Weeding out Conventionalized Metaphors: A Corpus of Novel Metaphor Annotations

Erik-Lân Do Dinh, Hannah Wieland, and Iryna Gurevych
Ubiquitous Knowledge Processing Lab (UKP-TUDA)
Department of Computer Science, Technische Universität Darmstadt

Abstract

We encounter metaphors every day, but only a few jump out on us and make us stumble. However, little effort has been devoted to investigating more novel metaphors in comparison to general metaphor detection efforts. We attribute this gap primarily to the lack of larger datasets that distinguish between conventionalized, i.e., very common, and novel metaphors. The goal of this paper is to alleviate this situation by introducing a crowdsourced novel metaphor annotation layer for an existing metaphor corpus. Further, we analyze our corpus and investigate correlations between novelty and features that are typically used in metaphor detection, such as concreteness ratings and more semantic features like the *Potential for Metaphoricity*. Finally, we present a baseline approach to assess novelty in metaphors based on our annotations.

1 Introduction

Metaphors have received considerable interest in NLP in recent years (see Shutova (2015)). Research questions range from direct detection of metaphors in text (*linguistic metaphors*) to finding mappings between conceptual source and target domains (*conceptual metaphors*).

However, an important aspect of metaphors—*novelty*—is often overlooked, or intentionally disregarded. Consider the metaphors (bold) in the following examples:

(1) We all live on **tight budgets**, but we still need to have some fun.

(2) They were beginning to attract a **penumbra** of gallery-goers, as though they were offering a guided tour.

The metaphor *tight budgets* in (1) is an often used collocation and therefore highly conventionalized. While the basic senses of *tight*—e.g., being physically close together or firmly attached—conflict with the more abstract *budget*, the metaphoric use as meaning *limited* can be readily understood. In contrast, the use of *penumbra* in (2) is more creative and novel. Its literal meaning is "an area covered by the outer part of a shadow."[1] Its metaphoric meaning is seldom encountered: Shadows follow objects that cast them, and especially penumbras can be perceived as having fuzzy outlines; attributes which are picked up by the metaphorical sense of a rather unspecified group of people following someone in differing vicinity.

Common linguistic metaphor definitions used in NLP (Steen et al., 2010; Tsvetkov et al., 2014) do not differentiate between *conventionalized* and *novel* metaphors. Some even allow for auxiliary verbs and prepositions to be annotated as metaphors when they are not used in their original sense (e.g., the non-spatially used *on* in "She wrote a study **on** metaphors"). While such cases can be filtered out rather easily from any given corpus—e.g., by using POS tag and lemma filters—many conventionalized metaphors persist. Existing work avoids this problem partially by only annotating certain grammatical constructions, such as adjective–noun or verb–object relations (Shutova et al., 2016; Rei et al., 2017). However, these too usually do not distinguish between conventionalized and novel metaphors.

Following Shutova (2015), we deem the distinction between conventionalized and novel metaphors important, because the meaning of conventionalized metaphors can usually be found in dictionaries or other resources like WordNet—novel metaphors on the other hand pose a more difficult challenge. But the lack of resources incorporating this distinction leads to few researchers

Brussels, Belgium, October 31 - November 4, 2018.

investigating novel metaphors, or the related measure of metaphoricity. They use small datasets that have been manually annotated by experts (Del Tredici and Bel, 2016), or focus crowdsourcing studies on a small number of instances (Dunn, 2014). It is only recently that any work has introduced larger-scale novel metaphor annotations (Parde and Nielsen, 2018). In contrast to our approach, they collect annotations on a relation level (see also Section 2).

Annotating metaphors is not an easy task, due to the inherent ambiguity and subjectivity. Therefore, we investigate approaches for annotating novelty in metaphors, before closing the resource gap for token-based annotations by creating a layer of novelty scores.

Our contributions are the following:

(1) We augment an existing metaphor corpus by assessing metaphor novelty on a token level using crowdsourcing, enabling larger research on novel metaphors,

(2) we analyze our corpus for correlation with features used for general metaphor detection or metaphoricity prediction, and

(3) we show that a baseline approach based on features usually used for (binary) metaphor detection can be useful for distinguishing novel and conventionalized metaphors.

In Section 2, we first discuss annotation guidelines that have been used for existing datasets, as well as prior work on novel metaphor detection and crowdsourcing in NLP. This discussion is followed by Section 3, where we detail the base corpus and the crowdsourced creation of our annotation layer. In Section 4, we describe our baseline for detecting novel metaphors and its results. We conclude in Section 5 with a summary of our contributions, and an outlook of what our newly introduced layer of annotations can enable.

2 Related Work

Annotating metaphors is a difficult task, because there is no single definition that can be adhered to. Instead, different researchers formulate their own versions, which can vary quite substantially.

The Pragglejaz Group (2007) created influential metaphor annotation guidelines, the *Metaphor Identification Procedure* (MIP). After reading a text, an annotator assesses each token as being used metaphorically or not; i.e., if the token has a more *basic* meaning that can be understood in comparison with the one it expresses in its current context. More basic is described as being:

- More concrete; what they evoke is easier to imagine, see, hear, feel, smell, and taste.
- Related to bodily action.
- More precise (as opposed to vague).
- Historically older.

They note that this basic meaning does not necessarily have to be the most frequent one. An extended version, MIPVU, was used to annotate parts of the British National Corpus (BNC Consortium, 2007, BNC), resulting in the VU Amsterdam Metaphor Corpus (Steen et al., 2010, VUAMC). Shutova and Teufel (2010) adapt the MIP as a prerequisite to annotating source and target domains of metaphor—the metaphoric mapping—in parts of the BNC.

Others use rather relaxed guidelines. Tsvetkov et al. (2014) rely on intuitive definitions by their annotators, not specifying metaphor more closely. They ask their annotators to mark words that “are used non-literally in the following sentences.” Jang et al. (2015) provide a Wikipedia definition of metaphor to users in a crowdsourcing study. Subsequently, the users are tasked with annotating forum posts by deciding “whether the highlighted word is used metaphorically or literally.”

A common trait of the listed works is that they do not distinguish between nuances of metaphoricity. Instead, they impose a binary scheme (metaphoric/literal) on the rather diffuse language phenomenon of metaphor. In contrast, Dunn (2014) introduces a scalar measurement of *metaphoricity* on a sentence level. He created a corpus of 60 genre-diverse sentences with varying levels of metaphoricity, which are rated in three crowdsourcing experiments: a binary selection, a ternary selection, and an ordering approach. The mean value for each sentence is then used as the metaphoricity value. Dunn (2014) uses this data to derive a computational measure of metaphoricity, which he then employs in an unsupervised system to label metaphoric sentences in the VUAMC. The evaluation, however, is only done on the binary labels provided therein.

In a similar direction, Del Tredici and Bel (2016) present their concept of *Potential of*

genre	tokens	metaphors	content tokens	content metaphors	novel metaphors
acprose	75,272	9,170	42,544	5,505	102
convrsn	57,249	3,841	22,019	1,774	25
fiction	54,115	5,349	26,935	3,174	94
news	51,672	7,580	29,346	4,727	132
total	238,308	25,940	120,844	15,180	353

Table 1: VUAMC corpus statistics. Content tokens include adjectives, adverbs, verbs (without *have*, *be*, *do*), and nouns. For the purpose of this table, metaphors with a novelty score higher than $T = 0.5$ are considered novel (the possible range is [–1,1]).

Metaphoricity (POM) of verbs. The POM describes the inherent potential of a verb to take on a metaphoric meaning, derived from its distributional behavior. They infer that low-POM verbs are only able to have low degrees of metaphoricity, thus can only evoke conventionalized metaphors. Therefore, they propose to exclude such low-POM verbs from novel metaphor detection systems.

Haagsma and Bjerva (2016) use violations of selectional preferences (Wilks, 1978) to find novel metaphors. Selectional preferences describe which semantic classes a verb prefers as its direct object. Since they are often mined from large corpora and based on frequency, they argue that this feature is more suited for novel metaphor detection than for general detection of (also conventionalized) metaphors. They evaluate their approach on the VUAMC; however, they acknowledge that their usage of this corpus is not optimal because it contains many conventionalized metaphors.

Parde and Nielsen (2018) create a corpus of novel metaphor annotations. For their crowdsourced annotation, they use a scale with four options. Unlike our approach, they annotate relations between words as novel or conventionalized. On the one hand, this is a sensible approach because generally the context of a word determines its metaphoricity (and indeed, its novelty in case of metaphoric use). On the other hand, such annotations lack the flexibility and ease of use of token-based annotations for which the context is not defined a priori.

