016a). In particular, our encoder and decoder GRUs have 100-dimensional hidden states. Our embeddings are 300-dimensional. For training, we use stochastic gradient descent, ADADELTA (Zeiler, 2012), and minibatches of size 20. After experiments on the development set, we decide on training SET1, SET2, and SET3 models for 50, 30, and 20 epochs, respectively. For paradigm transduction, we train all models for 25 additional epochs.

4.3 Baselines

In the following, we describe our baselines. COPY, MED, and PT are used for ablation and SIG17 for comparison with the state of the art.

COPY. As targets in many paradigm cells in many languages are identical to the lemma, we consider a copy baseline that simply copies the lemma.

MED. This is the model by Kann and Schütze (2016b), which performed best at SIGMORPHON 2016. For decoding, the lemma is used. Since MED is designed for the high-resource setting, we do not expect good performance for our minimal-resource scenario, but the comparison shows how much our enhancements improve performance.

Pure paradigm transduction (PT). PT is a seq2seq model exclusively trained on the input subset. Its performance sheds light on the importance of the initial inductive training.

SIG17. SIG17 is the official baseline of the CoNLL–SIGMORPHON 2017 shared task, which was developed to perform well with very little

	SET1	SET2	SET3
BL: COPY	.0810	.0810	.0810
BL: MED	.0004	.0432	.4211
BL: PT	.0833	.0833	.0775
BL: SIG17	.5012	.6576	.7707
SIG17+SHIP	**.5971**	.7355	.8008
MED+PT	.5808	.7486	.8454
MED+PT+SHIP	.5793	**.7547**	**.8483**

Table 1: Accuracy on PC for SIG17+SHIP (the shared task baseline SIG17 with SHIP), MED+PT (MED with paradigm transduction), MED+PT+SHIP (MED with paradigm transduction and SHIP), as well as all baselines (*BL*). Results are averaged over all languages, and best results are in bold; detailed accuracies for all languages can be found in Appendix A.

training data. Its design follows Liu and Mao (2016): SIG17 first aligns each input lemma and output inflected form. Afterwards, it assumes that each aligned pair can be split into a prefix, a stem, and a suffix. Based on this alignment, the system extracts prefix (resp. suffix) rules from the prefix (resp. suffix) pairings. At test time, suitable rules are applied to the input string to generate the target; more details can be found in Cotterell et al. (2017a).

4.4 Results

Our results are shown in Table 1. For SET1, SIG17+SHIP obtains the highest accuracy, while, for SET2 and SET3, MED+PT+SHIP performs best. This difference can be easily explained by the fact that the performance of neural networks decreases rapidly for smaller training sets, and, while paradigm transduction strongly mitigates this problem, it cannot completely eliminate it. Overall, however, SIG17+SHIP, MED+PT, and MED+PT+SHIP all outperform the baselines by a wide margin for all settings.

Effect of paradigm transduction. On average, MED+PT clearly outperforms SIG17, the strongest baseline: by .0796 (.5808-.5012) on SET1, .0910 (.7486-.6576) on SET2, and .0747 (.8454-.7707) on SET3.

However, looking at each language individually (refer to Appendix A for those results), we find that MED+PT performs poorly for a few languages, namely Danish, English, and Norwegian (Bokmål & Nynorsk). We hypothesize that this can most likely be explained by the size of the input subset of those languages being small (cf. Figure 2 for average input subset sizes per language). Recall that the input subset is explored by the model during transduction. Most poorly performing languages have input subsets containing only the lemma; in this case paradigm transduction reduces to autoencoding the lemma. Thus, we conclude that paradigm transduction can only improve over MED if two or more sources are given.

Conversely, if we consider only the languages with an average input subset size of more than 15 (Basque, Haida, Hindi, Khaling, Persian, and Quechua), the average accuracy of MED+PT for SET1 is 0.9564, compared to an overall average of 0.5808. This observation shows clearly that paradigm transduction obtains strong results if many forms per paradigm are given.

Effect of SHIP. Further, Table 1 shows that SIG17+SHIP is better than SIG17 by .0959 (.5971-.5012) on SET1, .0779 (.7355-.6576) on SET2, and .0301 (.8008-.7707) on SET3. Stronger effects for smaller amounts of training data indicate that SHIP's strategy of selecting a single reliable source is more important for weaker final models; in these cases, selecting the most deterministic source reduces errors due to noise.

In contrast, the performance of MED, the neural model, is relatively independent of the choice of source; this is in line with earlier findings (Cotterell et al., 2016). However, even for MED+PT, adding SHIP (i.e., MED+PT+SHIP) slightly increases accuracy by .0061 (.7547-.7486) on SET2, and .0029 (.8483-.8454) on SET3 (L53).

Ablation. MED does not perform well for either SET1 or SET2. In contrast, on SET3 it even outperforms SIG17 for a few languages. However, MED loses against MED+PT in all cases, highlighting the positive effect of paradigm transduction.

Looking at PT next, even though PT does not have a zero accuracy for any setting or language, it performs consistently worse than MED+PT. For SET3, PT is even lower than MED on average, by .3436 (.4211-.0775). Note that, in contrast to the other methods, PT's performance is not dependent on the size of the training set. The main determinant for PT's performance is the size of the input subset during transductive inference. If the input subset is large, PT can perform better than MED, e.g., for Hindi and Urdu. For Khaling SET1, PT even outperforms both MED and SIG17. However, in most cases, PT does not perform well on its own.

MED+PT outperforms both MED and PT. This confirms our initial intuition: MED and PT learn complementary information for paradigm

input	output		
	MED	PT	MED+PT
Schneemann N;GEN;PL	GetGächen	Scnneeeeennnnnnnnnnnnnnnnnnnnn	Schneemänner
dish V;V.PTCP;PRS	dising	dish	dishing
creer V;SBJV;PRS;1;PL	crezcamos	creyemos	creamos

Table 2: Analysis of the outputs of MED, PT, and MED+PT for SET2. Top to bottom: German, English, Spanish. MED and PT produce incorrect, MED+PT correct inflections.

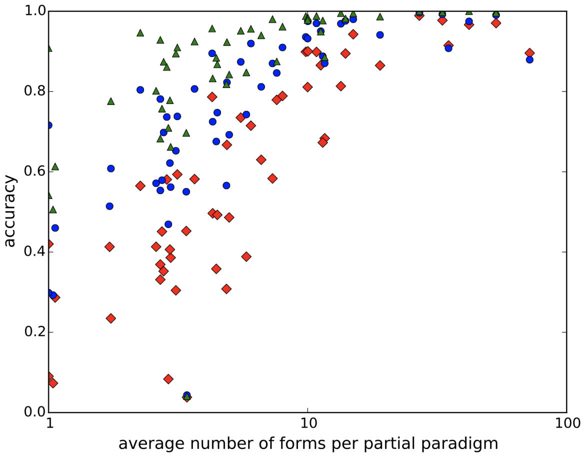

Figure 5: Accuracy of MED+PT as a function of the average input subset size. Red/diamonds: SET1; blue/circles: SET2; green/triangles: SET3.

completion. The base model learns the general structure of the language (i.e., correspondences between tags and inflections) while paradigm transduction teaches the model which character sequences are common in a specific test paradigm.

5 Analysis

5.1 On the Size of the Input Subset

We expect paradigm transduction to become more effective as the size of the input subset increases. Figure 5 shows the accuracy of MED+PT as a function of the average input subset size for SET1, SET2, and SET3. Accuracy for languages with input set sizes above 15 is higher than .8 in all settings. In general, languages with larger input set sizes perform better. The correlation is not perfect because languages have different degrees of morphological regularity. However, the overall trend is clearly recognizable.

The organizers of CoNLL–SIGMORPHON provided large input subsets in the development and test sets of languages with large paradigms. Thus, PT performs better for languages with many inflected forms per paradigm, i.e., large $|T(w)|$.

5.2 On the Effect of Paradigm Transduction

We further analyze why paradigm transduction improves the performance of the base model MED, using the German, English, and Spanish SET2 examples for MED, PT, and MED+PT given in Table 2.

German. MED generates an almost random sequence. However, it learns that the umlaut "ä" must appear in the target. PT only produces correct characters, but it produces far too many. The reason may be that the model is trained on both a double "e" and a double "n", learning that "e" and "n" are likely to appear repeatedly. MED+PT generates the correct target.

English. MED fails to generate "h" because the bigram "sh" did not occur in training, and so the probability of "h" following "s" is estimated to be low. PT fails to produce the suffix "ing", since it does not occur in the input subset, and, thus, PT has no way of learning it. Again, MED+PT generates the correct target.

Spanish. MED produces "crezcamos", a form that has the correct tag V;SBJV;PRS;1;PL, but is a form of "crecer" (which appears in the training set), not of "creer" (which does not). This demonstrates the problems resulting from a lack of lemma diversity during training. PT produces a combination of several of the forms in the input subset: subjunctive forms beginning with "crey" and "creemos" V;IND;PRS;1;PL. Again, MED+PT generates the correct target.

Overall, this analysis confirms that MED learns relationships between paradigm cells, while paradigm transduction adds knowledge about the idiosyncracies of a partial test paradigm.

5.3 Comparison to Multi-Source Models

In this section, we explicitly compare our approach to neural multi-source models for morphological generation.

Following Kann et al. (2017a), we employ attention-based RNN encoder-decoder networks with two or four input sources. The input to a

	SET1				SET2				SET3			
	1	2	4	+PT	1	2	4	+PT	1	2	4	+PT
dutch	.00	.00	.00	**.49**	.04	.01	.00	**.78**	.43	.65	.72	**.87**
german	.00	.00	.00	**.65**	.00	.00	.01	**.75**	.44	.42	.59	**.88**
icelandic	.00	.00	.00	**.41**	.03	.02	.02	**.50**	.24	.33	.35	**.77**
spanish	.00	.00	.00	**.92**	.03	.09	.09	**.98**	.59	.63	.83	**.99**
welsh	.00	.00	.00	**.91**	.05	.14	.15	**.97**	.35	.53	.70	**.99**

Table 3: MED accuracy on five randomly selected languages with 1, 2, and 4 sources and combined with paradigm transduction ("+PT"). Best results in bold.

multi-source model is the concatenation of all sources and corresponding tags. During training, we randomly sample (with repetition) one or three additional forms from the paradigm of each example. At test time, we sample the additional forms from the given partial paradigm; without repetition first, but repeating if not enough inflected forms are available. For autoencoding examples in the training data, we simply concatenate two or four copies of the source and the autoencoding tag. We randomly select five languages for this experiment.

Table 3 shows that, for SET3, four sources (column header "4") are generally better than two sources ("2"), which in turn are better than one source ("1"); thus, as expected, making additional sources available in training improves results. We attribute one exception (German accuracy is .4391 for "1" and .4179 for "2") to the noisiness of the problem—training sets in terms of number of paradigms are relatively small, even for SET3.

The improvements we see for SET3 are large. This suggests that using more than four sources would further improve results and perhaps reach the level of performance of MED+PT, at the cost of a long training time. However, for SET1 and SET2, there is no consistent improvement from 1 to 2 to 4 sources. While it is possible that further optimization could improve the best multi-source result given in Table 3, the gap to MED+PT is very large, and the improvement from 2 to 4 is small. This indicates that multi-source methods cannot compete with transductive learning for SET1 and SET2.

5.4 Qualitative Analysis of SHIP

For a qualitative analysis of SHIP, we look at the sources it selects for French verbs on the development set; the complete diagram is shown in Figure 6. For most verbs, future and conditional can be predicted from COND;1;PL (e.g., "finirions"), and indicative present, indicative imparfait and subjunctive present from IND;PRS;3;PL (e.g., "finissent").

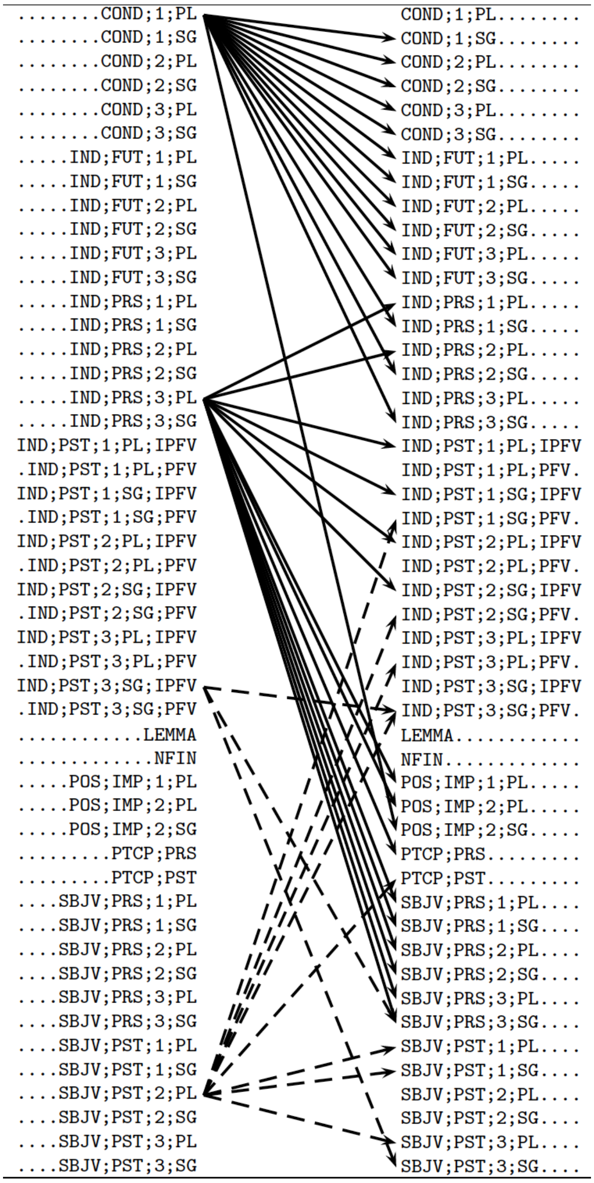

Figure 6: Right: output set target to be generated. Left: input set source selected by SHIP. Arrows for the two most frequently selected sources are solid, arrows for the two least frequently selected sources are dashed.

In case of ties, SHIP selects the alphabetically first tag; this explains why COND;1;PL gets preference over IND;PRS;3;PL for indicative present singular. These two forms represent two of the *principal* *parts* of French conjugation, the infinitive (almost always derivable from COND;1;PL) and the stem that is used for plural indicative, imparfait, and other paradigm cells—which is sometimes not derivable from the infinitive as is the case for "finir". In comparison, IND;PST;3;SG;IPFV and SBJV;PST;2;PL are less reliable sources. But they are still reasonably accurate if no better alternative is available; consider the following SBJV;PST;2;PL → IND;PST;1;SG;PFV generations: "parlassiez" ↦ "parlai", "finissiez" ↦ "finis", "missiez" ↦ "mis", "prissiez" ↦ "pris".

We thus conclude that SHIP indeed learns to select appropriate source forms.

6 Related Work

Morphological generation. In the last two years, most work on paradigm completion has been done in the context of the SIGMORPHON 2016 and the CoNLL–SIGMORPHON 2017 shared tasks (Cotterell et al., 2016, 2017a). Due to the success of neural seq2seq models in 2016 (Kann and Schütze, 2016b; Aharoni et al., 2016), systems developed for the 2017 edition were mostly neural (Makarov et al., 2017; Bergmanis et al., 2017; Zhou and Neubig, 2017). Besides the shared task systems, Kann and Schütze (2017) presented a paradigm completion model for a multi-source setting that made use of an attention mechanism to decide which input form to attend to at each time step. They used randomly chosen, independent pairs of source and target forms for training. This differs crucially from the setting we consider in that no complete paradigms were available in their training sets. Only Cotterell et al. (2017b) addressed essentially the same task we do, but they only considered the high-resource setting: their models were trained on hundreds of complete paradigms. The experiments reported in §5.3 empirically confirm that inductive-only models perform poorly in our setting.

Several ways to employ neural models for morphological generation with limited data have been proposed, e.g., semi-supervised training (Zhou and Neubig, 2017; Kann and Schütze, 2017) or simultaneous training on multiple languages (Kann et al., 2017b). The total number of sources in the training set in some of our settings may be comparable to this earlier work, but our training sets are less diverse since many forms come from the same paradigm. We argue in §1 that the number of paradigms (not the number of sources) measures the effective size of the training set.

Other important work on morphological generation—neural and non-neural—includes Dreyer et al. (2008); Durrett and DeNero (2013); Hulden et al. (2014); Nicolai et al. (2015); Faruqui et al. (2016); Yin et al. (2016).

Seq2seq models in NLP. Even though neural seq2seq models were originally designed for machine translation (Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2015), their application has not stayed limited to this area. Similar architectures have been successfully applied to many seq2seq tasks in NLP, e.g., syntactic parsing (Vinyals et al., 2015), language correction (Xie et al., 2016), normalization of historical texts (Bollmann et al., 2017), or text simplification (Nisioi et al., 2017). Transductive inference is similar to domain adaptation, e.g., in machine translation (Luong and Manning, 2015). One difference is that training set and test set can hardly be called different domains in paradigm completion. Another difference is that explicit structured labels (the morphological tags of the forms in the input subset) are available at test time in paradigm completion.

7 Conclusion

We presented two new methods for minimal-resource paradigm completion: paradigm transduction and SHIP. Paradigm transduction learns general inflection rules through standard inductive training and idiosyncracies of a test paradigm through transduction. We showed that paradigm transduction effectively mitigates the problem of overfitting due to a lack of diversity in the training data. SHIP is a robust non-neural method that identifies a single reliable source for generating a target. In the minimal-resource setting, this is an effective alternative to learning how to combine evidence from multiple sources. Considering the average over all languages of a 52-language benchmark dataset, we outperform the previous state of the art by at least 7.07%, and up to 9.71% absolute accuracy.

Implicational Universals in Stochastic Constraint-Based Phonology

Giorgio Magri
CNRS / University of Paris 8
`magrigrg@gmail.com`

Abstract

This paper focuses on the most basic implicational universals in phonological theory, called *T-orders* after Anttila and Andrus (2006). It shows that the T-orders predicted by stochastic and categorical Optimality Theory coincide. Analogously, the T-orders predicted by stochastic and categorical Harmonic Grammar coincide. In other words, these stochastic constraint-based frameworks do not tamper with the typological structure induced by the corresponding categorical frameworks.

1 Introduction

Phonology has traditionally focused on *alternations* revealed by paradigms such as the German final devoicing examples [baːt]/[bɛːdə] (‘bath-SG/PL’) and [tsuːk]/[tsyːgə] (‘train-SG/PL’). These alternations are usually modeled through *phonological grammars* which map from *underlying representations* (URs) to *surface representations* (SRs) (Chomsky and Halle, 1968). Constraint-based implementations of this combinatorial phonological theory include *Optimality Theory* (OT; Prince and Smolensky, 1997, 2004) and *Harmonic Grammar* (HG; Legendre et al., 1990; Smolensky and Legendre, 2006), reviewed below in sections 4 and 5.

More recently, phonology has extended its empirical coverage from categorical alternations to patterns of phonologically conditioned variation and gradient phonological (or phonotactic) judgements (see for instance Anttila, 2012 and Coetzee and Pater, 2011). This extension of the empirical coverage has required a corresponding extension of the theoretical framework. A phonological grammar cannot be construed anymore as a categorical function from URs to SRs. Instead, it must be construed as a function from URs to probability distributions over the entire set of SRs. Constraint-based implementations of this stochastic theory include *partial order OT* (Anttila, 1997b), *stochastic OT* (SOT; Boersma, 1997, 1998), and *stochastic HG* (SHG; Boersma and Pater, 2016)[1], recalled below in sections 4 and 5. Another framework explored in the recent literature on probabilistic constraint-based phonology is *MaxEnt* (ME; Goldwater and Johnson, 2003; Hayes and Wilson, 2008). Its T-orders are discussed in a companion paper (Anttila and Magri, 2018).

How can we investigate and understand the typological structure encoded by a probabilistic phonological framework? In the case of a categorical framework such as OT or HG, the predicted typological structure can be investigated directly by exhaustively listing all the grammars predicted for certain constraint and candidate sets. That is possible because the predicted typology of grammars is usually *finite*. The situation is rather different for probabilistic frameworks: the predicted typology always consists of an *infinite* number of probability distributions which therefore cannot be exhaustively listed and directly inspected. A more indirect strategy is needed to chart the predicted typological structure.

A natural indirect strategy that gets around the problem raised by an infinite typology is to enumerate, not the individual languages in the typology, but the set of implicational universals predicted by the typology. An *implicational universal* is an implication $P \xrightarrow{\mathfrak{T}} \widehat{P}$ which holds of a given typology $\mathfrak{T}$ whenever *every* language in the typology that satisfies the antecedent property P also satisfies the consequent property $\widehat{P}$ (Greenberg, 1963). Since implicational universals take

---

[1] Boersma and Pater (2016) actually use the term “noisy HG” instead of “stochastic HG”. We prefer “stochastic HG” to stress the analogy with Boersma’s earlier framework of stochastic OT. Furthermore, we prefer to use “stochastic” to describe a property of the framework, reserving “noisy” to describe a property of the learning scenario (as opposed to noise-free). Hayes (2017) discusses further stochastic variants of categorical HG.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3265–3274
Brussels, Belgium, October 31 - November 4, 2018.

into account every language in the typology, they chart the boundaries and measure the richness of the typological structure predicted by $\mathfrak{T}$.

Which antecedent and consequent properties P and $\widehat{P}$ should we focus on? To start from the simplest case, let us consider a typology $\mathfrak{T}$ of *categorical* phonological grammars, construed traditionally as mappings from URs to SRs. Within this categorical framework, the simplest, most basic, most atomic antecedent property P is the property of mapping a certain specific UR x to a certain specific SR y. Analogously, the simplest consequent property $\widehat{P}$ is the property of mapping a certain specific UR $\widehat{\mathsf{x}}$ to a certain specific SR $\widehat{\mathsf{y}}$. We thus focus on the following class of implications:

Definition 1 *The implicational universal* $(\mathsf{x},\mathsf{y}) \overset{\mathfrak{T}}{\rightarrow} (\widehat{\mathsf{x}},\widehat{\mathsf{y}})$ *holds relative to a categorical typology* $\mathfrak{T}$ *provided each grammar in* $\mathfrak{T}$ *which succeeds at the antecedent mapping (i.e., it maps the UR* x *to the SR* y*), also succeeds at the consequent mapping (i.e., it maps the UR* $\widehat{\mathsf{x}}$ *to the SR* $\widehat{\mathsf{y}}$*).* □

The relation $\overset{\mathfrak{T}}{\rightarrow}$ thus defined over mappings is a partial order (under mild additional assumptions). It is called the *T-order* induced by the typology $\mathfrak{T}$ (Anttila and Andrus, 2006). For example, any dialect of English that deletes t/d at the end of a coda cluster before a vowel also deletes it before a consonant (Guy, 1991; Kiparsky, 1993; Coetzee, 2004). The implication (/cost.us/, [cos.us]) → (/cost.me/, [cos.me]) thus holds relative to the typology $\mathfrak{T}$ of English dialects.

Implicational universals can also be statistical. For instance, in dialects of English where t/d deletion applies variably, deletion has been found to be more frequent before consonants than before vowels. To model these frequency effects, we need to consider a typology $\mathfrak{T}$ of *probabilistic* phonological grammars, construed as functions from URs to probability distributions over SRs. We propose to extend the notion of T-orders from the categorical to the probabilistic setting as follows:

Definition 2 *The implicational universal* $(\mathsf{x},\mathsf{y}) \overset{\mathfrak{T}}{\rightarrow} (\widehat{\mathsf{x}},\widehat{\mathsf{y}})$ *holds relative to a probabilistic typology* $\mathfrak{T}$ *provided each grammar in* $\mathfrak{T}$ *assigns a probability to the consequent mapping* $(\widehat{\mathsf{x}},\widehat{\mathsf{y}})$ *which is at least as large as the probability it assigns to the antecedent mapping* (x,y)*.* □

To illustrate, the implication (/cost.us/, [cos.us]) → (/cost.me/, [cos.me]) also holds relative to the typology $\mathfrak{T}$ of English dialects with variable deletion because the probability of the consequent (/cost.me/, [cos.me]) (i.e., the frequency of deletion before a consonant) in any dialect is at least as large as the probability of the antecedent (/cost.us/, [cos.us]) (i.e., the frequency of deletion before a vowel).

The original categorical definition 1 of T-orders is a special case of the probabilistic definition 2. In fact, suppose that a categorical grammar succeeds on the antecedent mapping (x,y). That grammar construed probabilistically thus assigns probability 1 to the antecedent mapping. Definition 2 then requires that grammar to also assign probability 1 to the consequent mapping $(\widehat{\mathsf{x}},\widehat{\mathsf{y}})$. In other words, the grammar construed categorically succeeds on the consequent mapping, as required by the original definition 1 of categorical T-orders.

T-orders are defined at the level of mappings from URs to SRs. They thus allow for cross-framework comparisons, even bridging across categorical and probabilistic frameworks. This paper (together with the companion Anttila and Magri 2018) thus uses T-orders to compare the probabilistic implementations of constraint-based phonology with the original categorical implementations.

The main result reported in this paper is that the T-orders predicted by stochastic OT (and by partial order OT) coincide with those predicted by categorical OT, no matter what the candidate and constraint sets look like, as shown in section 4. Analogously, the T-orders predicted by stochastic HG coincide with those predicted by categorical HG, as shown in section 5. In other words, these stochastic frameworks do not tamper with the typological structure induced by the original categorical frameworks, at least when that structure is measured in terms of T-orders. These specific results about OT and HG are derived as a special case of a more general result on stochastic typologies, developed in sections 2 and 3.

As discussed in a companion paper (Anttila and Magri, 2018), the situation is very different for ME. Both ME and stochastic HG can be construed as probabilistic variants of categorical HG. Stochastic and categorical HG share the same T-orders. The ME T-orders instead obey a rather different underlying convex geometry and turn out to be much sparser. In other words, ME yields a much richer probabilistic extension of categorical HG than stochastic HG does. Section 6 concludes the paper by discussing these results in the context of the recent literature on probabilistic constraint-based phonology.

2 Categorical and stochastic phonology

We assume a relation Gen which pairs each UR x with a set $Gen(\mathsf{x})$ of *candidate* SRs. As recalled above, a *categorical* phonological grammar G takes a UR x and selects a corresponding SR $\mathsf{y} = G(\mathsf{x})$ from the candidate set $Gen(\mathsf{x})$. A stochastic phonological grammar G instead takes a UR x and returns a probability distribution $G(\cdot\,|\,\mathsf{x})$ over $Gen(\mathsf{x})$ which assigns a probability $G(\mathsf{y}|\,\mathsf{x})$ to each candidate SR y in $Gen(\mathsf{x})$. This section illustrates a general method to leverage a given typology $\mathfrak{T}$ of categorical grammars into a typology of stochastic grammars. Sections 4 and 5 will then show that various stochastic frameworks in the recent constraint-based literature (such as partial order OT, stochastic OT, and stochastic HG) all fit within this general scheme.

Following common practice in constraint-based phonology, we assume that the categorical typology $\mathfrak{T}$ only contains a finite number of grammars.[2] We consider a probability mass function p over $\mathfrak{T}$. Thus, p assigns to each categorical grammar G in $\mathfrak{T}$ a nonnegative probability mass $p(G) \geq 0$ and these masses sum up to 1, namely $\sum_{G\in\mathfrak{T}} p(G) = 1$. We can then define the stochastic grammar G_p corresponding to the probability mass function p as the function which takes a UR x and returns the probability distribution $G_p(\cdot\,|\,\mathsf{x})$ over the candidate set $Gen(\mathsf{x})$ defined as in (1). It says that the probability $G_p(\mathsf{y}\,|\,\mathsf{x})$ that the UR x is mapped to the SR y is he probability mass allocated by p to the region $\{G \in \mathfrak{T}\,|\,G(\mathsf{x}) = \mathsf{y}\}$ of the typology $\mathfrak{T}$ consisting of those categorical grammars which succeed on the mapping (x, y).

$$G_p(\mathsf{y}\,|\,\mathsf{x}) = \sum_{\{G\in\mathfrak{T}\,|\,G(\mathsf{x})=\mathsf{y}\}} p(G) \qquad (1)$$

We assume next that each categorical grammar in the typology $\mathfrak{T}$ returns a *unique* SR y for each UR x.[3] This assumption suffices to ensure that G_p is indeed a probability distribution, namely that the sum of the probabilities $G_p(\mathsf{y}\,|\,\mathsf{x})$ over the candidates y in $Gen(\mathsf{x})$ is equal to 1, as shown in (2).

$$\sum_{\mathsf{y}\in Gen(\mathsf{x})} G_p(\mathsf{y}\,|\,\mathsf{x}) \overset{(a)}{=} \sum_{\mathsf{y}\in Gen(\mathsf{x})} \sum_{\{G\in\mathfrak{T}\,|\,G(\mathsf{x})=\mathsf{y}\}} p(G) \overset{(b)}{=} \sum_{G\in\mathfrak{T}} p(G) \overset{(c)}{=} 1 \qquad (2)$$

In step (2a), we have used the definition (1) of $G_p(\mathsf{y}\,|\,\mathsf{x})$. In step (2b), we have used the fact that every grammar in $\mathfrak{T}$ maps x to a unique SR y, so that the sets $\{G \in \mathfrak{T}\,|\,G(\mathsf{x}) = \mathsf{y}\}$ partition the typology $\mathfrak{T}$ into disjoint sets as y spans the candidate set $Gen(\mathsf{x})$. In step (2c), we have used the fact that p is a probability mass function over $\mathfrak{T}$ and thus adds up to 1.

A family $\mathcal{P}$ of probability mass functions $p_1, p_2, \ldots$ over the finite categorical typology $\mathfrak{T}$ thus induces a typology $\{G_{p_1}, G_{p_2}, \ldots\}$ of stochastic grammars. It is called the *stochastic* typology corresponding to the categorical typology $\mathfrak{T}$ and the probability family $\mathcal{P}$, and it is denoted by $\mathfrak{T}_{\mathcal{P}}$. We denote by $\xrightarrow{\mathfrak{T}}$ the T-order relative to the categorical typology $\mathfrak{T}$ in the sense of definition 1 and by $\xrightarrow{\mathfrak{T}_{\mathcal{P}}}$ the T-order relative to the stochastic typology $\mathfrak{T}_{\mathcal{P}}$ in the sense of definition 2. We want to investigate the relationship between these categorical and stochastic T-orders.

3 Relationship between categorical and stochastic T-orders

Let us suppose that the implication $(\mathsf{x}, \mathsf{y}) \overset{\mathfrak{T}}{\rightarrow} (\widehat{\mathsf{x}}, \widehat{\mathsf{y}})$ holds between an antecedent mapping (x, y) and a consequent mapping $(\widehat{\mathsf{x}}, \widehat{\mathsf{y}})$ relative to a categorical typology $\mathfrak{T}$. By definition 1, this means that every categorical grammar G in the typology $\mathfrak{T}$ that maps the antecedent UR x to the antecedent SR y (namely, $G(\mathsf{x}) = \mathsf{y}$) also maps the consequent UR $\widehat{\mathsf{x}}$ to the consequent SR $\widehat{\mathsf{y}}$ (namely, $G(\widehat{\mathsf{x}}) = \widehat{\mathsf{y}}$), yielding the inclusion (3).

$$\underset{\substack{\text{grammars consistent}\\ \text{with the antecedent}\\ \text{mapping}}}{\{G \in \mathfrak{T}\,|\,G(\mathsf{x})=\mathsf{y}\}} \subseteq \underset{\substack{\text{grammars consistent}\\ \text{with the consequent}\\ \text{mapping}}}{\{G \in \mathfrak{T}\,|\,G(\widehat{\mathsf{x}})=\widehat{y}\}} \qquad (3)$$

By (1), this inclusion (3) entails that the probability assigned by G_p to the consequent mapping $(\widehat{\mathsf{x}}, \widehat{\mathsf{y}})$ is at least as large as the probability assigned to the antecedent mapping (x, y), as stated in (4). This entailment follows from the sheer fact that

---

[2] This assumption always holds in OT, as the number of constraint rankings is finite. It might fail in HG, but only in rather pathological situations which do not seem germane to natural language phonology.

[3] Suppose instead that a categorical grammar were to return two different SRs y_1 and y_2 for some UR x. How should we interpret such a scenario? Plausibly, we should interpret the two SRs y_1 and y_2 as free variants with equal probability of 0.5 (while all other candidates have probability 0). But this means that our grammar is stochastic, not categorical.

probabilities are monotonic relative to set inclusion. The entailment from the inclusion (3) to the inequality (4) thus holds under no assumptions whatsoever on the probability mass function p used to define the stochastic grammar G_p.

$$\underset{\substack{\text{probability of the}\\ \text{antecedent mapping}}}{G_p(\mathsf{y}\,|\,\mathsf{x})} \;\leq\; \underset{\substack{\text{probability of the}\\ \text{consequent mapping}}}{G_p(\widehat{\mathsf{y}}\,|\,\widehat{\mathsf{x}})} \tag{4}$$

The latter inequality (4) finally says that the implication $(\mathsf{x},\mathsf{y}) \xrightarrow{\mathfrak{T}_{\mathcal{P}}} (\widehat{\mathsf{x}},\widehat{\mathsf{y}})$ holds also relative to the stochastic typology $\mathfrak{T}_{\mathcal{P}}$ in the sense of definition 2. In conclusion, a categorical T-order always entails the corresponding stochastic T-order, no matter the shape of the family $\mathcal{P}$ of probability mass functions used to derive the stochastic typology $\mathfrak{T}_{\mathcal{P}}$ from the categorical typology $\mathfrak{T}$.

We now turn to the reverse entailment. Suppose that an implication $(\mathsf{x},\mathsf{y}) \xrightarrow{\mathfrak{T}_{\mathcal{P}}} (\widehat{\mathsf{x}},\widehat{\mathsf{y}})$ holds between an antecedent mapping (x,y) and a consequent mapping $(\widehat{\mathsf{x}},\widehat{\mathsf{y}})$ relative to the stochastic typology $\mathfrak{T}_{\mathcal{P}}$. By definition 2, this means in turn that the inequality (4) holds between the probabilities $G_p(\mathsf{y}\,|\,\mathsf{x})$ and $G_p(\widehat{\mathsf{y}}\,|\,\widehat{\mathsf{x}})$ of the antecedent and the consequent mappings relative to any probability mass function p in the family $\mathcal{P}$. Suppose by contradiction that the corresponding implication $(\mathsf{x},\mathsf{y}) \xrightarrow{\mathfrak{T}} (\widehat{\mathsf{x}},\widehat{\mathsf{y}})$ relative to the original categorical typology $\mathfrak{T}$ instead fails. By definition 1, this means that the set inclusion (3) fails because there exists some grammar G_0 with the properties in (5): G_0 succeeds on the antecedent mapping, namely it maps x to y; but G_0 fails on the consequent mapping, namely it maps $\widehat{\mathsf{x}}$ to some loser candidate $\widehat{\mathsf{z}}$ different from the intended winner candidate $\widehat{\mathsf{y}}$.

$$G_0(\mathsf{x}) = \mathsf{y}, \qquad G_0(\widehat{\mathsf{x}}) = \widehat{\mathsf{z}} \neq \widehat{\mathsf{y}} \tag{5}$$

We would like to derive a contradiction from the assumption (4) that the stochastic implication $(\mathsf{x},\mathsf{y}) \xrightarrow{\mathfrak{T}_{\mathcal{P}}} (\widehat{\mathsf{x}},\widehat{\mathsf{y}})$ holds and the assumption (5) that the categorical implication $(\mathsf{x},\mathsf{y}) \xrightarrow{\mathfrak{T}} (\widehat{\mathsf{x}},\widehat{\mathsf{y}})$ fails.

Yet, no contradiction arises in the general case. Indeed, suppose that the probability mass functions in the family $\mathcal{P}$ all happen to assign zero (or tiny) probability mass to this grammar G_0 which flouts the categorical implication because of (5). This problematic grammar G_0 thus bears no (or only a tiny) effect on the total probabilities $G_p(\mathsf{y}\,|\,\mathsf{x})$ and $G_p(\widehat{\mathsf{y}}\,|\,\widehat{\mathsf{x}})$ of the two mappings (x,y) and $(\widehat{\mathsf{x}},\widehat{\mathsf{y}})$. The probability inequality (4) is therefore not necessarily compromised by the offensive behavior (5) of G_0, as long as the other grammars in the typology comply.