We tackle the lack of data by annotating an existing corpus using crowdsourcing; i.e., by splitting up the task in many small chunks which different, non-expert annotators are instructed to complete. Crowdsourcing has been used for a variety of annotation tasks in NLP, often using different study designs. Snow et al. (2008) obtain good annotation results for five tasks with different setups: two tasks ask for numerical values (affect recognition, word similarity), two other tasks require a binary decision (textual entailment recognition, event ordering), and a final task provides three options for the annotators (word sense disambiguation). Sukhareva et al. (2016) utilize crowdsourcing to annotate semantic frames. They design their task as a decision tree, with annotators moving down the tree when annotating. Mohammad et al. (2016) use crowdsourcing for metaphor and emotion annotation in order to investigate their correlation. They employ an ordering approach to annotation, and only consider verbs that already contain a metaphoric sense in WordNet. Kiritchenko and Mohammad (2016) obtain annotations for sentiment associations via crowdsourcing. They use *Best–Worst Scaling* (Louviere and Woodworth, 1990), an annotation approach which creates scores from ranking annotations.

3 Corpus

To obtain a corpus of novel metaphor annotations, we employ an existing metaphor corpus. This can potentially reduce ambiguity for annotators and allows us to focus on the creation of novelty scores. We use the VU Amsterdam Metaphor Corpus (Steen et al., 2010) as the base corpus for our novelty annotations due to its comparably large size and genre diversity. It is comprised of over 200,000 tokens from four genres: *academic*, *fiction*, and *news* texts, and *conversation* transcripts (Table 1). Further, reusing existing annotations enables us to only query annotators for novelty of already annotated metaphors, instead of having them analyze every token.

Using crowdsourcing (Amazon Mechanical Turk), we first conduct a pilot study to choose among four different annotations methods. We then employ the best method to collect annotations and create an additional *novelty score* between 1 (novel) and −1 (conventionalized) for each token labeled as metaphor in the VUAMC. Note that non-content words like prepositions and auxiliary verbs (*have*, *be*, *do*) are filtered out beforehand. Our annotations/scores can be integrated into the original VUAMC resource. We make the annotations and scripts to embed them into the original corpus publicly available.[2]

3.1 Pilot Study

Similar to Dunn (2014), we consider multiple annotation approaches. We compare them in a pilot study using 210 metaphor tokens with their sentence context, randomly chosen from the *fiction* subcorpus. For the sake of a meaningful evaluation, we ensured that 25% of these metaphorically used tokens were novel metaphors. Before choosing one approach for the entire corpus, we compare the following four annotation approaches:

- **binary annotation**: crowd workers decide if a given metaphoric token is used in a novel or conventionalized way;
- **scale annotation**: crowd workers decide on the novelty of a given metaphoric token on a four-point scale, from *very novel* to *very conventionalized*;
- **scale annotation (no metaphor)**: crowd workers decide on the "unusualness" of a given token in its context on a four-point scale, from *I've never heard it before* to *I'm using it everyday*; without giving information that the tokens represent metaphors;
- **best–worst scaling**: crowd workers pick the most novel and the most conventionalized metaphor from four samples.

Conceptually, the *binary annotation* should put the least cognitive load on the annotator, resulting in fast annotation times and efficient completion of the task. However, this method does not allow for nuances in annotation. Dunn (2014) counters this problem by assigning as the score the percentage of "metaphoric" labels for an instance. But this solution is only feasible for smaller datasets, as it requires many annotations per instance to yield nuanced scores.

	IAA	F_1	avg assignment completion time
binary	0.38	0.75	1:39 min
scale	0.32	0.75	1:04 min
scale w/o met.	0.16	0.67	2:10 min
BWS	—	0.84	1:58 min

Table 2: Comparison of the approaches investigated in the pilot study. Shown are inter-annotator agreement (Krippendorff's α, after mapping the scale annotations to binary labels), evaluation against our silver standard (F_1), and average completion time for an assignment (in case of binary, scale, and scale without metaphor this amounts to one decision, for BWS to two). Note that there is no IAA for the BWS approach because no two tuples are the same.

The next two approaches, *scale annotation* and *scale annotation (no metaphor)*, try to mitigate this problem by introducing four options to choose from. We choose a scale of four instead of three options to force the annotators to indicate a preference, rather than allowing a "neutral" answer. The difference between both scale approaches is in the guideline descriptions; for the second scale approach (no metaphor), we remove any mention of metaphor, and instead use paraphrases (e.g., instead of "novel metaphor" we use "I have not seen it before"). Our motivation behind this rephrasing is that we want to avoid confusion especially with regards to very conventionalized metaphors. By strictly asking for novelty of the expression/usage, we potentially simplify the task for the annotator.

The last approach uses *best–worst scaling* (BWS, see also Section 2). It has the advantage of not explicitly asking the annotator for a decision on a singular token/metaphor. Instead, they are asked to compare (four) different metaphors and select the most novel and the most conventionalized. A disadvantage is the higher workload for the annotator, since they have to read four sentences for one assignment.

In Table 2, we give a short overview of inter-annotator agreement (Krippendorff's α), the average completion time of an assignment, and a comparison with our semi-automatically created silver standard (F_1). The latter is built by using the majority vote of all four methods; ties are resolved manually by looking into the individual an-

---

[2] https://github.com/UKPLab/emnlp2018-novel-metaphors

notations. To obtain binary labels from the two scale approaches for majority voting, we map the two "more novel" options to novel, and the other two options to conventionalized. For the BWS approach, we first average the number of novel metaphors from the other three methods. From a sorted, decreasing list of BWS scores we then mark this many metaphors as novel. We compare against our own annotations as a sanity check.

Regarding completion time, we observe that the scale method is the fastest by a wide margin. This discrepancy is somewhat surprising, as the scale method introduces two more options to consider compared to the binary method. Apparently, these additional, intermediate options make it easier for annotators to come to a decision, especially for edge cases. On the other hand, scale without metaphors takes twice as long as the scale method. The latter only differs from the former in its inclusion of *metaphor* in the task description and the labels, which we thus interpret as creating a setting for the annotators where they may expect to have some kind of intuition about the task, and thus are more confident (and faster) in completing. Given the long completion time in conjunction with the lower F_1 score and the very low IAA, it seems clear that omitting the metaphor information and using a more colloquial task description make the scale annotation (no metaphor) by far the most difficult for workers to complete, resulting in the least usable annotations. While best–worst scaling is time consuming as well, it yields the best results with regards to the silver standard ($F_1 = 0.84$) by a large margin. We thus choose BWS for annotating the full corpus. Further details on the pilot study can be found in Wieland (2018).

3.2 Corpus Creation

We design our guidelines (see Appendix A) to be simple, but include redundancy in the description to address frequent misunderstandings and ambiguities. We also explicitly mention idioms and unrecognizable metaphors as cases of conventionalized metaphors, because these were sources of confusion in our pilot study. Unrecognizable here means that a word is used in an established, commonly understood—but not the most concrete—sense; e.g., *hard* in "She fought **hard**." Additionally, the annotators are provided with example metaphors of differing novelty.

After filtering out prepositions and auxiliary verbs (*have*, *be*, *do*) using the POS tags supplied by the VUAMC, we collect annotations covering 15,180 metaphors in total (Table 1). We only include workers located in the US. For creation of the best–worst scaling tuples, and for aggregation of the annotations, we use the scripts provided by Kiritchenko and Mohammad (2016).[3] We use a best-worst scaling factor of 1.5 and four items per tuple. Thus, each metaphor appears in six different best-worst scaling comparisons. This results in 22,770 best–worst scaling items to be annotated.

3.3 Analysis

Overall statistics about our created annotations are shown in Table 1 (along with the already existing annotations). For the sake of this overview, we introduce a threshold $T = 0.5$, and treat metaphors with a BWS score equal to or above this threshold as novel, metaphors with a BWS score below the threshold as conventionalized. For example, in this way the metaphor "[...] the artistic temperament which kept her **tight-coiled** as a spring [...]" (0.514) is treated as novel, while "To **quench** [thirst] is more than to refresh [...]" (0.424) is treated as conventionalized. However, since we provide the scores, this threshold can be adjusted to suit a given application. Note that, while novel metaphors are arguably much more scarce than conventionalized ones, BWS creates scores which are approximately normally distributed, supporting our threshold choice.

Before we conduct a more in-depth analysis of the annotated metaphors, we show some examples. In Table 3, we list four novel and four conventionalized metaphors (as annotated). A good example for a novel metaphor is the description of "words [...] as a **coat-hanger**" in Table 3 (3). This usage cannot be found in dictionaries, and clearly constitutes creative language use. In contrast, the meaning *to experience something bad* of *to go through [a situation]* (ibid., (7)), or the sense *to do/conduct* of *to get [something] done* (ibid., (5)), are strongly conventionalized, as indicated by their inclusion in dictionaries.[4]

We also group the tokens by lemma to examine if certain words are more likely to be used in a novel metaphoric way. Inspecting the mean

no	score	metaphor in context
(1)	0.765	Ron Todd [...] warned that party leaders could not expect everybody to '**goose-step**' in the same direction once the policy had been carried.
(2)	0.750	Westerns have a **gladiatorial**, timeless quality.
(3)	0.735	Allan Ahlberg says: 'In the past, a lot of children's books seemed to be the work of talented illustrators whose pictures looked brilliant framed in a gallery, but when you tried to read the book, there was nothing there, because the words started as a **coat-hanger** to hang pictures on.'
(4)	0.727	thus one can and must say ... that each fight is the singularisation of all the circumstances of the social whole in movement and that by this singularisation, it **incarnates** the enveloping totalization which the historical process is.
(5)	−0.765	If the complaint is proved, a nuisance order is made requiring the defendant to **get** the necessary work done.
(6)	−0.765	Apart from some dark patches on the wall that he hadn't noticed **before**, there was nothing to see.
(7)	−0.774	In relation to the sentence stem 'A girl and her mother ...', girls often produce responses like 'often **go** through a bad patch for a year but once they learn to understand each other, become the best of friends' or 'can help each other with their problems'.
(8)	−0.871	The analyst is then forced on the defensive, explaining why **new** features can not be included because they are technically difficult or prohibitively expensive.

Table 3: Example uses of very novel and very conventionalized annotated metaphorical tokens (bold) in sentence context, according to our aggregated annotations. Scores near 1 denote strong novelty, scores near -1 indicate very conventionalized metaphors.

scores, we see the large conventionalization of words such as *get* (−0.37), *see* (−0.35), or *new* (−0.35). Examples for words used in a mostly novel way are *envelop* (0.53), *incarnate* (0.50), and *thrust* (0.46). In the following sections, we examine the correlations with frequency and POM, which give further weight to the examples.

Further, we investigate how novelty is distributed over the different subcorpora (also see Table 1). Somewhat expectedly, the metaphors used in the academic subcorpus are mostly conventionalized (1.9% novel metaphors). A larger percentage of novel metaphors can be found in the news (2.8%) and fiction (3.0%) subcorpora. The conversation subcorpus shows the least amount of novel metaphors (1.3%), which we interpret as natural—more novel metaphors require some amount of creativity to create, which is arguably easier in writing. We also show the distribution of novel metaphors across POS tags (Table 4). It is striking that the verbs are least represented among the novel metaphors, especially compared to their overall metaphoric occurrence. In contrast, adjectives/adverbs and nouns are more likely to be used in a novel way.

POS	tokens	metaphors	novel metaphors
nouns	47,171	5,513	145
verbs	27,831	6,513	88
adj/adv	45,842	3,154	120

Table 4: Metaphor annotations grouped by POS tags. For this overview, we treat metaphors with a score above $T = 0.5$ as novel.

Correlation with Token Frequency We compare how the token frequency is related to novelty. Intuitively, words that are seldom used should show a higher (average) novelty. In turn, we expect often used words to exhibit a wider range of (already conventionalized) senses, thus having lower (average) novelty. We obtain token frequencies from a Wikipedia dump, and correlate them with the mean novelty scores from our annotations (disregarding part-of-speech tags). The relation in terms of Spearman's rank correlation is $\rho = -0.60$, which indicates a moderate anti-correlation. This can also be observed in Figure 1: while high frequency seems to hint at conventionalized metaphors, low frequency is not necessarily

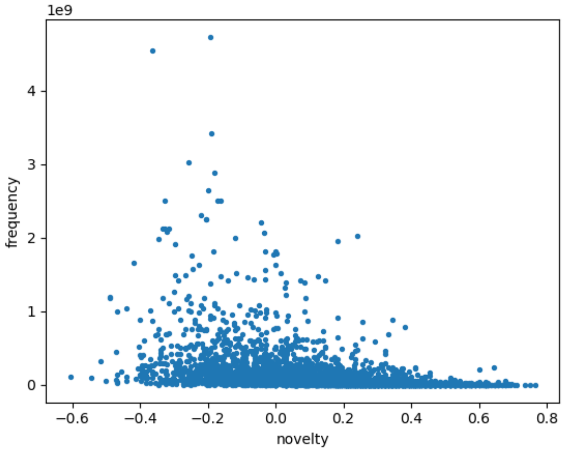

Figure 1: **Frequency.** Relation between average novelty score of metaphoric tokens and their frequency in Wikipedia (correlation of $\rho = -0.60$). Since we use the automatically created POS tags from the VUAMC to filter out non-content tokens, this can include erroneously tagged tokens. For an improved overview, we manually filtered out the five most frequent, incorrectly tagged tokens from this plot (*to*, *as*, *on*, *that*, and *this*).

an indication of novelty of metaphoric use.

Two prominent exceptions are the tokens *national* and *united* (Figure 1, upper right). While they show comparatively high novelty (both labeled as metaphorical only once in the VUAMC), they appear surprisingly often in Wikipedia. Another artifact of using Wikipedia as the background corpus can be seen on the left: *try* is only annotated as metaphoric in infinitive-compounds that are decidedly conventionalized (e.g., "trying to look"), yet it appears comparatively seldom in Wikipedia. However, we chose to use Wikipedia instead of the BNC in order to have an out-of-domain comparison with a more contemporary, larger background corpus.

Correlation with Concreteness The use of concreteness as a feature in automatic metaphor detection grounds in the Conceptual Metaphor Theory (Lakoff and Johnson, 1980). In short, metaphors are modeled as cognitive mappings between an often concrete source domain, and a usually more abstract target domain. For example, in "He **shot down** my arguments," the more concrete domain of ARMED CONFLICT (*shot*) is mapped to the rather abstract domain DISCUSSION (*argument*).

To analyze the relation between novelty and concreteness, we first extend the concreteness list by Brysbaert et al. (2014) using a technique similar to Mohler et al. (2014). For a given token *t*, we extract 20 approximate nearest neighbors *nn(t)* from Google News Embeddings (Mikolov et al., 2013) using Annoy.[5] The concreteness value for *t* is then computed by averaging its neighbors' concreteness values from the concreteness list.

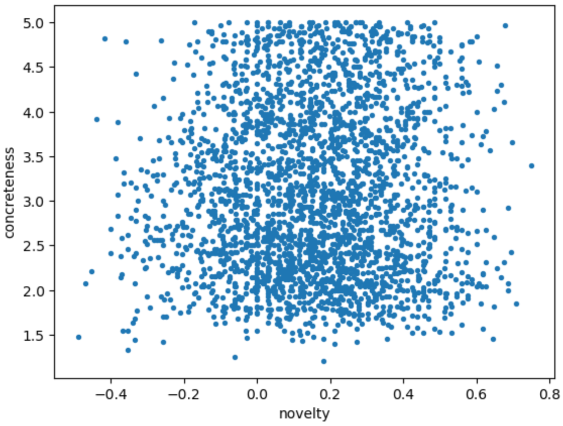

Figure 2: **Concreteness.** Relation between novelty score of metaphoric tokens and their concreteness, showing no discernible correlation ($\rho = 0.03$). A similar picture emerges if we only consider the manually annotated tokens included in the original concreteness list by Brysbaert et al. (2014).

Subsequently, we calculate the correlation between the average novelty and the concreteness of the lemmas. Both Pearson correlation ($r = 0.04$) and Spearman's rank correlation ($\rho = 0.03$) are close to zero and indicate no correlation (Figure 2). Thus, while concreteness has been shown to work well as a feature to distinguish between literal and non-literal language in general (Beigman Klebanov et al., 2014; Tsvetkov et al., 2014), it does not seem useful for discerning between novel and conventionalized metaphoric usage in particular. For example, the rather abstract *now* (1.48) and the very concrete *people* (4.82) are assigned similarly low novelty scores. On the other hand, *justice* has a quite high novelty score (0.65), while also being as abstract as *now*. One reason for this non-correlation between concreteness and novelty might be that the automatic induction of concreteness ratings introduces too much noise. However, an experiment where we only use tokens occurring in the manually composed list (Brysbaert et al., 2014) shows similarly low correlation. This could be influenced by artifacts in the concrete-

---

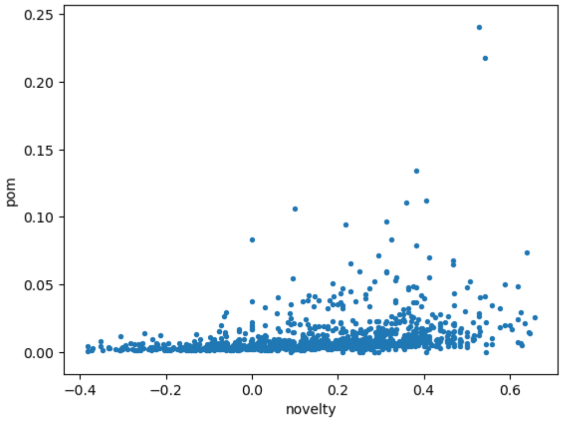

Figure 3: **POM.** Relation between average novelty score of verb lemmas and POM (correlation of $\rho = 0.52$).

ness list: as laid out by Beigman Klebanov et al. (2015), it exhibits some problems. For example, it shows high variance in the annotated concreteness scores for various non-concrete adjectives. But this does not explain the extent of the non-correlation. We thus believe that our results indeed indicate no relation between concreteness and metaphor novelty. And indeed, if a difference of concreteness between components of an expression hints at a metaphor, as is proposed by the conceptual metaphor theory, then it is plausible that it does not hint at novelty of the metaphoric expression at the same time. Consequently, we investigate a feature with more semantic capacity in the next subsection.