In order to derive a contradiction from these two conditions (4) and (5), we need to make some assumptions on the family $\mathcal{P}$ of probability mass functions. Indeed, the problem just discussed arises when *every* probability mass function p in $\mathcal{P}$ assigns zero (or tiny) probability to the problematic grammar G_0. We need to rule out this scenario. We propose to achieve that through the assumption that the family $\mathcal{P}$ satisfies the following

Definition 3 *The family $\mathcal{P}$ of probability mass functions over the finite categorical typology $\mathfrak{T}$ is* sufficiently rich *in the sense that for every categorical grammar G in $\mathfrak{T}$ and for any two URs x and $\widehat{\mathsf{x}}$, the following inequalities*

$$G_p(G(\mathsf{x})|\,\mathsf{x}) > 1/2, \quad G_p(G(\widehat{\mathsf{x}})|\,\widehat{\mathsf{x}}) > 1/2 \tag{6}$$

hold for some probability mass function p in $\mathcal{P}$. □

Here is the intuition behind this definition. Suppose that for every categorical grammar G, the family $\mathcal{P}$ contains a probability mass function p which assigns all the probability mass to that grammar G. By (1), the corresponding stochastic grammar G_p assigns probability 1 to the mappings enforced by G, as stated in (7).

$$G_p(G(\mathsf{x})|\,\mathsf{x}) = 1 \text{ for every UR } \mathsf{x} \tag{7}$$

In other words, the stochastic grammar G_p "coincides" with the categorical grammar G and the stochastic typology $\mathfrak{T}_{\mathcal{P}}$ thus "contains" or "extends" the original categorical typology $\mathfrak{T}$. In this special case, we obviously expect the stochastic implication $(\mathsf{x},\mathsf{y}) \xrightarrow{\mathfrak{T}_{\mathcal{P}}} (\widehat{\mathsf{x}},\widehat{\mathsf{y}})$ to entail the categorical implication $(\mathsf{x},\mathsf{y}) \xrightarrow{\mathfrak{T}} (\widehat{\mathsf{x}},\widehat{\mathsf{y}})$, as desired.

Condition (6) required by definition 3 is a weaker version of the latter condition (7). First, it is weaker because the requirement $G_p(G(\mathsf{x})|\,\mathsf{x}) = 1$ is replaced with the weaker requirement $G_p(G(\mathsf{x})|\,\mathsf{x}) > 1/2$: the probability assigned to the mappings enforced by G needs not be 1, as long as it is large enough, namely larger than 1/2. Second, this requirement $G_p(G(\mathsf{x})|\mathsf{x}) > 1/2$ needs not be satisfied by a unique mass p for all URs: it suffices to look at just two URs at the time.

If the family $\mathcal{P}$ is sufficiently rich in the sense of definition 3, the two conditions (4) and (5) are indeed contradictory. In fact, condition (5) now ensures that $\mathcal{P}$ contains a probability mass function

p_0 such that the corresponding stochastic grammar G_{p_0} maps x to y with probability larger than 1/2 and it maps $\widehat{\mathsf{x}}$ to $\widehat{\mathsf{z}}$ with probability larger than 1/2. The latter fact means in turn that G_{p_0} maps $\widehat{\mathsf{x}}$ to $\widehat{\mathsf{y}}$ with probability smaller than 1/2, because the probabilities of the various candidates $\widehat{\mathsf{y}}, \widehat{\mathsf{z}}, \dots$ in $Gen(\widehat{\mathsf{x}})$ must add up to 1. In conclusion, we have obtained $G_{p_0}(\mathsf{y}\,|\,\mathsf{x}) > 1/2$ and $G_{p_0}(\widehat{\mathsf{y}}\,|\,\widehat{\mathsf{x}}) < 1/2$, in blatant contradiction of (4).

The preceding reasoning is summarized in the following proposition 1, which says that the T-order relative to a categorical typology $\mathfrak{T}$ and the T-order relative to the corresponding stochastic typology $\mathfrak{T}_{\mathcal{P}}$ coincide, no matter what the family $\mathcal{P}$ of probability mass functions looks like, as long as it is sufficiently rich, in the sense of definition 3. Identity of T-orders holds even when the family $\mathcal{P}$ is infinite, so that the stochastic typology $\mathfrak{T}_{\mathcal{P}}$ contains an infinite number of stochastic grammars, while the categorical typology $\mathfrak{T}$ contains only a finite number of grammars.

Proposition 1 *Consider a finite typology $\mathfrak{T}$ of categorical grammars and a family $\mathcal{P}$ of probability mass functions on $\mathfrak{T}$. Let $\mathfrak{T}_{\mathcal{P}}$ be the typology of the corresponding stochastic grammars, defined through (1). If $\mathcal{P}$ is sufficiently rich in the sense of definition 3, the T-order $\xrightarrow{\mathfrak{T}}$ relative to the categorical typology $\mathfrak{T}$ and the T-order $\xrightarrow{\mathfrak{T}_{\mathcal{P}}}$ relative to the stochastic typology $\mathfrak{T}_{\mathcal{P}}$ coincide.* □

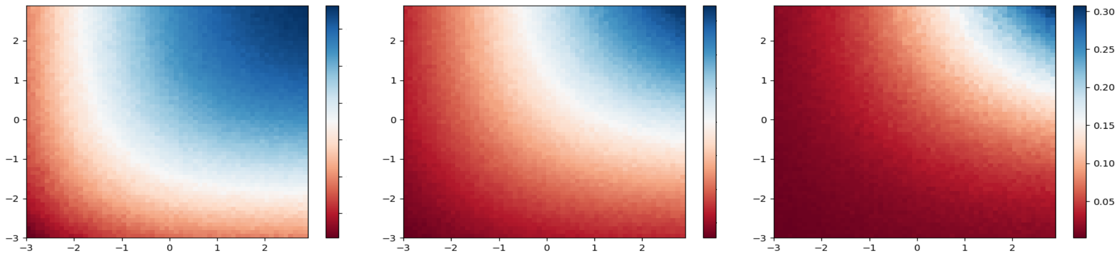
In the rest of the paper, we apply this result to various categorical and stochastic frameworks for constraint-based phonology.

4 Categorial OT, partial order OT, and stochastic OT induce the same T-orders

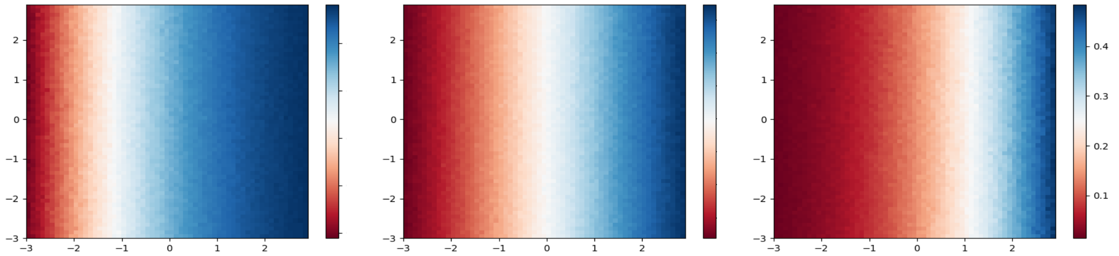
In this section, we focus on categorical and stochastic OT. We assume a set of n constraints $C_1, \dots, C_k, \dots, C_n$ and some candidacy relation Gen. We recall that a constraint C_k *prefers* a mapping (x, y) to another mapping (x, z) provided C_k assigns less violations to the former than to the latter, namely $C_k(\mathsf{x}, \mathsf{y}) < C_k(\mathsf{x}, \mathsf{z})$. A *constraint ranking* is an arbitrary linear order $\gg$ over the constraint set. A constraint ranking $\gg$ *prefers* a mapping (x, y) to another mapping (x, z) provided the highest $\gg$-ranked constraint which distinguishes between the two mappings (x, y) and (x, z) prefers (x, y). The *categorical OT grammar* corresponding to a ranking $\gg$ maps a UR x to that SR y such that $\gg$ prefers the mapping (x, y) to the mapping (x, z) corresponding to any other candidate z in $Gen(\mathsf{x})$ (Prince and Smolensky, 2004). We denote by $\overset{\mathrm{OT}}{\to}$ the T-order corresponding to the typology $\mathfrak{T}$ of the categorical OT grammars corresponding to all constraint rankings, in the sense of definition 2.

To illustrate, consider the following three constraints (from Kiparsky, 1993) for the process of t/d deletion mentioned in section 1: C_1 = SYLLABLEWELLFORMEDNESS (SWF) penalizes codas and tautosyllabic consonant clusters; C_2 = ALIGN penalizes resyllabification across word boundaries; and C_3 = MAX penalizes segment deletion. Suppose that the UR /cost us/ comes with the three candidate SRs [cost.us] (faithful), [cos.us] (with deletion), and [cos.tus] (with resyllabification). Analogously, suppose that the UR /cost me/ comes with the three candidate SRs [cost.me], [cos.me], and [cos.tme]. It is easy to verify that the implication (/cost.us/, [cos.us]) $\overset{\mathrm{OT}}{\to}$ (/cost.me/, [cos.me]) holds relative to the OT typology generated by constraints C_1, C_2, C_3 in the sense of definition 1: every ranking of the three constraints which succeeds on the antecedent mapping (/cost.us/, [cos.us]) also succeeds on the consequent mapping (/cost.me/, [cos.me]). In other words, t/d deletion before a vowel entails deletion before a consonant.

We now turn to the stochastic counterpart of this categorical framework. A *ranking vector* $\boldsymbol{\theta} = (\theta_1, \dots, \theta_k, \dots, \theta_n) \in \mathbb{R}^n$ assigns a numerical *ranking value* θ_k to each constraint C_k. The *stochastic ranking vector* $\boldsymbol{\theta} + \boldsymbol{\epsilon} = (\theta_1 + \epsilon_1, \dots, \theta_n + \epsilon_n)$ is obtained by adding to the ranking values $\theta_1, \dots, \theta_n$ some numbers $\epsilon_1, \dots, \epsilon_n$ sampled independently from each other according to some distribution $\mathcal{D}$ on $\mathbb{R}$. If the distribution $\mathcal{D}$ is continuous, the probability that two stochastic ranking values $\theta_h + \epsilon_h$ and $\theta_k + \epsilon_k$ coincide is equal to zero. The stochastic ranking vector $\boldsymbol{\theta} + \boldsymbol{\epsilon}$ thus describes the unique ranking $\gg_{\boldsymbol{\theta}+\boldsymbol{\epsilon}}$ which respects the relative size of the stochastic ranking values: a constraint C_h is ranked above a constraint C_k according to $\gg_{\boldsymbol{\theta}+\boldsymbol{\epsilon}}$ (namely, $C_h \gg_{\boldsymbol{\theta}+\boldsymbol{\epsilon}} C_k$) if and only if the stochastic ranking value of the former is larger than that of the latter (namely, $\theta_h + \epsilon_h > \theta_k + \epsilon_k$). A ranking vector $\boldsymbol{\theta}$ thus induces the probability mass function $p^{\mathcal{D}}_{\boldsymbol{\theta}}$ defined in (8) over the categorical OT typology $\mathfrak{T}$. Obviously, this definition yields a probability mass, namely the sum of the masses $p^{\mathcal{D}}_{\boldsymbol{\theta}}(G)$ over all the



(a) (/cost.us/, [cos.us]), $\theta_3 = -3$ (b) (/cost.us/, [cos.us]), $\theta_3 = 0$ (c) (/cost.us/, [cos.us]), $\theta_3 = 3$



(d) (/cost.me/, [cos.me]), $\theta_3 = -3$ (e) (/cost.me/, [cos.me]), $\theta_3 = 0$ (f) (/cost.me/, [cos.me]), $\theta_3 = 3$

Figure 1: SOT probabilities of the antecedent mapping (/cost.us/, [cos.us]) and the consequent mapping (/cost.me/, [cos.me]) as a function of θ_1 (horizontal axis) and θ_2 (vertical axis) for three choices of θ_3

categorical OT grammars G in $\mathfrak{T}$ is indeed 1.

$$p^{\mathcal{D}}_{\boldsymbol{\theta}}(G) = \text{the probability of sampling } \epsilon_1, \ldots, \epsilon_n \overset{i.i.d.}{\sim} \mathcal{D} \text{ such that the OT grammar corresponding to the ranking } \gg_{\boldsymbol{\theta}+\boldsymbol{\epsilon}} \text{ is indeed } G \tag{8}$$

The typology of stochastic grammars $\mathfrak{T}_{\mathcal{P}}$ obtained as in section 2 from the categorical OT typology $\mathfrak{T}$ and the family $\mathcal{P} = \{p^{\mathcal{D}}_{\boldsymbol{\theta}} \mid \boldsymbol{\theta} \in \mathbb{R}^n\}$ of probability mass functions $p^{\mathcal{D}}_{\boldsymbol{\theta}}$ corresponding to all ranking vectors $\boldsymbol{\theta}$ is called *stochastic OT* (SOT; Boersma, 1997, 1998). We denote by $\overset{\text{SOT}}{\longrightarrow}$ the T-orders corresponding to SOT in the sense of definition 2.

What is the typological structure encoded by SOT's T-orders? Given that the original OT typology is finite (because there are only a finite number of constraint rankings) while the SOT typology is infinite (it contains an infinite number of grammars which assign different probabilities), how much of OT's typological structure is preserved in SOT? These questions are crucial for phonological theory but technically nontrivial. To illustrate, figure 1 plots the SOT probability of the mappings (/cost.us/, [cos.us]) and (/cost.me/, [cos.me]) relative to the three constraints C_1, C_2, C_3 listed above as a function of the ranking value θ_1 of constraint C_1 (horizontal axis) and the ranking value θ_2 of constraint C_2 (vertical axis) for three choices of the ranking value θ_3 of constraint C_3.[4] These plots suggest that the implication (/cost.us/, [cos.us]) $\overset{\text{SOT}}{\rightarrow}$ (/cost.me/, [cos.me]) holds in SOT: the probability of the consequent (/cost.me/, [cos.me]) (plotted in the bottom row) seems to be always larger than the probability of the antecedent (/cost.us/, [cos.us]) (plotted in the top row). But how can this conjecture be checked, given that SOT probabilities seem not to admit a closed-form expression?

The result obtained in section 3 provides a straightforward solution to this problem. Suppose that there exists a positive constant Δ large enough that the distribution $\mathcal{D}$ concentrates most of the probability mass on the interval $[-\Delta, +\Delta]$, as stated in (9). This assumption holds in particular when $\mathcal{D}$ has a bounded support or it is defined through a density (such as a gaussian, as assumed in Boersma, 1997, 1998).

$$(\mathcal{D}([-\Delta, +\Delta]))^n > 1/2 \tag{9}$$

For any constraint ranking $\gg$, consider a ranking vector $\boldsymbol{\theta}$ such that the top $\gg$-ranked constraint has the largest ranking value; the second top $\gg$-ranked constraint has the second largest ranking value; and so on. Furthermore, assume that these ranking values are spaced apart by more than 2Δ. Since the numbers $\epsilon_1, \ldots, \epsilon_n$ are all bounded between $-\Delta$ and $+\Delta$ with probability at least 1/2

---

[4] These plots (as well as those in figure 2) are obtained by sampling for 10,000 times from each stochastic grammar. The distribution $\mathcal{D}$ is a gaussian with mean 0 and variance 2.

and since the ranking values are spaced apart by more than 2Δ, the constraint ranking $\gg_{\boldsymbol{\theta}+\boldsymbol{\epsilon}}$ corresponding to the stochastic ranking vector $\boldsymbol{\theta}+\boldsymbol{\epsilon}$ coincides with the original ranking $\gg$ with probability at least 1/2. In other words, the probability mass function $p^{\mathcal{D}}_{\boldsymbol{\theta}}$ corresponding to this ranking vector $\boldsymbol{\theta}$ according to (8) assigns more than half of the probability mass to the OT grammar corresponding to the ranking $\gg$. The family $\mathcal{P} = \{p^{\mathcal{D}}_{\boldsymbol{\theta}} \,|\, \boldsymbol{\theta} \in \mathbb{R}^n\}$ is therefore sufficiently rich in the sense of definition 3. Proposition 1 thus yields the following

Corollary 1 *Under the mild assumption (9) on the distribution $\mathcal{D}$, the T-order $\xrightarrow{SOT}$ relative to SOT is identical to the T-order $\xrightarrow{OT}$ relative to categorical OT for any constraint and candidate set.* □

In conclusion, despite the SOT typology being infinite, SOT induces the same typological structure as categorical OT, at least when typological structure is measured in terms of T-orders. Furthermore, the technical problem of computing T-orders relative to SOT is reduced to the much easier problem of computing T-orders relative to categorical OT, which indeed admits an efficient solution (Magri, 2018a). This result extends to *partial order OT* (Anttila, 1997a), as the latter is a special case of SOT.

5 Categorial HG and stochastic HG induce the same T-orders

This section shows that completely analogous considerations hold for HG. A weight vector $\mathbf{w} = (w_1, \ldots, w_k, \ldots, w_n) \in \mathbb{R}^n_+$ assigns a nonnegative weight $w_k \geq 0$ to each constraint C_k. The $\mathbf{w}$-*harmony* of a mapping (x, y) is the weighted sum of the constraint violations multiplied by -1, namely $-\sum_{k=1}^{n} w_k C_k(\mathsf{x}, \mathsf{y})$. Because of the minus sign, mappings with a large harmony have few constraint violations. The categorical HG grammar corresponding to a weight vector $\mathbf{w}$ maps a UR x to the surface form y such that the mapping (x, y) has a larger $\mathbf{w}$-harmony than the mapping (x, z) corresponding to any other candidate z in $Gen(\mathsf{x})$ (Legendre et al., 1990; Smolensky and Legendre, 2006). We denote by $\overset{\text{HG}}{\to}$ the T-order corresponding to the typology $\mathfrak{T}$ of the categorical HG grammars corresponding to all nonnegative weight vectors, in the sense of definition 2.

To illustrate, it is easy to verify that the implication (/cost.us/, [cos.us]) $\overset{\text{HG}}{\to}$ (/cost.me/, [cos.me]) considered above holds also relative to the HG typology in the sense of definition 1: every weighting of the three constraints which succeeds on the antecedent mapping (/cost.us/, [cos.us]) also succeeds on the consequent mapping (/cost.me/, [cos.me]). In general, the HG typology is a proper superset of the OT typology (when the set of URs is finite). The HG T-order is therefore a subset of the corresponding OT T-order.

We now turn to the stochastic counterpart of this categorical framework. The *stochastic weight vector* $\mathbf{w}+\boldsymbol{\epsilon} = (w_1+\epsilon_1, \ldots, w_n+\epsilon_n)$ is obtained by adding to the weights $w_1, \ldots, w_n$ some numbers $\epsilon_1, \ldots, \epsilon_n$ sampled independently from each other according to some distribution $\mathcal{D}$ on $\mathbb{R}$.[5] A weight vector $\mathbf{w}$ induces the corresponding probability mass function $p^{\mathcal{D}}_{\mathbf{w}}$ on the categorical HG typology $\mathfrak{T}$ defined in (10). Obviously, this definition yields a probability mass, namely the sum of the masses $p^{\mathcal{D}}_{\mathbf{w}}(G)$ over all the categorical grammars G in the HG typology $\mathfrak{T}$ is equal to 1.

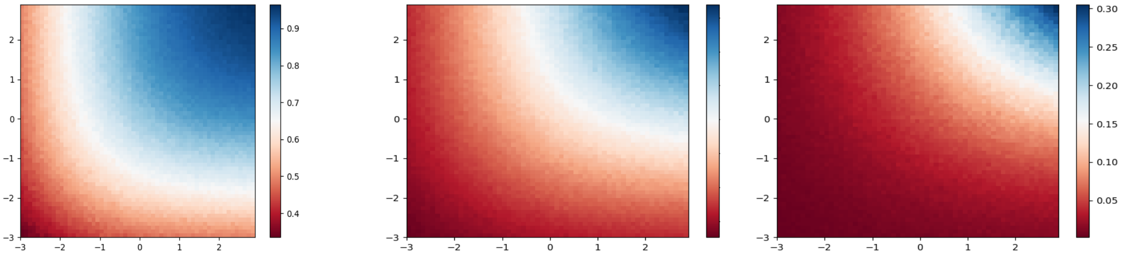
$$p^{\mathcal{D}}_{\mathbf{w}}(G) = \begin{array}{l}\text{the probability of sampling}\\ \epsilon_1, \ldots, \epsilon_n \overset{i.i.d.}{\sim} \mathcal{D} \text{ such that the}\\ \text{HG grammar corresponding to}\\ \text{the weight vector } \mathbf{w}+\boldsymbol{\epsilon} \text{ is } G\end{array} \tag{10}$$

The typology of stochastic grammars $\mathfrak{T}_{\mathcal{P}}$ obtained as in section 2 from the categorical HG typology $\mathfrak{T}$ and the family $\mathcal{P} = \{p^{\mathcal{D}}_{\mathbf{w}} \,|\, \mathbf{w} \in \mathbb{R}^n_+\}$ of probability mass functions $p^{\mathcal{D}}_{\mathbf{w}}$ corresponding to all nonnegative weight vectors $\mathbf{w}$ is called *stochastic HG* (SHG; Boersma and Pater, 2016). We denote by $\xrightarrow{\text{SHG}}$ the T-orders corresponding to SHG in the sense of definition 2.

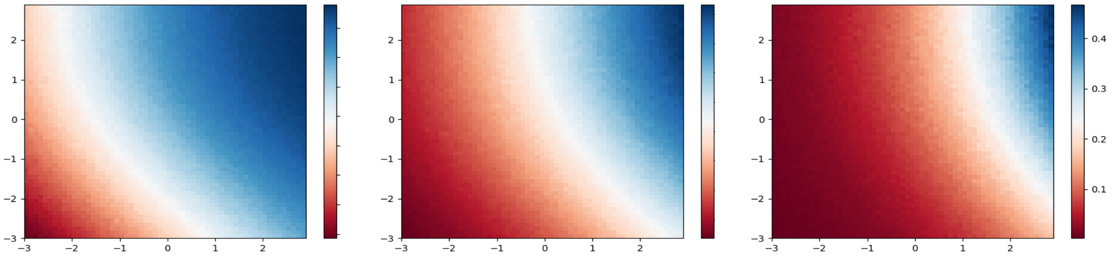
To illustrate, figure 2 plots the SHG probability of the mappings (/cost.us/, [cos.us]) and (/cost.me/, [cos.me]) as a function of the ranking values of the three constraints C_1, C_2, C_3 listed above. These plots suggest that the implication (/cost.us/, [cos.us]) $\overset{\text{SHG}}{\to}$ (/cost.me/, [cos.me]) holds in SHG as well: the probability of the consequent (/cost.me/, [cos.me]) (plotted in the bottom row) seems to be always larger than the probability of the antecedent (/cost.us/, [cos.us]) (plotted in the top row). The result obtained in section 3 makes sense of this observation, as follows.

---

[5] Some component $w_k+\epsilon_k$ of the corrupted weight vector $\mathbf{w}+\boldsymbol{\epsilon}$ could be negative. In this case, $\mathbf{w}+\boldsymbol{\epsilon}$ could correspond to no HG grammar in $\mathfrak{T}$ and the probability mass defined in (10) could therefore add up to less than 1. This problem can be avoided simply by truncating the corrupted weights at zero, namely by replacing $w_k+\epsilon_k$ with $\max\{w_k+\epsilon_k, 0\}$ in the definition of the corrupted weight vector $\mathbf{w}+\boldsymbol{\epsilon}$ (Magri, 2015).



(a) (/cost.us/, [cos.us]), $\theta_3 = -3$ (b) (/cost.us/, [cos.us]), $\theta_3 = 0$ (c) (/cost.us/, [cos.us]), $\theta_3 = 3$



(d) (/cost.me/, [cos.me]), $\theta_3 = -3$ (e) (/cost.me/, [cos.me]), $\theta_3 = 0$ (f) (/cost.me/, [cos.me]), $\theta_3 = 3$

Figure 2: SHG probabilities of the antecedent mapping (/cost.us/, [cos.us]) and the consequent mapping (/cost.me/, [cos.me]) as a function of θ_1 (horizontal axis) and θ_2 (vertical axis) for three choices of θ_3

We consider two URs x and $\widehat{\mathsf{x}}$. We assume that x comes with a finite number $m+1$ of candidates $\mathsf{y}, \mathsf{z}_1, \dots, \mathsf{z}_m$ and that $\widehat{\mathsf{x}}$ comes with a finite number $\widehat{m}+1$ of candidates $\widehat{\mathsf{y}}, \widehat{\mathsf{z}}_1, \dots, \widehat{\mathsf{z}}_{\widehat{m}}$. This assumption is nonrestrictive. In fact, each UR admits only a finite number of optima in HG (Magri, 2018b). Candidate sets can thus be assumed to be finite without loss of generality. We consider a categorical HG grammar in the typology $\mathfrak{T}$ and assume that it maps x and $\widehat{\mathsf{x}}$ to y and $\widehat{\mathsf{y}}$, respectively. This means that any weight vector $\mathbf{w} = (w_1, \dots, w_n)$ corresponding to this HG grammar assigns a larger harmony to the winner mappings (x, y) and $\widehat{\mathsf{x}}, \widehat{\mathsf{y}})$ than to any of the loser mappings $(\mathsf{x}, \mathsf{z}_i)$ and $(\widehat{\mathsf{x}}, \widehat{\mathsf{z}}_j)$ respectively, as stated in (11).

$$\begin{aligned}
&\underbrace{\min_{i=1,\dots,m} \sum_k w_k(C_k(\mathsf{x},\mathsf{z}_i) - C_k(\mathsf{x},\mathsf{y}))}_{\xi} > 0 \\
&\underbrace{\min_{j=1,\dots,\widehat{m}} \sum_k w_k(C_k(\widehat{\mathsf{x}},\widehat{\mathsf{z}}_j) - C_k(\widehat{\mathsf{x}},\widehat{\mathsf{y}}))}_{\widehat{\xi}} > 0
\end{aligned} \tag{11}$$

Let B be an upper bound on the constraint violation differences, so that $|C(\mathsf{x}, \mathsf{z}_i) - C(\mathsf{x}, \mathsf{y})| \leq B$ and $|C(\widehat{\mathsf{x}}, \widehat{\mathsf{z}}_j) - C(\widehat{\mathsf{x}}, \widehat{\mathsf{y}})| \leq B$ for every $i = 1, \dots, m$ and $j = 1, \dots, \widehat{m}$. Suppose again that there exists a positive constant Δ large enough that the distribution $\mathcal{D}$ concentrates most of the probability mass on $[-\Delta, +\Delta]$, in the sense that it satisfies the inequality (9). We consider the weight vector $\lambda\mathbf{w} = (\lambda w_1, \dots, \lambda w_n)$ obtained by rescaling the weight vector $\mathbf{w}$ by a positive scalar $\lambda > 0$ sufficiently large, in the sense of (12).

$$\lambda > \max\left\{\frac{n\Delta B}{\xi}, \frac{n\Delta B}{\widehat{\xi}}\right\} \tag{12}$$

Whenever $\boldsymbol{\epsilon} \in [-\Delta, +\Delta]^n$, the HG grammar corresponding to the stochastic rescaled weight vector $\lambda\mathbf{w} + \boldsymbol{\epsilon}$ maps the UR x to the SR y, as shown in (13). An analogous reasoning shows that it also maps $\widehat{\mathsf{x}}$ to $\widehat{\mathsf{y}}$. In step (13a), we have used the definition (11) of ξ. In step (13b), we have lower bounded $C(\mathsf{x}, \mathsf{z}_i) - C(\mathsf{x}, \mathsf{y})$ with $-B$. In step (13c), we have used the definition (12) of λ.

$$\begin{aligned}
&\sum_k (\lambda w_k + \epsilon_k)(C_k(\mathsf{x},\mathsf{z}_i) - C_k(\mathsf{x},\mathsf{y})) = \\
&= \lambda \sum_k w_k(C_k(\mathsf{x},\mathsf{z}_i) - C_k(\mathsf{x},\mathsf{y})) + \\
&\qquad + \sum_k \epsilon_k(C_k(\mathsf{x},\mathsf{z}_i) - C_k(\mathsf{x},\mathsf{y})) \\
&\overset{(a)}{\geq} \lambda\xi + \sum_k \epsilon_k(C_k(\mathsf{x},\mathsf{z}_i) - C_k(\mathsf{x},\mathsf{y})) \\
&\overset{(b)}{\geq} \lambda\xi - n\Delta B \overset{(c)}{>} 0
\end{aligned} \tag{13}$$

The intuition behind this reasoning (13) is as follows. The rescaled weight vector $\lambda\mathbf{w}$ generates

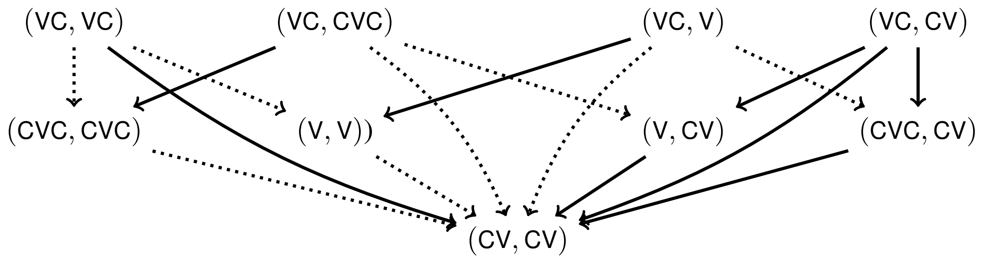


Figure 3: Solid arrows are entailments that hold in OT, HG, SOT, SHG, and ME; dotted arrows are entailments that fail in ME.

the same HG grammar as the weight vector $\mathbf{w}$. If λ is large, the nonzero weights of the rescaled vector $\lambda\mathbf{w}$ are very large (in absolute value). On the other hand, the stochastic values $\epsilon_1, \ldots, \epsilon_n$ are instead small (because bounded between $-\Delta$ and $+\Delta$) and therefore negligible relative to the rescaled weights. The original weight vector $\mathbf{w}$ and the stochastic rescaled vector $\boldsymbol{\epsilon} + \lambda\mathbf{w}$ thus generate the same HG grammar.

In conclusion, the SOT grammar $G_{p^{\mathcal{D}}_{\lambda\mathbf{w}}}$ corresponding to the probability mass function $p^{\mathcal{D}}_{\lambda\mathbf{w}}$ (corresponding to the rescaled weight vector $\lambda\mathbf{w}$) satisfies the identities $G_{p^{\mathcal{D}}_{\lambda\mathbf{w}}}(\mathsf{y}\,|\,\mathsf{x}) > 1/2$ and $G_{p^{\mathcal{D}}_{\lambda\mathbf{w}}}(\widehat{\mathsf{y}}\,|\,\widehat{\mathsf{x}}) > 1/2$. This shows that the family $\mathcal{P} = \{p^{\mathcal{D}}_{\mathbf{w}} \,|\, \mathbf{w} \in \mathbb{R}^n_+\}$ of probability masses is sufficiently rich in the sense of definition 3. Proposition 1 thus yields the following:

Corollary 2 *Under the mild assumption (9) on the distribution $\mathcal{D}$, the T-order $\xrightarrow{SHG}$ relative to SHG is identical to the T-order $\xrightarrow{HG}$ relative to categorical HG for any constraint set and any candidate set which assigns a finite number of candidates to each UR (while the number of URs can be infinite).* □

6 Conclusions

Phonology has traditionally focused on patterns of categorical alternations modeled within categorical frameworks such as OT and HG. More recently, phonology has extended its empirical coverage to quantitative data such as gradient judgments and patterns of variation. This move has required a parallel extension from categorical to stochastic frameworks, such as partial order OT, stochastic OT, and stochastic HG. These stochastic frameworks are "extensions" of the original categorical frameworks in the sense discussed in section 3. One might thus expect the stochastic frameworks to be typologically less restrictive than the original categorical frameworks. This paper has shown that is not the case, at least when typological restrictiveness is measured in terms of the most basic implicational universals, namely T-orders. Indeed, the T-orders induced by partial order and stochastic OT coincide with those induced by categorical OT. Analogously, the T-orders induced by stochastic HG coincide with those induced by categorical HG.

As discussed in a companion paper (Anttila and Magri, 2018), the situation is very different in ME. To illustrate, consider the *basic syllable system* of Prince and Smolensky (2004). The set of forms consists of the four syllable types CV, CVC, V, and VC. Each of them is a candidate of each other. The constraint set consists of the four constraints ONSET, NOCODA, MAX, and DEP. The HG and OT T-orders coincide and consist of 16 entailments with a feasible antecedent, plotted in figure 3. These entailments extend to SOT and SHG, by virtue of the corollaries 1 and 2 obtained above.

ME instead misses the eight dotted entailments. Of the eight entailments which do survive in ME, seven are such that the antecedent and the consequent surface form coincide, plus the entailment $(\mathsf{VC}, \mathsf{VC}) \rightarrow (\mathsf{CV}, \mathsf{CV})$, which is a quirk due to the fact that VC is the most marked syllable type. This restriction to entailments whose antecedent and consequent surface forms coincide is not phonologically plausible. Anttila and Magri (2018) conclude that the ME formalism imposes typological restrictions at odds with phonological intuition.

Explaining Character-Aware Neural Networks for Word-Level Prediction: Do They Discover Linguistic Rules?

Fréderic Godin, Kris Demuynck, Joni Dambre, Wesley De Neve and Thomas Demeester

IDLab, Ghent University - imec, Ghent, Belgium
`firstname.lastname@ugent.be`

Abstract

Character-level features are currently used in different neural network-based natural language processing algorithms. However, little is known about the character-level patterns those models learn. Moreover, models are often compared only quantitatively while a qualitative analysis is missing. In this paper, we investigate which character-level patterns neural networks learn and if those patterns coincide with manually-defined word segmentations and annotations. To that end, we extend the contextual decomposition (Murdoch et al., 2018) technique to convolutional neural networks which allows us to compare convolutional neural networks and bidirectional long short-term memory networks. We evaluate and compare these models for the task of morphological tagging on three morphologically different languages and show that these models implicitly discover understandable linguistic rules.

1 Introduction

Character-level features are an essential part of many Natural Language Processing (NLP) tasks. These features are for instance used for language modeling (Kim et al., 2016), part-of-speech tagging (Plank et al., 2016) and machine translation (Luong and Manning, 2016). They are especially useful in the context of part-of-speech and morphological tagging, where for example the suffix *-s* can easily differentiate plural words from singular words in English or Spanish.

The use of character-level features is not new. Rule-based taggers were amongst the earliest systems that used character-level features/rules for grammatical tagging (Klein and Simmons, 1963). Other approaches rely on fixed lists of affixes (Ratnaparkhi, 1996; Toutanova et al., 2003). Next, these features are used by a tagging model, such as a rule-based model or statistical model. Rule-based taggers are transparent models that allow us to easily trace back why the tagger made a certain decision (e.g., Brill (1994)). Similarly, statistical models are merely a weighted sum of features.

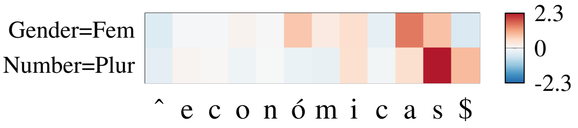

Figure 1: Individual character contributions of the Spanish adjective *económicas*. The character *a* has the highest positive (red) contribution for predicting the label *Gender=Fem*, and the character *s* for predicting the label *Number=Plur*. This coincides with our linguistic knowledge of Spanish.

For example, Brill (1994)'s transformation-based error-driven tagger uses a set of templates to derive rules by fixing errors. The following rule template:

> *"Change the most-likely tag* ***X*** *to* ***Y*** *if the last (1,2,3,4) characters of the word are* ***x****"*,

resulted in the rule:

> *"Change the tag* ***common noun*** *to* ***plural common noun*** *if the word has suffix* ***-s****"*.

Subsequently, whenever the tagger makes a tagging mistake, it is easy to trace back why this happened. Following the above rule, the word *mistress* will mistakingly be tagged as a plural common noun while it actually is a common noun[1].

This is in stark contrast with the most recent generation of part-of-speech and morphological taggers which mainly rely on neural networks.

---

[1] In Brill (1994), an additional rule encodes an exception to this rule to correctly tag the word *mistress*.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3275–3284

Words are split into individual characters and are in general either aggregated using a Bidirectional Long Short-Term Memory network (BiLSTM) (Plank et al., 2016) or Convolutional Neural Network (CNN) (dos Santos and Zadrozny, 2014). However, it is currently unknown which character-level patterns these neural network models learn and whether these patterns coincide with our linguistic knowledge. Moreover, different neural network architectures are currently only compared quantitatively and lack a qualitative analysis.

In this paper, we investigate which character patterns neural networks learn and to what extent those patterns comprise any known linguistic rules. We do this for three morphologically different languages: Finnish, Spanish and Swedish. A Spanish example is shown in Figure 1. By visualizing the contributions of each character, we observe that the model indeed uses the suffix *-s* to correctly predict that the word is plural.