Correlation with POM The *Potential for Metaphoricity* (POM) of verbs was introduced by Del Tredici and Bel (2016) (Section 2). It denotes the a priori chance of a verb to occur in highly metaphoric contexts; in essence, it measures the contextual flexibility of a verb. Generally, very novel metaphors also display a high metaphoricity. Therefore, we expect that low-POM verbs (i.e., verbs that occur similarly often in many different contexts) exhibit a low novelty score on average and low variance, while high-POM verbs should show a higher average novelty score. The POM can be regarded as a variant of selectional preference strength, which measures how strongly a verb constrains its direct object in terms of semantic classes. As such, we forgo an analysis of selectional preference violations in favor of examining the POM. Hovy et al. (2013) generalize the notion of selectional preferences to other forms of grammatical relations. However, instead of generating scores, they use dependency trees in an SVM with tree kernels. The POM could be similarly generalized to all POS tags, e.g., by including head and dependent tokens as context.

We create the POM for all annotated verbs using the same procedure as Del Tredici and Bel (2016). First, we extract the context (i.e., subject and object) for each occurrence of a verb from a large, parsed corpus (Wikipedia). To compute context vectors, the word embeddings (Levy and Goldberg, 2014) of subject and object are averaged (if only one of the two is available, the embedding for this token serves as the context). For each verb, the context vectors are then clustered using Birch clustering (Zhang et al., 1996). Finally, the standard deviation between the sizes of the context clusters denotes the POM of the verb.

As with our previous experiments, we compute Spearman's rank correlation between the mean novelty scores of the verb lemmas and the corresponding POMs. We arrive at Spearman's $\rho = 0.52$, which indicates moderate correlation (Figure 3). Verbs like *pique* (POM: 0.218) and *slit* (0.134) are more often used in a novel metaphoric way, while low-POM verbs *show* and *see* (both: 0.01) are only used as conventional metaphors. Even though the correlation is only moderate, it supports the WordNet-based evaluation by Del Tredici and Bel (2016), who found that high-POM verbs generally induced novel metaphoric sentences. Note that their POM values are higher because they optimize the clustering parameters, which we leave at the default setting.

4 Baseline

While the main focus of this work is the analysis of our new annotation layer, we also create a simple baseline regression system for predicting the novelty scores. We run the system using two configurations: first with only word embeddings as input, then augmented with frequency and POM scores.

4.1 System

We implement a single-layer BiLSTM for predicting the novelty score. As input, we use a padded 11-token window (five before, five after the token) of dependency-based word embeddings by Levy and Goldberg (2014) that we also employed for the POM computation. The BiLSTM layer has 50 dimensions and ReLu activation. Training is done in maximally 20 epochs, but can halt earlier due to early stopping on the development set. The data is split into training (50%), development (25%), and test set (25%). We only conduct experiments on verbs, so that we can compare the performance when including additional features.

Following our analysis of typically used features for metaphor detection in relation to novelty, we incorporate the relative frequency of a token into the model, to investigate if the substantial correlation observed in Section 3.3 has an impact on our regression experiments. Further, we include the POM, as it also showed a moderate correlation with novelty. Both additional features are concatenated with the respective word embeddings and the resulting vectors are fed to the BiLSTM.

4.2 Results

We evaluate our results using mean absolute error (MAE), and average it over 10 runs with different random seeds. Recall that the possible values lie between −1 and 1, leading to a possible MAE between 0 (best) and 2 (worst). The baseline results over different runs are stable, we show the regression plot for one configuration in Figure 4.

The mean absolute error for the configuration using only the embeddings is MAE = 0.166. In contrast, we obtain MAE = 0.163 for the same configuration when we add the frequency and the POM features. Thus, while small, the latter model shows improvements over the word embedding baseline. As can be seen in the plot, there is still much room for improvement (e.g., we did not conduct extensive hyper-parameter optimization). The network makes errors both in underestimating ("they can be seen as **riddled** with holes") and overestimating novelty ("veins branching off it to **form** a network"). These errors are in many cases independent from POM and frequency features. Thus, while a better optimization (e.g., in the clustering step when creating the POM) might reduce estimation errors, we also need to consider further features for metaphor novelty estimation.

5 Conclusion

We presented a new layer of novelty scores for the VU Amsterdam Metaphor Corpus, created using crowdsourcing. To this end, we conducted a pilot study to choose an appropriate method for metaphor novelty annotation and found that best–worst scaling outperformed binary and scale methods. Our corpus analysis of typically used features for metaphor detection showed no correlation of novelty with concreteness. However, we found substantial correlation with frequency of tokens in a background corpus and with potential for metaphoricity, a context-based a priori metaphoricity measure. Further, we created a baseline to distinguish novel from conventionalized metaphors. For our approach, the latter two features could improve results only slightly, indicating a need for more sophisticated features.

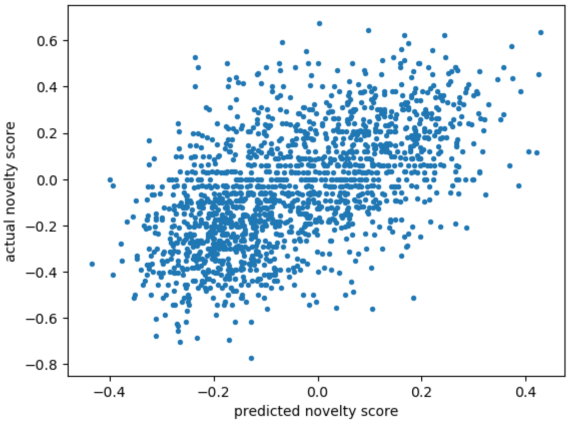

Figure 4: Predicted and actual novelty score of metaphoric tokens in the VUAMC for a baseline configuration (word embeddings only, without adding frequency and POM information).

Previous work in automatic metaphor processing has largely focused on general detection of linguistic and conceptual metaphors, mostly disregarding the subject of novelty. Our corpus enables new evaluation and training possibilities for detecting the latter. In future work, we want to develop more sophisticated methods to detect and distinguish novel metaphors. For example, we want to extend the notion of POM to nouns and adjectives, and investigate other a priori measures for metaphor novelty. Further, we want to jointly detect metaphors and score their novelty. Another interesting direction is to investigate the correlation between perceived novelty and the existence of dictionary definitions for metaphoric senses of a token or expression.

A Guidelines

This task is about metaphors. A metaphor is a figure of speech that describes one thing by mentioning another thing. You can divide metaphors into two types: conventional and novel ones. In the following texts some words are marked as metaphorical.
You will be given four metaphors and your task is to decide which metaphor is the most conventional and which metaphor is the most novel.
Conventional metaphors are metaphors which are often used in everyday language.
In contrast novel metaphors which are usually not used in everyday language.
Please check the instructions and examples below before starting with the HIT!

Instructions and hints:

- Please read the whole context around the metaphors before deciding which metaphor is most novel or most conventional.
- You have to answer two questions per task:

  The first question is which metaphor is most *conventional*. That means you have to select the metaphor which is the most common in everyday language.

  The second question is which metaphor is the most *novel*. That means you have to select the metaphor that is the most uncommon in everyday language.
- Expressions that are so common that you cannot recognize them as a metaphor are candidates for the most conventional metaphor.
- Idioms are rather conventional metaphors.
- Each task is about four metaphors which are marked in red.
- The sentence which contain the metaphor are highlighted in bold letters.
- You have to fully complete all three tasks to get paid.

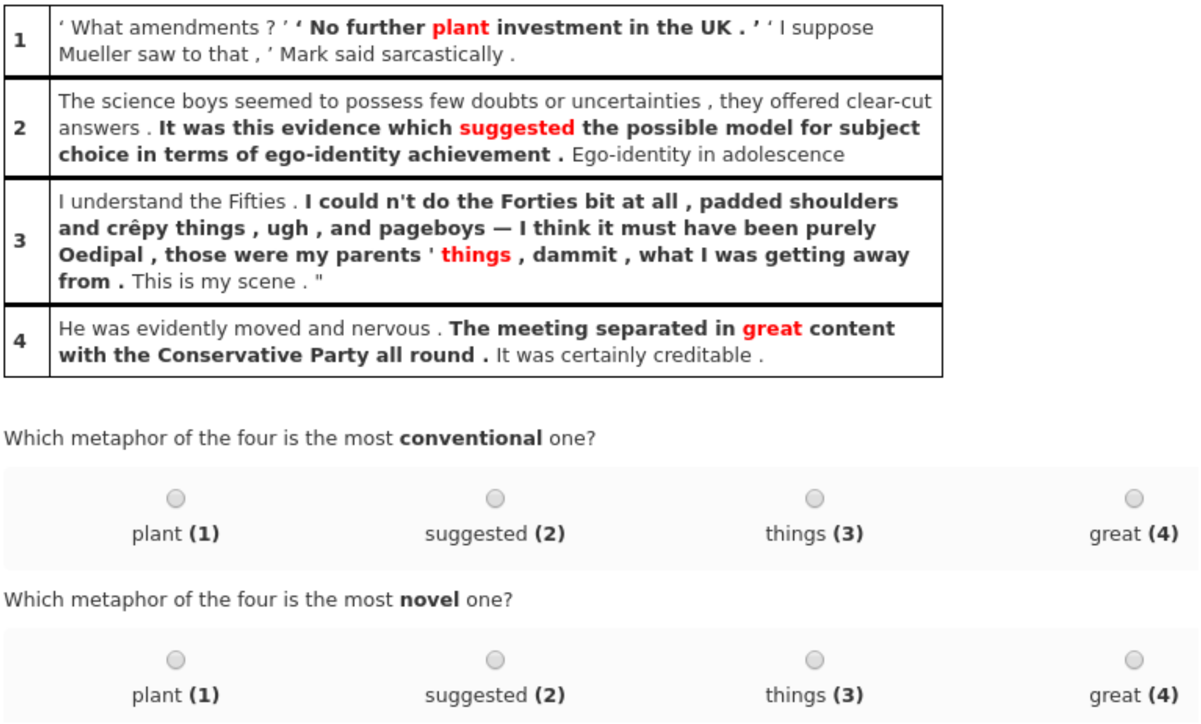
Examples:

1: “She **gave** him that idea.”
2: “I see the **point**.”
3: “Some books have to be **tasted**.”
4: “Time **flies.**”

- Answer: most conventional metaphor: **gave** (1); most novel metaphor: **tasted** (4).
- Explanation: “gave” is in the expression “to give someone an idea” so common that you can barely see the metaphor, that means it is extremely conventional. “to *taste* books” in contrast is a very uncommon use of the word “taste” and thus a novel metaphor. The other two metaphors are idioms which are conventional but not as conventional as “to give someone an idea.”.

Figure 5: Annotation guidelines for best-worst scaling HITs.

B Example of a Best-Worst Scaling HIT



1	‘ What amendments ? ’ **‘ No further plant investment in the UK . ’** ‘ I suppose Mueller saw to that , ’ Mark said sarcastically .

Abstract

Accurately and efficiently estimating word similarities from text is fundamental in natural language processing. In this paper, we propose a fast and lightweight method for estimating similarities from streams by explicitly counting second-order co-occurrences. The method rests on the observation that words that are highly correlated with respect to such counts are also highly similar with respect to first-order co-occurrences. Using buffers of co-occurred words per word to count second-order co-occurrences, we can then estimate similarities in a single pass over data without having to do prohibitively expensive similarity calculations. We demonstrate that this approach is scalable, converges rapidly, behaves robustly under parameter changes, and that it captures word similarities on par with those given by state-of-the-art word embeddings.

1 Introduction

Word similarities play an integral part in many natural language processing applications. Improving similarity estimates will therefore in turn potentially improve a broad range of areas, including word alignment (Songyot and Chiang, 2014), query expansion (Diaz et al., 2016), simplification (Biran et al., 2011), document classification (Arras et al., 2017), lexical substitution (McCarthy and Navigli, 2009) and many more.

The prevalent approach to estimate similarities is to first embed words in a vector space using techniques such as word2vec (Mikolov et al., 2013a,b) and GloVe (Pennington et al., 2014), and then calculate the similarities between words as the similarities between corresponding vectors. Finding all significant similarities among a set of words in this way, however, is computationally demanding due to the large number of pairwise similarity calculations involved (scaling as the square of the vocabulary size at worst). All-to-all similarity calculations are in particular strenuous, if at all feasible, in a streaming setting due to tight latency and memory constraints.

In this paper we address this by proposing a method that *finds significant similarities without calculating any similarities*. This seemingly contradictory feat is possible by explicitly counting *second-order* co-occurrences (SOCOs for short) and calculating correlations with respect to these. Two words w and v are said to have a SOCO if there is a third word u with whom both w and v co-occur (not necessarily together). For example, if the words *hot* and *coffee* co-occur at some point in a corpus or stream, and *hot* and *tea* co-occur at some other point in the same corpus or stream, then *coffee* and *tea* have a SOCO relation since they both co-occur with *hot*. The key observation then, as depicted in Fig. 1, is that *words that are highly correlated with respect to second-order co-occurrences are highly similar with respect to first-order co-occurrences*. This relation enables us to avoid pairwise similarity calculations altogether and instead acquire similarities directly from the SOCO counts.

The contribution of this paper is mainly twofold. Firstly, we introduce an operational definition of SOCO probabilities. To the best of our knowledge, this has not been done before in this explicit manner. Secondly, we apply this definition to efficiently estimate word similarities from streams. In practice we achieve this by keeping small buffers of co-occurred words per context word, and then incrementing SOCO counts of new co-occurred words and those in the buffer. Importantly, this enables us to pass over data only once. To ensure scalability in memory usage and runtime, approximate SOCO counts are then maintained in a count-min sketch table (Cormode and Muthukrishnan, 2005) that keeps the algorithm lightweight.

The benefits of our approach are not only com-

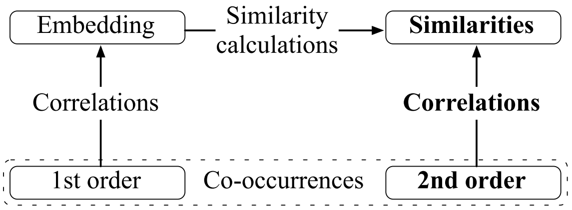

Figure 1: Diagram that describes the relationship between 1st and 2nd order co-occurrences. Instead of first embedding words with regard to 1st order co-occurrences and then calculating pairwise similarities between word vectors, we acquire similarities by directly correlating words with respect to their explicit 2nd order co-occurrences (encompassing labels in boldface).

putational in allowing us to avoid both multi-pass batch processing and the quadratic time complexity that comes with pairwise similarity calculations. Since the method is based on simple counting of SOCOs, it is also completely transparent and interpretable. By comparison, most first-order word embeddings – word2vec and GloVe are again good examples – are relatively opaque and difficult to interpret. The simplicity of our method also makes it straightforward to implement while having only a handful of parameters to tune compared to prevalent embedding methods that typically involve a large number hyperparameters.

The remainder of this paper is outlined as follows: Next we will relate our proposed method to current approaches for calculating word similarities. The method is described in Sec. 3, followed by a complexity analysis in Sec. 4 where we theoretically and experimentally show that our approach indeed is suitable for stream mining. In Sec. 5, we evaluate the method with respect to convergence, accuracy and parameter sensitivity. The paper is concluded in Sec. 6 with a summary and a discussion on possible future directions.

2 Related work

The explicit use of second-order co-occurrences has so far gained little attention in word similarity mining. The typical approach is rather to express word similarities as similarities between vector representations that in turn are based on first-order co-occurrences (this is also the case in (Islam and Inkpen, 2006), despite the name of their approach[1]).

There is a large body of work in this area, predominantly based on Harris' distributional hypothesis (Harris, 1954), from seminal approaches such as LSA/LSI (Deerwester et al., 1990), HAL (Lund and Burgess, 1996) and Random indexing (Kanerva et al., 2000) and onward. See (Levy et al., 2015) for an extensive review. A common approach then is to represent words in terms of co-occurrence correlations – e.g. using Pointwise mutual information (PMI) (Church and Hanks, 1990) and variants thereof (Levy et al., 2015) – either explicitly or through dimensionality reduction (Pennington et al., 2014). Another prevalent approach is to generate vector representations based on prediction tasks, where words are predicted from their contexts or vice versa; Continuous bag of words and Skip-gram (Mikolov et al., 2013a,b) are prominent examples. However, these methods are batch-based and typically require multiple passes over data (3 to 50 training epochs in the case of word2vec, for instance (Mikolov et al., 2013b)). Approaches that are more suitable for streaming data have also been developed, e.g. for calculating the most PMI-correlated words per word (Durme and Lall, 2009) and, more recently, neural network methods (primarily based on Skip-gram) adapted to enable incremental updating (Luo et al., 2015; Kaji and Kobayashi, 2017; Bamler and Mandt, 2017; Peng et al., 2017). Note though that in all of the above cases vector representations capture *first-order* co-occurrences. When using PMI for example, the correlation between two words is high if they co-occur more frequently than expected from chance, but high correlation does not equate high similarity (consider the words *red* and *wine* for example). Estimating word similarities would therefore require the extra step of calculating similarities between vectors, something that our approach bypasses by explicitly counting SOCOs.