Our main contributions are as follows:

- We show how word-level tagging decisions can be traced back to specific sets of characters and interactions between them.
- We extend the contextual decomposition method (Murdoch et al., 2018) to CNNs.
- We quantitatively compare CNN and BiLSTM models in the context of morphological tagging by performing an evaluation on three manually segmented and morphologically annotated corpora.
- We found out that the studied neural models are able to implicitly discover character patterns that coincide with the same rules linguists use to indicate the morphological function of subword segments.

Our implementation is available online[2].

2 Related Work

Neural network-based taggers currently outperform statistical taggers in morphological tagging (Heigold et al., 2017) and part-of-speech tagging (Plank et al., 2016) for a wide variety of languages. Character-level features form a crucial part of many of these systems. Generally, two neural network architectures are considered for aggregating the individual characters: a BiLSTM (Ling et al., 2015; Plank et al., 2016) or a CNN (dos Santos and Zadrozny, 2014; Bjerva et al., 2016; Heigold et al., 2017). These architectures outperform similar models that use manually defined features (Ling et al., 2015; dos Santos and Zadrozny, 2014). However, it is still unclear which useful character-level features they have learned. Architectures are compared quantitatively but lack insight into learned patterns. Moreover, Vania and Lopez (2017) showed in the context of language modeling that training a BiLSTM on ground truth morphological features still yields better results than eight other character-based neural network architectures. Hence, this raises the question which patterns neural networks learn and whether these patterns coincide with manually-defined linguistic rules.

While a number of interpretation techniques have been proposed for images (Springenberg et al., 2014; Selvaraju et al., 2017; Shrikumar et al., 2017), these are generally not applicable in the context of NLP where LSTMs are mainly used. Moreover, gradient-based techniques are not trustworthy when strongly saturating activation functions such as *tanh* and *sigmoid* are used (e.g., Li et al. (2016a)). Hence, current interpretations in NLP are limited to visualizing the magnitude of the LSTM hidden states of each word (Linzen et al., 2016; Radford et al., 2017; Strobelt et al., 2018), removing words (Li et al., 2016b; Kádár et al., 2017) or changing words (Linzen et al., 2016) and measuring the impact, or training surrogate tasks (Adi et al., 2017; Chrupała et al., 2017; Belinkov et al., 2017). These techniques only provide limited local interpretations and do not model fine-grained interactions of groups of inputs or intermediate representations. In contrast, Murdoch et al. (2018) recently introduced an LSTM interpretation technique called Contextual Decomposition (CD), providing a solution to the aforementioned issues. We will build upon this interpretation technique and introduce an extension for CNNs, making it possible to compare different neural network architectures within a single interpretation framework.

3 Method

For visualizing the contributions of character sets, we use the recently introduced Contextual Decomposition (CD) framework, as originally developed for LSTMs (Murdoch et al., 2018), and extend it to

---

[2] `https://github.com/FredericGodin/ContextualDecomposition-NLP`

CNNs. First, we introduce the concept of CD, followed by the extension for CNNs. For details on CD for LSTMs, we refer the reader to the aforementioned paper. Finally, we explain how the CD of the final classification layer is done.

3.1 Contextual decomposition

The idea behind CD is that, in the context of character-level decomposition, we can decompose the output value of the network for a certain class into two distinct groups of contributions: (1) contributions originating from a specific character or set of characters within a word and (2) contributions originating from all the other characters within the same word.

More generally, we can decompose every output value z of every neural network component into a relevant contribution β and an irrelevant contribution γ:

$$z = \beta + \gamma \tag{1}$$

3.2 Decomposing CNN layers

A CNN typically consist of three components: the convolution itself, an activation function and an optional max-pooling operation. We will discuss each component in the next paragraphs.

Decomposing the convolution Given a sequence of character embeddings $\boldsymbol{x}_1, ..., \boldsymbol{x}_T \in \mathbb{R}^{d_1}$ of length T, we can calculate the convolution of size n of a single filter over the sequence $\boldsymbol{x}_{1:T}$ by applying the following equation to each n-length subsequence $\{\boldsymbol{x}_{t+i}, i = 0, .., n-1\}$, denoted as $\boldsymbol{x}_{t:t+n-1}$:

$$z_t = \sum_{i=0}^{n-1} W_i \cdot \boldsymbol{x}_{t+i} + b, \tag{2}$$

with $z_t \in \mathbb{R}$ and where $W \in \mathbb{R}^{d_1 \times n}$ and $b \in \mathbb{R}$ are the weight matrix and bias of the convolutional filter. W_i denotes the i-th column of the weight matrix W.

When we want to calculate the contribution of a subset of characters, where $\boldsymbol{S}$ is the set of corresponding character position indexes and $\boldsymbol{S} \subseteq \{1, ..., T\}$, we should decompose the output of the filter z_t into three parts:

$$z_t = \beta_t + \gamma_t + b. \tag{3}$$

That is, the relevant contribution β_t originating from the selected subset of characters with indexes $\boldsymbol{S}$, the irrelevant contribution γ_t originating from the remaining characters in the sequence, and a bias which is deemed neutral (Murdoch et al., 2018).

This can be achieved by decomposing the convolution itself as follows:

$$\beta_t = \sum_{i=0}^{n-1} W_i \cdot \boldsymbol{x}_{t+i} \qquad (t+i) \in \boldsymbol{S}, \tag{4}$$

$$\gamma_t = \sum_{i=0}^{n-1} W_i \cdot \boldsymbol{x}_{t+i} \qquad (t+i) \notin \boldsymbol{S}, \tag{5}$$

Linearizing the activation function After applying a linear transformation to the input, a nonlinearity is typically applied. In CNNs, the ReLU activation function is often used.

In Murdoch et al. (2018), a linearization method for the non-linear activation function f is proposed, based on the differences of partial sums of all N components y_i involved in the preactivation sum z_t. In other words, we want to split $f_{ReLU}(z_t) = f_{ReLU}(\sum_{i=1}^{N} y_i)$ into a sum of individual linearized contributions $L_{f_{ReLU}}(y_i)$, namely $f_{ReLU}(\sum_{i=1}^{N} y_i) = \sum_{i=1}^{N} L_{f_{ReLU}}(y_i)$. To that end, we compute $L_{f_{ReLU}}(y_k)$, the linearized contribution of y_k as the average difference of partial sums over all possible permutations $\pi_1, ..., \pi_{M_N}$ of all N components y_i involved:

$$L_f(y_k) = \frac{1}{M_N} \sum_{i=1}^{M_N} [f(\sum_{l=1}^{\pi_i^{-1}(k)} y_{\pi_i(l)}) - f(\sum_{l=1}^{\pi_i^{-1}(k)-1} y_{\pi_i(l)})] \tag{6}$$

Consequently, we can decompose the output c_t after the activation function as follows:

$$\begin{aligned} c_t &= f_{ReLU}(z_t) && (7) \\ &= f_{ReLU}(\beta_{z,t} + \gamma_{z,t} + b) && (8) \\ &= L_{ReLU}(\beta_{z,t}) \\ &\quad + [L_{ReLU}(\gamma_{z,t}) + L_{ReLU}(b)] && (9) \\ &= \beta_{c,t} + \gamma_{c,t} && (10) \end{aligned}$$

Following Murdoch et al. (2018), $\beta_{c,t}$ contains the contributions that can be directly attributed to the specific set of input indexes $\boldsymbol{S}$. Hence, the bias b is part of $\gamma_{c,t}$. Note that, while the decomposition in Eq. (10) is exact in terms of the total sum, the individual attribution to relevant ($\beta_{c,t}$) and irrelevant ($\gamma_{c,t}$) is an approximation, due to the linearization.

Max-pooling over time When applying a fixed-size convolution over a variable-length sequence, the output is again of variable size. Hence, a max-pooling operation is executed over the time dimension, resulting in a fixed-size representation that is independent of the sequence length:

$$c = \max_t(c_t). \tag{11}$$

Instead of applying a max operation over the $\beta_{c,t}$ and $\gamma_{c,t}$ contributions separately, we first determine the position t of the highest c_t value and propagate the corresponding $\beta_{c,t}$ and $\gamma_{c,t}$ values.

3.3 Calculating the final contribution scores

The final layer is a classification layer, which is the same for a CNN- or LSTM-based architecture. The probability p_j of predicting class j is defined as follows:

$$p_j = \frac{e^{W_j \cdot \boldsymbol{x} + b_j}}{\sum_{i=1}^{C} e^{W_i \cdot \boldsymbol{x} + b_i}}, \tag{12}$$

in which $W \in \mathbb{R}^{d_2 \times C}$ is a weight matrix and W_i the i-th column, $\boldsymbol{x} \in \mathbb{R}^{d_2}$ the input, $\boldsymbol{b} \in \mathbb{R}^{d_2}$ the bias vector and b_i the i-th element, d_2 the input vector size and C the total number of classes.

The input $\boldsymbol{x}$ is either the output $\boldsymbol{c}$ of a CNN or $\boldsymbol{h}$ of a LSTM. Consequently, we can decompose $\boldsymbol{x}$ into $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}$ contributions. In practice, we only consider the preactivation and decompose it as follows:

$$W_j \cdot \boldsymbol{x} + b_j = W_j \cdot \boldsymbol{\beta} + W_j \cdot \boldsymbol{\gamma} + b_j. \tag{13}$$

Finally, the contribution of a set of characters with indexes $\boldsymbol{S}$ to the final score of class j is equal to $W_j \cdot \boldsymbol{\beta}$. The latter score is used throughout the paper for visualizing contributions of sets of characters.

4 Experimental Setup

We execute experiments on morphological tagging in three different languages: Finnish, Spanish and Swedish. We describe the dataset in Section 4.1, whereas model and training details can be found in Section 4.2.

4.1 Dataset

For our experiments, we use the Universal Dependencies 1.4 (UD) dataset (Nivre et al., 2016), which contains morphological features for a large number of sentences. Additionally, we acquired manually-annotated character-level morphological segmentations and labels for a subset of the test set for three morphological different languages: Finnish, Spanish and Swedish. [3]

Table 1: Overview of the training, validation and test set used.

	Finnish	**Spanish**	**Swedish**
Train words	53547	62556	16295
Valid words	2317	4984	1731
Test words	2246	956	3538
Annotated Test pairs	278	340	137

For each language, Silfverberg and Hulden (2017) selected the first non-unique 300 words from the UD test set and manually segmented each word according to the associated lemma and morphological features in the dataset. Whenever possible, they assigned each feature to a specific subset of characters. For example, the Spanish word "económicas" is segmented as follows:

- económic : lemma=económico
- a : gender=feminine
- s : number=plural

For our experiments, we are only interested in word/feature pairs for which a feature can be assigned to a specific subset of characters. Hence, we filter the test set on those specific word/feature pairs. In the above example, we have two word/feature pairs. This resulted in 278, 340 and 137 word/feature pairs for Finnish, Spanish and Swedish, respectively. Using the same procedure, we selected relevant feature classes, resulting in 12, 6 and 9 feature classes for Finnish, Spanish and Swedish, respectively.[4] For each class, when a feature was not available, we introduced an additional *Not Applicable* (NA) label.

We always train and validate on the full UD dataset for which we have filtered out all duplicate words. After that, we perform our analysis on either the UD test set or the annotated subset of manually segmented and annotated words. An overview can be found in Table 1.

---

4.2 Model

We experiment with both a CNN and BiLSTM architecture for character-level modeling of words.

At the input, we split every word into characters and add a start-of-word (^) and an end-of-word ($) character. With every character, we associate a character embedding of size 50.

Our CNN architecture is inspired by Kim et al. (2016) and consists of a set of filters of varying width, followed by a ReLU activation function and a max-over-time pooling operation. We adopt their small-CNN parameter choices and have 25, 50, 75, 100, 125 and 150 convolutional filters of size 1, 2, 3, 4, 5 and 6, respectively. We do not add an additional highway layer.

For the character-level BiLSTM architecture, we follow the variant used in Plank et al. (2016). That is, we simply run a BiLSTM over all the characters and concatenate the final forward and backward hidden state. To obtain a similar number of parameters as the CNN model, we set the hidden state size to 100 units for each LSTM.

Finally, the word-level representation generated by either the CNN or BiLSTM architecture is classified by a multinomial logistic regression layer. Each morphological class type has a different layer. We do not take into account context to rule out any influence originating from somewhere other than the characters of the word itself.

Training details For morphological tagging, we train a single model for all classes at once. We minimize the joint loss by summing the cross-entropy losses of each class. We orthogonally initialize all weight matrices, except for the embeddings, which are uniformly initialized ([-0.01;0.01]). All models are trained using Adam (Kingma and Ba, 2015) with minibatches of size 20 and learning rate 0.001. No specific regularization is used. We select our final model based on early stopping on the validation set.

5 Experiments

First, we verify that the CD algorithm works correctly by executing a controlled experiment with a synthetic token. Next, we quantitatively and qualitatively evaluate on the full test set.

5.1 Validation of contextual decomposition for convolutional neural networks

To verify that the contextual decomposition of CNNs works correctly, we devise an experiment in which we add a synthetic token to a word of a certain class, testing whether this token gets a high attribution score with respect to that specific class.

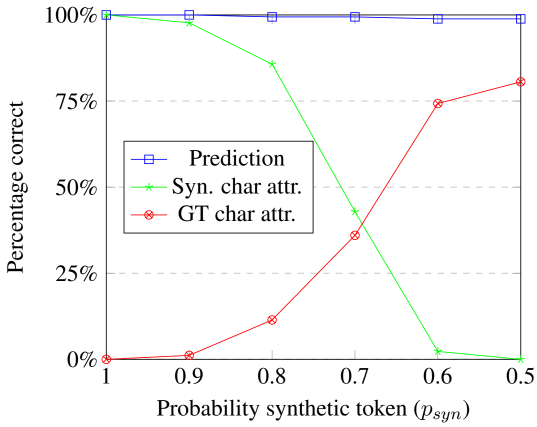

Figure 2: Comparison of the contribution of the synthetic character versus the Ground Truth (GT) character for the class $t = 1$. The prediction curve denotes the classification accuracy for class $t = 1$, and consequently, the prediction curve denotes the upper bound for the attributions.

Given a word w and a corresponding binary label t, we add a synthetic character c to the beginning of word w with probability p_{syn} if that word belongs to the class $t = 1$ and with probability $1 - p_{syn}$ if that word belongs to the class $t = 0$. Consequently, if $p_{syn} = 1$, the model should predict the label with a 100% accuracy, thus attributing this to the synthetic character c. When $p_{syn} = 0.5$, the synthetic character does not provide any additional information about the label t, and c should thus have a small contribution.

Experimental setup We train a CNN model on the Spanish dataset and only use words having the morphological label *number*. This label has two classes *plur* and *sing*, and assign those classes to the binary labels zero and one, respectively. Furthermore, we add a synthetic character to each word with probability p_{syn}, varying p_{syn} from 1 to 0.5 with steps of 0.1. We selected 112 unique word/feature pairs from our test set with label *sing* or *plur*. While plurality is marked by the suffix *s*, a variety of suffixes are used for the singular form. Therefore, we focus on the latter class ($t = 1$). The corresponding suffix is called the Ground Truth (GT) character.

To measure the impact of p_{syn}, we add a synthetic character to each word of the class $t = 1$ and

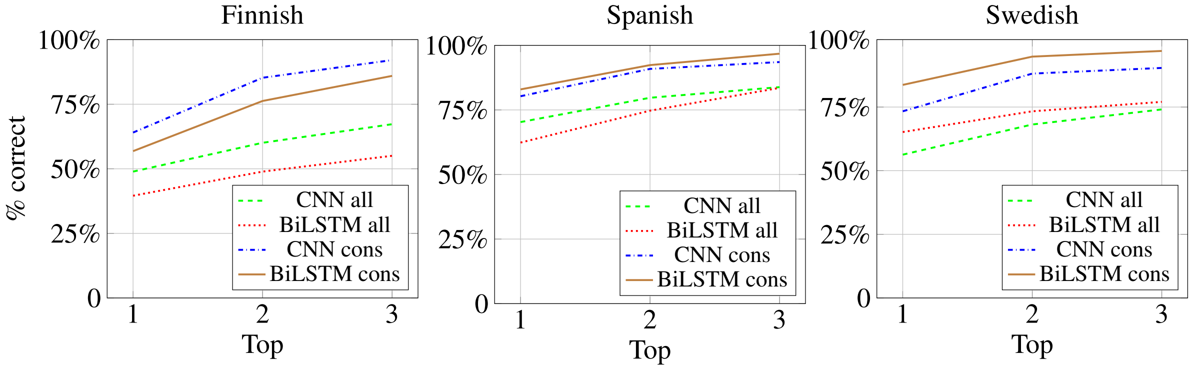

Figure 3: Evaluation of the attributions of CNN and BiLSTM models on the three different languages.

calculate the contribution of each character by using the CD algorithm. We run the experiment five times with a different random seed and report the average correct attribution. The attribution is correct if the contribution of the synthetic/GT character is the highest contribution of all character contributions.

Results The results of our evaluation are depicted in Figure 2. When $p_{syn} = 1$, all words of the class $t = 1$ contain the synthetic character, and consequently, the accuracy for predicting $t = 1$ is indeed 100%. Moreover, the correct prediction is effectively attributed to the synthetic character ('syn. char attr.' in Figure 2 at 100%), with the GT character being deemed irrelevant. When the synthetic character probability p_{syn} is lowered, the synthetic character is less trustworthy and the GT character becomes more important (increasing 'GT char attr.' in Figure 2). Finally, when $p_{syn} = 0.5$, the synthetic character is equally plausible in both classes. Hence, the contribution of the synthetic character becomes irrelevant and the model attributes the prediction to other characters.

Consequently, we can conclude that whenever there is a clear character-level pattern, the model learns the pattern and the CD algorithm is able to accurately attribute it to the correct character.

5.2 Evaluation of character-level attribution

In this section, we measure and analyze (1) which characters contribute most to the final prediction of a certain label and (2) whether those contributions coincide with our linguistic knowledge about a language. To that end, we train a model to predict morphological features, given a particular word. The model does not have prior word segmentation information and thus needs to discover useful character patterns by itself. After training, we calculate the attribution scores of each character pattern within a word with respect to the correct feature class using CD, and evaluate whether this coincides with the ground truth attribution.

Table 2: Average accuracy of all models trained on Finnish, Spanish and Swedish for the task of morphological feature prediction for all unique words in the full UD test set.

	Finnish	**Spanish**	**Swedish**
Maj. Vote	82.20%	72.39%	69.79%
CNN	94.81%	88.93%	**90.09%**
BiLSTM	**95.13%**	**89.33%**	89.45%

Model We train CNN and BiLSTM models on Finnish, Spanish and Swedish. The average accuracies on the full test set are reported in Table 2.[5] As a reference for the trained models' ability to predict morphological feature classes, we provide a naive baseline, constructed from the majority vote for each feature type.

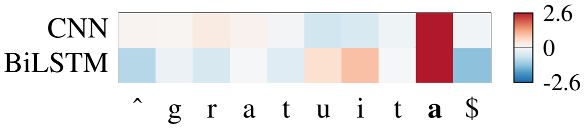
Overall, our neural models yield substantially higher average accuracies than the baseline and perform very similar. Consequently, both the CNN and LSTM models learned useful character patterns for predicting the correct morphological feature classes. Hence, this raises the question whether these patterns coincide with our linguistic knowledge.

Evaluation For each annotated word/feature pair, we measure if the ground truth character se-

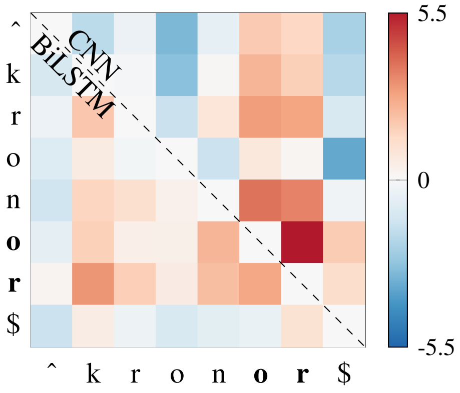
---

[5] The results of the individual classes are provided as supplementary material.

(a) Example of Finnish. Word (verb): *ol**i**vat (were)*, target class: *Tense=Past*



(b) Example of Spanish. Word (adjective): *gratuit**a** (free)*, target: *Gender=Fem.*



(c) Example of Swedish. Word (noun): *kron**or** (Swedish valuta as in dollars)*, target: *Number=Plur.*

Figure 4: Character-level contributions for predicting a particular class. Positive contributions are highlighted in red and negative contributions in blue. The ground truth character sequence is highlighted in bold.

quence corresponds to the set or sequence of characters with the same length within the considered word that has the highest contribution for predicting the correct label for that word.

In the first setup, we only compare with character sequences having a consecutive set of characters (denoted *cons*). In the second setup, we compare with any set of characters (denoted *all*). We rank the contributions of each character set and report top one, two, and three scores. Because start-of-word and end-of-word characters are not annotated in the dataset, we do not consider them part of the candidate character sets.

Results The aggregated results for all classes and character sequence lengths are shown in Figure 3. In general, we observe that for almost all models and setups, the contextual decomposition attribution coincides with the manually-defined segmentations for at least half of the word/feature pairs. When we only consider the top two consecutive sequences (marked as *cons*), accuracies range from 76% up to 93% for all three languages. For Spanish and Swedish, the top two accuracies for character sets (marked as *all*) are still above 67%, despite the large space of possible character sets, whereas all ground truth patterns are consecutive sequences. While the accuracy for Finnish is lower, the top two accuracy is still above 50%.

Examples for Finnish, Spanish and Swedish are shown in Figure 4. For Finnish, the character with the highest contribution *i* coincides with the ground truth character for the CNN model. This is not the case for the BiLSTM model which focuses on the character *v*, even though the correct label is predicted. For Spanish, both models strongly focus on the ground truth character *a* for predicting the feminine gender. For Swedish, the ground truth character sequence is the suffix *or* which denotes plurality. Given that *or* consists of two characters, all contributions of character sets of two characters are visualized. As can be seen, the most important set of two characters is {o,r} for the CNN and {k,r} for the BiLSTM model. However, {o,r} is the second most important character set for the BiLSTM model. Consequently, the BiLSTM model deemed the interaction between a root and suffix character more important than between two suffix characters.

5.3 Analysis of learned patterns

In the previous section, we showed that there is a strong relationship between the manually-defined morphological segmentation and the patterns a neural network learns. However, there is still an accuracy gap between the results obtained using consecutive sequences only and results obtained using all possible character sets. Hence, this leads to the question which patterns the neural network focuses on, other than the manually defined patterns we evaluated before. To that end, for each of the three languages, we selected a morphological class of interest and evaluated for all words in the full UD test set that were assigned to that class what the most important character set of length one, two and three was. In other words, we evaluated for each word for which the class was cor-

Table 3: The most frequent character sets used by a model for predicting a specific class. The frequency of occurrence is shown between brackets. An underscore denotes an unknown character.

		One character	**Two characters**	**Three characters**	**Examples**
Finnish Tense=Past	BiL.	i (69%), t (22%), v (4%), a (2%)	ti (13%), t_i (12%), v_t (9%), ui (6%)	tti (8%), iv_t (5%), t__ti (3%), sti (3%)	ol**iv**a**t**, näy**tti**kään
	CNN	i (71%), t (8%), s (6%), o (5%)	ui (12%), si (11%), ti (11%), oi (9%)	a__ui (3%), tii (3%), iv__$ (2%), ui__t (2%)	tie**si**, me**i**dät
Spanish Gend=Fem	BiL.	a (69%), i (16%), d (6%), e (4%)	as (23%), a$ (13%), ad (7%), ia (5%)	ia$ (4%), ad$ (3%), da$ (3%), ca$ (2%)	toleranc**ia**, ciud**ad**
	CNN	a (77%), ó (14%), n (4%), d (3%)	a$ (34%), as (20%), da (8%), ió (7%)	dad (5%), da$ (4%), a_ió (4%), sió (2%)	firm**as**, preci**sió**n
Swedish Numb=Plur	BiL.	n (25%), r (19%), a (14%), g (7%)	na (13%), a__r (4%), or (3%), n__r (3%)	iga (5%), rna (3%), ner (1%), der (1%)	kron**or**, perio**der**
	CNN	n (21%), a (18%), r (15%), d (5%)	rn (8%), na (5%), or (4%), er (3%)	rna (7%), arn (3%), iga (2%), n_ar (2%)	krafte**rna**, sak**er**

rectly predicted, which character set had the highest positive contribution towards predicting that class. The results can be found in Table 3.

Finnish In Finnish, adding the suffix *i* to a verb, transforms it in the past tense. Sometimes the character *s* is added, resulting in the suffix *si*. The latter is a frequently used bigram pattern by the CNN but less by the BiLSTM. The BiLSTM combines the suffix *i* with another suffix *vat* which denotes third person plural in the character pattern *iv_t*.

Spanish While there is no single clear-cut rule for the Spanish gender, in general the suffix *a* denotes the feminine gender in adjectives. However, there exist many nouns that are feminine but do not have the suffix *a*. Teschner and Russell (1984) identify *d*, and *ión* as typical endings of feminine nouns, which our models identified too as for example *ad$* or *ió/sió*.

Swedish In Swedish, there exist four suffixes for creating a plural form: *or*, *ar*, *(e)r* and *n*. Both models identified the suffix *or*. However, similar to Finnish, multiple suffixes are merged. In Swedish, the suffix *na* only occurs together with one of the first three plural suffixes. Hence, both models correctly identified this pattern as an important pattern for predicting the class number=plural, rather than the linguistically-defined pattern.

5.4 Interactions of learned patterns

In the previous section, the pattern *a$* showed to be the most important pattern in 34% of the correctly-predicted feminine Spanish words in our dataset. However, there exist many words that end with the character *a* that are not feminine. For example the third person singular form of the verb *gustar* is *gusta*. Hence, this raises the question if the model will classify *gusta* wrongly as feminine or correctly as NA. As an illustration of the applicability of CD for morphological analysis, we will study this case in more detail.

From the full UD test set, we selected all words that end with the character *a* and that do not belong to the class gender=feminine. Using the Spanish CNN model, we predicted the gender class for each word and divided the words into two groups: predicted as feminine and predicted as not-feminine (_NA_ or masculine). The resulted in 44 and 199 words. Next, for each word in both groups we calculated the most positively and negatively contributing character set out of all possible character sets of any length within the considered word, using the CD algorithm. We compared the contribution scores in both groups using a Kruskal-Wallis significance test.[6] While no significant ($p < 0.05$) difference could be found between the positive contributions of both groups (p=1.000), a borderline significant difference could be found between the negative

---

[6] The full statistical analysis is provided as supplementary material.

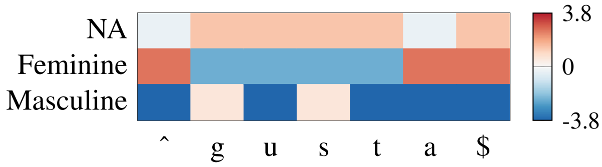


Figure 5: Visualization of the most positively and negatively contributing character set for each class of the morphological feature class gender for the Spanish verb *gusta* (likes).

contributions of words predicted as feminine and words predicted as not-feminine (p=0.070).

Consequently, the CNN model's classification decision is based on finding enough negative evidence to counteract the positive evidence found in the pattern *a$*, which CD was able to uncover.

A visualization of this interaction is shown in Figure 5 for the word *gusta*. While the positive evidence is the strongest for the class feminine, the model identifies the verb stem *gust* as negative evidence which ultimately leads to the correct final prediction NA.

6 Conclusion

While neural network-based models are part of many NLP systems, little is understood on how they handle the input data. We investigated how specific character sequences at the input of a neural network model contribute to word-level tagging decisions at the output, and if those contributions follow linguistically interpretable rules.

First, we presented an analysis and visualization technique to decompose the output of CNN models into separate input contributions, based on the principles outlined by Murdoch et al. (2018) for LSTMs. This allowed us then to quantitatively and qualitatively compare the character-level patterns the CNNs and BiLSTMs learned for the task of morphological tagging. We showed that these patterns generally coincide with the morphological segments as defined by linguists for three morphologically different languages, but that sometimes other linguistically plausible patterns are learned. Finally, we showed that our CD algorithm for CNNs is able to explain why the model made a wrong or correct prediction.

By visualizing the contributions of each input unit or combinations thereof, we believe that much can be learned on how a neural network handles the input data, why it makes certain decisions, or even for debugging neural network models.

Abstract

Much work in Natural Language Processing (NLP) has been for resource-rich languages, making generalization to new, less-resourced languages challenging. We present two approaches for improving generalization to low-resourced languages by adapting continuous word representations using linguistically motivated subword units: phonemes, morphemes and graphemes. Our method requires neither parallel corpora nor bilingual dictionaries and provides a significant gain in performance over previous methods relying on these resources. We demonstrate the effectiveness of our approaches on Named Entity Recognition for four languages, namely Uyghur, Turkish, Bengali and Hindi, of which Uyghur and Bengali are low resource languages, and also perform experiments on Machine Translation. Exploiting subwords with transfer learning gives us a boost of +15.2 NER F1 for Uyghur and +9.7 F1 for Bengali. We also show improvements in the monolingual setting where we achieve (avg.) +3 F1 and (avg.) +1.35 BLEU.

1 Introduction

Continuous word representations have demonstrated utility in state-of-the-art neural models for several NLP tasks, such as named entity recognition (NER; Ma and Hovy (2016)), machine reading (Tan et al., 2017), sentiment analysis (Tang et al., 2016; Yu et al., 2018), and machine translation (MT; Qi et al. (2018)). While the training of these word vectors does not rely on explicit human supervision, their quality is highly contingent on the size and quality of the unlabeled corpora available. There are over 7000 languages in the world (Hammarström et al., 2018), and corpora with sufficient size and coverage are available for just a handful, making it unclear how these methods will perform in the more common low-resource setting.

Disheartening though this high dependence on resources sounds, several efforts (Adams et al., 2017; Haghighi et al., 2008; Bharadwaj et al., 2016; Mayhew et al., 2017) have shown considerable performance gains across different tasks in the low resource setting by transferring knowledge from related high-resource languages. Most existing approaches for learning cross-lingual word embeddings (Ruder, 2017) either extend the monolingual objective function by adding a cross-lingual regularization objective which is then jointly optimized or use mapping-based approaches to align similar words across languages. These post-hoc coordination methods rely on bilingual lexicons or parallel corpora, which are typically of limited quantity and uncertain quality.

In this paper, we take a different task: focusing instead on the *similarity of the surface forms, phonology, or morphology* of the two transfer languages. Specifically, inspired by Ling et al. (2015), who demonstrate the effectiveness of character-level modeling for knowledge sharing in multilingual scenarios, we propose two approaches to transfer word embeddings using different types of linguistically-inspired subword-level information. Both approaches focus on mapping the low resource language embeddings closer to those of the high resource language and are executed using two different training regimes. We explore the effect of different subword units—characters, lemmas, inflectional properties, and phonemes— as each one offers a unique linguistic insight, discussed more in Section 3. Our proposed approaches do require language specific resources, but importantly do not depend on cross-lingual resources and achieve considerable performance gains over existing methods which do.

We evaluate our proposed approach on two downstream tasks: NER, which deals with detecting and classifying Named Entities (NEs) into pre-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3285–3295
Brussels, Belgium, October 31 - November 4, 2018.

defined categories (Nadeau and Sekine, 2007), and MT to English. For the purposes of error analysis and discussion, we focus on the NER task in particular. NEs are typically noun phrases and occur rarely in the corpus, making the generalization across types and domains difficult. We chose NER as our test bed because word vectors have a direct impact on NER model performance— as suggested by (Ruder, 2017) and observed by us in Table 3, where the model without any pre-trained embeddings scores an average of 18 F1 points less. It thus provides a transparent way to measure the effectiveness of different subword units.

This paper makes the following contributions:

1. We show that embeddings trained on subword representations yield better task performance than those trained only on whole words. This is especially true in a transfer setting, where subword representations also outperform a word alignment based method. We further show that embeddings trained on morphological representations often outperform those trained only on whole words.
2. We demonstrate that training embeddings on character-based phonemic representations presents substantial performance advantages over training on orthographic characters in some transfer settings, e.g. when there are script differences across languages. These advantages are in addition to those from morphological representations (lemmas and morphological properties).
3. We produce continuous representations for each subword unit, giving researchers the ability to use them in their own tasks as they see fit. The code [1] for training word embeddings and the embeddings [2] which produced the best results are publicly available. We also release morphological analyzers for Hindi and Bengali[3].

2 Skipgram Objective

The two most popular training objectives for monolingual word embeddings are the skipgram and continuous-bag-of-words (CBOW), introduced by Mikolov et al. (2013a). The skipgram model attempts to predict the context surrounding a word, given the word itself whereas CBOW predicts the word given its context. Formally, given a corpus having a sequence of words $w_1, w_2, \cdots, w_T$, the skip-gram model maximizes the following log-likelihood:

$$\sum_{i=1}^{T} \sum_{v \in C_i} \log p(v|w_i) \tag{1}$$

where C_i are the context tokens, within a specified window of the focus word w_i and $p(v|w_i)$ is the probability of observing context word v given focus word w_i. The skipgram was originally defined using the softmax function:

$$p(v|w_i) = \frac{e^{s(v,w_i)}}{\sum_{j=1}^{W} e^{s(w_i,j)}} \tag{2}$$

where s is a scoring function mapping v and w_i to $\mathbb{R}$. The summation in the denominator is over the entire vocabulary W which makes this formulation computationally inefficient as cost of gradient computation is proportional to W which is quite large ($\sim 10^6$). Mikolov et al. (2013b) hence employ negative sampling to make this computation efficient and robust (Levy et al., 2015) and give better representations for infrequent words[4], which is crucial for the low resource settings. Negative sampling represents the above objective function (Equation 1) using a binary logistic loss as shown below:

$$\sum_{i=1}^{T} \left(\sum_{w_c \in C_i} l(s(w_i, w_c)) + \sum_{w_n \in N_i} l(-s(w_i, w_n)) \right) \tag{3}$$

where N_i are the negative words sampled randomly from vocabulary and l is the log-sigmoid function. The scoring function s is a dot product similarity function given by $s(w_i, w_c) = \mathbf{u}_{w_i}^{\top} \mathbf{v}_{w_c}$ where $\mathbf{u}_{w_i}$ and $\mathbf{v}_{w_c}$ are the embeddings of the focus word and its context word respectively.

3 Subword Representation

Mikolov et al. (2013b)'s model fails to capture internal structure of words and does not generalize for out of vocabulary words that may share morphemes with in-vocabulary words. The problems of this method are particularly salient for

morphologically rich languages such as Turkish, Uyghur, Hindi, and Bengali. Although, given a large enough training corpus, most or all morphological forms of a lexeme (of which there may be many) could theoretically learn to have similar vector representations, it will be vastly more data efficient if we can take into account regularities of their form to model morphology explicitly. We explore the following methods for doing so:

Orthographic units: Wieting et al. (2016) and Bojanowski et al. (2016) show the utility of character-level modeling by representing the focus word w_i as a set of its character ngrams, denoted by $\mathbf{u}_{w_i} = \frac{1}{|G|} \sum_{g \in G} \mathbf{x}_g$, where G is the set of character ngrams and $\mathbf{x}_g$ is the vector representation of ngram g. Such representations capture morphological information in a brute-force but principled fashion—words that share the same morpheme are more likely to share the same character ngrams than words that do not.

Morphological units: Previous work has found that morphological relationships between words can be captured more directly if embeddings are trained on morphological representations (Luong et al., 2013; Botha and Blunsom, 2014; Cotterell and Schütze, 2015). Avraham and Goldberg (2017) explicitly model lemmas (stems or citation forms) and morphological properties (the sets of which are sometimes called “tags”) for training the word embeddings. Lemmas capture information about the lexical identity of a word and are closely correlated with the semantics of a word; tags capture information about the syntactic context of a word. See Figure 1 for an example. We take inspiration from the above work in adapting these subword units for cross-lingual transfer.

Phonological units: Subword units other than tags might seem to be of no use in closely-related languages with different scripts (such as Serbian and Croatian). Following Bharadwaj et al. (2016), we convert text from its orthographic form into a phonemic representation, stated in terms of the International Phonetic Alphabet (IPA). We then train embeddings on this representation. This means that, roughly speaking, morphemes that sound the same will be represented in the same way across languages.

phoneme ngrams	$x_{<qa} + x_{qar} + \ldots + x_{majdu>}$
lemma	x_{qari}
morphemes	$x_{Verb} + x_{Pot} + \ldots + x_{A3sg}$

Figure 2: Vector representations of a word in Uyghur

4 Cross-lingual Transfer

In this section we discuss in detail both our approaches for cross-lingual transfer along with the relevant baselines.

4.1 Proposed Approach

We propose to use phoneme ngrams, represented using IPA, in addition to the lemma and morphological tags, to enable effective transfer across languages. Tsvetkov and Dyer (2016) demonstrate the effectiveness of projecting words from orthographic space to phonemic space as related languages often share similar phonological patterns. More formally, let P_w be the set of linguistic properties of a word consisting of the phoneme ngrams $(\mathbf{I}_g)$, lemma $(\mathbf{L})$ and individual morphological tags $(\mathbf{M}_m)$. The focus word is then represented as the average sum of its linguistically motivated subword units:

$$\mathbf{v}_{w_c} = \frac{1}{|P_{w_c}|} \sum_{p \in P_{w_c}} \mathbf{x}_p$$

where $\mathbf{x}_p$ is the vector representation of subword unit p of word w_c. The average operation is important to remove any bias towards words having too many or too few subword units. For instance, the Uyghur word in Figure 1 is represented using its phoneme-ngrams ranging from 3-grams to 6-grams, lemma and morphological tags as shown in Figure 2. Avraham and Goldberg (2017) instead encode the different morphological inflections as one tag, so that *Verb+Pot+Neg+Pres+A3sg* would be encoded as $x_{Verb+Pot+Neg+Pres+A3sg}$. We encode each property in a tag separately to avoid data sparsity issues and empirically find this approach to perform better.

We present two training regimes for transferring knowledge from a related language, namely **CT-**

Joint and **CT-FineTune** by explicitly incorporating the subword units. We hypothesize that having word representations of both languages lying in a similar space will aid the low resource language in leveraging resources from the high resource language, including annotations for the downstream task. These two regimes are described below:

CT-Joint: This model explicitly maps the word representations of the two languages into the same space by training simultaneously on both. This is achieved simply by combining the corpora of both the high-resource and the low-resource language and training jointly using the skip-gram objective, discussed above. The central intuition is as follows: once two related languages are placed in the same phonological and morphological space, they will share many subword units in common and this will make joint training profitable. Duong et al. (2016) and Gouws et al. (2015) have previously shown the advantages of joint training and we observe this to be true in our case as well.

CT-FineTune: This model implicitly maps the word representations of the two languages into the same space. The model attempts this by taking the learned continuous representations of the high resource subword units, referred to by $\mathbf{x}^{Hi}_{SWU}$, and uses them to initialize the model for the low resource language. The model is first trained using all subword units on the high resource language and the learned representations are then used for initializing the subword units for the low resource language. To elucidate which pretrained subword helped the most on the low resource language, we use the same model for different experiments, which is trained using all subword units—phoneme-ngrams, lemma and morphological properties. The linguistic intuition behind CT-FineTune is similar to that behind CT-Joint. This idea of transferring parameters from high resource language has been previously explored by Zoph et al. (2016) for low resource neural machine translation which showed considerable improvement.

5 Evaluation

In this section, we first describe the model setup for training word embeddings followed by details on NER and MT experiments.

5.1 Implementation details

We base our model on the C++ implementation of *fasttext*[5](Bojanowski et al., 2016) with modifications as described above.

Data: We represent a word in the training corpus using the format presented by Avraham and Goldberg (2017). For instance, the Uyghur word in Figure 1 is represented as follows: phoneme **ipa:** *qarijalmajdu*, lemma **l:***qari*, and morphological inflections **m:***Verb+Pot+Neg+Pres+A3sg*. We consider phoneme-ngrams ranging from 3-grams to 6-grams and append a special start symbol < and end symbol > to the word. We discard unigrams and bigram ngrams on the assumption that they don't contribute much to the word.

Linguistic properties: We experiment with different subword units for both the transfer setting and the monolingual setting. We use the orthography-to-IPA tool *Epitran* (Mortensen et al., 2018) to obtain the phonemic representations. The lemmas and morphological properties for a word in context are obtained using a rule-based morphological analyzer in such a fashion as to produce tags similar to the high resource language. For Turkish we use the morphological disambiguator developed by (Shen et al., 2016), which in turn is based on an FST-based morphological analyzer developed by Oflazer (1994). For Uyghur, we took a (parser combinator based) morphological analyzer that had been developed for a DARPA LORELEI evaluation and modified it to output part-of-speech tags and to use a property set that was as close as possible to that of the Oflazer Turkish analyzer. The analyzer for Turkish produces 116 inflectional properties and for Uyghur we get 54 properties, of which 64% are shared with Turkish. Unfortunately, we did not have access to existing morphological analyzers for Hindi or Bengali. Many Hindi morphological analyzers exist, but they are not typically released publicly (Malladi and Mannem, 2013; Goyal and Lehal, 2008). We developed our own analyzers using a stemmer-like framework[6] over a span of few weeks (2-3), which gave 8 unique morphological tags for Hindi and 10 for Bengali (for both languages, noun inflection only) of which just 2 were shared with Hindi.

Morphologically speaking, we only use inflec-

---

[5] `https://github.com/facebookresearch/fastText/`

[6] `https://github.com/dmort27/mstem`

tional properties. For most languages, we considered derivational affixes to be part of the stem, since they change the meaning and grammatical category of the word rather than simply expressing syntactic information. An exception to this was Turkish, where the available morphological analyzer segments all affixes off from the root. However, even there we confined our use of morphological properties to inflectional properties. Derivational affixes display scopal behavior; since we wanted to treat the morphological properties of a word as a set, rather than a sequence, we were required to choose this option.

Hyperparameters: During training, we consider context tokens within a window size 3 of the focus word and we sample 5 negative examples from the vocabulary. We chose a window size of only 3 based on the fact that we are working with morphologically rich languages with a relatively high information to token ratio (otherwise a window size of 5 may be more appropriate). Subword units are initialized with uniform samples from $\left[\frac{-1}{dim}, \frac{1}{dim}\right]$ where $dim = 100$. We use the same training regime as Bojanowski et al. (2016). For CT-FineTune, instead of uniform samples we initialize the subword units of the low resource language from the learnt $\mathbf{x}_{SWU}^{Hi}$.

Lang.	Train	Dev	Test
Turkish	3376	1126	1126
Uyghur	1822	240	2448*
Hindi	3974	497	497
Bengali	1908	53	7012

Table 1: Sentences in train/dev/test set for NER. (*Unsequestered set. The full test set has 12,546 sentences.)

5.2 Baselines

For comparison, we train multilingual embeddings using MultiCCA (Ammar et al., 2016) as our baseline. It employs canonical correlation analysis by projecting multiple languages in the same shared space of one language, also referred to as multilanguage space. This method learns linear projections for each language into this common language space using bilingual lexicons. English is used as a common vector space due to availability of corresponding bilingual lexicons between English and each of our languages. For a fair comparison, we run MultiCCA on monolingual embeddings trained with different subword units. We use 100 dimension (Bojanowski et al., 2016) embeddings for English.

For NER, we also compare with Bharadwaj et al. (2016) who use a neural attention model over phonological features and report the best performance for Turkish using transfer from Uzbek and Uyghur, and Mayhew et al. (2017) who use a cheap translation method to translate training data from high-resource language into the low-resource language and report best NER results for Uyghur, as part of the LORELEI program. Our work differs from these primarily on two fronts: a) it is independent of the downstream task and can easily be adapted across various tasks, and b) it doesn't require parallel corpora or bilingual dictionaries. For our monolingual experiments, we compare our proposed approach with models using subword representations—Bojanowski et al. (2016) and Avraham and Goldberg (2017).

5.3 Named Entity Recognition Task

We use state-of-the-art NER architecture (Ma and Hovy, 2016) as our model for evaluation. The task is to identify NEs and categorize them into four types. Since this is a supervised model, the performance is highly contingent on the quality of labeled data. F1 scores are used as the evaluation metric.

5.3.1 Experiments

We conduct the two main sets of NER experiments,

1. Transfer experiments on the low resource languages—Uyghur and Bengali—using Turkish and Hindi as the high resource languages respectively. We show results using both our proposed models, CT-Joint and CT-FineTune.

2. Monolingual experiments on all four languages: Uyghur, Turkish, Bengali and Hindi. We do an ablation study using different combinations of subword units.

These language pairs were chosen partly out of convenience—the data were available to us as part of the DARPA LORELEI program—and partly because they satisfied certain deeper desiderata. Turkish and Uyghur are fairly closely related to one another, as are Hindi and Bengali. Despite this relationship, the members of both pairs are written

Model	subword units	Uyghur	Bengali
CT-Joint	phoneme-ngrams + lemma + morph	55.00	**60.33**
	phoneme-ngrams + lemma	**56.20**	59.63
	phoneme-ngrams	54.90	58.50
	phoneme	51.30	53.75
	char-ngrams + lemma + morph	50.20	55.10
	char-ngrams + lemma	48.20	53.83
	char-ngrams	49.60	52.77
	word	51.80	53.69
CT-FineTune	phoneme-ngrams + lemma + morph	48.60	56.19
	lemma + morph	52.80	57.72
	phoneme-ngrams + lemma	51.00	56.83
	phoneme-ngrams	50.50	57.69
	phoneme	49.20	59.86
MultiCCA (Baseline)	char-ngrams + lemma + morph	41.00	50.63
	char-ngrams + lemma	43.10	50.63
	char-ngrams	45.80	38.06
	word	42.70	45.86

Table 2: Transfer experiments on NER. Metric F1 (out of 100%). Uyghur transfer is from Turkish; Bengali transfer is from Hindi

in different scripts (Roman and Perso-Arabic; Devanagari and Bengali). Finally, all four languages are morphologically rich, especially Turkish and Uyghur. These qualities allow us to showcase the value of embeddings with subword units.

Data Preprocessing: We use data, comprised of unlabeled corpora, English bilingual dictionaries, annotations, from the Linguistic Data Consortium (LDC) language packs—Turkish and Hindi [7], Bengali[8], from which we generate train-dev-test splits. Uyghur data was released as part of LoReHLT16 task, organized by NIST [9] under the aegis of DARPA, and training annotations were acquired using native speakers as part of the task. For Uyghur we evaluate on an unsequestered set consisting of 199 annotated evaluation documents, released by NIST. For Turkish, Hindi and Bengali, we create our own train-dev-test splits (Table 1). The exact documents from which Mayhew et al. (2017) and Bharadwaj et al. (2016) created their test set is not apparent. The Uyghur corpus has 27 million tokens and the Turkish corpus has about 40 million tokens. Although Bengali is widely-spoken and the unlabeled corpus contains more than 140 million tokens, there are very few named entity annotations available, making it a low-resource language for the purposes of this exercise. To have a fair experimental setup across language pairs, we sub-sample the Bengali and Hindi corpora to have comparable corpus sizes with Uyghur and Turkish respectively. We also up-sample the low resource data for both unlabeled corpora and NER annotations, so the model doesn't become biased towards the high resource language.

NER model setup: We train the model using 100-dimensional word embeddings, pre-trained using the above discussed strategies, and use hidden dimension of size 100 for each direction of the LSTM. Stochastic gradient descent was used as the optimizer with a learning rate of 0.015. Dropout of 0.5 was used in the LSTM layer to prevent over-fitting. Uyghur and Turkish were trained for 100 epochs, Bengali and Hindi converged after 70 epochs.

5.3.2 Results and Discussion

Transfer Experiments: From Table 2 we note that our CT-Joint model trained with phoneme-ngrams, lemma, and morphological tags outperforms the MultiCCA baseline by a significant margin. MultiCCA strongly depends on

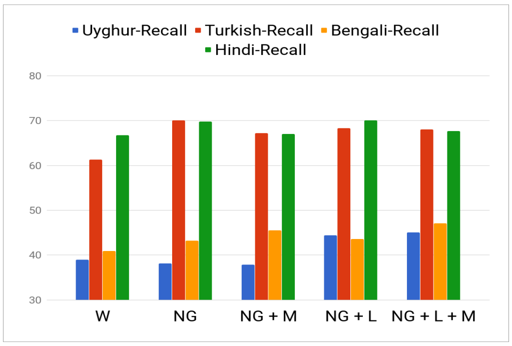

Figure 3: Recall for all languages (monolingual) **W**:Word, **NG**:Char-ngrams, **L**:Lemma, **M**:Morph

bilingual dictionaries which is possibly why it performs poorly in our low resource setting, where these dictionaries are not of high quality. The advantage of phoneme-ngrams over char-ngrams is quite apparent here. *phoneme-ngrams+lemma+morph* performs +5.2 F1 points better than *char-ngram+lemma+morph* for both Uyghur and Bengali, and similar increase is observed across other combinations, the only exception being the *phoneme* case for Uyghur which performed -0.5 F1 with respect to its counterpart *word*.

We find CT-Joint to be consistently better performing than CT-FineTune. Interestingly, the performance of CT-FineTune model converges to the monolingual performance. We hypothesize that the model forgets the pre-trained subword units as training progresses.

For CT-FineTune, the column *subword units* in Table 2 refers to the subword units which were pre-trained on a high resource related language. For example *lemma + morph* means lemma and morph embeddings are first pre-trained on the resouce-rich language and then used to initialize the respective lemma and morph representations for the low resource language.

Monolingual Experiments: Table 3 shows our results on all languages. We get +5.8 F1 points for Turkish, +4.8 F1 for Uyghur, +0.8 F1 for Hindi and +0.7 F1 for Bengali over the existing methods. We observe that a combination of character-ngrams, lemma and morphological properties gives the best performance for Uyghur and Bengali. Adding *morph* hurts in Turkish, in contrast to Hindi, where it helps. Section 5.3.3 discuses plausible reasons for this.

We report official NIST scores on the full evaluation set for Uyghur, as part of LORELEI Offical Retest. Additionally, we compare our results with

Model	subword units	Uyghur	Bengali
CT-Joint	phoneme-ngrams + lemma + morph	23.04	7.88
	phoneme-ngrams + lemma	23.24	7.62
	phoneme-ngrams	23.25	7.45

the best results reported on the same LORELEI dataset. Results are seen in Table 4.

5.3.3 Error analysis

We plot recall curves for all languages. As seen in Figure 3, adding subword units boosts the recall consistently across all languages, more so for Uyghur. For Turkish, *lemma* performs better than *lemma+morph*, perhaps because the morphological analyzer outputs so many redundant properties which reduce the distance between words that are not particularly similar. In contrast, *morph* helps and *lemma* hurts in Hindi, perhaps because the morph analyzer outputs only a small number of highly informative properties, but is a poor general-purpose lemmatizer.

We analyze our results for Uyghur language, as it was part of the LORELEI challenge and presents a situation close to a real-life application. We base our analysis on the unsequestered set since annotations for full test data are not released. There are 1,341 NE's in this set, 396 of which are covered by the word embeddings when trained with just monolingual corpus. One obvious advantage of jointly training with a resource-rich corpus is that coverage of NEs increases, as validated in our case where jointly training with Turkish corpus adds 114 more NEs.

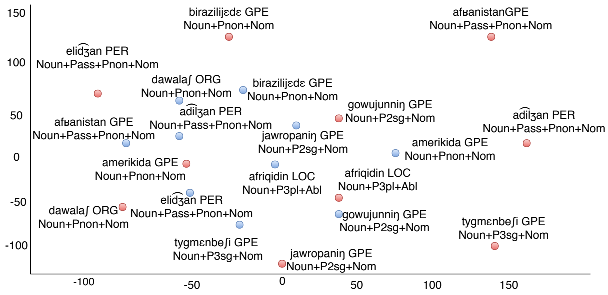

Figure 4: Two-dimensional PCA projection of select NEs from word embeddings for Uyghur—**CT-Joint** model trained with *phoneme-ngrams+lemma+morph* (blue) and monolingual model trained with *char-ngrams+lemma+morph*

Figure 4 shows ten named entities in two different embeddings (CT-Joint: *phoneme-ngrams+lemma+morph* and monolingual: *char-ngram+lemma+morph*). The difference is striking—in the monolingual condition, the NEs are widely dispersed, but in the bilingual condition, the NEs cluster together. This suggests that phonologically-mediated transfer through Turkish is resulting in embeddings in which NEs are close to one another, relative to monolingual Uyghur embeddings.

5.4 Machine Translation Task

In addition to NER, we test the performance of our proposed approaches on the MT task to test generality of our conclusions. We use XNMT toolkit

(Neubig et al., 2018) to translate sentences from the low-resource language to English. We run similar transfer and monolingual experiments as done for NER. Due to space limitations, we use select subword combinations for the experiments, details of which can be found in Appendix. BLEU is used as the evaluation metric.

From Table 6, we observe that the combination of *character-ngrams* and *lemma* performs the best for Uyghur (+0.1) and the combination of *character-ngrams*, *lemma* and *morph* gives the best performance for Bengali (+1.7), over the *word* baseline, which demonstrates the importance of subword units for low-resource MT as well. One likely reason that the combination of character-ngrams and lemmas consistently show the best performance is that, together, they capture lexical similarity, which is more important to translation than the syntactic information captured by morphological inflection ("morph"). However, experiments using CT-Joint and CT-FineTune (Table 5) do not follow the same trend as that of NER. We hypothesize that this is because the MT models were trained on a training set that did not have translation pairs from the high resource language. As Qi et al. (2018) note, when training MT systems on a single language pair, it is less necessary for the embeddings to be coordinated across the languages.

6 Related Work

Word Embedding Models: Most algorithms for learning embeddings take inspiration from language modeling (Bengio et al., 2003), motivated by distributional hypothesis (Harris, 1954), and employ a shallow neural network to map the words into a low dimensional space. Pennington et al. (2014) built over the above local context window model by combining it with global matrix factorization (Levy and Goldberg, 2014). Recently, Peters et al. (2018) show significant gains across various tasks by learning word vectors as hidden states of a deep bi-directional language model. This was originally conceived for resource-abundant languages, hence it is as-of-yet unclear how generalizable they are to low-resource settings.

Modeling subword information: Various methods have validated the importance of modeling subword units in downstream tasks. Xu et al. (2016); Chen et al. (2015) experiment at the character level whereas Luong et al. (2013) use morphemes as a basic unit in recursive neural network (RNN) to get morphologically-aware word representations. Xu and Liu (2017) incorporate the morphemes' meanings as part of the word representation to implicitly model the morphological knowledge.

Transfer learning: Most recent works using transfer in low resource setting are coupled tightly with the downstream task. Jin and Kann (2017) use morpheme units for cross-lingual transfer in a paradigm completion task using sequence-to-sequence models. Tsai et al. (2016) employ a language-independent method for NER by grounding non-English phrases to English Wikipedia. Interestingly, Kim et al. (2017) use separate encoders for modeling language-specific and language-agnostic features for part-of-speech (POS) tagging, and make use of no cross-lingual resources.

7 Conclusion

In this paper, we explored two simple methods for cross-lingual transfer, both of which are task-independent and use transfer learning for leveraging subword information from resource-rich languages, especially through phonological and morphological representations. CT-Joint and CT-FineTune do not require morphological analyzers, but we have found that even a morphological analyzer built in 2-3 weeks can boost performance and is a worthwhile investment of resources. Preliminary evaluation on a separate task of MT reconfirms the utility of subword units and further research will reveal what these learned subword representations can contribute to other tasks.

Abstract

Several NLP studies address the problem of figurative language, but among non-literal phenomena, they have neglected exaggeration. This paper presents a first computational approach to this figure of speech. We explore the possibility to automatically detect exaggerated sentences. First, we introduce HYPO, a corpus containing overstatements (or hyperboles) collected on the web and validated via crowdsourcing. Then, we evaluate a number of models trained on HYPO, and bring evidence that the task of hyperbole identification can be successfully performed based on a small set of semantic features.

1 Introduction

Very often, when humans recount their experiences, describe objects or verbalize ideas, they exaggerate in some respects. "*All you need is love*", sang The Beatles in one of their most iconic recordings; many centuries before, Shakespeare had Romeo say that there was "*more danger in Juliet's eyes than in twenty swords*"; and Maximus Meridius, a Roman commander in the movie The Gladiator, incited his legion to battle by the words "*At my signal, unleash hell*". Exaggerating, like in these quotes, is a linguistic tendency that unfolds in a variety of situations. From TV advertisements to debates in politics, our verbal productions are infused with statements, or more precisely overstatements, that puff up facts.

The study of exaggeration dates back to ancient Greece, and its centrality in the spectrum of figures of speech has long been established. Empirical evidence has shown that it is the most used rhetorical device, second only to metaphor (Kreuz et al., 1996), but in comparison to its kin tropes, this phenomenon represents an under-researched field in NLP. In effect, the problem of automatic detection of exaggerations (or hyperboles) has been quite dismissed. On the one hand, determining that a sentence speaks an excess is often a complex and context dependent act, on the other, no resource has ever been made available to specifically address the figure. To overcome this issue, we build HYPO, the first dataset focused on exaggeration, and introduce the task of automatic hyperbole detection. Specifically, the goal of this work is to find an automatic solution to establish if the topic of a sentence is aggrandized or, on the contrary, is presented as it is in reality.

Effective identification of overstatements would benefit theoretical and applied approaches to natural language. It can represent both a deterministic strategy to test hypotheses about exaggerations, as well as a boost for dialogue systems, information extraction, and all such AI endeavors to understand how humans talk. In fact, automating the intuition that a text says more than is true can meet a number of useful applications. Endowed with this ability, automatic tools might support our recognition of some kind of fake news, which blow information out of proportion; they might ascertain whether the promises of testimonials and politicians constitute a form of puffery; they might even be exploited for health-related objectives, as auxiliary tools for the diagnosis of psychological conditions (e.g., depression, narcissistic disorder) which use exaggerations to depict extremely unnuanced views of the world.

To tackle the problem, the paper starts with a synthesis of past theoretical work, which provides a guideline for building HYPO. Data was collected by a manual crawl on the web and its quality was tested via crowdsourcing. We then use the overstatements of HYPO for learning to classify a sentence as hyperbolic or literal. Experimental results show that a number of models can solve the problem with above chance accuracy, thus confirming that the task is feasible and that HYPO can be ex-

ploited for similar purposes in future work.

2 Related Work

A long lasting challenge in NLP is to reason about figurative language, and in fact, scientists have achieved groundbreaking results in the study of a range of figures. Nevertheless, they have given scarce attention to hyperbole – if any at all. Only relatively recently has this trope become an object of interest of corpus linguistics, and some insights on its nature have been delivered by statistics extracted from written and spoken sources.

The bulk of research points out that a hyperbole is not perceived nor produced as a lie. It makes things sound bigger than they actually are, but with the goal of emphasizing them, of clarifying ideas, of adding interest and humor to the conversation (Roberts and Kreuz, 1994). In other words, speakers exaggerate to accentuate the one element, account or aspect of reality that is important to them, in order to make others see truth from their perspective (Ritter, 2012). Hearers, on their part, suspend disbelief towards the literal content of the hyperbolic expression, which is mendacious, and recover its intended meaning, which is instead in accord with reality. Basically, to find this non-literal content, they reformulate a hyperbole as a paraphrase devoid of figures of speech, which is softer than the hyperbole itself and still conveys a strong concept (Fogelin, 1988).

Another point on which the literature agrees is that hyperboles are pragmatic acts. They may entirely rely on the concrete context of their production, like in the statement "It took ages to build the castle", which carries both an exaggerated and a literal sense, depending on whether it refers to a playful sand castle or to a strong walled construction. McCarthy and Carter (2004) endorse this view based on the need of contextual, extra-linguistic information, and claim that understanding an overstatement is to perceive a 'contrast' between the expression itself and its referent, i.e. a discrepancy between reality as it is and as is described.

Focusing on this contrast, Cano Mora (2010) provides a handcrafted framework of the semantic fields in which it tends to arise. Her taxonomy develops along a quantitative and a qualitative dimensions, suggesting that any exaggeration inflates either a measurable or a subjective property of the topic of discourse. However, given that any type of speaking non-literal is a departure from actual facts, the notion of 'contrast' can be referred to figures of speech in general. With this regard, an important point is made about the peculiarities of hyperbole (Colston and O'Brien, 2000; Carston and Wearing, 2011). Exaggerating presents facts with a greater degree, e.g. being bigger, more desirable, so it prompts a contrast of magnitude. Other tropes engender a contrast of kind for they portray an object via some types of qualities that it does not actually have. Metaphors, for instance, borrow those qualities from the vehicle term.

Therefore, the major contribution yielded by past corpus research is to have made explicit a few typically hyperbolic characteristics, which will come handy for the construction of our corpus.

3 HYPO

Hyperboles over-blow the truth, by augmenting or down-toning the qualities of the referent of discourse, e.g., an event, an object, a person, etc. If a referent has a feature X, a hyperbole presents it as having more of that X than warranted by reality (Claridge, 2011): what is big becomes bigger (e.g. [1]) and what is small becomes smaller (e.g. [2]). This causes a discrepancy between the linguistic expression and the actual state of affairs, and provides the former with a non-literal meaning.

[1] Her morning jog turned into a marathon.

[2] I'm ready in no time.

Drawing on example from (McCarthy and Carter, 2004), we use this 'contrast' or 'counter-factuality' as the central condition that makes a statement hyperbolic. It can be noticed that the extent of the contrast corresponds to different types of overstatements, which can go from slight distortions of real situations (e.g. [1]), to representations of absurd worlds (e.g. [2]). In the second instance, the contrast is grasped with no need for pragmatic information, but other types of overstatements can be perceived as such only if one knows the contextual setting in which they were produced. In those cases, readers evaluate the credibility of the sentence, that is, they confront how the sentence presents property X of the topic to how they expect it to be, given their previous experience and their common knowledge about the world (Ferré, 2014). For instance, although one cannot verify if proposition [1] is in contrast with the truth, hardly would one believe that a routine jog has equaled a marathon.

[3] I won't wait for you: it took you centuries to get dressed.

[4] That bag is to die for!

The above examples picture some peculiar traits of hyperboles. First, they require the possibility to present concepts with different intensities, by shifting ideally towards the extremes of a continuous semantic scale. Second, there are two scales on which this shift occurs (Cano Mora, 2010). One is quantitative, and it allows to inflate objective, measurable features (e.g. time [3]), while the other is qualitative and serves to augment subjective characteristics (e.g. appreciation [4]).

Another defining element of hyperboles is their emotional bent. When we exaggerate, we accentuate some pieces of evidence that supports our thoughts and perspectives, while downplaying competing alternatives. We present an extravagant view of reality with the goal of manifesting our positive or negative involvement towards it. This might appear obvious for qualitative hyperboles such as [4], for the property they enlarge is subjective, but quantitative overstatements have an evaluative trait as well. As an example, the overstatement [3] frames an antipathetic position by increasing an impartial, unemotional measure.

To sum up, there are three criteria that were deemed to characterize a hyperbole. They are the non-literal meaning, the upsurge on a semantic scale and a connotative trait. Hyperbolic candidates entered the corpus only if they were considered to have a figurative content rather than a deceptive one, if the figurative component emerged as a contrast of magnitude with reality, and if the contrast seemed to color reality with an evaluative tone.

3.1 Dataset Description

HYPO is a collection of 709 objects that comply with the three definitional requirements, and that can be deemed exaggerated without knowing the context in which they were originally produced[1].

Sentences can be semantically grouped into basic and composite items, which respectively preserve and modify the semantic domain of their referent (Claridge, 2011). For instance, [5] is basic, because the intended and literal meanings have the same domain (i.e. size) though they differ in magnitude. Instead, the exclamation in [6] is composite, as the intended meaning concerns human emotions but is expressed with a quality inherent to stones. This results both in a metaphor, since it describes a psychological state by means of a domain transfer, and in a hyperbole, because among all the things that have limited movement capabilities, it pinpoints the stones, which are completely motionless.

[5] The house is the size of a postage stamp.

[6] First I was afraid, I was petrified!

[7] I avoid crowded places like the plague.

[8] She agreed with every word of my argument.

Other hyperboles arise from the combination with figures different than metaphors, such as comparatives [7] and synecdoches [8].

From a syntactic point of view, exaggerations in the data either spread over phrases, or pop up as single words that belong to any sorts of grammatical classes. One peculiar instance is that of Extreme Case Formulations (ECFs), which are adjectives ("absolute, whole"), quantifiers and nouns ("all, no, everybody"), adverbs ("always, never"), phrases ("as good as it gets") and superlative constructions ("ever, the most") that engender extreme utterances by evoking the highest degree on a semantic scale (Pomerantz, 1986). Although ECFs might not be "heard as absurd or counterfactual and often display a degree of conventionality" (McCarthy and Carter, 2004), they share the three fundamental characteristics of the trope: they build expressions around semantic acmes, which lessens their credibility and prompts hearers to grasp their non-literal content, namely, one that expresses an evaluation. Some ECFs are at work in the following propositions.

[9] This is the best pizza in history.

[10] Everybody loves chocolate.

Within the above groups lie qualitative [9] and quantitative [5] hyperboles, creative [7] and conventional [10] ways of exaggerating. Notably,

---

[1] As an example, rather than "It took ages to build the castle", which can be read as hyperbolic or literal depending on contextual information, our dataset would be appended with "It took ages to build the castle. After a few minutes, my little brother had already destroyed it!", which is non-literal regardless of the context of its production.

such categories can criss-cross (Peña and Ruiz de Mendoza, 2017) like in "I'd bake cakes again and again and again", an instance of a quantitative hyperbole that encompasses multiple tokens, as it is merged with a polysyndeton.

4 Resource Construction

The collection of data for HYPO proceeded along two lines. One involved our own effort to invent overstatements. The other consisted of a manual crawl of the Internet and targeted the scripts of animated cartoons, advertisements, love letters, clickbait headlines, as well as other material that allegedly fulfilled the communicative objectives of exaggerations (see Roberts and Kreuz, 1994), and therefore was likely to include instances of this figure of speech. A total of 804 overstatements was obtained which comply with the definition presented in Section 3.

These candidate items underwent a validation stage on the Crowdflower/Figure Eight platform[2], where their hyperbolicity was judged by external annotators, and the final corpus was determined. Ideally, our microtask was feasible by any English speaker. It asked workers to read 10 sentences, one of which was a test item, and to answer 6 questions aimed at determining if and how the texts overstate their topic. Gold units consisted of 42 hyperboles, together with 50 non-hyperbolic statements to ensure that raters would not learn to mark all items as exaggerated. Each of the 854 sentences was expected to be judged by 5 annotators provided with minimal instructions on the subject at hand.

In particular, the annotators decided if a sentence contained a hyperbole (*Question 1*), and if so, they highlighted the words that caused its hyperbolic bent (*Question 2*), paraphrased it without exaggerating (*Question 3*), classified the hyperbole as quantitative or qualitative (*Question 4*), rated the degree of the exaggeration (*Question 5*) and established whether it was creative or conventional (*Question 6*).

With the first question, candidate items for HYPO were validated. In the second, annotators selected the smallest number of words (or minimal units) that convey the exaggeration, like "million" in "I've told you a *million* times". This assignment enabled us to collect the units perceived as hyperbolic, and to use them for creating another corpus, that is, a dataset of sentences which include the hyperbolic tokens of HYPO, but without their hyperbolic twist (see 4.2). Similarly, the rationale beyond the third question was the construction of a corpus devoid of exaggerations. People had to paraphrase the sentences without exaggerating. They were encouraged to reword or delete the portion of text highlighted in *Question 2*, such that the resulting sentences would have differed from the original ones only for the absence of hyperbolic tokens. Basically, we explored the idea that understanding a hyperbole requires a sort of readjustment, where concepts are toned down, but still to a high degree. For instance, an overstatement such as "I've told you a *million* times" could have been modified as in "I've told you a lot of times".

In *Question 4*, the annotators decided if a hyperbole belonged to a quantitative or a qualitative class, according to whether it exaggerated something which is objective and quantifiable with a number (e.g. "He *never* says no") or which is subjective and unmeasurable (e.g. "He seems to *come from another world*!"). This was meant to label sentences with one of the two semantic dimensions along which a concept is aggrandized, as proposed in the literature (Cano Mora, 2010). As for *Question 5*, an exaggeration was rated as either 'Possible', if it denoted an extreme but conceivable situation (e.g. "I avoid crowded places like the plague"), or 'Impossible', when it described an absurd or paradoxical situation (e.g. "My father always works"). We collected these scores to test the hypothesis that sentences with a higher hyperbolic degree are classified more accurately in the experiment because their excess is easier to detect. In the sixth question, exaggerations were judged either as conventional ("He died of envy") or creative ways to express an idea ("It got so cold that all spoken words froze solid"). The answers were expected to show if there is a correlation between conventional and 'Possible' hyperboles of *Question 5* (i.e. if conventional items are perceived as softer exaggerations)[3].

4.1 Evaluation Measures

Only 750 sentence received 5 reliable judgments. Therefore, to evaluate the quality of the results, the

---

[2] https://www.figure-eight.com

[3] For the quality check, we only required the raters to correctly judge questions 1 and 2. Question 3 was not included as no unique answer exists. Questions 4, 5 and 6 were also not included because, due to their difficulty, we expected some amount of disagreement among the raters.

inter-annotator agreement was observed on those. We calculated two measures of agreement for the task of recognizing hyperboles (Question 1). First, we measured the raw agreement (RA) that is the proportion of items with unanimous judgments (i.e. the sentences marked as either hyperbolic or non-hyperbolic by all the workers) out of the total number of items with 5 judgments. The final score showed that annotators agreed in 58.5% of the cases, which we considered an acceptable metric for the reliability of the annotation process.

That people had the same understanding of hyperboles in more than half the items seemed reasonable, because it can be challenging to establish if a statement is extreme, especially for non-expert workers. In fact, contextual knowledge, which in everyday situations enables interlocutors to grasp the inflation of a sentence, is neglected in an experiment that revolves around isolated textual passages. Moreover, the RA measure is extremely sensitive to the inconsistency of results, as the presence of one incongruous annotation out of 5 is enough to lower the outcome.

Therefore, we used a second measure to take into consideration the difficulty of having 5 people agree. Since items were labeled by more than two annotators, we computed a pairwise agreement, as suggested by (Artstein and Poesio, 2008). We exploited the Observed Agreement (A_O) as defined in Fleiss's κ, which consists of the proportion of items on which pairs of annotators agree out of the total number of judgment pairs. Also in this case we observed a substantial agreement (A_O=80.2%) corroborating the quality of our results.

4.2 Final Datasets

The logic behind the validation of our resource was to obtain adequate information to train a classifier of hyperboles. Given the consistency of annotations, we selected the sentences to be inserted into the corpus of hyperboles and built two control datasets. The outcome is a set of hyperboles (HYPO) with two types of non-figurative counterparts, that is, their paraphrases, and literal sentences that include the words that are hyperbolic in HYPO, but with a literal connotation. By means of illustration, while HYPO would incorporate a sentence like "Her morning jog turned into a marathon", the Paraphrases corpus and the Minimal Units Corpus would respectively include "Her morning jog turned into a very long run" and "There is a marathon in the city today".

HYPO The sentences in HYPO are the items that at least 3 annotators out of 5 perceived as exaggerations. From the total of 854 judged sentences, we discarded the non-hyperbolic units, those that received less than 5 judgments and those which were not classified as hyperbolic by the majority of annotators. The final result is a corpus of 709 hyperboles[4].

Paraphrases Corpus The corpus of paraphrases was created by choosing one paraphrase for each hyperbolic sentence, i.e. the one that introduced the smallest change in the syntax and the semantics of the corresponding hyperbole. The result is a collection of 709 sentences which say the same things as their hyperbolic counterparts but are devoid of exaggerations.

Minimal Units Corpus To build this dataset, we used the minimal units selected by the annotators in Question 2. We wanted to end up with sentences which are not hyperbolic and which contain the same hyperbolic words of HYPO.

For each exaggeration we considered the tokens that were selected by the majority of annotators. They either consisted of a single term, or a phrase, or long-distance words. Then, we extracted sentences containing these tokens from sources such as the WaCKy corpus, a dump of the English Wikipedia, whose editorial criteria force the entries to be neutral and verifiable, and thus, unlikely to incorporate excessive statements. Whenever this approach did not produce results, we ran a Google search. The final corpus contains 698 non-hyperbolic sentences.

5 Experiment

The task of hyperbole detection is formulated as a supervised learning problem, and specifically, as a sentence-based classification with two classes, that is, hyperbolic and literal.

5.1 Features Set

To describe sentences, we define two sets of features that incorporate the qualitative and quantitative criteria proposed in the literature[5].

---

[4] The dataset will be made publicly available under a Creative Commons License for free cultural works.

[5] These terms do not refer to the semantic scale on which the shift of meaning occurs, which vary depending on the topic of hyperboles, but to the counterfactuality and the connotative traits that characterize them all.

All of the features take on values in the interval [-1,1], and some are encoded in multiple ways to ensure richer information. As for the quantity group, the notion that hyperboles say *more of* X when X is the case is decomposed into two features, i.e. imageability and unexpectedness, while the qualitative marker of hyperboles, or the view that they shape a speaker's perspective about X, is rendered by the polarity, the subjectivity and the emotional strength of sentences.