3 Method

3.1 Second-order co-occurrences

We define the SOCO probability of words w and v as

$$P(w\!:\!v) := \sum_{u\in\mathcal{V}} P(u)P(w|u)P(v|u), \tag{1}$$

where $w\!:\!v$ denotes a SOCO and $\mathcal{V}$ is the vocabulary. That is, $P(w:v)$ is the probability that two

---

[1] In general, the term *second-order co-occurrence* is sometimes used in NLP to describe second-order representations based on first-order word vectors, such as in (Schütze, 1998). This does not involve explicit SOCO counts as in our case though.

randomly selected words co-occurring with a randomly selected word u are w and v. Since

$$\begin{aligned} P(w\!:\!v) &= \sum_{u\in\mathcal{V}} P(w,u)P(v|u) \\ &= \sum_{u\in\mathcal{V}} P(w)P(u|w)P(v|u), \end{aligned} \tag{2}$$

an alternative interpretation of SOCO is the chain of randomly selecting a word w, one of its co-occurring words u, and in turn one of *its* co-occurring words v.

3.2 Correlation measure

Our ansatz is that two words have a high degree of similarity if they are highly correlated with respect to SOCO, since this would imply that the words are relatively interchangeable in their respective contexts. We quantify a SOCO correlation using standard pointwise mutual information (PMI):

$$M(w\!:\!v) = \log_2 \frac{P(w\!:\!v)}{P(w)P(v)}, \tag{3}$$

where the denominator is the SOCO probability of w and v given that they are independent of u, since then

$$P(w\!:\!v) = \sum_{u\in\mathcal{V}} P(u)P(w)P(v). \tag{4}$$

3.3 Estimating correlations

Making the simplifying assumptions that a stream is stationary and that co-occurrence correlations decay rapidly with word-to-word distance in the stream (or corpus), we can estimate Eq. 3 in one pass using counters of word occurrences and SOCOs. See Fig. 2 for a schematic overview and Algorithm 1 for a detailed description of our approach.

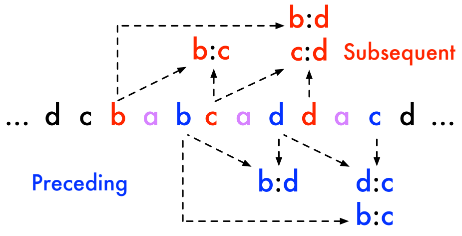
3.3.1 Co-occurrence buffers

Approximate SOCO counts are maintained by keeping small buffers (on the order of 1 to 10 words) of previously observed words with a given context. The context of a word is here given by the position relative to the word (say, -1 for the preceding word) and the word occupying that position. For example, if we observe the word *fox* in the sequence

> *The quick brown fox jumps over the lazy dog.*

fox is added to the buffer of previously observed words with context (-1, *brown*) (*bear*, *bag* and *eyes* perhaps). Note that *fox* then has a SOCO relation with the words in the buffer. The SOCO counters of (*fox*, w) for all words w in the buffer are therefore incremented (for (*fox*, *bear*) for instance) before *fox* is added to the buffer. If the buffer is full – we cap the number of prior words stored – the oldest word is discarded prior to adding the new one.

(a) Second-order co-occurrences



(b) Co-occurrence buffers

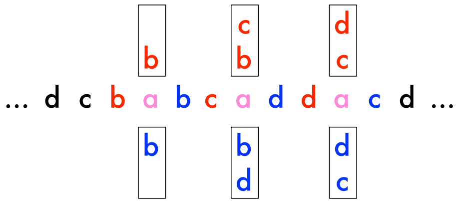


Figure 2: (a) Words that share a context word (the word a in this example) at a given position (as a preceding and subsequent word, in blue and red, respectively) are said to co-occur to the second order. For example, b and c have a SOCO relation $b:c$ since they both have a as a subsequent word. (b) We count second-order co-occurrences by keeping buffers of co-occurring words for a given context. The buffer for context (1, a) is shown above the sequence (i.e., when a occurs as a subsequent word) and (-1, a) below the sequence (a as a preceding word). Both buffers (implemented as queues, where the most recent observations are stored) are limited to two words in this example. Before a word is added to a buffer, the second-order co-occurrence counts of the word and the words in the buffer are incremented. For instance, the counts of $b\!:\!d$ and $c\!:\!d$ are incremented before the buffer $[c, b]$ is updated to $[d, c]$.

The same procedure is performed for all context positions in a sliding window of a given length (e.g., for positions $\{-2, -1, 1, 2\}$ if we consider symmetric contexts in a five-word window). By simultaneously estimating word frequencies by counting current words we can in this way incrementally maintain estimates of $M(w\!:\!v)$.

3.3.2 Probabilistic counting

Since the number of SOCOs may be very large, we keep approximate counts of these using a count-min sketch table (Cormode and Muthukrishnan, 2005). The table, denoted d, has h rows and g columns, where the rows are associated with h pairwise independent hash functions, f_i, and where entries are initialized to 0. When a SOCO $w : v$ for words w and v is observed, each hash function maps $w : v$ to an index $f_i(w : v)$ of row i. Entry $(i, f_i(w\!:\!v))$ is then incremented by 1.

After populating d the approximate count of $w\!:\!v$ is given by the minimum count of the entries $(i, f_i(w\!:\!v))$:

$$\tilde{c}(w\!:\!v) = \min_i d(i, f_i(w\!:\!v)). \tag{5}$$

Note that $\tilde{c}$ may overestimate the true count $c(w\!:\!v)$ due to hash collisions (this is indeed what keeps the data structure sublinear with respect to the number of SOCOs). To reduce overestimations we can employ conservative updates by only updating an entry $(i, f_i(w\!:\!v))$ if it is exceeded by the current incremented approximate SOCO count (Goyal et al., 2012):

$$d(i, f_i(w\!:\!v)) \leftarrow \max\{d(i, f_i(w\!:\!v)), \tilde{c}(w\!:\!v)\}. \tag{6}$$

This is the approach used in all experiments presented below.

3.3.3 Top-k correlations

Rather than storing all SOCO correlations, which is infeasible for large vocabularies and wide context ranges, we keep track of the k most correlated words for each word in the vocabulary. We achieve this scalably by adapting the approach proposed by Durme and Lall for calculating first-order co-occurrence correlations in streams (Durme and Lall, 2009). We keep track of occurred SOCOs in non-overlapping meta-windows (on the order of 10^5 to 10^7 tokens long). For each meta-window, we calculate PMIs for occurred SOCOs using exact word counts (having a comparably small memory footprint) and approximate SOCO counts, and then update priority queues with the most similar words per word accordingly. In this way the number of SOCOs stored is kept approximately constant as we consume the stream.

4 Complexity analysis

4.1 Time

For each token in the stream, updating word counts takes constant time using an associative array. The algorithm also goes through $2n$ context words, where n is the context range. For each context word, the count-min table that stores approximate SOCO counts is updated at most r times, where r is the maximum buffer size. Since each update takes $O(h)$ time for a count-min table with h rows (a hash function is called for each row), the time complexity for updating counters is $O(nrh)$. Updating a co-occurrence buffer, i.e. by inserting and (possibly) deleting a word index in a queue, takes $O(1)$ time, and so the total time complexity per token when consuming a meta-window is $O(nrh)$.

Algorithm 1 Estimate $M(w\!:\!v)$ for stream $[s_1, s_2, ..., s_m]$, vocabulary $\mathcal{V}$, context range n, buffer capacity r, meta-window size N and count-min (C-m) table with h rows and g columns. Note that m may approach infinity.

```
$l \leftarrow \{-n, ..., -1, 1, ..., n\}$ {context positions}
$c(w) \leftarrow 0; w \in \mathcal{V}$ {word counts}
$d_{i,j} \leftarrow 0; i = 1, ..., g, j = 1, ..., h$ {C-m table}
$t_w \leftarrow 0$ {total word count}
$t_s \leftarrow 0$ {total SOCO count}
$q(i, w) \leftarrow \emptyset; w \in \mathcal{V}, i \in l$ {context queues}
$\mathcal{S}(w) \leftarrow \emptyset; w \in \mathcal{V}$ {similar word queues}
$\mathcal{P} \leftarrow \emptyset$ {observed SOCOs}
for $i = n + 1$ to $m - n$ do {consume stream}

Between meta-windows, we update the top cor-

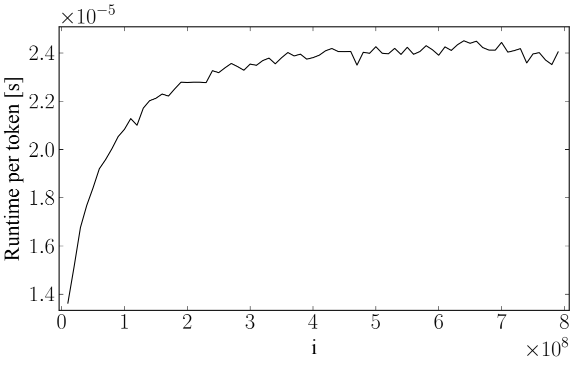

Figure 3: Runtime per token at stream position i (Python implementation run on a MacBook Pro with a 2.8 GHz Intel Core i7 processor and 16 GB of memory).

related words per word. We first update frequency estimates of words, which takes $O(|\mathcal{V}|)$ time. For each SOCO that has been observed in the meta-window, $|\mathcal{P}|$ of them, we update the priority queues with the most correlated words of the words involved in the SOCOs. Each such update takes $O(\log k)$, where the parameter k is the number of most correlated words of a word.

Altogether, the time complexity is hence $O(nrh + \frac{|\mathcal{V}|+|\mathcal{P}|\log k}{N})$ per token. Note that $n, r, h, k \ll |\mathcal{V}|, |\mathcal{P}|$, where n, r, h and k are all small fixed parameters ($n \sim 1$ to 10, $r \sim 10$, $k \sim 10$ to 100 and $h \sim 10$ typically). Given that the stream is roughly stationary (which has been the case in our experiments), the size of $\mathcal{P}$ is approximately constant. With a fixed vocabulary and N, the runtime per token is therefore also kept approximately constant. We confirm this experimentally, see Fig. 3, by running the algorithm on English Wikipedia (as of March 7, 2015) using a context range of one (window size three), a vocabulary constituted by the 10^4 most frequent words, meta-windows of length 10^7 and five-word co-occurrence buffers, a count-min table with 8 rows and $3.4 \cdot 10^7$ columns, and where the 10 most similar words per word are stored. As expected, the runtime per token increases initially as the co-occurrence buffers are filled up, and then converges towards a constant value.

4.2 Space

With regard to memory the algorithm requires that we keep a co-occurrence buffer for each word in the vocabulary and for each context position. The space complexity of the buffers is therefore $O(nr|\mathcal{V}|)$. In addition, there are $|\mathcal{V}|$ word counters and priority queues of size k for storing top-k similar words, a count-min sketch table with gh entries, where the fixed parameter g is the number of columns in the count-min table, and a index pair set of size $|\mathcal{P}|$ for storing occurred SOCOs that have occurred in a meta-window. The total space required is hence $O((nr + k)|\mathcal{V}| + gh + |\mathcal{P}|)$.

For example, assume we have a vocabulary with a million words, a context range of 5 (i.e., window size 5+1+5), a buffer size of 10, a count-min table with $3 \cdot 10^8$ columns and 8 rows, and that we keep the 10 most similar words per word. We then need to store $10^6 \cdot 2 \cdot 5 \cdot 10 = 10^8$ items in the co-occurrence buffers. If each item requires 4 bytes (a word index constituted by an unsigned integer), the buffers take up 400 MB of space. Add to that another 4 MB for the word counters (10^6 of them à 4 bytes), 40 MB ($10^6 \cdot 4 \cdot 10$ bytes) for the top 10 similar word indices per word and 9.6 GB ($8 \cdot 3 \cdot 10^8 \cdot 4$ bytes) for the count-min sketch table. Set the meta-window length so that $|\mathcal{P}| \leq 7.4 \cdot 10^8$ (taking up a bit less than 6 GB of memory at most) and we end up with a total footprint of approximately 16 GB – a memory requirement even met by many present-day laptops.

5 Evaluation

5.1 Examples

In Table 1 we show a set of examples of the most SOCO-correlated words per word as output by the algorithm (using Wikipedia, a context range of 2, buffer size of 10 and a count-min table with 8 rows and $2.7 \cdot 10^8$ columns). Although the examples are anecdotal, they illustrate that the method manages to mine word similarities that make intuitive sense, such that *Wednesday* is most similar to other days in the week (interestingly, it is most similar to adjacent days, *Tuesday* and *Thursday*) and *yellow* is most similar to other colors, etc.

5.2 Convergence

It is crucial that the method converges within a reasonable amount of time in order for it to be of practical use. To test this we run the algorithm and measure how the sets of top-k similar words change as the stream progresses. We quantify these changes using the Jaccard index between a word set of a word w at position i in the stream, $\mathcal{S}_i(w)$, and the corresponding word set at Δi tokens prior,

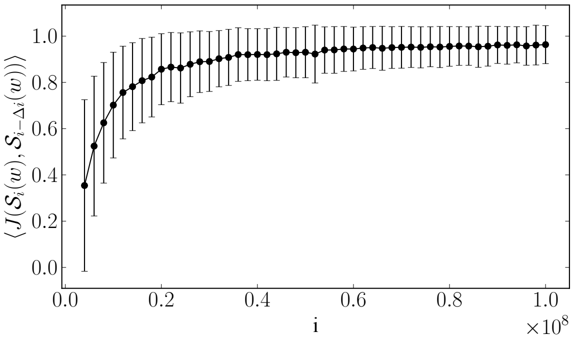

Figure 4: Average change of top-k word sets over words at stream position i. Standard deviation shown by error bars.

$\mathcal{S}_{i-\Delta i}(w)$. That is,

$$J(\mathcal{S}_i(w), \mathcal{S}_{i-\Delta i}(w)) = \frac{|\mathcal{S}_i(w) \cap \mathcal{S}_{i-\Delta i}(w)|}{|\mathcal{S}_i(w) \cup \mathcal{S}_{i-\Delta i}(w)|}, \tag{7}$$

where $J = 1$ if there is no change and the sets are identical. As seen in Fig. 4, the top-k sets converge as both the mean of $J(\mathcal{S}_i(w), \mathcal{S}_{i-\Delta i}(w))$ over words w tends towards one while the standard deviation decreases. In this experiment, applied on Wikipedia and a vocabulary of 10^4 words, the top ten words per word were stored. Further, $\Delta i = 10^6$ tokens, contexts of range one, a count-min table with 8 rows and $3.4 \cdot 10^7$ columns, and co-occurrence buffers of size five were used.

5.3 Accuracy

To quantitatively evaluate the accuracy of the method, we use a collection of established word similarity benchmarks: SimLex-999 (SIMLEX) (Hill et al., 2015), SimVerb (SIMVERB) (Gerz et al., 2016), MTurk-287 (MT-287) (Radinsky et al., 2011), MTurk-771 (MT-771) (Halawi et al., 2012) and WordSim (WS-353) (Finkelstein et al., 2001). Each of these benchmarks contains a set of word pairs and their similarities as judged by human annotators. Comparing these word rankings with rankings given by Eq. 3, we get an indication of how well our method captures human notions of similarity and relatedness. The agreement is quantified with the standard Spearman's rank correlation coefficient.

The results are also compared to the ranking agreements for popular word embeddings – GloVe (Pennington et al., 2014) (GLOVE), Continuous Bag of words (CBOW) and Skip-gram (SGM) (Mikolov et al., 2013a,b) – as well as for the pointwise mutual information between regular first-order co-occurrences (FOCO). In all these cases, word similarities are given by the cosine similarity,

$$\sigma(v_i, v_j) = \frac{v_i \cdot v_j}{|v_i|_2 |v_j|_2}, \tag{8}$$

where v_i and v_j are vectors associated with words i and j. All word embeddings are in 300 dimensions. Remaining parameters are set to default values, with the exception that no explicit word count thresholding is used in order to avoid loss of benchmark words. (Applying thresholds at 3-5 occurrences gives comparable results as those reported here, but for fewer word pairs.) For all benchmarks the One billion word corpus[2] (Chelba et al., 2013) is used with a vocabulary consisting of the $3 \cdot 10^4$ most frequent words, except the Stanford CoreNLP stopwords.[3] A context range of 2, count-min tables with 8 rows and $3.4 \cdot 10^7$ columns, and a buffer size of 10 are used throughout. Since many word pairs in the benchmarks are dissimilar we keep all SOCO correlations for the benchmark word pairs in this experiment. A small fraction of benchmark words are either not present in the corpus or captured by SOCO or the embedding methods due to sampling. To ensure a fair comparison between methods, only word pairs that are represented by all approaches are therefore considered.

The results are summarized in Table 2, where we note that the coverage (the fraction of benchmark pairs represented) is high, from 95% for MT-287 to 99% for SIMLEX. The relative performance of SOCO varies over benchmarks: in two out of five cases the performance is roughly on par with SGM, and compared to GLOVE, CBOW and FOCO, our method performs best in three out of five benchmarks. Thus the overall picture is that our approach indeed is able to capture meaningful similarity relations, and that it performs comparably to regular first-order word embedding methods.

5.4 Parameter sensitivity