Imageability is the degree to which a word can evoke a mental image. Speakers hyperbolize to convey meanings with strength, and we assumed that such a goal might be backed by a highly picturable vocabulary. This feature is extracted from the resource of Tsvetkov et al. (2014), who propagated the imageability ratings of the MRC psycholinguistic database to 150.114 terms. For each sentence, we averaged the imageability values of all its words.

Unexpectedness refers to the fact that hyperboles are less predictable expressions than literals. Basically, minimal hyperbolic units modify the real characteristics of X, and in this sense, they are incoherent with the rest of discourse about X: they are out of context, and come unexpected to the hearers of overstatements.

We conjecture that word vectors may capture if an expression is being used "unexpectedly" because they encode the contexts in which terms frequently occur, as well as contrasts and similarities among their meanings. In fact, according to the Distributional Hypothesis (Harris, 1954), lexical items appearing in similar contexts tend to have similar meanings. Our expectation is that the words of a figurative sentence carry less similar meanings compared to those of a literal instance, and hence, that their vectorial representations turn out to be more distant.

For every sentence in the dataset, we map its words onto both the pre-trained vectors of Mikolov et al. (2013), obtained from the Skip-gram model, and the GloVe vectors by Pennington et al. (2014). Then, we consider the cosine distance between all possible word pairs to score their semantic similarity. The unexpectedness feature of a sentence is found in two ways: as the average similarity among all of its word pairs, and as the lowest of those pair similarities. Both measures are separately computed with Skip-Gram and GloVe vectors, resulting in 4 scores.

Polarity corresponds to the sentiment of a statement. It is extracted through both TextBlob (Loria, 2014), a system that directly scores sentences, and SentiWords (Gatti et al., 2016), which lists polarity values for 155k POS-tagged lemmas. With this lexicon, we find the sentiment of a sentence by averaging the sentiment of all of its word lemmas.

Subjectivity, found with TextBlob, which specifies if a statement conveys an objective information or a personal opinion. Ideally, the higher the absolute value of polarity in the range [0,1], the more subjective a sentence.

Emotional intensity stands for the strength of sentiment. It captures if the utterer of a sentence is sympathetic towards the thing being said, while quantifying the emphasis with which such position is communicated. The scores are obtained from VADER (Hutto and Gilbert, 2014).

5.2 Experimental Setup and Results

A simple pre-processing is applied to HYPO, the Paraphrases and the Minimal Units corpora prior to the experiment. We remove the stopwords, for which the quality scores are not available. The resulting sentences are represented by 9-dimensional vectors, in which 5 entries stand for the quantity features and 4 belong to the quality group.

For classification, we experiment with various algorithms, such as Logistic Regression (LR), Naive Baies (NB), k-Nearest Neighbors (KNN), Decision Trees (DT), Support Vector Machine (SVM) and Linear Discriminant Analysis (LDA). The models are evaluated by comparing their average accuracy on a 10-fold cross-validation against three baselines: a classifier that randomly associates inputs to the hyperbolic and literal labels, one that classifies sentences using the 300 features of the pre-trained Skip-gram representations, and a third that relies on the 300-dimensional GloVe vectors trained by their authors. Sentences fed to the baseline classifiers were represented as the sum of their word vectors[6].

---

[6] Other types of compositional methods yield results analogous to those in Table 1 and Table 2.

	Baseline1	QQ	Skip-gram	GloVe	Skip-gram+QQ	GloVe+QQ
LR	.50	.64	.68	.66	**.72**	.69
KNN	.50	.63	.47	.43	.52	.48
NB	.50	.66	.69	.66	.69	.68
DT	.50	.60	.54	.53	.55	.54
SVM	.50	.64	.15	.62	.63	.64
LDA	.50	.61	.67	.65	.68	.67

Table 1: Mean accuracy of 10-fold cross validation in the Hype-Par setting. Column QQ shows results for our handcrafted quality and quantity features; the last two columns are concatenations of QQ with the Skip-gram and GloVe baseline features.

	Baseline1	QQ	Skip-gram	GloVe	Skip-gram+QQ	GloVe+QQ
LR	.50	.44	.60	.58	.61	.59
KNN	.50	.47	.49	.48	.50	.51
NB	.50	.50	.64	.64	.62	**.68**
DT	.50	.51	.51	.52	.56	.54
SVM	.50	.02	.09	.59	.13	.60
LDA	.50	.52	.54	.34	.57	.56

Table 2: Mean accuracy of 10-fold cross validation in the Hype-Min setting.

Cross-validation is conducted in two settings. In one (Hype-Par), the non-hyperbolic sentences are paraphrases, in the other (Hype-Min), literal data come from the Minimal Units Corpus. The results are shown in Table 1 and Table 2.

While in the Hype-Min setting the performance is not satisfying, estimators achieve above chance accuracy using paraphrases as literal inputs. In fact, in Table 1, the accuracy scores based on quantity-quality vectors (QQ column) suggest that our handcrafted features are actually useful for detecting hyperboles. Therefore, to gain further insight on their informativeness, we conduct a recurrent feature ablation and observed how different subsets affect predictions. Figure 1 illustrates that 5 features can maximize the accuracy of LR. SVM and LDA behave the same with a set of the same size, and they all assign high weights to imageability, unexpectedness and subjectivity. The three models become comparable to, and yet do not outperform, the second and third baselines.

In the attempt to improve the models' description of the data, we repeat the experiment with yet another set of features. We merge the QQ with the Skip-Gram and GloVe features, by separately concatenating the two types of vectors to our data representations (Skip-Gram+QQ and GloVe+QQ columns).

An interesting trend appears both for Hype-Par and Hype-Min: with Skip-Gram+QQ, algorithms perform better than relying on Skip-Gram or QQ alone, and the same happens for Glove+QQ. The new sets of features produce a consistent improvement over the baselines and over our own features. LR outstands other classifiers in the Skip-Gram+QQ combination, reaching .72 mean accuracy and .76 average F1-score (see Table 3).

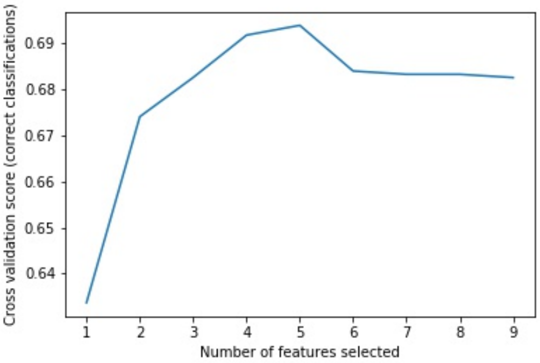

Figure 1: Recurrent Feature Elimination with LR in the Hype-Par setting.

5.3 Analysis

The concatenation of vectors enhance performances and it provides evidence that our quantity and quality vectors enrich both Skip-Gram and GloVe with some useful information about hyperbole. This observation, together with the outcome of LR, suggests that the task introduced in the

Table 4: Annotators' judgments about 93 misclassified hyperboles.

present work delineates a promising field of inquiry, and that it can benefit from our QQ features.

To deepen our understanding of the results, we analyze the errors made in the Hype-Par classification. This conclusive stage of the study serves to probe if the overstatements that tend to be misclassified share some characteristics that are missing from our group of features.

From a test set of 468 data points, we collect those that are incorrectly labeled by all of the models, which comprise 185 sentences, 93 of which are hyperbolic. Examples are: "He's more aged than the hills" (Hype), "They will die of envy" (Hype), "You get into that university, you won't get out alive" (Hype), "He hiccuped for a long time" (Par).

We investigate the characteristics for which we collected judgments in the Crowdflower experiment (Questions 4, 5 and 6 in the Section above), that is, the measurable trait of exaggerations, and their degree of hyperbolicity and conventionality. Table 4 details the judgments about misclassified hyperboles, as rated by the the majority of their annotators. More than half hyperboles were declared conventional, impossible and non-measurable.

It appears that conventional hyperboles are more difficult to recognize (the test set comprises an equal number of conventional and creative items). This is not surprising if we consider that the classifiers have especially relied on the unexpectedness feature. Vectors encode information relative to the context where words occur, so they might capture that the words of a conventional hyperbole are likely to be used together, since they are highly common in language (e.g. [2]).

As for the second characteristic, the majority of hyperboles amplifies, according to the annotators, an unmeasurable trait of the topic of discourse. This sheds light on the topic of the errors: understanding that a sentence overshoots reality with respect to a subjective impression (e.g. heaviness of commitment [3]) is harder than with an objective quality (e.g. age [1]). In future work, we may investigate how to better formalize the counterfactuality condition, by specifying different strategies to use in the two cases.

Lastly, errors regarding the degree of hyperbolicity run up against our expectations. We hypothesized that a more exaggerated hyperbole (i.e. impossible) is easier to identify, but statistics suggest the opposite. Impossible hyperboles may be obvious for humans, who use pragmatic knowledge, but not for an agent which entirely relies on linguistic information. Prospective research may test if this problem can be overcome with the help of multimodal strategies.

6 Conclusions

Hyperbole, the figure of exaggeration and one of the hallmarks of human communication, is tackled in this paper from a computational perspective. Our research aimed at answering the question whether it is possible to endow a system with the ability to identify exaggerated sentences. Experimental results showed promising directions for their automatic detection and suggest that the execution of this task can be based on semantic features. As a novel approach to hyperboles, the project started with no related studies to compare to, nor useful resources to investigate. Hence, its main contribution to the field of NLP is the proposal of a new task together with the construction of a corpus of hyperboles, and its main achievement is the devising of a procedure to learn such figurative mechanism. Specifically, the described experiment tested the hypothesis that quantity and quality, which emerge from the body of literature as two core features of exaggerations, are also useful for the automatic processing of the figure.

As a future work, we plan to investigate if our QQ-based models are enhanced by extra-linguistic knowledge, and to incorporate contextual, multimodal features along semantic ones.

Building Context-aware Clause Representations for Situation Entity Type Classification

Zeyu Dai, Ruihong Huang

Texas A&M University
`{jzdaizeyu, huangrh}@tamu.edu`

Abstract

Capabilities to categorize a clause based on the type of situation entity (e.g., events, states and generic statements) the clause introduces to the discourse can benefit many NLP applications. Observing that the situation entity type of a clause depends on discourse functions the clause plays in a paragraph and the interpretation of discourse functions depends heavily on paragraph-wide contexts, we propose to build context-aware clause representations for predicting situation entity types of clauses. Specifically, we propose a hierarchical recurrent neural network model to read a whole paragraph at a time and jointly learn representations for all the clauses in the paragraph by extensively modeling context influences and inter-dependencies of clauses. Experimental results show that our model achieves the state-of-the-art performance for clause-level situation entity classification on the genre-rich MASC+Wiki corpus, which approaches human-level performance.

1 Introduction

Clauses in a paragraph play different discourse and pragmatic roles and have different aspectual properties (Smith, 1997; Verkuyl, 2013) accordingly. We aim to categorize a clause based on its aspectual property and more specifically, based on the type of Situation Entity (SE)[1] (e.g., events, states, generalizing statements and generic statements) the clause introduces to the discourse, following the recent work by (Friedrich et al., 2016). Understanding SE types of clauses is beneficial for many NLP tasks, including discourse mode identification[2] (Smith, 2003, 2005), text summarization, information extraction and question answering.

The situation entity type of a clause reflects discourse roles the clause plays in a paragraph and discourse role interpretation depends heavily on paragraph-wide contexts. Recently, Friedrich et al. (2016) used insightful syntactic-semantic features extracted from the target clause itself for SE type classification, which has achieved good performance across several genres when evaluated on the newly created large dataset MASC+Wiki. In addition, Friedrich et al. (2016) implemented a sequence labeling model with conditional random fields (CRF) (Lafferty et al., 2001) for fine-tuning a sequence of predicted SE types. However, other than leveraging common SE label patterns (e.g., GENERIC clauses tend to cluster together.), this approach largely ignored the wider contexts a clause appears in when predicting its SE type.

To further improve the performance and robustness of situation entity type classification, we argue that we should consider influences of wider contexts more extensively, not only by fine-tuning a sequence of SE type predictions, but also in deriving clause representations and obtaining precise individual SE type predictions. For example, we distinguish GENERIC statements from GENERALIZING statements depending on if a clause expresses general information over classes or kinds instead of specific individuals. We recognize the latter two clauses in the following paragraph as GENERALIZING because both clauses describe situations related to the Amazon river:

(1): *[Today, the Amazon river is experiencing a crisis of overfishing.]*STATE *[Both subsistence fishers and their commercial rivals compete in netting large quantities of pacu,]*GENERALIZING

---

[1] The Situation Entity (SE) type of a clause is defined with respect to three situation-related features: the main NP referent type (specific or generic), fundamental aspectual class (stative or dynamic), and whether the situation evoked is episodic or habitual (Friedrich and Palmer, 2014b).

[2] E.g., EVENTs and STATEs are dominant in *narratives* while GENERALIZINGs and GENERICs are dominant in *informative* discourses.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3305–3315
Brussels, Belgium, October 31 - November 4, 2018.

*[which bring good prices at markets in Brazil and abroad.]*GENERALIZING

If we ignore the wider context, the second clause can be wrongly recognized as GENERIC easily since "fishers" usually refer to one general class rather than specific individuals. However, considering the background introduced in first clause, "fishers" here actually refer to the fishers who fish on Amazon river which become specific individuals immediately.

Therefore, we aim to build context-aware clause representations dynamically which are informed by their paragraph-wide contexts. Specifically, we propose a hierarchical recurrent neural network model to read a whole paragraph at a time and jointly learn representations for all the clauses in the paragraph. Our paragraph-level model derive clause representations by modeling inter-dependencies between clauses within a paragraph. In order to further improve SE type classification performance, we also add an extra CRF layer at the top of our paragraph-level model to fine-tune a sequence of SE type predictions over clauses (Friedrich et al., 2016), which however is not our contribution.

Experimental results show that our paragraph-level neural network model greatly improves the performance of SE type classification on the same MASC+Wiki (Friedrich et al., 2016) corpus and achieves robust performance close to human level. In addition, the CRF layer further improves the SE type classification results, but by a small margin. We hypothesize that situation entity type patterns across clauses may have been largely captured by allowing the preceding and following clauses to influence semantic representation building for a clause in the paragraph-level neural net model.

2 Related Work

2.1 Linguistic Categories of SE Types

The situation entity types annotated in the MASC+Wiki corpus (Friedrich et al., 2016) were initially introduced by Smith (2003), which were then extended by (Palmer et al., 2007; Friedrich and Palmer, 2014b). The situation entity types can be divided into the following broad categories:

- **Eventualities** (EVENT, STATE and REPORT): for clauses representing actual happenings and world states. STATE and EVENT are two fundamental aspectual classes of a clause (Siegel and McKeown, 2000) which can be distinguished by the semantic property of dynamism. REPORT is a subtype of EVENT for quoted speech.
- **General Statives** (GENERIC and GENERALIZING): for clauses that express general information over classes or kinds, or regularities related to specific main referents. The type GENERIC is for utterances describing a general class or kind rather than any specific individuals (e.g., *People love dogs.*). The type GENERALIZING is for habitual utterances that refer to ongoing actions or properties of specific individuals (e.g., *Audubon educates the public.*).
- **Speech Acts** (QUESTION and IMPERATIVE): for clauses expressing two types of speech acts (Searle, 1969).

2.2 Situation Entity (SE) Type Classification

Although situation entities have been well-studied in linguistics, there were only several previous works focusing on data-driven SE type classification using computational methods. Palmer et al. (2007) first implemented a maximum entropy model for SE type classification relying on words, POS tags and some linguistic cues as main features. This work used a relatively small dataset (around 4300 clauses) and did not achieve satisfied performance (around 50% of accuracy).

To bridge the gap, Friedrich et al. (2016) created a much larger dataset MASC+Wiki (more than 40,000 clauses) and achieved better SE type classification performance (around 75% accuracy) by using rich features extracted from the target clause. The feature sets include POS tags, Brown cluster features, syntactic and semantic features of the main verb and main referent as well as features indicating the aspectual nature of a clause. Friedrich et al. (2016) further improved the performance by implementing a sequence labeling (CRF) model to fine-tune a sequence of SE type predictions and noted that much of the performance gain came from modeling the label pattern that GENERIC clauses often occur together. In contrast, we focus on deriving dynamic clause representations informed by paragraph-level contexts and model context influences more extensively.

Becker et al. (2017) proposed a GRU based neural network model that predicts the SE type for one clause each time, by encoding the content of the target clause using a GRU and incorporating several sources of context information, including contents and labels of preceding clauses as well as genre information, using additional separate GRUs (Chung et al., 2014). This model is different from our approach that processes one paragraph (with a sequence of clauses) at a time and extensively models inter-dependencies of clauses.

Other related tasks include predicting aspectual classes of verbs (Friedrich and Palmer, 2014a), classifying genericity of noun phrases (Reiter and Frank, 2010) and predicting clause habituality (Friedrich and Pinkal, 2015).

2.3 Paragraph-level Sequence Labeling

Learning latent representations and predicting a sequence of labels from a long sequence of sentences (clauses), such as a paragraph, is a challenging task. Recently, various neural network models, including Convolution Neural Network (CNN) (Wang and Lu, 2017), Recurrent Neural Network (RNN) based models (Wang et al., 2015; Chiu and Nichols, 2016; Huang et al., 2015; Ma and Hovy, 2016; Lample et al., 2016) and Sequence to Sequence models (Vaswani et al., 2016; Zheng et al., 2017), have been applied to the general task of sequence labeling. Among them, the bidirectional LSTM (Bi-LSTM) model (Schuster and Paliwal, 1997) has been widely used to process a paragraph for applications such as language generation (Li et al., 2015), dialogue systems (Serban et al., 2016) and text summarization (Nallapati et al., 2016), because of its capabilities in modeling long-distance dependencies between words. In this work, we use two levels of Bi-LSTMs connected by a max-pooling layer to abstract clause representations by extensively modeling paragraph-wide contexts and inter-dependencies between clauses.

3 The Hierarchical Recurrent Neural Network for SE Type Classification

We design an unified neural network to extensively model word-level dependencies as well as clause-level dependencies in deriving clause representations for SE type prediction. Figure 1 shows the architecture of the proposed paragraph-level neural network model which includes two Bi-LSTM layers, one max-pooling layer in between and one final softmax prediction layer.

Given the word sequence of one paragraph as input, the word-level Bi-LSTM will firstly generate a sequence of hidden states as word representations, then a max-pooling layer will be applied to abstract clause embeddings from word representations within a clause. Next, another clause-level Bi-LSTM will run over the sequence of clause embeddings and derive final clause representations by further modeling semantic dependencies between clauses within a paragraph. The softmax prediction layer will then predict a sequence of situation entity (SE) types with one label for each clause, based on the final clause representations.

Word Vectors: To transform the one-hot representation of each word into its distributed word vector (Mikolov et al., 2013), we used the pre-trained 300-dimension Google English word2vec embeddings[3]. For the words which are not included in the vocabulary of Google word2vec, we randomly initialize their word vectors with each dimension sampled from the range $[-0.25, 0.25]$.

For situation entity type classification, it is important to recognize certain types of words such as punctuation marks (e.g., "?" for QUESTION and "!" for IMPERATIVE) as well as entities such as locations and time values. We therefore created feature-rich word vectors by concatenating word embeddings with parts-of-speech (POS) tag and named-entity (NE) tag one-hot embeddings[4].

Deriving Clause Representations: In designing the model, we focus on building clause representations that sufficiently leverage cues from paragraph-wide contexts for SE type prediction, including both preceding and following clauses in a paragraph. To process long paragraphs which may contain a number of clauses, we utilize a two-level bottom-up abstraction approach and progressively obtain the compositional representation of each word (low-level) and then compute a compositional representation of each clause (high-level), with a max-pooling layer in between.

At both word-level and clause-level, we choose the Bi-LSTM as our basic neural net component for representation learning, mainly considering its ability to capture long-distance dependencies between words (clauses) and to integrate influences of context words (clauses) from both directions.

Given a word sequence $X = (x_1, x_2, ..., x_L)$

---

[3] Downloaded from `https://docs.google.com/uc?id=0B7XkCwpI5KDYNlNUTTlSS21pQmM`

[4] Our feature-rich word vectors are of dimension 343, including 300 dimensions for Google word2vec + 36 dimensions for POS tags + 7 dimensions for NE tags. We used the Stanford CoreNLP to generate POS tags and NE tags.

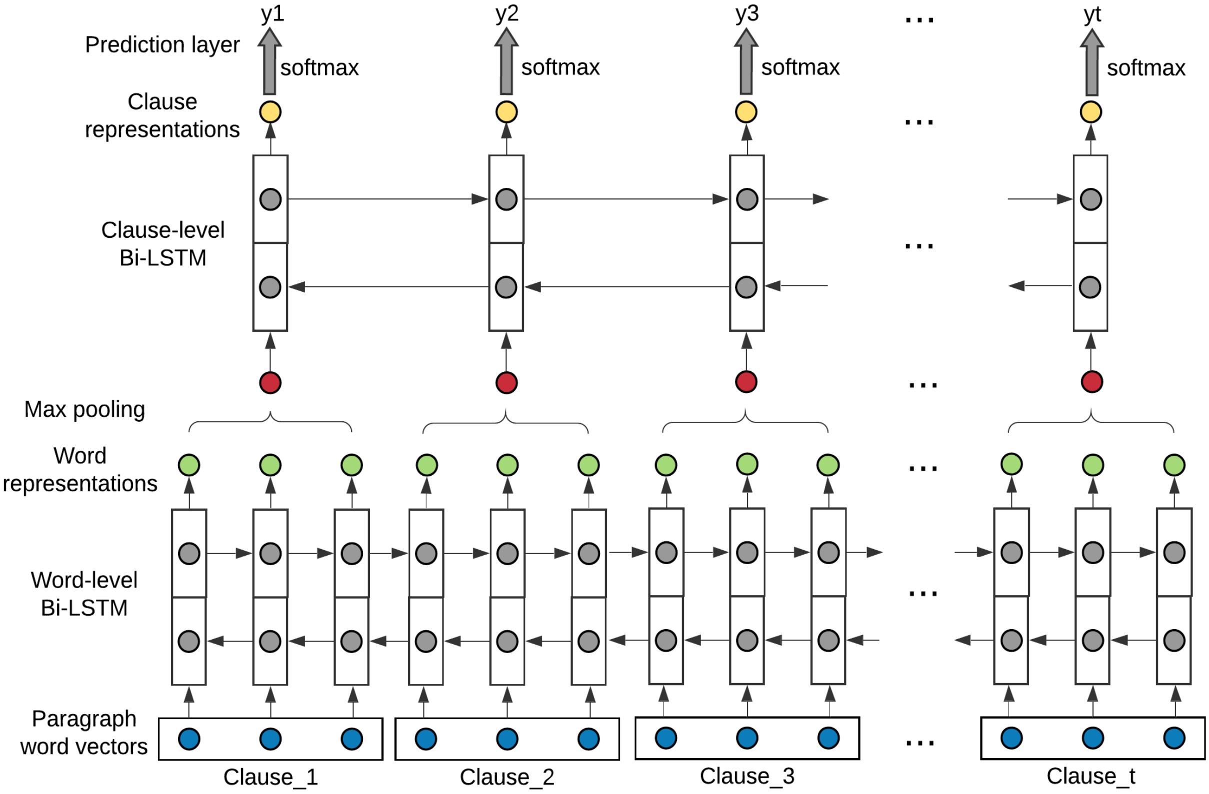

Figure 1: The Paragraph-level Model Architecture for Situation Entity Type Classification.

in a paragraph as the input, the word-level Bi-LSTM will process the input paragraph by using two separate LSTMs, one processes the word sequence from the left to right while the other processes the sequence from the right to left. Therefore, at each word position t, we obtain two hidden states $\overrightarrow{h_t}, \overleftarrow{h_t}$ and concatenate them to get the word representation $h_t = [\overrightarrow{h_t}, \overleftarrow{h_t}]$. Then we apply the max-pooling operation over the sequence of word representations for words within a clause in order to get the initial clause embedding:

$$h_{Clause}[j] = \max_{t=Clause\_start}^{Clause\_end} h_t[j] \quad (1)$$

$$where, 1 \leq j \leq hidden\_unit\_size \quad (2)$$

Next, the clause-level Bi-LSTM will process the sequence of initial clause embeddings in a paragraph and generate refined hidden states $\overrightarrow{h_{Clause\_t}}$ and $\overleftarrow{h_{Clause\_t}}$ at each clause position t. Then, we concatenate the two hidden states for a clause to get the final clause representation $h_{Clause\_t} = [\overrightarrow{h_{Clause\_t}}, \overleftarrow{h_{Clause\_t}}]$.

Situation Entity Type Classification: Finally, the prediction layer will predict the situation entity type for each clause by applying the softmax function to its clause representation:

$$y_t = softmax(W_y * h_{Clause\_t} + b_y) \quad (3)$$

3.1 Fine-tune Situation Entity Predictions with a CRF Layer

Previous studies (Friedrich et al., 2016; Becker et al., 2017) show that there exist common SE label patterns between adjacent clauses. For example, Friedrich et al. (2016) reported the fact that GENERIC sentences usually occur together in a paragraph. Following (Friedrich et al., 2016), in order to capture SE label patterns in our hierarchical recurrent neural network model, we add a CRF layer at the top of the softmax prediction layer (shown in figure 2) to fine-tune predicted situation entity types.

The CRF layer will update a state-transition matrix, which can effectively adjust the current label depending on its preceding and following labels. Both the training and decoding procedures of the CRF layer can be conducted efficiently using the Viterbi algorithm. With the CRF layer, the model jointly assigns a sequence of SE labels, one label per clause, by considering individual clause representations as well as common SE label patterns.

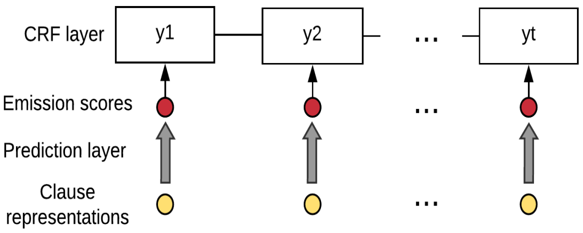

Figure 2: Fine-tune a Situation Entity Label Sequence with a CRF layer.

3.2 Parameter Settings and Model Training

We finalized hyperparameters based on the best performance with 10-fold cross-validation on the training set. The word vectors were fixed during model training. Both word representations and clause representations in the model are of 300 dimensions, and all the Bi-LSTM layers contain 300 hidden units as well. To avoid overfitting, we applied dropout mechanism (Hinton et al., 2012) with dropout rate of 0.5 to both input and output vectors of Bi-LSTM layers. To deal with the exploding gradient problem in LSTMs training, we utilized gradient clipping (Pascanu et al., 2013) with gradient L2-norm threshold of 5.0 and used L2 regularization with $\lambda = 10^{-4}$ simultaneously. These parameters remained the same for all our proposed models including our own baseline models.

We chose the standard cross-entropy loss function for training our neural network models and adopted Adam (Kingma and Ba, 2014) optimizer with the initial learning rate of 0.001 and the batch size[5] of 128. All our proposed models were implemented with Pytorch[6] and converged to the best result within 40 epochs. Note that to diminish the effects of randomness in training neural network models and report stable experimental results, we ran each of the proposed models as well as our own baseline models ten times and reported the averaged performance across the ten runs.

4 Evaluation

4.1 Dataset and Preprocessing

The MASC+Wiki Corpus: We evaluated our neural network model on the MASC+Wiki corpus[7] (Friedrich et al., 2016), which contains more than 40,000 clauses and is the largest annotated dataset for situation entity type classification. The MASC+Wiki dataset is composed of documents from Wikipedia and MASC (Ide et al., 2008) covering as many as 13 written genres (e.g., news, essays, fiction, etc). Table 1 shows statistics of the dataset, from which you can see that the SE type distribution is highly imbalanced. The majority SE type of MASC documents is STATE while the majority SE type of Wikipedia documents is GENERIC. To make our results comparable with previous works (Friedrich et al., 2016; Becker et al., 2017), we used the same 80:20 train-test split with balanced genre distributions.

SE type	MASC	Wiki	Count
STATE	49.8%	24.3%	18337
EVENT	24.3%	18.9%	9688
REPORT	4.8%	0.9%	1617
GENERIC	7.3%	49.7%	7582
GENERALIZING	3.8%	2.5%	1466
QUESTION	3.3%	0.1%	1056
IMPERATIVE	3.2%	0.2%	1046

Table 1: MASC+Wiki Dataset Statistics.

Preprocessing: As described in (Friedrich et al., 2016), texts were split into clauses using SPADE (Soricut and Marcu, 2003). There are 4,784 paragraphs in total in the corpus; and on average, each paragraph contains 9.6 clauses. In figure 4, the horizontal axis shows the distribution of paragraphs based on the number of clauses in a paragraph. The annotations of clauses are stored in separate files from the text files. To recover the paragraph contexts for each clause, we matched its content with the corresponding raw document.

4.2 Systems for Comparisons

We compare the performance of our neural network model with two recent SE type classification models on the MASC+Wiki corpus as well as humans' performance (upper bound).

- CRF (Friedrich et al., 2016): a CRF model that relies heavily on features extracted from the target clause itself.
- GRU (Becker et al., 2017): a GRU based neural network model that incorporates context information by using separate GRU units and predicts the SE type for one clause each time.
- Humans (Friedrich et al., 2016): one annotator's performance when using two other an-

Table 2: Situation Entity Type Classification Results on the Training Set of MASC+Wiki with 10-Fold Cross-Validation. We report accuracy (Acc), macro-average F1-score (Macro) and class-wise F1 scores for STATE (STA), EVENT (EVE), REPORT (REP), GENERIC (GENI), GENERALIZING (GENA), QUESTION (QUE) and IMPERATIVE (IMP).

Model	Macro	Acc
CRF (Friedrich et al., 2016)	69.3	74.7
GRU (Becker et al., 2017)	68.0	71.1
Clause-level Bi-LSTM	73.5	76.7
Paragraph-level Model	77.0	80.0
Paragraph-level Model + CRF	**77.4**	**80.7**

Table 3: Situation Entity Type Classification Results on the Test Set of MASC+Wiki. We report accuracy (Acc) and macro-average F1 (Macro).

notators' annotation as "gold labels". It has been reported that labeling SE types is a non-trivial task even for humans.

In addition, we implemented a clause-level Bi-LSTM model as our own baseline, which takes a single clause as its input. Since there is only one clause, the upper Bi-LSTM layer shown in Figure 1 is meaningless and removed in the clause-level Bi-LSTM model.

4.3 Experimental Results

Following the previous work (Friedrich et al., 2016) on the same task and dataset, we report accuracy and macro-average F1-score across SE types on the test set of MASC+Wiki.

The first section of Table 3 shows the results of the previous works. The second section shows the result of our implemented clause-level Bi-LSTM baseline, which already outperforms the previous best model. This result proves the effectiveness of the Bi-LSTM + max pooling approach in clause representation learning (Conneau et al., 2017). The third section reports the performance of the paragraph-level models that uses paragraph-wide contexts as input. Compared with the baseline clause-level Bi-LSTM model, the basic paragraph-level model achieves 3.5% and 3.3% of performance gains in macro-average F1-score and accuracy respectively. Building on top of the basic paragraph-level model, the CRF layer further improves the SE type prediction performance slightly by 0.4% and 0.7% in macro-average F1-score and accuracy respectively. Therefore, our full model with the CRF layer achieves the state-of-the-art performance on the MASC+Wiki corpus.

5 Analysis

5.1 10-Fold Cross-Validation

We noticed that the previous work (Friedrich et al., 2016) did not publish the class-wise performance of their model on the test set, instead, they reported the detailed performance on the training set using 10-fold cross-validation. For direct comparisons, we also report our 10-fold cross-validation results[8] on the training set of MASC+Wiki.

Table 2 reports the cross-validation classification results. Consistently, our clause-level baseline model already outperforms the previous best model. By exploiting paragraph-wide contexts, the basic paragraph-level model obtains consistent performance improvements across all the classes compared with the baseline clause-level prediction model, especially for the classes GENERIC and GENERALIZING, where the improvements are significant. After using the CRF layer to fine-tune the predicted SE label sequence, slight performance improvements were observed on the four small classes. Overall, the full paragraph-level neural network model achieves the best macro-average F1-score of 77.8% in predicting SE types, which not only outperforms all previous approaches but also reaches human-like performance on some classes.

---

[8] The original folds split used by Friedrich et al. (2016) is not available. So we manually split folds by ourselves with even genre distribution across folds.

Model	Macro	Acc	STA	EVE	REP	GENI	GENA	QUE	IMP
CRF (Friedrich et al., 2016)	66.6	71.8	78.2	77.0	76.8	44.8	27.4	81.8	70.8
Clause-level Bi-LSTM	69.3	73.3	79.5	78.7	82.8	47.6	31.9	86.9	77.7
Paragraph-level Model	73.2	77.2	81.5	80.1	83.2	64.7	37.2	88.1	**77.8**
Paragraph-level Model+CRF	**73.5**	**77.4**	81.5	**80.3**	**83.7**	**66.5**	**37.4**	**88.5**	76.7

Table 4: Cross-genre Classification Results on the Training Set of MASC+Wiki. We report accuracy (Acc), macro-average F1-score (Macro) and class-wise F1 scores.

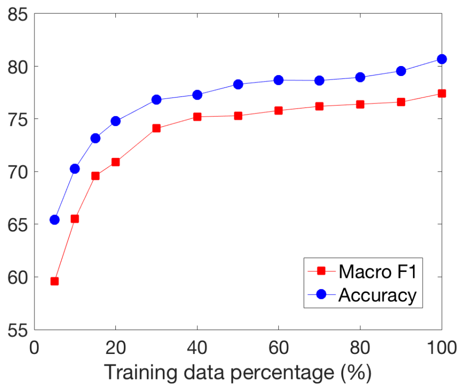

Figure 3: Learning Curve of the Paragraph-level Model + CRF on MASC+Wiki.

5.2 Impact of Genre

Considering that MASC+Wiki is rich in written genres, we additionally conduct cross-genre classification experiments, where we use one genre of documents for testing and the other genres of documents for training. The purpose of cross-genre experiment is to see whether the model can work robustly across genres.

Table 4 shows cross-genre experimental results of our neural network models on the training set of MASC+Wiki by treating each genre as one cross-validation fold. As we expected, both the macro-average F1-score and class-wise F1 scores are lower compared with the results in Table 2 where in-genre data were used for model training as well. But the performance drop on the paragraph-level models is little, which clearly outperform the previous system (Friedrich et al., 2016) and the baseline model by a large margin. As shown in Table 5, benefited from modeling wider contexts and common SE label patterns, our full paragraph-level model improves performance across almost all the genres. The high performance in the cross-genre setting demonstrates the robustness of our paragraph-level model across genres.

Table 5: Cross-genre Classification Results by Genre on the Training Set of MASC+Wiki. Baseline: Clause-level Bi-LSTM; Full Model: Paragraph-level Model + CRF. We report macro-average F1-score for each genre.

5.3 Impact of Training Data Size

In order to understand how much training data is required to train the paragraph-level model and obtain a good performance for SE type classification, we plot the learning curve shown in Figure 3 by training the full model several times using an increasing amount of training data. The classification performance increased quickly before the amount of training data was increased to 30% of the full training set; then the learning curve starts to become saturated afterwards. We conclude that the paragraph-level model can achieve a high performance quickly without requiring a large amount of training data.

5.4 Impact of Paragraph Length

To study the influence of paragraph lengths to the performance of the paragraph-level models, we report the performance of our proposed models on subsets of the test set, with paragraphs divided based on the number of clauses in a para-

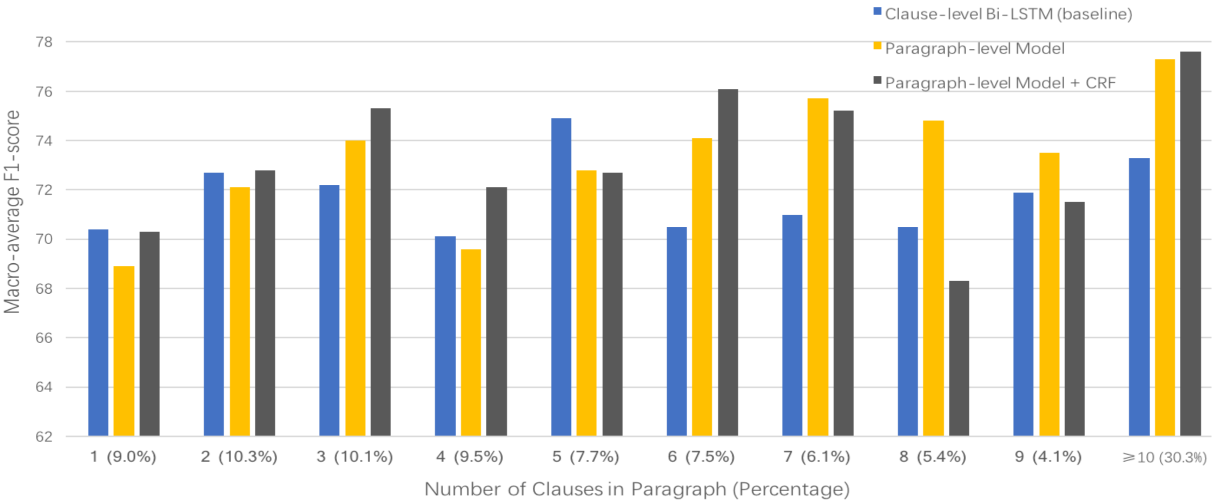

Figure 4: Impact of Paragraph Lengths. We plot the macro-average F1-score for each paragraph length.

graph. The histogram in Figure 4 compares performance of the two paragraph-level models and the baseline model. Note that the last bucket (paragraphs containing ten or more clauses) of the histogram is especially large and contains over 30% of all the paragraphs in the test set. Clearly, the paragraph-level model greatly outperforms the baseline clause-level model on paragraphs containing more than 6 clauses, which covers over 50% of the test set. Adding the CRF layer further improves the performance of the paragraph-level model on long paragraphs (with 10 or more clauses), while the influences to the performance are mixed on short paragraphs. Therefore, it is beneficial to model wider paragraph-level contexts and inter-dependencies between clauses for situation entity type classification, especially when processing long paragraphs.

5.5 Impact of Discourse Connective Phrases

As one aspect of modeling context influences and clause inter-dependencies in SE type identification, we investigated the role of discourse connective phrases in determining the SE type of clauses they connect. Our assumption is that discourse connectives are important to glue clauses together and removing them affects text coherence and information flow between clauses. Intuitively, the connective “and” may occur between two clauses with the same SE type; “for example” may indicate that the following clause is not GENERIC. Therefore, we designed a pilot experiment to see whether discourse connective phrases are indispensable in building clause representations.

In this pilot experiment, we extracted a list of 100 explicit discourse connectives. PDTB corpus (Prasad et al., 2008) and identified clauses that start with a discourse connecte[9]. Then we ran the full paragraph-level model with one modification, i.e., disregarding words in connective phrases when conducting the max-pooling operation in equation (1), thus we did not consider discourse connective phrases directly when building a clause representation.

As shown in Table 6, for clauses containing a discourse connective phrase, both macro-average F1-score and accuracy dropped due to the exclusion of discourse connective phrases. The performance was negatively influenced across all the SE types except the type of QUESTION and IMPERATIVE[10]. The performance decreases on three SE types, REPORT, GENERIC and GENERALIZING, are noticeable. To some extent, this pilot study shows that modeling text coherence and the overall discourse structure of a paragraph is important in situation entity type classification.

5.6 Confusion Matrix

Table 7 reports the confusion matrix of the full model on the training set of MASC+Wiki with cross-validation. We can see that the four situation entity types, including two eventualities (STATE and EVENT) and two general sta-

---

[9] We found that 20.6% of clauses in the MASC+Wiki corpus contain a discourse connective phrase.

[10] A possible explanation is that recognizing QUESTION (IMPERATIVE) clauses mainly relies on seeing certain punctuation marks and key words, such as “?” (“!”) and “why” (“please”), which are independent from discourse connectives.

Macro	Acc	STA	EVE	REP	GENI	GENA	QUE	IMP

Table 7: Confusion Matrix of the Paragraph-level Model + CRF on the Training Set of MASC+Wiki with 10-Fold Cross-Validation.

tives (GENERIC and GENERALIZING), are often mutually confused with each other. To further improve the performance of situation entity type classification, it is important to accurately detect events within a clause (for fixing STATE/EVENT errors) and identify the genericity of main referents (for fixing STATE/GENERIC and GENERIC/GENERALIZING errors), which can be potentially achieved by incorporating linguistic features into neural net models.

6 Conclusion

We presented a paragraph-level neural network model for situation entity (SE) type classification which builds context-aware clause representations by modeling inter-dependencies of clauses in a paragraph. Evaluation shows that the paragraph-level model outperforms previous systems for SE type classification and approaches human-level performance. In the future, we plan to incorporate SE type information in various downstream applications, e.g., many information extraction applications that require distinguishing specific fact descriptions from generic statements.

Abstract

In news and discussions, many articles and posts are provided without their related previous articles or posts. Hence, it is difficult to understand the context from which the articles and posts have occurred. In this paper, we propose the Hierarchical Dirichlet Gaussian Marked Hawkes process (HD-GMHP) for reconstructing the narratives and thread structures of news articles and discussion posts. HD-GMHP unifies three modeling strategies in previous research: temporal characteristics, triggering event relations, and meta information of text in news articles and discussion threads. To show the effectiveness of the model, we perform experiments in narrative reconstruction and thread reconstruction with real world datasets: articles from the New York Times and a corpus of Wikipedia conversations. The experimental results show that HD-GMHP outperforms the baselines of LDA, HDP, and HDHP for both tasks.

1 Introduction

Online news sites and discussion forums generate large volumes of articles and discussions, which we can call "events". To fully understand the discussions and the news stories, one often needs a larger context for that text, such as what related posts and relevant articles have been posted before. For instance, to understand a news article about the *presidential elections*, we would need to know the history of the candidates' political actions through relevant previous articles. While there are some news articles with a curated set of related articles and discussion threads with a well-organized structure, there are many more articles and discussion threads for which the structure is absent or incomplete. In this context, automatically reconstructing the narrative of articles and thread structure is an important problem.

Generally, textual information and various meta information such as location and keywords are used as features to solve this problem of narrative reconstruction. With these features, previous research mainly focus on three modeling strategies. First, they model the triggering relationship of events to identify which preceding events led to the occurrence of the current event. Second, they use meta information such as location and keywords. Third, they consider the temporal characteristics in the event stream, such that events in close temporal proximity are more likely to be related. However, there is no method that effectively considers all three of these. In narrative reconstruction, there are several approaches that focus on using meta information and temporal characteristics with clustering methods (Zhou et al., 2016; Tang et al., 2015; Ahmed et al., 2011), and there are several approaches using the Hawkes process to model the temporal characteristics (Du et al., 2015; Mavroforakis et al., 2017; Jankowiak and Gomez-Rodriguez, 2017). In thread reconstruction, there are approaches that focus on modeling triggering relationships of events and using meta information (Kim et al., 2010; Louis and Cohen, 2015; Wang et al., 2011b).

In this paper, we propose a novel Gaussian Marked Hawkes Process (GMHP) that effectively reconstructs the narrative structure of articles and the thread structure of discussions considering all three modeling strategies. GMHP uses the Hawkes process to model events in continuous time, a Gaussian distribution for modeling the meta information of text, and the mixture of Gaussian for modeling the triggering relationships of events. The detailed modeling strategies are described as follows. We use the Hawkes process to model time in the continuous domain, as the Hawkes process is a stochastic process used to understand a sequence of events in continuous time

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3316–3325
Brussels, Belgium, October 31 - November 4, 2018.

(Iwata et al., 2013; Rong et al., 2015). To use meta information, we represent text and meta information in a general vector form and use the Hawkes process to handle the vector of event information with a Gaussian distribution. To model the triggering relationships, we assume a model structure parameterized by each preceding event so that an event can be directly generated from a probability distribution parameterized by preceding events.

The GMHP models a single narrative or thread in event streams. To find the narratives or threads from a mixture of event streams, we combine our GMHP model with the Hierarchical Dirichlet Process to build HD-GMHP.

We evaluate the effectiveness of our model with two real world datasets: articles from the New York Times, and discussion threads from Wikipedia. In the New York Times dataset, we perform a narrative reconstruction experiment and compare the results with the human annotated narrative labels. In the Wikipedia discussion corpus, we perform two kinds of thread reconstruction experiment. One is grouping posts in the same thread. The other is reconstructing the post-reply structure of the posts. From these experiments, we see that our model outperforms the state-of-the-art model, the hierarchical Dirichlet Hawkes process (HDHP) (Mavroforakis et al., 2017).

The contributions of our research are threefold. First, we propose the Gaussian Marked Hawkes Process that effectively models a single narrative (event stream) with all three modeling strategies used in previous research. Second, we propose HD-GMHP, a combination of the GMHP model with the HDP to reconstruct the narratives of articles and the thread structure of discussions from a mixture of event streams. Finally, we propose a novel inference algorithm of the HD-GMHP with the Sequential Monte Carlo method (Doucet et al., 2001).

2 Related Work

Narrative Reconstruction: One major approach to reconstructing narratives from news articles is clustering articles by using a variant of the Chinese Restaurant Process (CRP). Related work such as (Zhou et al., 2016; Tang et al., 2015; Ahmed et al., 2011) models chronologically ordered news articles with text and various meta information including author, organization, keywords, and location. They use the CRP, distant-dependent CRP (Blei and Frazier, 2011). There is research that uses recurrent CRP (Ahmed and Xing, 2008) and exponential time decaying kernel to model probability of time difference between two relevant events. But they use discrete time information instead of continuous form and handcrafted parameters of the kernel (Ahmed et al., 2011).

There is another approach that reconstructs narratives by directly extracting important sentences from articles. (Xu et al., 2013) proposes a model that considers the sentence and image level narrative reconstruction as an optimization problem and solves it by maximizing the divergence of narratives with some constraints. (Wang et al., 2016) solves the narrative reconstruction problem as a sentence recommendation problem and uses matrix factorization. But these existing models focus on how to handle text and meta information of articles, while our model uses the Hawkes process to effectively model continuous time information of events.

Discussion Thread Reconstruction: There are several approaches to reconstruct threads from a corpus of unstructured discussions. (Wang et al., 2011a) uses Conditional Random Field to reconstruct reply structure in discussion corpus. (Balali et al., 2014) uses content, time and author information as features of a single post with rank SVM to reconstruct thread structure. (Dehghani et al., 2013; Aumayr et al., 2011) uses SVM and a decision tree with meta information of posts.

However, a major limitation in these previous research is that they are assuming that for each post, the main thread where it belongs is given. That is, the problem they solve is finding the post for which a post is immediately replying, rather than treating the corpus as a single set of posts with no known information about the threads, the initial post of each thread, and the posts that belong to each thread. This limitation of the previous research means those approaches are not applicable in more general online conversation data, such as IRC or a Facebook group chat which is a massive unstructured online discussion for which the initial post of a thread is not labeled. Unlike this strong assumption in previous research, we use a more general assumption that the initial posts are unknown, so our approach would be applicable to a wider, more general discussion data. Also, as in the narrative reconstruction research area, previous research focuses on how to handle text and meta information in posts. Again, unlike previous research, our research uses the Hawkes process to model continuous time information.

Continuous Time Modeling: The Hawkes process, a stochastic process that models continuous time information of events with event occurrence history, is an effective solution to model events in continuous time. One of the main research themes in the Hawkes process literature is finding which events trigger which other events. (He et al., 2015) models the topic diffusion patterns in a social network by inferring the triggering node with the Hawkes process. The Hawkes process is also used to model social event streams (Rong et al., 2015) and to classify rumors (Lukasik et al., 2016), and a combination of the Hawkes process and the Dirichlet mixture model is used to cluster event streams (Xu and Zha, 2017).

Recent research clusters text streams with the Hawkes process and the Chinese Restaurant Process or the Chinese Restaurant Franchise (Mavroforakis et al., 2017; Du et al., 2015). They use the bag-of-words representation of text in their model, while (Jankowiak and Gomez-Rodriguez, 2017) proposes a Hawkes process model that can handle a more general vector representation of events. The main difference of our model compared to this research is that we add the triggering relationship of two events. With this addition, our model can reconstruct narratives with an explicit relation of two documents.

3 Hawkes Processes

Before we describe our proposed model, we briefly explain the Hawkes process, one of two main stochastic processes used in our model. We leave out the explanation of the HDP due to space.

The Hawkes process (Hawkes, 1971) is a subclass of temporal point processes, whose functional form for intensity with exponential decaying kernel is represented as

$$\lambda^*(t) = \lambda_0(t) + \int_0^t \alpha\beta e^{-\beta(t-s)} dN(s),$$

where the intensity, $\lambda^*(t)$ represents the conditional probability of an event occurrence within time window $[t, t+dt)$. The Hawkes process is used to model the number of occurrences of events where one event can trigger other events. In the equation above, the base intensity $\lambda_0(t)$ models the intensity of events that occur on their own initiative whereas $\alpha\beta e^{-\beta(t-s)}$ models the intensity of events that are triggered by the previous event that occurred at time s. Here, multiplication of α and β represents influence of the previous event and β represents decaying rate of the influence. Thus, the effect of the previous event exponentially decays with respect to the time difference. From the definition of intensity $\lambda^*(t)$, the derived likelihood form of the Hawkes process is as follows,

$$f(D|\Theta) = e^{-\Lambda(T)} \prod_{i=1}^{n} \lambda^*(t_i), \tag{1}$$

where $\Lambda(T) = \int_0^T \lambda^*(t)dt$.

4 Problem Setting

In this section, we define the event stream and the narrative and the thread reconstruction problems.

Definition of Event Stream: If a text appears at time t_i, we define the event s_i as $(t_i, \vec{e_i}, z_i, x_i)$. Here, $\vec{e_i}$ is the feature vector of the text, x_i is the latent global cluster indicator of event s_i which represents the cluster for events with similar text information, and z_i is the latent local cluster indicator for events that are temporally related in the same cluster. We define event stream S as $[s_1, .., s_n]$.

Assumptions: 1) We assume that two events in same local cluster occur in near time and have similar feature vectors $\vec{e}$. These properties are called temporal and spatial locality. 2) We assume hierarchy structure of a global cluster and a local cluster. That is, one global cluster can consist of multiple local clusters.

Problem Formulation: We formulate the spatial locality of two events in the same local cluster with a Gaussian distribution. If two events s_i and s_j are in the same local cluster and $t_i > t_j$, then we assume the later event $\vec{e_i}$ is generated from one of two relations,

$$\vec{e_i} \sim \mathcal{N}(\vec{e_j}, \Sigma_v), \quad \vec{e_i}, \sim \mathcal{N}(\vec{e}_0, \Sigma_0).$$

Here, $\vec{e}_0$ is the base event vector and Σ_0 is the covariance matrix of the cluster. Σ_v is the covariance matrix of the Gaussian distribution generated by a past event in the cluster.

We use the Hawkes process to formulate the temporal locality of two events in the same local cluster. If event s_i and s_j are in the same local cluster and $t_i > t_j$, then t_i is generated from in either following relations,

$$t_i \sim \text{Poisson Process}(\mu),$$
$$t_i - t_j \sim \text{Hawkes}(\alpha, \beta).$$

Here, if t_i is generated from Hawkes process of parameter α and β with time t_j and $\vec{e}_i$ is generated from $\vec{e}_j$, then we say that event s_j is the *parent event* of event s_i.

We formulate the hierarchy structure of the global cluster and the local cluster with Hierarchical Dirichlet Process (Teh et al., 2006). If the parameters θ_{z_i} of local clusters $z_1, z_2, .., z_n$ are equal to the parameters of the global cluster Θ_x, then we say that there is a hierarchy between all the local clusters and the global cluster. And this hierarchy structure can be written as follows,

$$\Theta_x = \theta_{z_1} = \theta_{z_2} = ... = \theta_{z_n}.$$

Now, we define the narrative reconstruction and the thread reconstruction problem as a problem of inferring the latent variables in S.

5 Model

We now describe clustering a mixture of event stream S with the Gaussian Marked Hawkes Process and the hierarchical Dirichlet process. We first propose Gaussian Marked Hawkes Process (GMHP) that models temporal and spatial locality assumptions that described in section 4. And after defining the GMHP, we propose Hierarchical Dirichlet Gaussian Marked Hawkes Process (HD-GMHP), a combination of the GMHP with the Hierarchical Dirichlet Process. The GMHP models event streams with the same local cluster z and HDP groups the local clusters to one global cluster x.

5.1 Gaussian Marked Hawkes Processes

5.1.1 Model Description

In GMHP, we assume events are generated by a past event or by their own initiative. If event s_i is generated by event s_j, then we say that event s_j is the parent event of event s_i. If event s_i occurs on their own initiative, the index of the parent event is 0. We define the intensity function with the given parent event c_i as follows,

$$\lambda(t_i|c_i) = \begin{cases} \mu & \text{if } c_i = 0 \\ \alpha\beta e^{-\beta(t_i - t_{c_i})} & \text{otherwise} \end{cases} \quad (2)$$

To model the spatial locality of two D-dimensional event vectors $\vec{e}_i$, $\vec{e}_{c_i}$, we define probability distribution for $\vec{e}_i$ as follows,

$$p_{c_i}(\vec{e}_i) = \begin{cases} \mathcal{N}(\vec{e}_i|\vec{e}_0, \Sigma_0) & \text{if } c_i = 0 \\ \mathcal{N}(\vec{e}_i|\vec{e_{c_i}}, \Sigma_v) & \text{otherwise} \end{cases} \quad (3)$$

Here, $\vec{e}_0$ is the base event vector for when $c_i = 0$. Σ_0 and Σ_v are covariance matrix for when an event occurs by their own initiative or occurs by past event. From the above definitions, we can calculate the intensity of the event vector $\vec{e}$ at time t as follows,

$$\lambda_{\vec{e}}(t) = \mu\mathcal{N}(\vec{e}|\vec{e}_0, \Sigma_0) + \sum_{t_j<t} \lambda(t|j)\mathcal{N}(\vec{e}|\vec{e}_j, \Sigma_v). \quad (4)$$

The total intensity of GMHP can be obtained by integrating the above intensity with the event vector $\vec{e}$.

$$\lambda(t) = \int_{\mathbb{R}^D} \lambda_{\vec{e}}(t)\, d\vec{e} = \mu + \sum_{t_j<t} \lambda(t|j). \quad (5)$$

5.1.2 Parameter estimation

From equation 1, the likelihood of the observed event stream can be computed as follows,

$$f(D|\theta) = e^{-\Lambda(T)} \prod_{i=1}^{n} \sum_{0\le j<i} p_j(\vec{e_i})\lambda(t_i|j), \quad (6)$$

where $\Lambda(T) = \mu T + \sum_{i=1}^{n} \alpha(1 - e^{-\beta(T-t_i)})$.

Since the likelihood of GMHP is hard to maximize, instead of using the likelihood, we define a likelihood with the given parent events as follows,

$$\begin{aligned} f(D|C,\theta) =& e^{-\Lambda(T)} \times \prod_{i=1}^{n}\{(\mu\mathcal{N}(\vec{e}_i|\vec{e}_0, \Sigma_0))^{C_{i0}} \times \\ & \prod_{j=1}^{i-1}(\alpha\beta e^{\beta(t_i-t_j)}\mathcal{N}(\vec{e}_i|\vec{e}_j, \Sigma_v))^{C_{ij}}\}, \end{aligned} \quad (7)$$

where C_{ij} becomes 1 when $c_i = j$ and 0 otherwise. By maximizing equation 7, we can estimate the parameter $\theta = \{\mu, \alpha, \vec{e}_0, \Sigma_0, \Sigma_v\}$. The inference step of the parent events is described in section 6.

5.2 Modeling a Mixture of GMHP with the HDP

When clustering a mixture of streams using the Hawkes process, the exponential triggering function prevents two events with a large time difference from being assigned to the same global cluster. To solve this problem, (Mavroforakis et al., 2017) uses the HDP instead of using the Dirichlet process used in (Du et al., 2015). The hierarchy structure of the HDP assigns a cluster label with a probability proportional to the size of the cluster. This allows assignment of two events with a large time difference to the same cluster. For the same reason, we use the HDP to model mixture of the GMHP. We consider each GMHP in mixture as a table in the Chinese Restaurant Franchise metaphor. Since the intensity of k'th GMHP, $\lambda_k(t)$ represents how likely an event occurs in table k at time t, we use the intensity as the number of customers in the CRF metaphor. The whole generative process of HD-GMHP is as follows.

1. Initialize the number of local clusters $K = 0$, the number of global clusters $M = 0$.
2. For $n \in 1, 2, ..., N$
   (a) Draw t_n from Hawkes($\lambda_0 + \sum_{k=0}^{K} \lambda_k$)
   (b) Draw z_n as follows.
   $$z_n \sim \lambda_0 \delta(K+1) + \sum_{k=1}^{K} \lambda_k \delta(k) \quad (8)$$
   (c) If $z_n = K + 1$, assign global cluster x_n, which is interpreted as parameter(θ_{x_n}) for local cluster z_n, and Increment K. Here, N_m is number of local cluster in global cluster m.
   $$x_n \sim \gamma\delta(M+1) + \sum_{m=1}^{M} N_m \delta(m) \quad (9)$$
   (d) If $x_n = M + 1$, increment M and draw new parameter as follows.
   $\alpha_{x_n} \sim \Gamma(\alpha_a, \beta_a)$, $\mu_{x_n} \sim \Gamma(\alpha_\mu, \beta_\mu)$
   $\frac{1}{\Sigma_0^{x_n}} \sim \Gamma(\alpha_0, \beta_0)$, $\frac{1}{\Sigma_v^{x_n}} \sim \Gamma(\alpha_v, \beta_v)$
   $\vec{e}_{0,x_n} \sim \mathcal{N}(\vec{e}_0, \Sigma_0^{x_n}/\vec{\lambda}_{e0})$
   Note that we assume that the covariance matrix $\Sigma_v^{x_n}$, and $\Sigma_0^{x_n}$ are diagonal.
   (e) Draw c_n and $\vec{e}_n$. Here, $g_{x_n}(t) = \alpha_{x_n}\beta e^{-\beta(t_n - t)}$.
   $$c_n \sim \mu_{x_n}\delta(N_{z_n} + 1) + \sum_{j=1}^{N_{z_n}} g_{x_n}(t_j)\delta(j) \quad (10)$$
   if $c_n = N_{z_n} + 1$, then replace c_n with 0 and sample event vector.
   $$\vec{e}_n \sim \begin{cases} \mathcal{N}(\vec{e}_{0,x_n}, \Sigma_0^{x_n}) & \text{if } c_n = 0 \\ \mathcal{N}(\vec{e}_{c_n}, \Sigma_v^{x_n}) & \text{otherwise} \end{cases} \quad (11)$$

λ_0, γ, $\vec{e}_0, \vec{\lambda}_{e0}$, (α_a, β_a), (α_μ, β_μ), (α_0, β_0), and (α_v, β_v) are the hyperparameters used in HD-GMHP.

6 Inference

To infer the latent variables z and x for each event from an observed event stream $s_o^{1:n}$ where $s_o^i = (t_i, \vec{e}_i)$ with observation time T, we propose an online inference algorithm with Sequential Monte Carlo (SMC) (Doucet et al., 2001). To calculate the posterior of the latent variables z and x for each timestamp t_i in the inference, we need the estimated parameter to calculate the intensity at each time t_i, $\lambda(t_i)$. As described in section 5.1.2, the parameter estimation step needs the parent event information. In our proposed inference, the parent events are inferred from SMC. The inference algorithm is summarized in algorithm 1.

Algorithm 1 Inference

```
Input: Stream data $S_o$
Initialize $w_1^i = \frac{1}{P}, i \in \{1, 2, ..., P\}$.
for $n = 1$ to $N$ do
    for $i = 1$ to $P$ do
        Update $\Theta$ as described in section 6.2.
        Sample $(x, z, c)_n^i$ with equation 16, 10
        Update $w_n^i$ with equation 17
    end for
    Normalize $w_n^{1:P}$
    if $||w_n||_2^{-2} < thresh$ then
        Resample particles
    end if
end for
```

6.1 Sequential Monte Carlo with parent event inference

To approximate the posterior of the latent variables, SMC samples the latent variables from the proposal distribution and calculates the weight of each sampled variables which is called the particle weight. To infer the parent event in SMC, we define the particle weight of our modified SMC as follows:

$$w_n^i = \frac{p(\psi_{1:n}^i | s_o^{1:n})}{q(\psi_{1:n}^i | s_o^{1:n})} \frac{p(c_{1:n}^i | \psi_{1:n}^i, s_o^{1:n})}{q(c_{1:n}^i | \psi_{1:n}^i, s_o^{1:n})} \quad (12)$$

Here, ψ_n^i is (x_n^i, z_n^i). Let the left part on the right hand term and right part on the right hand term of the equation 12 are $w_{\psi_n}^i$ and $w_{c_n}^i$. Then the terms can be calculated by $w_{\psi_n}^i = \eta_\psi w_{\psi_{n-1}}^i$ and $w_{c_n}^i = \eta_c w_{c_{n-1}}^i$, where the η_ψ is

$$\frac{p(\vec{e}_n, t_n, \psi_n | s_o^{1:n-1}, \psi_{1:n-1}^i)}{q(\psi_n^i | \psi_{1:n-1}^i, s_o^{1:n})}. \quad (13)$$

and η_c is

$$p(\vec{e}_n | t_n, s_o^{1:n-1}, \delta_{1:n}^i) \frac{p(c_n^i | t_n, \delta_{1:n-1}^i, s_o^{1:n-1}, \psi_n^i)}{q(c_n^i | \delta_{1:n-1}^i, s_o^{1:n}, \psi_n^i)}. \quad (14)$$

Here, δ_n^i is (x_n^i, z_n^i, c_n^i).

We use $p(\psi_n|\psi_{1:n-1}, s_o^{1:n})$ as the proposal distribution of ψ_n^i in the equation 13 to minimize the variance of w_n^i (Doucet et al., 2000) and $p(c_n|\delta_{1:n-1}, \psi_n, t_n, s_o^{1:n-1})$ as the proposal distribution of c_n^i in the equation 14. From the above proposal distribution, $\eta_{c_n}^{\ i}$ can be calculated as $\eta_{c_n}^{\ i} = p(\vec{e}_n|t_n, s_o^{1:n-1}, c_{1:n}^i, \psi_{1:n})$ and $\eta_{\psi_n}^{\ i}$ can be calculated by the following form .

$$\begin{aligned}\eta_{\psi_n}^{\ i} =& p(t_n|\psi_{1:n-1}, z_n, s_o^{1:n-1}) \\ & \times \sum_{z_n} (p(\vec{e}_n|\psi_{1:n-1}, z_n, t_n, s_o^{1:n-1}) \\ & \times p(z_n|t_n, \psi_{1:n-1}, s_o^{1:n-1}))\end{aligned} \tag{15}$$

From the proposal distribution of ψ_n^i, we can sample ψ_n^i as follows:

$$\begin{aligned}p(\psi_n|rest) \propto & p(\vec{e}_n|\psi_{1:n}, t_n, s_o^{1:n-1}) \\ & \times p(\psi_n|\psi_{1:n-1}, t_n, s_o^{1:n-1}) \\ & \times p(t_n|\psi_{1:n-1}, s_o^{1:n-1})\end{aligned} \tag{16}$$

Here, the term $p(\vec{e}_n|\psi_{1:n}, t_n, s_o^{1:n-1}) \times p(\psi_n|\psi_{1:n-1}, t_n, s_o^{1:n})$ can be simply calculated by the student's t-distribution derived from the conjugate relation between the parameter $\{\vec{e}_{k0}, \Sigma_{0,k}, \Sigma_{v,k}\}$ and the normal-inverse-gamma and inverse-gamma prior in the generative process of HD-GMHP.

From $\eta_{c_n}^{\ i} = p(\vec{e}_n|t_n, s_o^{1:n-1}, c_{1:n}^i, \psi_{1:n})$ and 15, the particle weight can be updated by the following,

$$\begin{aligned}w_n^i \propto & w_{n-1}^i \\ & \times p(t_n|s_o^{1:n-1}, \psi_{1:n}^i) p(\vec{e}_n|c_n, t_n, s_o^{1:n-1}, \psi_{1:n}) \\ & \times \sum_{z_n} (p(\vec{e}_n|z_n, \psi_{1:n-1}, t_n, s_o^{1:n-1}) \\ & \times p(z_n|t_n, \psi_{1:n-1}, s_o^{1:n-1})).\end{aligned} \tag{17}$$

When calculating the probability of t_n in 17, we assume the parameters $\mu_{1:K}, \alpha_{1:K}$ are given (Carvalho et al., 2010). From the likelihood of GMHP, the probability term $p(t_n|\psi_{1:n}, s_o^{1:n-1})$ in equation 17 can be calculated by $\lambda_{z_n}(t_n)e^{-\Lambda(t_n, t_{n-1})}$. Where $\Lambda(t_n, t_n - 1)$ is

$$\begin{aligned}& \lambda_0(t_n - t_{n-1}) + (t_n - t_{n-1}) \sum_{k=1}^{K} \mu_k \\ & + \frac{1}{\beta}(1 - e^{-\beta(t_n - t_{n-1})}) \sum_{k=1}^{K} \lambda_k(t_{n-1}).\end{aligned} \tag{18}$$

In the case of the probability term $p(\vec{e}_n|c_n, rest)$ and $p(\vec{e}_n|z_n, rest)$ in 17, as explained in the sampling process of ψ_n, we can calculate the terms by student's t-distribution. With the particle weight update rule 17 and the parameter update rule described in section 6.2, we infer latent variables with algorithm 1.

6.2 Updating Parameter

From the equation 7 and the prior of the parameters used in GMHP, we can estimate the parameters by following form.

$$\alpha_m = \frac{\alpha_a - 1 + \sum_{x_i = m} \sum_{0<j<i} C_{ij}}{\beta_a + \sum_{x_i=m} (1 - e^{-\beta(T - t_i)})} \tag{19}$$

$$\mu_m = \frac{\alpha_\mu - 1 + \sum_{x_i=m} C_{i0}}{\beta_\mu + \sum_{\theta_k = \Theta_m} (T - t_{0,k})} \tag{20}$$

$$\vec{e}_{0,m} = \frac{\vec{e}_0 \circ \vec{\lambda}_{e0} + \sum_{x_i=m} C_{i0}\vec{e}_i}{\vec{\lambda}_{e0} + \sum_{x_i=m} C_{i0}} \tag{21}$$

$$\begin{aligned}diag(\Sigma_0^m) =& \{\vec{\lambda}_{e0} \circ (\vec{e}_{0,m} - \vec{e}_0)^2 + 2\vec{\beta}_0 \\ & + \sum_{x_i=m} C_{i0}(\vec{e}_i - \vec{e}_{0,m})^2\} \\ & \times \{2\vec{\alpha}_0 + 3 + \sum_{x_i=m} C_{i0}\}^{-1}\end{aligned} \tag{22}$$

$$diag(\Sigma_v^m) = \frac{2\vec{\beta}_v + \sum_{x_i=m} \sum_{0<j<i} C_{ij}(\vec{e}_i - \vec{e}_j)^2}{2 + 2\vec{\alpha}_v + \sum_{x_i=m} \sum_{0<j<i} C_{ij}} \tag{23}$$

6.3 Approximation

To reduce the computation time in the inference algorithm, we use several approximation strategies.

6.3.1 Marginal distribution Approximation

To calculate $p(\vec{e}_n|z_n, \psi_{1:n-1}, t_n, {s_o}^{1:n-1})$ in the equation 17, we need marginalization of $p(\vec{e}_n, c_n|z_n, \psi_{1:n-1}, t_n, s_o^{1:n-1})$ which takes time complexity of O(n of events in z_n) and cause the time complexity of the equation 17 to be $O(n)$. To reduce the time complexity, we note that event vector $\vec{e}_n$ is sampled from a Gaussian mixture that the influence of each Gaussian distribution is exponentially decreases. We assume the marginal distribution $p(\vec{e}_n|z_n, \psi_{1:n-1}, t_n, s_o^{1:n-1})$ can be approximated to $p(\vec{e}_n|c_{1:n} = 0, z_n, \psi_{1:n-1}, t_n, s_o^{1:n-1})$. From the approximation, we can calculate the posterior predictive with student's t-distribution. The result of approximation is as follows,

$$p(\vec{e}_n|z_n, \psi_{1:n-1}, t_n, s_o^{1:n-1}) = t_{\nu_n}(\vec{e}_n|\vec{m}_n, \frac{\vec{\kappa}_n + 1}{\vec{\kappa}_n \nu_n}\vec{S}_n), \quad (24)$$

where

$$\nu_n = 2\alpha_0 + N_{z_n}, \quad \kappa_n = \vec{\lambda}_{e_0} + N_{z_n},$$

$$\vec{m}_n = \frac{\vec{\lambda}_{e_0} \circ \vec{e}_0 + \sum_{z_i = z_n} \vec{e}_i}{\vec{\kappa}_n},$$

$$\vec{S}_n = 2\beta_0 + \sum_{z_i = z_n} \vec{e}_i^{\,2} + \vec{\lambda}_{e_0} \circ \vec{e}_0^{\,2} - \kappa_n \vec{m}_n^{\,2}.$$

To calculate $p(\vec{e}_n|c_n, t_n, s_o^{1:n-1}, \psi_{1:n})$ in the equation 17, we need to calculate posterior predictive for each past event. To reduce the computation time in the process of calculation, we approximate the probability distribution $p(\vec{e}_n|c_n, t_n, s_o^{1:n-1}, \psi_{1:n})$ as follows.

$$p(\vec{e}_n|c_n, t_n, s_o^{1:n-1}, \psi_{1:n}) \approx \begin{cases} \mathcal{N}(\vec{e}_{0,x_n}, \Sigma_0^{x_n}) & \text{if } c_n = 0 \\ \mathcal{N}(\vec{e}_{c_n}, \Sigma_v^{x_n}) & \text{otherwise} \end{cases} \quad (25)$$

6.3.2 Sampling c_n from recent W events

Sampling c_n has time complexity of $O(N_{z_n})$. To reduce the time complexity to $O(1)$, we sample c_n from recent W events in the local cluster z_n.

7 Experiment

In this section, we demonstrate the narrative reconstruction and thread reconstruction performance of our model on a corpus of the New York Times articles and the Wikipedia conversation dataset.

7.1 Dataset

New York Times Dataset: We collected 112,538 New York Times news articles from January 2016 to July 2017. The dataset contains the text, timestamp, the news section, and the keywords. These keywords are semantic tags specified by the newsroom to indicate the main topics of the articles. We select news articles in sections "U.S.", "World", "Opinion", and "Sports" that contain at least one of the top ten most frequently used keywords. The statistics of these keywords are described in table 1. Further, we select articles with more than ten words in its body. The final number of articles used in our experiment is 16,858. The dataset is publicly available [1].

Table 1: Statistics of keywords. "N" column lists the number of articles with the corresponding keyword.

Keyword	N
Trump, Donald J	7940
Presidential Election of 2016	5737
United States Politics and Government	4986
Republican Party	2371
Clinton, Hillary Rodham	2330
Baseball	2058
United States International Relations	1817
Terrorism	1618
Obama, Barack	1551
Russia	1400

Wikipedia Conversation Dataset is released by (Danescu-Niculescu-Mizil et al., 2012). The dataset contains the timestamp, the initial post of the conversation, "reply to" link information, and the text information of each post in conversation threads in Wikipedia talk pages. We select threads that have ten or more posts from September 2010 to December 2010. The final number of posts used in our experiment is 2,004 and the final number of threads is 154.

7.2 Preprocessing

To apply our model to the real world datasets, we represent each event with time information and an event vector. For the time information, we take the first article or post and set the time as zero, the last article or post as one, and scale the timestamps of all other articles and posts accordingly. To extract the event vectors, we use different vectorization methods for the two datasets. For the NYT dataset, we use the document topic vector from LDA (Blei et al., 2003). For the Wikipedia dataset, because there are only a few words in each post, we cannot use the LDA topic vector, so we use the averaged word embedding vector (Mikolov et al., 2013) of the words used in each post.

---

	HDP + DBSCAN	0.0260	0.0203
	HDHP	0.1768	0.0746
	HD-GMHP (100D)	**0.2479**	**0.1416**
Wiki	W2V + DBSCAN	0.0055	0.0001
	HDHP	0.4240	0.3512
	HD-GMHP (100D)	**0.5848**	**0.3834**

7.3 Task

Narrative reconstruction: To demonstrate the narrative reconstruction performance of our model, we apply the inference method to our corpus of NYT articles. We use a set of multiple keywords of each article as the ground truth label. Then we run our model and consider the set of articles with the same global cluster information as one narrative. We compare the results with the ground truth labels using the common clustering metrics AMI and ARI (Hubert and Arabie, 1985; Vinh et al., 2010) to evaluate the narrative reconstruction performance of our model. We compare HD-GMHP with the following baselines: LDA and HDP with DBSCAN, and the Hierarchical Dirichlet Hawkes Process (HDHP) (Mavroforakis et al., 2017) which is a state-of-the-art model for text and continuous timestamps of an event. Also, to measure the similarity of each recovered narrative and the ground truth narrative, we use the F1 score of the top ten narratives.

Thread reconstruction: In this experiment, we use two evaluation criteria. One is post grouping and the other is reply structure recovery, which is simply the recovery of the child nodes. Here, we use a different child node recovery task compared to the child node recovery used in previous research. In our task, we do not give the initial post of each thread, while previous research does. This makes thread reconstruction problem more general and more difficult.

In post grouping, we use the initial post of each of the posts as the ground truth label and measure the clustering metrics used in the NYT dataset. In the child node recovery experiment, we use the parent event information inferred from our method as the recovered tree structure of the threads. We measure the performance with node precision and node recall metrics (Wang et al., 2011a; Dehghani et al., 2013). We compare our model with the following baselines: HDHP, and a naive baseline that reconstructs threads in the form of a single linked list of posts in chronological order.

Table 3: F1-score of each label

Label	N	HD-GMHP	HDHP
Baseball	2011	0.8114	0.8899
Trump, Donald &Politics and Government	1664	0.1833	0.2157
Terrorism	1260	0.6052	0.4059
Trump, Donald &Election	1110	0.2537	0.1939
Trump, Donald	994	0.0975	0.1227
Politics and Government	822	0.1677	0.1215
Clinton, Hillary &Election &Trump, Donald	755	0.1754	0.1402
Election	714	0.1378	0.1280
Clinton, Hillary &Election	665	0.1669	0.1157
Russia	637	0.3177	0.2223
Micro F-score	N/A	**0.2874**	0.2189
Macro F-score	N/A	**0.3637**	0.3165

7.4 Metrics

AMI, ARI are commonly used to measure clustering performance (Hubert and Arabie, 1985; Vinh et al., 2010). $\mathbf{P_{node}}$, $\mathbf{R_{node}}$ measure local similarity between two thread structures (Wang et al., 2011a).

$$\mathrm{P_{node}} = \frac{1}{N} \sum_{i=1:N} \frac{|\mathrm{child_{GT}}(i) \cap \mathrm{child_{E}}(i)|}{|\mathrm{child_{E}}(i)|}$$

$$\mathrm{R_{node}} = \frac{1}{N} \sum_{i=1:N} \frac{|\mathrm{child_{GT}}(i) \cap \mathrm{child_{E}}(i)|}{|\mathrm{child_{GT}}(i)|}$$

where, $\mathrm{child_{GT}}(i)$ and $\mathrm{child_{E}}(i)$ are the sets of children of node i in the ground truth thread structure and the recovered thread structure, respectively. The author (Wang et al., 2011a) also proposed $\mathrm{P_{path}}$, $\mathrm{R_{path}}$ to measure the similarity of the global structure of two threads. The path metrics are sensitive to the recovered initial post of each thread, but since we do not give the initial post of each thread in our experiment, the path metrics are

Table 4: Reply structure recovery results in Wikipedia conversation dataset.

	P_{node}	R_{node}	$F1_{node}$
Naive Baseline	0.3223	**0.6501**	0.4310
HDHP	0.5598	0.5834	0.5714
HD-GMHP	**0.6433**	0.5468	**0.5911**

no longer proper in our experiment. So we measure the node metrics only.

7.5 Results

Table 2 shows the clustering accuracy of our method and the baseline methods in real world datasets. We average the results with five runs for each model. The highest value for each metric is indicated with boldface. From the results, we establish that our model outperforms the baseline methods in both the NYT narrative reconstruction task and the Wikipedia thread reconstruction task.

For the NYT, to see the accuracy of our model in more detail, we compute and show the F-scores for the top ten most frequent labels and the micro and macro averages in table 3. To compute the F-score between the true labels and the recovered cluster labels, we select the cluster with the highest F-score as the corresponding cluster. From the results, we establish that our model performs better than the baseline model, HDHP.

Table 4 shows the thread reconstruction results of our model and the baseline models in the Wikipedia conversation dataset. Since the HDHP model does not infer the parent event, we reconstruct threads in the form of chronologically ordered linked list of posts in each local cluster that inferred from HDHP. From the $F1_{node}$ score of the results, we establish our model performs better than other baseline models.

To demonstrate the robustness of HD-GMHP on dimensional change of the input vector, we measure the performance of each task in using 50, 100, and 150 dimensional vectors. The results are described in table 5 and 6. From the results, we verify there are no drastic changes in performance in both the NYT dataset and the Wikipedia dataset.

8 Conclusion

In this paper, we defined the narrative and thread reconstruction problems as clustering problems. To cluster the event streams with continuous time information and triggering event information, we proposed the Gaussian Marked Hawkes process that models event streams with additional event information represented in a vector form. Furthermore, we combined our model GMHP with the HDP to cluster event streams (HD-GMHP). We showed that our model performs better than several baseline methods in both narrative reconstruction in a dataset of NYT articles and thread reconstruction in a dataset of Wikipedia conversations.

Abstract

Exponential growth in the number of scientific publications yields the need for effective automatic analysis of rhetorical aspects of scientific writing. Acknowledging the argumentative nature of scientific text, in this work we investigate the link between the argumentative structure of scientific publications and rhetorical aspects such as discourse categories or citation contexts. To this end, we (1) augment a corpus of scientific publications annotated with four layers of rhetoric annotations with argumentation annotations and (2) investigate neural multi-task learning architectures combining argument extraction with a set of rhetorical classification tasks. By coupling rhetorical classifiers with the extraction of argumentative components in a joint multi-task learning setting, we obtain significant performance gains for different rhetorical analysis tasks.

1 Introduction

Scientific publications, as "tools of persuasion" in research (Gilbert, 1977), are carefully composed documents written to convince the reader of the validity and merit of the researchers' work. As such, they are inherently argumentative and often adhere to well-trodden rhetorical patterns and argumentation schemes of the respective research field. The accelerated growth of scientific literature (Bornmann and Mutz, 2015) makes exploration and analysis of relevant publications increasingly difficult. This yields the need for automatic analyses of these documents, including their argumentative and rhetorical structure.

Accordingly, computational models already support publication analysis tasks, e.g., classification of citation purpose and polarity (Jha et al., 2017; Lauscher et al., 2017b, *inter alia*) and classification of (sentential) discourse roles (Teufel et al., 1999; Liakata et al., 2010, *inter alia*). Further, rhetorical predictions at the (sub-)sentence level obtained using these models have been shown useful in higher-level downstream tasks such as publication classification (Teufel et al., 1999), (extractive) publication summarization (Cohan and Goharian, 2015), and research trend prediction (McKeown et al., 2016).

To allow for the holistic analysis of scientific publications with respect to the interactions between different rhetorical aspects of scientific text Fisas et al. (2016) created a corpus of scientific publications with manual annotations of several high-level rhetorical aspects of scientific writing (e.g., sentence-level discourse roles), but without annotations of the argumentative structure of publications. Despite (1) scientific texts being inherently argumentative (Gilbert, 1976), (2) the existence of theoretical argumentative frameworks (Toulmin, 2003; Kirschner et al., 2015), and (3) a wide range of argument extraction models in other domains (e.g., debates or essays, see Palau and Moens (2009); Habernal and Gurevych (2017), *inter alia*), there is still very little work on automatic argumentation mining from scientific literature. Consequently, there has been no work analyzing associations between argumentation and other rhetorical constructs in scientific writing, although such dependencies exist. Consider the following example:

> *"In general, our OMR preserves the high frequency content of the motion quite well [claim], since inverse rate control is directed by Jacobian values [data]."*

Here, the authors make a *claim* (underlined text) about their approach and support it with a technical fact (*data*) about the method (wave-underlined text). At the same time, regarding other rhetorical constructs, this sentence is stating the subjective aspect of *advantage* (of the proposed method), belongs to the discourse category of *outcome* (of the

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 3326–3338
Brussels, Belgium, October 31 - November 4, 2018.

authors' work), and may be considered *relevant* for the (extractive) summary of the publication. We argue that these rhetorical dimensions are interconnected and that fine-grained argumentation underpins other rhetorical layers in scientific text. For example, sentences stating an *advantage* of a method are likely to be argumentative and may contain *claims* that should be included in the summary.

Assuming that argumentation guides rhetorics in scientific text, we investigate neural multi-task learning (MTL) models which couple argument extraction with several other rhetorical analysis tasks. To this end, we augment the existing corpus of scientific publications (Fisas et al., 2016), containing several layers of rhetorical annotations, with an additional layer of argumentative components and relations. We then explore two neural MTL architectures based on shared recurrent encoders, intra-sentence attention, and private task-specific classifiers and couple the neural architectures with a joint MTL objective with uncertainty-based weighting of task-specific losses (Kendall et al., 2018). We validate our approach by testing that it outperforms traditional machine learning models in single-task settings. We finally show that coupling rhetorical analysis tasks with argument extraction using MTL models significantly improves the results for the rhetorical analysis tasks.

Contributions. We create the first corpus of scientific publications in English annotated with fine-grained argumentative structures and carry out the first study on dependencies between different rhetorical dimensions in scientific writing. Using MTL models, we show that argumentation informs other rhetorical analysis tasks. Finally, in the context of MTL research, our results indicate that the dynamic uncertainty-based loss weighting (Kendall et al., 2018) is beneficial for high-level natural language processing tasks.

2 Related Work

We provide an overview of (1) studies analyzing rhetorical aspects in scientific publications and (2) a large body of work on argumentation mining.

2.1 Rhetorical Analysis of Scientific Texts

Previous work has analyzed a number of rhetorical aspects of scientific publications. Teufel et al. (1999, 2009) analyzed the discourse structure of scientific publications. They annotated sentences with discourse categories named *argumentative zones*. Liakata et al. (2010) proposed a more general discourse scheme dubbed *core scientific concepts* and in subsequent work (Liakata et al., 2012) trained a conditional random fields (CRF) model to assign discourse labels to text spans. Several authors focused on tasks relating to citations: extraction of citation context (e.g., Abu-Jbara et al., 2013; Jha et al., 2017), classification of citation polarity (e.g., Athar, 2011) and purpose (e.g., Teufel et al., 2006; Jochim and Schütze, 2012), and the automatic detection of referenced parts of the cited publication (Jaidka et al., 2017). Both discourse and citation information have been exploited for summarizing scientific publications (Cohan and Goharian, 2015; Teufel and Moens, 2002; Abu-Jbara and Radev, 2011; Chen and Zhuge, 2014; Lauscher et al., 2017a). Intuitively, citation contexts may contain information relevant to the summary. Similarly, summaries commonly contain sentences with diversified discourse properties.

Fisas et al. (2016) provided different layers of rhetorical annotations on the same corpus of scientific text.Their Dr. Inventor Corpus is annotated with a combination of existing discourse annotation schemes (Teufel et al., 2009; Liakata et al., 2010) and citation-based annotations. Despite the argumentative nature of scientific texts, the Dr. Inventor Corpus contains no annotations of argumentative components such as claims. Several computational studies followed, addressing the rhetorical tasks corresponding to the layers of the Dr. Inventor Corpus (Ronzano and Saggion, 2015, 2016; Accuosto et al., 2017), but none of them investigated dependencies between different tasks.

The work of Kirschner et al. (2015) is the closest to ours, since they also annotated scientific publications with fine-grained argumentation. However, their corpus is in German and contains no annotations of other rhetorical dimensions. Moreover, their corpus is significantly smaller than the Dr. Inventor Corpus (Fisas et al., 2016). In contrast, we augment the Dr. Inventor Corpus with an argumentation layer, effectively allowing for combinations of argumentation extraction and other rhetorical analysis tasks in MTL settings.

2.2 Argumentation Mining

Argumentation mining (AM) refers to extracting (and ideally understanding) arguments from natural language text (Lippi and Torroni, 2015, 2016) and includes tasks like argument detection (Palau and Moens, 2009), argument component identification (Daxenberger et al., 2017), and argument relation classification (Boltužić and Šnajder, 2014). In their pioneering work on automatic AM, Palau and Moens (2009) discriminated argumentative from non-argumentative sentences and proposed a rule-based approach for extracting argumentative structures in documents. Habernal and Gurevych (2016, 2017) extracted argumentative components from online discussions. They framed the argumentative component extraction as a sequence labeling task and applied structured SVMs as a learning model.

Recent work started exploiting dependencies between AM tasks using global optimization (Peldszus and Stede, 2015; Persing and Ng, 2016; Stab et al., 2014) and MTL models (Eger et al., 2017; Niculae et al., 2017). Peldszus and Stede (2015) used decoding based on minimum spanning trees to jointly predict argumentative segments and their types as well as argumentative relations, to generate an argumentation graph from text. Persing and Ng (2016) and Stab and Gurevych (2017) similarly produced argumentative structures by globally optimizing local predictions of argumentative components and relations. Potash et al. (2017) proposed a neural architecture based on a pointer network for jointly predicting types of argumentative components and identifying argumentative relations. In a similar effort, Eger et al. (2017) combined the AM tasks using the MTL framework of Søgaard and Goldberg (2016). Remedying for data sparsity, Schulz et al. (2018) treated different argumentation formalisms as different tasks and combined respective extraction tasks and datasets in a MTL setting. In contrast to these efforts that combine several AM subtasks or formalisms with joint optimization and MTL models, in this work we examine the dependencies between argumentative components and other rhetorical aspects of scientific writing.

3 Data Annotation

We first briefly describe the Dr. Inventor Corpus (Fisas et al., 2016), which we augment with argumentative annotations. We then explain in more detail our argumentation annotation scheme and the annotation process.

3.1 Dr. Inventor Corpus

We chose the Dr. Inventor Corpus (Fisas et al., 2015, 2016) as a starting point for two reasons. First, containing 40 publications with a total of 10, 789 sentences, it is one of the largest corpora of scientific text manually labeled with rhetorical information. Secondly, it contains *four* different layers of rhetorical annotations: (1) a *discourse* layer, specifying discourse roles of sentences, (2) a *citation context* layer, specifying the textual context of citations, (3) a layer with *subjective aspect* categories assigned to sentences, and (4) a *summarization relevance* layer, indicating how relevant sentences are for the summary. The overview of labels for all annotation layers with the distribution of instances across labels is shown in Table 1. For more details on the original Dr. Inventor Corpus we refer the reader to (Fisas et al., 2015, 2016).

3.2 Argumentation Annotation Scheme

We considered several existing argumentation frameworks (e.g., Anscombre and Ducrot, 1983; Walton et al., 2008; Dung, 1995, *inter alia*) and selected the Toulmin's model (Toulmin, 2003) as a starting point for our study. We chose the Toulmin's model because: (1) it is a well-established in philosophy as well as in computer science (e.g, Freeman, 1991; Bench-Capon, 1998; Verheij, 2009, *inter alia*) and (2) it contains different types of argumentative components and relations between them into account, which is useful for fine-grained argumentative analyses.

To test the applicability of the framework for our purposes,we first carried out a small preliminary annotation round with two expert annotators and adjusted the annotation scheme according to their observations.

Argumentative components. We devised an adapted version of the Toulmin model,[1] containing the following argumentative components:

- *Background claim*: An argumentative statement related to the work of other authors, state-of-the-art methods, or common practices;

  "The range of breathtaking realistic 3D models is only limited by the creativity of artists and resolution of devices."

- *Own claim*: An argumentative statement about own work, covered by the publication itself;

  "Using our method, character authors may use any tool they like to author characters."

- *Data*: A fact that the authors state as evidence that either supports or contradicts a claim.

  "SSD is widely adopted in games, virtual reality, and other realtime applications due to its ease of implementation and low cost of computing."

Argumentative components are annotated as arbitrary spans of text (in terms of length, annotated components ranged from a single token to multiple sentences). Annotators were instructed to annotate the shortest possible span of text that completely captures the argumentative component. Thus, we do not bind arguments to sentences, i.e., we allow for fine-grained argumentative components.

Argumentative relations. Authors connect argumentative components in order to form convincing reasoning chains. To allow for the detection of long argumentation chains, we also annotated relations between argumentative components. Following proposals from previous work (Dung, 1995; Bench-Capon, 1998), we distinguish between three relation types:

- *Supports*: indicates that a *claim* component is supported by a data component or another claim. The (assumed) validity of the *supporting* component (data or claim) contributes to the validity of the *supported* claim.

- *Contradicts*: indicates that the validity of a claim decreases with the validity of another argumentative component. If an argumentative component is assumed to be true, the claim it contradicts is assumed to be false, and vice versa.

- *Same claim*: connects different mentions of what is essentially the same claim. It is common to repeat important claims (e.g., the central claim) of the work several times in the publication (*claim coreference*).

Further details about the annotation scheme can be found in the annotation guidelines we provided to our annotators.[2]

3.3 Annotation Procedure and Results

Annotation process. We hired four annotators for the task, one of whom we considered to be an *expert* annotator[3] and executed the process in two phases. In the first phase, we calibrated the annotators for the task in five iterations, on five publications from the Dr. Inventor Corpus. After all annotators labeled one of the five documents, we met with them, discussed the disagreements, identified erroneous annotations, and, when required, revised the annotation guidelines. At the end of the calibration phase, the annotators re-annotated the five calibration publications and resolved the remaining disagreements by consensus.

In Figure 1 we show the IAA for both component identification and relation classification, in terms of averaged pairwise F_1 score,[4] after each of the five calibration iterations. It can be seen that the discussions in the calibration phase helped to get a common understanding of the task among the annotators. However, we note that when considering argumentative relations in addition to the components only, the agreement decreases. Apart from the increased complexity compared to the component identification only this is due to the high ambiguity of argumentative structures, which is one of the main challenges in argument mining,

---

[1] We omitted some of Toulmin's component types (e.g., *Backing*) due to very rare occurrence in the corpus.

[2] `http://data.dws.informatik.uni-mannheim.de/sci-arg/annotation_guidelines.pdf`

[3] A researcher in computer science, albeit not in computer graphics, which is the domain of the corpus.

[4] We measured the agreement in terms of the F_1 measure because (1) it is straight-forward to compute, (2) it is directly interpretable, and (3) it can account for spans of varying length, allowing for computing relaxed agreements in terms of partial overlaps, and (4) the chance-corrected measures, e.g., Cohen's Kappa, approach F_1-measure when the number of negative instances grows (Hripcsak and Rothschild, 2005).

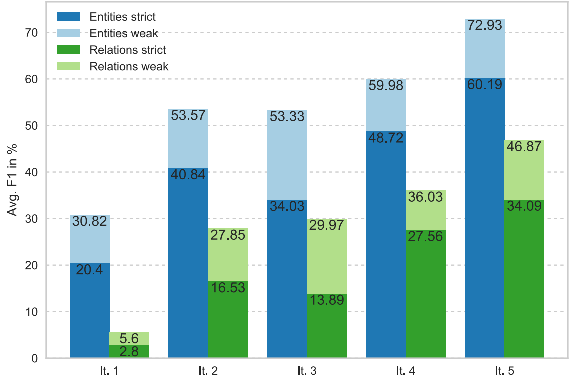

Figure 1: IAA evolution over calibration phases (*blue* for argumentative components; *green* for relations). We report both *strict* (annotated components match in span and type; relations match in type and components at both ends match strictly) and *relaxed* agreement scores (components match in type and overlap in span; relations match in type and their components at both ends match according to the relaxed criterion).

as suggested by Stab et al. (2014). Moreover, disagreements in the argumentative component identification are propagated and cause disagreements in relation annotations, since relation annotations match only when the agreement criterion for the components at both ends is met. Interestingly, the average agreement of our *expert* annotator with *non-expert* annotators was similar to the average agreement between non-expert annotators. This is encouraging, because it suggests that annotating argumentative structures in scientific text does not require expert knowledge of the domain. In the second phase, we evenly split the remaining 35 documents of the Dr. Inventor Corpus among the four annotators, without any overlaps.

The augmented corpus. We make the Dr. Inventor Corpus augmented with argumentation annotations (together with the annotation guidelines) publicly available.[5] The final corpus contains $12,289$ annotations of argumentative components and $6,530$ relation annotations. We show the distributions of labels in Table 2.

The number of *own claims* doubles the number of *background claims*. This is not surprising considering that the Dr. Inventor Corpus contains only original research articles (i.e., no survey nor position articles), in which authors primarily emphasize the contributions of their own work. There are two main reasons for having a smaller number of *data* components compared to *claims*. On one hand, there are longer argumentative chains in which claims are supported by other claims (i.e., only the first claim is supported by the data component). On the other hand, there is also a non-negligible amount of standalone (i.e., unsupported and unchallenged) claims, implied also by having less annotated relations than claims.

Category	Label	Occurrences	%
Component	*Background claim*	2,751	22.4
	Own claim	5,445	44.3
	Data	4,093	33.3
Relation	*Supports*	5,790	88.7
	Contradicts	696	10.7
	Semantically same	44	0.7

	AC	DR	SA	SR
AC	–	–	–	–
DR	**0.22**	–	–	–
SA	0.08	0.11	–	–
SR	0.04	0.10	0.13	–
CC	**0.18**	0.10	0.04	0.01

Table 3: Normalized mutual information between the label sets of the annotation layers indicating argument components (AC), discourse roles (DR), subjective aspects (SA), and citation contexts (CC) in the extended Dr. Inventor Corpus.

To obtain an initial insight on the interrelations between the different rhetorical aspects in scientific writing, we conduct an information-theoretic analysis and assess the amount of information shared among the annotation layers by computing the normalized mutual information (Strehl and Ghosh, 2003). Normalized mutual information is a variant of mutual information, which has been shown to correlate with the gains that can be obtained in multi-task learning settings (Bjerva, 2017). The results can be seen in Table 3. The strongest link is observed between argument components and discourse roles, followed by argument components and citation contexts.

4 Multi-task Learning for Rhetorical Analysis of Scientific Writing

We next exploit the augmented corpus to exploit the dependencies between argumentation and other rhetorical dimensions. To this end, we adopt neural MTL as a methodological framework.

4.1 Tasks

The following are the rhetorical analysis and argument extraction tasks we investigate.

Argumentative Component Identification (ACI). The task is to extract and classify argumentative components. We frame ACI as a token-level sequence labeling task: given a sequence of tokens $\mathbf{x} = (x_1, .., x_n)$ of length n, the task is to assign a sequence of tags $\mathbf{y}_{aci} = (y_1, .., y_n), y_i \in Y_{aci}$. The tagset Y_{aci} contains seven token-level tags, obtained by combining the standard B-I-O annotation scheme with three types of argumentative components: *Own claim*, *Background claim*, and *Data*.

Discourse Role Classification (DRC). The multi-class classification task in which each sentence needs to be assigned one out of the set of discourse roles $Y_{drc} = \{$*Background*, *Unspecified*, *Challenge*, *FutureWork*, *Approach*, *Outcome*$\}$.

Citation Context Identification (CCI). The task is to identify the span of the publication text that introduces or explains a reference. It is also a token-level sequence-labeling task – a sequence of tags $\mathbf{y}_{cci} = (y_1, .., y_n)$ with $y_i \in Y_{cci} = \{B_{CC}, I_{CC}, O\}$ is assigned to a sequence of tokens $\mathbf{x} = (x_1, .., x_n)$.

Subjective Aspect Classification (SAC). Another sentence-level classification task in which each sentence is assigned one of the subjective aspect labels, $Y_{sac} = \{$*None*, *Limitation*, *Advantage*, *Disadvantage-Advantage*, *Disadvantage*, *Common Practice*, *Novelty*, *Advantage-Disadvantage*$\}$.

Summary Relevance Classification (SRC). The task is to predict the relevance of a sentence for the (extractive) summary of the publication. Each sentence needs to be assigned one of the labels $Y_{src} = \{$*Very relevant*, *Relevant*, *May appear*, *Should not appear*, *Totally irrelevant*$\}$.

ACI and CCI are token-level sequence labeling tasks. The remaining three tasks can be cast as either (1) plain sentence classification tasks or (2) sentence-level sequence labeling tasks (assuming that there are regularities in sequences of sentence-level labels that can be captured). We propose one MTL architecture for each of the two possibilities.

4.2 Multi-Task Learning Models

We propose two different MTL architectures for the rhetorical and argumentative analysis of scientific publications. The *Simple model* treats sentence-level tasks (DRC, SAC, and SRC) as plain classification tasks (i.e., the prediction for each sentence ignores the content and labels of other, neighboring sentences). The *Hierarchical model* addresses sentence-level tasks as sequence labeling tasks. This model can be seen as a hierarchical sequence labeling model, in which the sentence-level recurrent network is stacked on top of the token-level sequence labeling network. Both architectures are illustrated in Figure 2.

Token-level Predictions. Given a sentence $s_i = (x_{i1}, .., x_{in})$ out of a sequence of sentences $d = (s_1, .., s_m)$ we first retrieve the pre-trained embedding vector for each token x_{ij}.We then obtain context-aware token representations h_{ij} by applying a bidirectional recurrent network with long short-term memory cells (Hochreiter and Schmidhuber, 1997) on the sequence of pre-trained word embeddings:

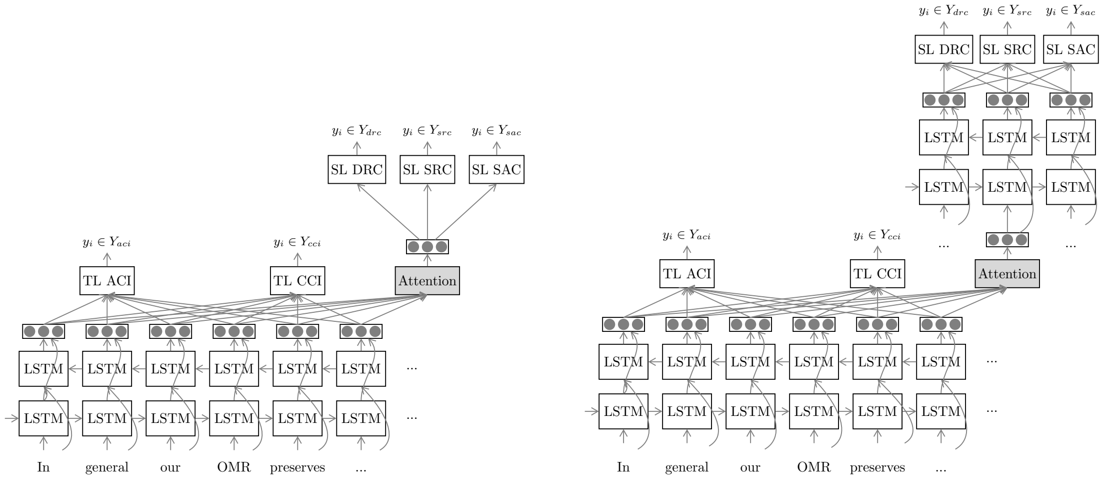
$$h_{ij} = [\overrightarrow{LSTM}(x_{i1}, \ldots, x_{ij}); \overleftarrow{LSTM}(x_{in}, \ldots, x_{ij})] \,. \quad (1)$$

This token-level Bi-LSTM encoder is shared between the tasks combined by the MTL models. Next, we define a separate classifier for each of the token-level (TL) tasks (i.e., ACI and CCI) and feed the contextualized token representations h_{ij} to these classifiers. Each of the classifiers is defined as a feed-forward network with a single hidden layer. The label probability distribution is obtained by applying the *softmax* function on its output.

$$y_{ijt} = \text{softmax}(W_t h_{ij} + b_t) \,, \quad (2)$$

where $W_t \in \mathbb{R}^{2K \times |Y_t|}$ and $b_t \in \mathbb{R}^{|Y_t|}$ are the task-specific classification parameters for the task t, with K being the size of the LSTM state and $|Y_t|$ the number of discrete labels of task t.

Sentence-level Predictions. We learn to aggregate a sentence representation s_i from contextualized vectors of its tokens, h_{ij} (produced by the



(a) Simple model.

(b) Hierarchical model.

Figure 2: Neural MTL architectures for rhetorical and argumentative analysis of scientific publications: (a) the *Simple model* addresses sentence-level tasks (DRC, SAC, SRC) as plain classification tasks, whereas (b) the *Hierarchical model* treats sentence-level tasks as sequence labeling tasks. Both models address ACI and CCI as token-level sequence labeling tasks.

token-level Bi-LSTM), using the intra-sentence attention mechanism (Yang et al., 2016):

$$s_i = \sum_j \alpha_{ij} h_{ij} \,, \tag{3}$$

with the weights α_i computed dynamically as:

$$\alpha_i = \text{softmax}(U_i \, u_{att}) \,, \tag{4}$$

where u_{att} is the trainable attention head vector and U_i is a matrix with non-linearly transformed token representations (h_{ij}) as rows:

$$U_{ij} = \tanh(W_{att} h_{ij} + b_{att}) \,. \tag{5}$$

In the *Simple* architecture, sentence representations s_i are fed directly to the sentence-level task-specific classifiers, which are also feed-forward networks with a single hidden layer:

$$y_{it} = \text{softmax}(W_t s_i + b_t) \,. \tag{6}$$

Within the *Hierarchical* architecture, sentence representations are first contextualized with representations of other sentences via the sentence-level Bi-LSTM layer (denoted with the function Bi-LSTM$_S$) and then forwarded to the classifier:

$$y_{it} = \text{softmax}(W_t \text{Bi-LSTM}_S(s_i) + b_t) \,. \tag{7}$$

Joint optimization and loss functions. All of the tasks we consider are framed as multi-class classification tasks. Thus, we simply specify all task-specific losses to be L2-regularized cross-entropy errors. Let y_{to} be the one-hot ground truth label vector for the prediction instance o[6] of the task t, and let y'_{to} be the predicted probability distribution over the task labels for the same instance. With Y_t as the set of labels for task t, the task-specific loss L_t is computed as follows:

$$L_t = \lambda \|\Omega_t\|_2 - \sum_o \sum_{k=1}^{|Y_t|} y_{to}^{(k)} \cdot \ln\left(y_{to}^{\prime(k)}\right) , \tag{8}$$

where Ω_t is the set of model's parameters relevant for the task t[7] and λ is the regularization factor. We train the MTL model jointly on different tasks by defining and minimizing the joint loss function L that combines task-specific losses L_t. Instead of using constant weights, we opt for dynamic weighting of task-specific losses during the training process, based on the homoscedastic uncertainty of tasks, as proposed by Kendall et al. (2018):

$$L = \sum_t \frac{1}{2\sigma_t^2} L_t + \ln \sigma_t^2 \,, \tag{9}$$

where σ_t is the variance of the task-specific loss over training instances, used to quantify the uncertainty of task t. Kendall et al. (2018) show that better MTL results can be obtained by dynamically

---

[6] The prediction instance is a token for ACI and CCI, and a sentence for DRC, SAC, and SRC.

[7] The set of relevant parameters differs across tasks: for token-level tasks (e.g., ARI) Ω_t denotes token-level Bi-LSTM parameters and the parameters W_t and b_t of task t's classifier; for a sentence-level task (e.g., DRC) within the *Hierarchical* architecture, Ω_t includes all parameters of both token- and sentence-level Bi-LSTMs, intra-sentence attention parameters, and parameters of the task-specific classifier.

assigning less weight to the more uncertain tasks, as opposed to constant task weights throughout the whole training process.

5 Evaluation

We run two sets of experiments. First, we evaluate the performance of the *Simple* and the *Hierarchical* neural models on individual tasks (i.e., in single-task learning (STL) scenarios). We then evaluate the impact of the argumentative signal on other dimensions of rhetorical analysis by combining them in joint MTL settings.

5.1 Experimental Setup.

We randomly split the corpus on the document-level into train (roughly 70%, 28 documents containing 6,697 sentences) and test portions (roughly 30%; 12 documents with 2,874 sentences). We used roughly 20% of the train portion as the validation set for model selection.

Model configuration and training. We ran an initial grid search on the validation set with possible values for the hyperparameters learning rate $\nu \in \{10^{-4}, 10^{-5}\}$, L2 regularization factor $\lambda \in \{0.001, 0, 0001\}$, and LSTM states $K \in \{64, 128, 256\}$ and found the hyperparameter configuration $\nu = 10^{-4}$, $\lambda = 0.001$, and $K = 128$ to be optimal for the vast majority of the STL and MTL models. In all experiments, we represent tokens with pre-trained 300-dimensional GloVe embeddings (Pennington et al., 2014)[8] and optimize the model parameters using the Adam algorithm (Kingma and Ba, 2015). We initialize all model parameters using Xavier initialization (Glorot and Bengio, 2010), train the models in batches of $N = 16$ sentences and apply early stopping based on the validation set performance.

Baselines. As a type of "sanity check", we first compare the performance of the two neural architectures against traditional supervised machine learning algorithms on each of the tasks separately. For the token-level sequence labeling tasks (ACI and CCI) we use Hidden Markov Models (HMM) and Conditional Random Fields (CRF) (Lafferty et al., 2001) as baselines. The HMM works directly on the tokens, while we feed either the lexical representation or the embedding representation of the tokens as features for the CRF. For the sentence classification tasks (DRC, SAC, and SRC), we evaluate as baselines (1) the linear Support Vector Machines (SVM) with TF-IDF feature vectors and (2) SVM with RBF kernel and embedding features. In the latter case we obtain a sentence representation by averaging the pre-trained embeddings of sentence words. We tune the hyperparameter values of the SVM by conducting a grid search with possible penality parameter values $c \in \{0.1, 1.0, 10.0\}$ (linear SVM and SVM with RBF kernel) and the parameter of the radial basis function $\gamma \in \{0.01, 0.1, 1.0\}$ (SVM with RBF kernel). The possible hyperparameter values for the L1 regularization coefficient $c1$ and for L2 regularization coefficient $c2$ of the CRF are $c1, c2 \in \{0.1, 0.2, 0.001, 0.0001\}$.

In MTL experiments, we consider the respective task performances from single-task experiments and MTL with a joint loss function with equal weighting of the task losses as baselines.

Model	ACI			CCI		
	P	R	F	P	R	F
HMM	30.8	17.2	20.8	18.3	13.1	15.0
CRF$_{lexical}$	38.8	29.1	31.7	15.3	17.8	16.4
CRF$_{embeddings}$	37.9	23.3	26.1	12.8	1.4	2.5
Neural: *Simple*	**47.0**	**44.5**	**44.7**	**48.7**	**43.8**	**46.1**

Table 4: Single-task results for token-level tasks (macro-averaged F_1 performances).

Model	DRC	SAC	SRC
SVM$_{tfidf}$	34.0	10.3	22.2
SVM$_{embeddings}$	25.7	08.5	19.3
Neural: *Simple*	**44.1**	**20.5**	31.5
Neural: *Hierarchical*	42.6	19.1	**33.2**

Table 5: Single-task results for sentence-level tasks (macro-averaged F_1 scores).

Single-Task Experiments. We first report the model performances for individual tasks in STL settings. Results for token-level tasks are shown in Table 4, whereas Table 5 displays results for sentence-level tasks. The scores (precision, recall, and F_1 score) are reported as macro-averages over all task labels. Expectedly, our neural architectures substantially outperform the traditional machine learning baselines on all tasks. For the three sentence-level tasks, the *Hierarchical* architecture outperforms the *Simple* model only when classifying sentences by summary relevance (SRC). This result seems intuitive – a *Very relevant* sentence is likely to be surrounded with *Relevant* and *May*

Table 6: MTL results: rhetorical analysis tasks coupled with argumentative component identification. We report the F1 score macro-averaged over the classes. The scores achieved for ACI are shown in parentheses.[9]

appear sentences (and an *Irrelevant* sentence with other *Irrelevant* and *Should not appear* sentences). The fact that we observe no gains from the additional sentence-level Bi-LSTM encoder for the DRC and SAC tasks suggests that the content of the sentence informs its discourse role and subjective aspect much more strongly than neighboring sentences. In other words, the DRC and SAC seem to be more localized classification tasks than SRC.

Multi-Task Learning Results. Our core research question relates to the effect that recognizing fine-grained argumentative components has on other rhetorical analysis tasks. This is why, in our central set of experiments, we evaluate MTL models with homoscedastic uncertainty weighting which combine the ACI (as an auxiliary task) with each of the four other tasks. In each multi-task learning model, the token-level Bi-LSTM encoder is shared between the two tasks. For sentence-level tasks (DRC, SAC, SRC), we evaluate both the *Simple* and *Hierarchical* architecture. In Table 6 we show the performance of the MTL models on rhetorical analysis tasks (these can be compared to the respective single-task model performances from Tables 4 and 5.

When coupled in MTL settings with argumentation component identification (ACI) using the joint loss formulation of Kendall et al. (2018), the results significantly[10] improve for all rhetorical analysis tasks and models (except for SAC with the *Hierarchical* model), in comparison with the respective single-task models. However, the performance for the argumentation component identification does not improve in MTL. In other words, the extraction of fine-grained argumentative components seems to inform higher-level rhetorical analysis tasks, but not vice-versa. This indeed supports the hypothesis that argumentation guides scientific writing and influences rhetorical structure of publications. Furthermore, our results support the findings of Schulz et al. (2018) who show that, opposed to initial results of Alonso and Plank (2017), MTL can yield performance gains for higher-level semantic tasks.

6 Conclusion

Acknowledging the argumentative nature of scientific text, we investigated the role of argumentation in the rhetorical analysis of scientific publications. We first extended an existing corpus annotated with four different layers of rhetorical information with annotations of argumentative components and relations, creating the largest argumentation-labeled corpus of scientific text in English. We explored intuitive neural architectures with recurrent encoders for argument extraction and rhetorical analysis tasks and showed significant improvements over traditional machine learning models. We then coupled argument extraction with different rhetorical analysis tasks in MTL models with dynamic loss weighting and demonstrated that the argumentative signal has a positive impact on high-level rhetorical analysis tasks.

Admittedly, the corpus we used in this work is limited to the domain of computer graphics. Nonetheless, we believe that our findings relating to the argumentative nature of scientific text and links between argumentation and other rhetorical aspects generalize to other domains too. This is also supported by the comparable agreement observed between expert and non-expert annotators.

In the future work, we would like to extend the collection of scientific text to other fields. Next, we intend to explore a wider range of MTL models, especially those involving more than two tasks. Having annotated argumentative relations, we will work on models for their automated identification in scientific publications.

Acknowledgments

This research was partly funded by the German Research Foundation (DFG), grant number EC 477/5-1 (LOC-DB). We thank our four annotators for their dedicated annotation effort and the anonymous reviewers for constructive and insightful comments.

Neural Ranking Models for Temporal Dependency Structure Parsing

Yuchen Zhang

Nianwen Xue
Brandeis University
`xuen@brandeis.edu`

Abstract

We design and build the first neural temporal dependency parser. It utilizes a neural ranking model with minimal feature engineering, and parses time expressions and events in a text into a temporal dependency tree structure. We evaluate our parser on two domains: news reports and narrative stories. In a parsing-only evaluation setup where gold time expressions and events are provided, our parser reaches 0.81 and 0.70 f-score on unlabeled and labeled parsing respectively, a result that is very competitive against alternative approaches. In an end-to-end evaluation setup where time expressions and events are automatically recognized, our parser beats two strong baselines on both data domains. Our experimental results and discussions shed light on the nature of temporal dependency structures in different domains and provide insights that we believe will be valuable to future research in this area.

1 Introduction

Temporal relation classification is important for a range of NLP applications that include but are not limited to story timeline construction, question answering, summarization, etc. Most work on temporal information extraction models the task as a pair-wise classification problem (Bethard et al., 2007; Chambers et al., 2007; Chambers and Jurafsky, 2008; Ning et al., 2018a): given an individual pair of time expressions and/or events, the system predicts whether they are temporally related and which specific relation holds between them. An alternative approach is to model the temporal relations in a text as a temporal dependency structure (TDS) for the entire text (Kolomiyets et al., 2012). Such a temporal dependency structure has the advantage that (1) it can be easily used to infer additional temporal relations between time expressions and/or events that are not directly connected via the transitivity properties of temporal relations, (2) it is computationally more efficient because a model does not need to consider all pairs of time expressions and events in a text, and (3) it is easier to use for downstream applications such as timeline construction.

However, most existing automatic systems are pair-wise models trained with traditional statistical classifiers using a large number of manually crafted features (Bethard et al., 2017). The few exceptions include the work of Kolomiyets et al. (2012), which describes a temporal dependency parser based on traditional feature-based classifiers, and Dligach et al. (2017), which describes a system using neural network based models to classify individual temporal relations. More recently, a semi-structured approach has also been proposed (Ning et al., 2018b).

In this work, taking advantage of a newly available data set annotated with temporal dependency structures – the Temporal Dependency Tree (TDT) Corpus[1] (Zhang and Xue, 2018), we develop a neural temporal dependency structure parser using minimal hand-crafted linguistic features. One of the advantages of neural network based models is that they are easily adaptable to new domains, and we demonstrate this advantage by evaluating our temporal dependency parser on data from two domains: news reports and narrative stories. Our results show that our model beats a strong logistic regression baseline. Direct comparison with existing models is impossible because the only similar dataset used in previous work that we are aware of is not available to us (Kolomiyets et al., 2012), but we show that our models are competitive against similar systems reported in the literature.

The main contributions of this work are:

- We design and build the first end-to-end neu-

ral temporal dependency parser. The parser is based on a novel neural ranking model that takes a raw text as input, extracts events and time expressions, and arranges them in a temporal dependency structure.

- We evaluate the parser by performing experiments on data from two domains: news reports and narrative stories, and show that our parser is competitive against similar parsers. We also show the two domains have very different temporal structural patterns, an observation that we believe will be very valuable to future temporal parser development.

The rest of the paper is organized as follows. Since temporal structure parsing is a relatively new task, we give a brief problem description in §2. We describe our end-to-end pipeline system in §3. Details of the neural ranking model are discussed in §4. In §5 we present and discuss our experimental results, and error analysis are presented in §6. In §7 we discuss related work and situate our work in the broader context, and we conclude our paper in §8.

2 Problem Description

In this section we give a brief description of the temporal dependency parsing task (more details in Zhang and Xue (2018)). In a temporal structure parsing task, a text is parsed into a dependency tree structure that represents the inherent temporal relations among time expressions and events in the text. The nodes in this tree are mostly time expressions and events which are represented as contiguous spans of words in the text. They can also be pre-defined meta nodes, which serve as reference times for other time expressions and events, and they constitute the top-most part of the tree. For example, *Past_Ref*, *Present_Ref*, *Future_Ref*, and *Document Creation Time (DCT)* are all pre-defined meta nodes. The edges in the tree represent temporal relations between each parent-child pair. The temporal relations can be one of *Includes*, *Before*, *Overlap*, and *After*, or *Depend-on* which holds between two time expressions. Unlike syntactic dependency parsing where each word in a sentence is a node in the dependency structure, in a temporal dependency structure only some of the words in a text are nodes in the structure. Therefore, this process naturally falls into two stages: first time expression and event recognition, and then temporal relation parsing. Figure 1 is an example temporal dependency tree for a news report paragraph.

Due to the fact that different types of time expressions and events behave differently in terms of what can be their antecedents, and recognition of these types can be helpful for determining temporal relations, finer classifications of time expressions and events are also defined. Time expressions are further classified into *Vague Time*, *Absolute Concrete Time*, and *Relative Concrete Time*, according to whether or not the time expression can be located on the timeline, and whether or not the interpretation of its temporal location depends on another time expression. Events are further classified into *Eventive Event*, *State*, *Habitual Event*, *Completed Event*, *Ongoing Event*, *Modalized Event*, *Generic Habitual*, and *Generic State*, according to the eventuality type of the event. Our experiments will show that these fine-grained classifications are very helpful for the overall temporal structure parsing accuracy.

3 A Pipeline System

We build a two-stage pipeline system to tackle this temporal structure parsing problem. The first stage performs event and time expression identification. In this stage, given a text as input, spans of words that indicate events or time expressions are identified and categorized. We model this stage as a sequence labeling process. A standard Bi-LSTM sequence model coupled with BIO labels is applied here. Word representations are the concatenation of word and POS tag embeddings.

The second stage performs the actual temporal structure parsing by identifying the antecedent for each time expression and event, and identifying the temporal relation between them. In this stage, given events and time expressions identified in the first stage as input, the model outputs a temporal dependency tree in which each child node is an event or time expression that is temporally related to another event or time expression or pre-defined meta node as its parent node. This stage is modeled as a ranking process: for each node, a finite set of neighboring nodes are first selected as its candidate parents. These candidates are then ranked with a neural network model and the highest ranking candidate is selected as its parent. We use a ranking model because it is simple, more intuitive and easier to train than a traditional transition-based or graph-based model, and

Example News Paragraph[a]**:**
Jorn Utzon, the Danish architect who designed the Sydney Opera House, has died$_{e1}$ in Copenhagen. Born$_{e2}$ in 1918$_{t1}$, Mr Utzon was inspired$_{e3}$ by Scandinavian functionalism in architecture, but made a number of inspirational trips$_{e4}$, including to Mexico and Morocco. In 1957$_{t2}$, Mr Utzon's now-iconic shell-like design for the Opera House unexpectedly won$_{e5}$ a state government competition for the site on Bennelong Point on Sydney Harbour. However, he left$_{e6}$ the project in 1966$_{t3}$. His plans for the interior of the building were not completed$_{s1}$. The Sydney Opera House is$_{s2}$ one of the world's most classic modern buildings and a landmark Australian structure. It was declared$_{e7}$ a UNESCO World Heritage site last year$_{t4}$.

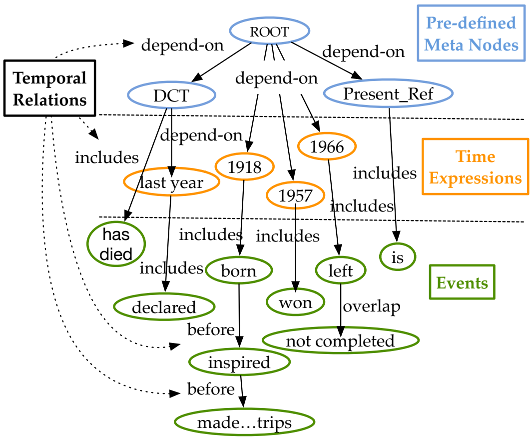

Figure 1: Example text and its temporal dependency tree. DCT is Document Creation Time.

the learned model rarely makes mistakes that violate the structural constraint of a tree.

Since the model we use for Stage 1 is a very standard model with little modifications, we don't describe it in detail in this paper due to the limitation of space. Our neural ranking model for Stage 2 is described in detail in the next section.

4 Neural Ranking Model

4.1 Model Description

We use a neural ranking model for the parsing stage. For each time expression or event node i in a text, a group of candidate parent nodes (time expressions, events, or pre-defined meta nodes) are selected. In practice, we select a window from the beginning of the text to two sentences after node i, and select all nodes in this window and all pre-defined meta nodes as the candidate parents if node i is an event. Since the parent of a time expression can only be a pre-defined meta node or another time expression as described in Zhang and Xue (2018), we select all time expressions in the same window and all pre-defined meta nodes as the candidate parents if node i is a time expression. Let y'_i be a candidate parent of node i, a score is then computed for each pair of (i, y'_i).Through ranking, the candidate with the highest score is then selected as the final parent for node i.

Model architecture is shown in Figure 2. Word embeddings are used as word representations (e.g. $\boldsymbol{w}_k$). A Bi-LSTM sequence layer is built on each word over the entire text, computing Bi-LSTM output vectors for each word (e.g. $\boldsymbol{w}_k^*$). The node representation for each time expression or event is the summation of the Bi-LSTM output vectors of all words in the text span (e.g. $\boldsymbol{x}_i$). The pair representation for node i and one of its candidates y'_i is the concatenation of the Bi-LSTM output vectors of these two nodes $\boldsymbol{g}_{i,y'_i} = [\boldsymbol{x}_i, \boldsymbol{x}_{y'_i}]$, which is then sent through a Multi-Layer Perceptron to compute a score for this pair s_{i,y'_i}. Finally all pair scores of the current node i are concatenated into vector $\boldsymbol{c}_i$, and taking $softmax$ on it generates the final distribution $\boldsymbol{o}_i$, which is the probability distribution of each candidate being the parent of node i.

Formally, the **Forward Computation** is:

$$\begin{aligned}
\boldsymbol{w}_k^* &= BiLSTM(\boldsymbol{w}_k) \\
\boldsymbol{x}_i &= sum(\boldsymbol{w}_{k-1}^*, \boldsymbol{w}_k^*, \boldsymbol{w}_{k+1}^*) \\
\boldsymbol{g}_{i,y'_i} &= [\boldsymbol{x}_i, \boldsymbol{x}_{y'_i}] \\
\boldsymbol{h}_{i,y'_i} &= tanh(\mathbf{W_1} \cdot \boldsymbol{g}_{i,y'_i} + \mathbf{b_1}) \\
s_{i,y'_i} &= \mathbf{W_2} \cdot \boldsymbol{h}_{i,y'_i} + \mathbf{b_2} \\
\boldsymbol{c}_i &= [s_{i,1}, ..., s_{i,i-1}, s_{i,i+1}, ..., s_{i,i+t}] \\
\boldsymbol{o}_i &= softmax(\boldsymbol{c}_i)
\end{aligned}$$

4.2 Learning

Let D be the training data set of K texts, N_k the number of nodes in text D_k, and y_i the gold parent for node i. Our neural model is trained to maximize $P(y_1, ..., y_{N_k}|D_k)$ over the whole training set. More specifically, the cost function is defined as follows:

$$\begin{aligned}
C &= -log \prod_k^K P(y_1, ..., y_{N_k}|D_k) \\
&= -log \prod_k^K \prod_i^{N_k} P(y_i|D_k) \\
&= \sum_k^K \sum_i^{N_k} -logP(y_i|D_k)
\end{aligned}$$

For each training example, cross-entropy loss is minimized:

$$L = -logP(y_i|D_k) \\ = -log\frac{exp[s_{i,y_i}]}{\sum_{y_i'} exp[s_{i,y_i'}]}$$

where $s_{i,y_i'}$ is the score for child-candidate pair (i, y_i') as described in §4.1.

4.3 Decoding

During decoding, the parser constructs the temporal dependency tree incrementally by identifying the parent node for each event or time expression in textual order. To ensure the output parse is a valid dependency tree, two constraints are applied in the decoding process: (i) there can only be one parent for each node, and (ii) descendants of a node cannot be its parent to avoid cycles. Candidates violating these constraints are omitted from the ranking process.[2]

4.4 Temporal Relation Labeling

The neural model described above generates an unlabeled temporal dependency tree, with each parent being the most salient reference time for the child. However it doesn't model the specific temporal relation (e.g. "before", "overlap") between a parent and a child. We extend this basic architecture to both identify parent-child pairs and predict their temporal relations. In this new model, instead of ranking child-candidate pairs (i, y_i'), we rank child-candidate-relation tuples (i, y_i', l_k), where l_k is the kth relation in the pre-defined set of possible temporal relation labels L. We compute this ranking by re-defining the pair score $s_{i,y_i'}$. Here, pair score $s_{i,y_i'}$ is no longer a scalar score but a vector $\boldsymbol{s}_{i,y_i'}$ of size $|L|$, where $\boldsymbol{s}_{i,y_i'}[k]$ is the scalar score for y_i' being the parent of i with temporal relation l_k. Accordingly, the lengths of $\boldsymbol{c}_i$ and $\boldsymbol{o}_i$ are $number\ of\ candidates * |L|$. Finally, the tuple (i, y_i', l_k) associated with the highest score in $\boldsymbol{o}_i$ predicts that y_i' is the parent for i with temporal relation label l_k.

4.5 Variations of the Basic Neural Model

4.5.1 Linguistically Enriched Models

A variation of the basic neural model is a model that takes a few linguistic features as input explicitly. In this model, we extend the pair representation $\boldsymbol{g}_{i,y_i'}$ with local features: $\boldsymbol{g}_{i,y_i'} = [\boldsymbol{x}_i, \boldsymbol{x}_{y_i'}, \phi_{i,y_i'}]$.

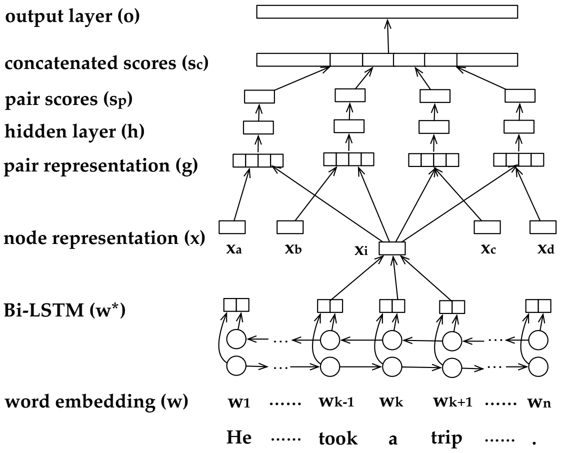

Figure 2: Neural Ranking Model Architecture. $\boldsymbol{x_i}$ is the current child node, and $\boldsymbol{x_a}, \boldsymbol{x_b}, \boldsymbol{x_c}, \boldsymbol{x_d}$ are the candidate parent nodes for $\boldsymbol{x_i}$. Arrows from Bi-LSTM layer to $\boldsymbol{x_a}, \boldsymbol{x_b}, \boldsymbol{x_c}, \boldsymbol{x_d}$ are not shown.

Time and event type feature: Stage 1 of the pipeline not only extracts text spans that are time expressions or events, but also labels them with pre-defined categories of different types of time expressions and events. Readers are referred to Zhang and Xue (2018) for the full category list. Through a careful examination of the data, we notice that time expressions or events are selective as to what types of time expression or events can be their parent. In other words, the category of the child time expression or event has a strong indication on which candidate can be its parent. For example, a time expression's parent can only be another time expression or a pre-defined meta node, and can never be an event; and an eventive event's parent is almost certainly another eventive event, and is highly unlikely to be a stative event. Therefore, we include the time expression and event type information predicted by stage 1 in this model as a feature. More formally, we represent a time/event type as a fixed-length embedding $\boldsymbol{t}$, and concatenate it to the pair representation $\boldsymbol{g}_{i,y_i'} = [\boldsymbol{x}_i, \boldsymbol{x}_{y_i'}, \boldsymbol{t}_i, \boldsymbol{t}_{y_i'}]$.

Distance features: Distance information can be useful for predicting the parent of a child. Intuitively, candidates that are closer to the child are more likely to be the actual parent. Through data examination, we also find that a high percentage of nodes have parents in close proximity. Therefore,

---

[2] An alternative decoding approach would be to perform a global search for a Maximum Spanning Tree. However, due to the nature of temporal structures, our greedy decoding process rarely hits the constraints.

we include two distance features in this model: the node distance between a candidate and the child $\boldsymbol{nd}_{i,y'_i}$, and whether they are in the same sentence $\boldsymbol{ss}_{i,y'_i}$. One-hot representations are used for both features to represent according conditions listed in Table 1.

conditions for feature $\boldsymbol{nd}_{i,y'_i}$:
$i.node\_id - y'_i.node\_id = 1$
$i.node\_id - y'_i.node\_id > 1$ and $i.sent\_id = y'_i.sent\_id$
$i.node\_id - y'_i.node\_id > 1$ and $i.sent\_id \neq y'_i.sent\_id$
$i.node\_id - y'_i.node\_id < 1$
conditions for feature $\boldsymbol{ss}_{i,y'_i}$:
$i.sent\_id = y'_i.sent\_id$
$i.sent\_id \neq y'_i.sent\_id$

Table 1: Conditions for node distance and same sentence features.

The final pair representation for our linguistically enriched model is as follows:

$$\boldsymbol{g}_{i,y'_i} = [\boldsymbol{x}_i, \boldsymbol{x}_{y'_i}, \boldsymbol{t}_i, \boldsymbol{t}_{y'_i}, \boldsymbol{nd}_{i,y'_i}, \boldsymbol{ss}_{i,y'_i}]$$

4.5.2 Attention Model on Time and Event Representation

In the basic neural model, a straight-forward sum-pooling is used as the multi-word time expression and event representation. However, multi-word event expressions usually have meaning-bearing head words. For example, in the event "took a trip", "trip" is more representative than "took" and "a". Therefore, we add an attention mechanism (Bahdanau et al., 2014) over the Bi-LSTM output vectors in each multi-word expression to learn a task-specific notion of headedness (Lee et al., 2017):

$$\alpha_t = tanh(\boldsymbol{W} \cdot \boldsymbol{w}^*_t)$$

$$w_{i,t} = \frac{exp[\alpha_t]}{\sum_{k=START(i)}^{END(i)} exp[\alpha_k]}$$

$$\hat{\boldsymbol{x}}_i = \sum_{t=START(i)}^{END(i)} w_{i,t} \cdot \boldsymbol{w}^*_t$$

where $\hat{\boldsymbol{x}}_i$ is a weighted sum of Bi-LSTM output vectors in span i. The weights $w_{i,t}$ are automatically learned. The final pair representation for our attention model is as follows:

$$\boldsymbol{g}_{i,y'_i} = [\boldsymbol{x}_i, \boldsymbol{x}_{y'_i}, \boldsymbol{t}_i, \boldsymbol{t}_{y'_i}, \boldsymbol{nd}_{i,y'_i}, \boldsymbol{ss}_{i,y'_i}, \hat{\boldsymbol{x}}_i, \hat{\boldsymbol{x}}_{y'_i}]$$

This model variation is also beneficial in an end-to-end system, where time expression and event spans are automatically extracted in Stage 1. When extracted spans are not guaranteed correct time expressions and events, an attention layer on a slightly larger context of an extracted span has a better chance of finding representative head words than a sum-pooling layer strictly on words within a event or time expression span.

5 Experiments

5.1 Data

All of our experiments are conducted on the datasets described in Zhang and Xue (2018). This is a temporal dependency structure corpus in Chinese. It covers two domains: news reports and narrative fairy tales. It consists of 115 news articles sampled from Chinese TempEval2 datasets (Verhagen et al., 2010) and Chinese Wikipedia News[3], and 120 fairy tale stories sampled from Grimm Fairy Tales[4]. 20% of this corpus, distributed evenly on both domains, are double annotated with high inter-annotator agreements. We use this part of the data as our development and test datasets (10% documents for development and 10% for testing), and the remaining 80% as our training dataset.

5.2 Baseline Systems

We build two baseline systems to compare with our neural model. The first is a simple baseline which links every time expression or event to its immediate previous time expression or event. According to our data, if only position information is considered, the most likely parent for a child is its immediate previous time expression or event. This baseline uses the most common temporal relation edge label in the training datasets, i.e. "overlap" for news data, and "before" for grimm data.

The second baseline is a more competitive baseline for stage 2 in the pipeline. It takes the output of the first stage as input, and uses a similar ranking architecture but with logistic regression classifiers instead of neural classifiers. The purpose of this baseline is to compare our neural models against a traditional statistical model under otherwise similar settings. We conduct robust feature engineering on this logistic regression model to make sure it is a strong benchmark to compete against. Table 2 lists the features and feature combinations used in this model.

5.3 Evaluation

We perform two types of evaluations for our systems. First, we evaluate the stages of the pipeline and the entire pipeline, i.e. end-to-end systems where both time expression and event recognition, as well as temporal dependency structures are automatically predicted. Our models are compared against the two strong baselines described in §5.2. These evaluations are described in §5.3.1.

The second evaluation focuses only on the temporal relation structure parsing part of our pipeline (i.e. Stage 2), using gold standard time expression and event spans and labels. Since most previous work on temporal relation identification use gold standard time expression and event spans, this evaluation gives us some sense of how our models perform against models reported in previous work even though a strict comparison is impossible because different data sets are used. These evaluations are described in §5.3.2.

All neural networks in this work are implemented in Python with the DyNet library (Neubig et al., 2017). The code is publicly available[5].

For Stage 1, all models are trained with Adam optimizer with early stopping and learning rate 0.001. The dimensions of word embeddings, POS tag embeddings, Bi-LSTM output vectors, and MLP hidden layers are tuned on the dev set to 256, 32, 256, and 256 respectively. POS tags in Stage 1 are acquired using the joint POS tagger from Wang and Xue (2014). The tagger is trained on Chinese Treebank 7.0 (Xue et al., 2010). For Stage 2, the dimensions of word embeddings, time/event type embeddings, Bi-LSTM output vectors, and MLP hidden layers are tuned on the dev set to 32, 16, 32, and 32 respectively. The optimizer is Adam with early stopping and learning rate 0.001.

5.3.1 End-to-End System Evaluation

Stage 1: Time and Event Recognition For Stage 1 in the pipeline, we perform BIO tagging with the full set of time expression and event types (i.e. a 11-way classification on all extracted spans). Extracted spans will be nodes in the final dependency tree, and time/event types will support features in the next stage. We evaluate Stage 1 performance using 10-fold cross-validation of the entire data set. We use the "exact match" evaluation metrics for BIO sequence labeling tasks, and compute precision, recall, and f-score for each label type.

We first ignore fine-grained time/event types and only evaluate unlabeled span detection and time/event binary classification to show how well our system identify events and time expressions, and how well our system distinguishes time expressions from events. Table 3 shows the cross-validation results on these two evaluations. Span detection and event recognition show similar per-

Table 5: Stage 2 results (f-scores) with gold spans and timex/event labels (top), and automatic spans and timex/event labels generated by stage 1 (bottom). Best performances are in bold.

formance on both news and narrative domains. Time expressions have a higher recognition rate than events in news data, which is consistent with the observation that time expressions usually have a more limited vocabulary and more strict lexical patterns. On the other hand, due to the scarcity of time expressions in the Grimm data, time expression recognition in this domain has a very high precision but low recall, which results in a much lower f-score than news.

Labeled full set evaluation results on time/event type classification are reported in Table 4. Time expressions have higher recognition rates than events on both domains, and dominant event types ("event", "state", etc.) have higher and more stable recognition rates than other types. Event types with very few training instances, such as "modalized event" (<7%), achieve lower and more unstable recognition rates. Other types with less than 2% instances achieve close to 0 recognition f-scores, and are not reported in this table.

Stage 2: Temporal Dependency Parsing For Stage 2 in the pipeline, we conduct experiments on the five systems described above: a simple baseline, a logistic regression baseline, a basic neural model, a linguistically enriched neural model, and an attention neural model. All models are trained on automatically predicted spans of time expressions and events, and time/event types generated by Stage 1 using 10-fold cross-validation, with gold standard edges (and edge labels) mapped onto the automatic spans. Evaluations in Stage 2 are against gold standard spans and edges, and evaluation metrics are precision, recall, and f-score on $\langle child, parent\rangle$ tuples for unlabeled trees, and $\langle child, relation, parent\rangle$ triples for labeled trees.

Bottom rows in Table 5 report the end-to-end performance of our five systems on both domains. On both labeled and unlabeled parsing, our basic neural model with only lexical input performs comparable to the logistic regression model. And our enriched neural model with only three simple linguistic features outperforms both the logistic regression model and the basic neural model on news, improving the performance by more than 10%. However, our models only slightly improve the unlabeled parsing over the simple baseline on narrative Grimm data. This is probably due to (1) it is a very strong baseline to link every node to its immediate previous node, since in an narrative discourse linear temporal sequences are very common; and (2) most events breaking the temporal linearity in a narrative discourse are implicit stative descriptions which are harder to model with only lexical and distance features. Finally, attention mechanism improves temporal relation labeling on both domains.

5.3.2 Temporal Relation Evaluation

To facilitate comparison with previous work where gold events are used as parser input, we report our results on temporal dependency parsing with gold time expression and event spans in Table 5 (top rows). These results are in the same ballpark as what is reported in previous work on temporal relation extraction. The best performance in Kolomiyets et al. (2012) are 0.84 and 0.65 f-scores for unlabeled and labeled parses, achieved by temporal structure parsers trained and evaluated on narrative children's stories. Our best performing model (Neural-attention) reports 0.81 and 0.70 f-scores on unlabeled and labeled parses respectively, showing similar performance. It is important to note, however, that these two works use different data sets, and are not directly comparable. Finally, parsing accuracy with gold time/event spans as input is substantially higher than that with predicted spans, showing the effects of error propagation.

6 Error Analysis

We perform error analysis on the output of our best model (Neural-attention) on the development data sets. We focus on analyzing our neural ranking model (i.e. Stage 2), with gold time expression and event spans and labels as input.

First, we look at errors by the types of antecedents. Most events in both news and grimm data depend on their immediate previous event or time expression as their reference time parent. 71% of the events in the news data set and 78% of the events in the Grimm data have the immediate previous node as their antecedent. The confusion matrix in Table 6 illustrates how strongly this bias affects our models. Our model learns the bias and incorrectly links around half of the events (47% in news and 46% in grimm) to their immediate previous node when the *correct* temporal dependency is further back in the text.

	news			**grimm**		
	pre	**far**	**total**	**pre**	**far**	**total**
pre	317	11	328	750	60	810
far	65	72	137	104	122	226
total	382	83	465	854	182	1036

Table 6: Parent node confusion matrix. Rows are gold parents and columns are automatically parsed parents. "pre" means the parent is the immediate previous node of the child event, "far" means the parent is further back from the child event.

Second, we look at errors in temporal relation labels. Considering only correctly recognized parent-child pairs, we draw a confusion matrix as in Table 7. Our data has very few *after* relations in both domains, which explains why the model has difficulty identifying this relation. There are also very few *include* and *depend-on* relations in the Grimm data, however they are identified with a relatively high accuracy. This is probably because, according to the temporal dependency structure design (Zhang and Xue, 2018), these relations hold only between restricted pairs of parent and child: *include* requires a time expression parent and an event child, and *depend-on* requires that the parent be the rootf. The main confusion among temporal relations is between *before* and *overlap*. In news data, with a high occurrence of *overlap* relations (60% *overlap* and 5% *before*), most *before* parents are wrongly recognized as *overlap*. Grimm data has a more balanced distribution of these two temporal relations (46% *overlap* and 50% *before*), however, 13% *before* and 17% *overlap* are wrongly labeled as the other.

7 Related Work

7.1 Related Work on Temporal Relation Modeling

There is a significant amount of research on temporal relation extraction (Bethard et al., 2007; Bethard, 2013; Chambers and Jurafsky, 2008; Chambers et al., 2014; Ning et al., 2018a). Most of the previous work models temporal relation extraction as pair-wise classification between individual pairs of events and/or time expressions. Some of the models also add a global reasoning step to local pair-wise classification, typically using Integer Linear Programming, to exploit the transitivity property of temporal relations (Chambers and Jurafsky, 2008). Such a pair-wise classification approach is often dictated by the way the data is annotated. In most of the widely used temporal data sets, temporal relations between individual pairs of events and/or time expressions are annotated independently of one another (Pustejovsky et al., 2003; Chambers et al., 2014; Styler IV et al., 2014; O'Gorman et al., 2016; Mostafazadeh et al., 2016).

Our work is most closely related to that of Kolomiyets et al. (2012), which also treats temporal relation modeling as temporal dependency structure parsing. However, their dependency structure, as described in Bethard et al. (2012), is only over events, excluding time expressions which are an important source of temporal information, and it also excludes *states* (stative events), which makes the temporal dependency structure incomplete. Moreover, their corpus only consists of data in the narrative stories domain. We instead choose to develop our model based on the data set described in Zhang and Xue (2018), which introduces a more comprehensive and linguistically grounded annotation scheme for temporal dependency structures. This structure includes both events and time expressions, and uses the linguistic notion of *temporal anaphora* to guide the annotation of the temporal dependency structure. Since in this temporal dependency structure each parent-child pair is considered to be an instance of temporal anaphora, the parent is also called the *antecedent* and the child is also referred to as the *anaphor*. Their corpus consists of data from two domains: news reports and narrative stories.

More recently, Ning et al. (2018b) proposed a semi-structured approach to model temporal relations in a text. Based on the observation that not all pairs of events have well-defined temporal relations, they propose a multi-axis representation in which well-defined temporal relations only hold between events on the same axis. The temporal relations between events in a text form multiple disconnected subgraphs. Like other work before them, their annotation scheme only covers events, to the exclusion of time expressions.

7.2 Related Work on Neural Dependency Parsing

Most prior work on neural dependency parsing is aimed at syntactic dependency parsing, i.e. parsing a sentence into a dependency tree that represents the syntactic relations among the words. Recent work on dependency parsing typically uses transition-based or graph-based architectures combined with contextual vector representations learned with recurrent neural networks (e.g. Bi-LSTMs) (Kiperwasser and Goldberg, 2016).

Temporal dependency parsing is, however, different from syntactic dependency parsing. In temporal dependency parsing, for each event or time expression, there is more than one other event or time expression that can serve as its reference time, while the most closely related one is selected as the gold standard reference time parent. This naturally falls into a ranking process where all possible reference times are ranked and the best is selected. In this sense our neural ranking model for temporal dependency parsing is closely related to the neural ranking model for coreference resolution described in Lee et al. (2017), both of which extract related spans of words (entity mentions for coreference resolution, and events or time expressions for temporal dependency parsing). However, our temporal dependency parsing model differs from Lee et al's coreference model in that the ranking model for coreference only needs to output the best candidate for each individual pairing and cluster all pairs that are coreferent to each other. In contrast, our ranking model for temporal dependency parsing needs to rank not only the candidate antecedents but also the temporal relations between the antecedent and the anaphor. In addition, the model also adds connectivity and acyclic constraints in the decoding process to guarantee a tree-structured output.

8 Conclusion and Future Work

In this paper, we present the first end-to-end neural temporal dependency parser. We evaluate the parser with both gold standard and automatically recognized time expressions and events. In both experimental settings, the parser outperforms two strong baselines and shows competitive results against prior temporal systems.

Our experimental results show that the model performance drops significantly when automatically predicted event and time expressions are used as input instead of gold standard ones, indicating an error propagation problem. Therefore, in future work we plan to develop joint models that simultaneously extract events and time expressions, and parse their temporal dependency structure.

Causal Explanation Analysis on Social Media

Abstract

Understanding causal explanations — reasons given for happenings in one's life — has been found to be an important psychological factor linked to physical and mental health. Causal explanations are often studied through manual identification of phrases over limited samples of personal writing. Automatic identification of causal explanations in social media, while challenging in relying on contextual and sequential cues, offers a larger-scale alternative to expensive manual ratings and opens the door for new applications (e.g. studying prevailing beliefs about causes, such as climate change). Here, we explore automating causal explanation analysis, building on discourse parsing, and presenting two novel subtasks: *causality detection* (determining whether a causal explanation exists at all) and *causal explanation identification* (identifying the specific phrase that is the explanation). We achieve strong accuracies for both tasks but find different approaches best: an SVM for causality prediction ($F1 = 0.791$) and a hierarchy of Bidirectional LSTMs for *causal explanation identification* ($F1 = 0.853$). Finally, we explore applications of our complete pipeline ($F1 = 0.868$), showing demographic differences in mentions of causal explanation and that the association between a word and sentiment can change when it is used within a causal explanation.

1 Introduction

Explanations of happenings in one's life, *causal explanations*, are an important topic of study in social, psychological, economic, and behavioral sciences. For example, psychologists have analyzed people's causal explanatory style (Peterson et al., 1988) and found strong negative relationships with depression, passivity, and hostility, as well as positive relationships with life satisfaction, quality of life, and length of life (Scheier et al., 1989; Carver and Gaines, 1987; Peterson et al., 1988).

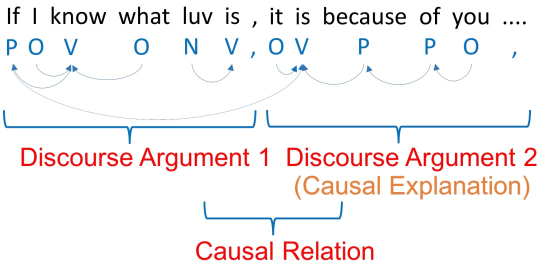

Figure 1: A casual relation characterizes the connection between two discourse arguments, one of which is the *causal explanation*.

To help understand the significance of causal explanations, consider how they are applied to measuring optimism (and its converse, pessimism) (Peterson et al., 1988). For example, in "My parser failed *because I always have bugs.*", the emphasized text span is considered a causal explanation which indicates pessimistic personality – a negative event where the author believes the cause is pervasive. However, in "My parser failed *because I barely worked on the code.*", the explanation would be considered a signal of optimistic personality – a negative event for which the cause is believed to be short-lived.

Language-based models which can detect causal explanations from everyday social media language can be used for more than automating optimism detection. Language-based assessments would enable other large-scale downstream tasks: tracking prevailing causal beliefs (e.g., about climate change or autism), better extracting process knowledge from non-fiction (e.g., gravity causes objects to move toward one another), or detecting attribution of blame or praise in product or service reviews ("I loved this restaurant because the fish was cooked to perfection").

In this paper, we introduce causal explanation analysis and its subtasks of detecting the presence of causality (*causality prediction*) and identifying explanatory phrases (*causal explanation identification*). There are many challenges to achieving these task. First, the ungrammatical texts in social media incur poor syntactic parsing results which drastically affect the performance of discourse relation parsing pipelines [1]. Many causal relations are *implicit* and do not contain any discourse markers (e.g., 'because'). Further, *Explicit* causal relations are also more difficult in social media due to the abundance of abbreviations and variations of discourse connectives (e.g., 'cuz' and 'bcuz').

Prevailing approaches for social media analyses, utilizing traditional linear models or bag of words models (e.g., SVM trained with n-gram, part-of-speech (POS) tags, or lexicon-based features) alone do not seem appropriate for this task since they simply cannot segment the text into meaningful discourse units or discourse arguments [2] such as clauses or sentences rather than random consecutive token sequences or specific word tokens. Even when the discourse units are clear, parsers may still fail to accurately identify discourse relations since the content of social media is quite different than that of newswire which is typically used for discourse parsing.