The algorithm has two key parameters: the co-occurrence buffer capacity and the size of the count-min sketch table. Since the approximation errors induced by the latter is thoroughly analyzed in (Cormode and Muthukrishnan, 2005) we will here focus on how the buffer size influences similarity accuracy. Using the same corpus and benchmark suite as in Sec. 5.3, we evaluate how the accuracy varies with the buffer capacity. To again make a fair comparison, we then only include those benchmark word-pairs that are covered in all experiments.

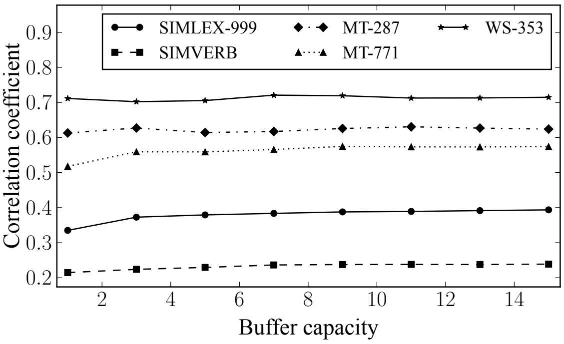

Figure 5: Spearman's rank correlation coefficients for different benchmarks and buffer capacities.

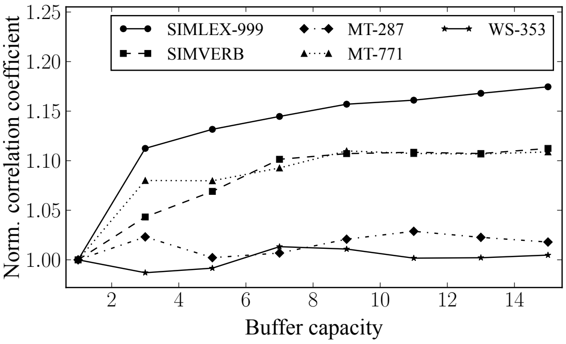

Figure 6: Relative Spearman's rank correlation coefficients with respect to correlations at buffer capacity 1 for different benchmarks and buffer capacities.

As seen in Fig. 5, the method is insensitive to the buffer capacity size as the accuracy stays approximately constant for buffers of sizes larger than 3. This is also the case in relative terms: see Fig. 6 where we plot the accuracy relative to the accuracy for buffers of size 1. The improvement is then largest for SIMLEX-999, where going from buffers of size 1 to 15 yields an approximate difference of 17% in accuracy. The relative accuracy, however, varies little from buffer capacity 3 and upward. With regard to coverage, see Fig. 7, the buffer capacity has a significant effect up until buffer size 9, after which the coverage settles at around 95-99%.

We can conclude that the method is robust with regard to buffer capacity, resulting in predictable and smooth changes in output, and that it suffices to keep small buffers to maintain both accuracy and coverage. Since the buffers in effect tend to store the most frequent co-occurrences per word, these results indicate that it is possible to accurately estimate similarities using only salient co-occurrences. This is also supported by Polajnar and Clark's finding (2014) that only a handful of the most frequent context words yields the best results when estimat-

ing similarities from co-occurrence frequencies.

6 Conclusions

We have presented a method for estimating word similarities from corpora or streams using an explicit notion of SOCO. Our approach is simply to count such co-occurrences and calculate correlations between words with respect to these counts. Words that are highly correlated are then also highly similar with respect to first-order co-occurrences. By using co-occurrence buffers and count-min sketches for estimating SOCO counts, the method keeps both the runtime per token and memory usage constant while only needing one pass over data. These properties makes our approach ideal for low-cost stream mining.

Despite its simplicity and modest computational requirements, benchmark experiments show that the method performs comparably to calculating similarities between best-in-class word vectors. This not only makes our approach a feasible alternative for calculating word similarities on the cheap, but in some cases it may be the only viable option. Consider for instance an embedded system in a decentralized machine learning or edge computing scenario. Then real-time computing constraints and scarce memory would rule out both multi-pass word embeddings and pairwise similarity calculations in favor of similarities readily available from SOCO counts.

There are numerous possible future directions, exploring correlation measures other than PMI being one. Also, by grouping words in concurrence with finding top-k similar words per word, an extended method could be used for word clustering. Possible ways to find groups of inter-similar words – constituting abstract concepts (Görnerup et al., 2017) – is then to use label propagation on a graph (Raghavan et al., 2007) (with words constituting vertices and the top-k similar words directed edges), or agglomerative hierarchical clustering. How to do this efficiently and scalably is currently under study. Moreover, in this paper we have exclusively considered text data and word similarities. The method, however, is domain-agnostic and may be applied on other types of data, in and beyond the NLP domain. There is a wide range of potential application areas, presumably in everything from biology and physics to social science and economics – in essence in any domain where objects co-occur and where these co-occurrences carry some relevant information or meaning.

Acknowledgments

The authors thank the anonymous reviewer for bringing to their attention the link between most frequent co-occurrences and the sufficiency of small buffer sizes.

Abstract

Distributional semantic models (DSMs) generally require sufficient examples for a word to learn a high quality representation. This is in stark contrast with human who can guess the meaning of a word from one or a few referents only. In this paper, we propose Mem2Vec, a memory based embedding learning method capable of acquiring high quality word representations from fairly limited context. Our method directly adapts the representations produced by a DSM with a longterm memory to guide its guess of a novel word. Based on a pre-trained embedding space, the proposed method delivers impressive performance on two challenging few-shot word similarity tasks. Embeddings learned with our method also lead to considerable improvements over strong baselines on NER and sentiment classification.

1 Introduction

Humans can learn a new word quickly from minimal exposure to its context, as in the following example:

> The *Labrador* runs happily towards me, barking and wagging its tail.

Even this is the first time one hears about *Labrador*, we can guess it should be an animal or even further a dog easily, since it runs, barks and has a tail. Such ability to efficiently acquire representation from small data, namely fast mapping, is thought to be the hallmark of human intelligence that a cognitive plausible agent should strive to reach (Xu and Tenenbaum, 2007; Lake et al., 2015).

However, as the mainstream of text representation learning in NLP, most distributed semantic models (DSMs) don't fare well in tiny data (Lazaridou et al., 2017; Herbelot and Baroni, 2017; Wang et al., 2016). Even if they have learned a lot of words, they still need sufficient examples to acquire a high-quality representation for a novel word. This not only constitutes a blow to DSM's cognitive plausibility but also limits its practical usage in NLP. Because plentiful enough data is not always available, especially in domain specific tasks. Even if a large corpora is at hand, low-frequency words in it are still more than highly frequent ones, according to the Zipfian distribution of natural language.

Given the above reasons, it's desirable to build a word embedding method capable of acquiring high quality representations with limited contexts, i.e., few shot word representation learning. We take lessons from hypothesis constraint (HC) theory to achieve this goal. HC is an influential proposal for human's fast mapping (Xu and Tenenbaum, 2007). It indicates that people learn a new word by eliminating incorrect hypotheses about the word meaning, based on usage of the target word and prior knowledge of context words. This is instructive to us since embedding a word in the high-dimensional vector space also faces nearly unlimited candidate hypotheses (Wang et al., 2018) . General DSMs can't efficiently handle these candidates, so they fall back on multiple context examples to find the path, while we propose to let a memory show the way. We augment DSM with an longterm memory to transfer knowledge from a large general domain corpora to adapt the representation learning on the small text. In context of the HC theory, we directly constrain the hypothesis a DSM makes about the target word by its current usage and prior knowledge acquired from a large corpora. Experiments show our method makes educated guess of a novel word efficiently with fairly limited examples, just as humans do in the fast mapping.

It's worth noting that us attaching importance

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1435–1444
Brussels, Belgium, October 31 - November 4, 2018.

to few-shot word representation learning doesn't mean we need to learn words, no matter frequent or rare, all in the few-shot way. DSMs have done pretty well in frequent words learning with large corpus. We augment a DSM with an external memory for few-shot representation learning, under the assumption that gradual acquisition of frequent words plus fast learning of rare words make an integrated word representation learning scheme. Our ultimate goal is certainly an all-round architecture that learns text representations from any amount of data. We believe Mem2Vec, which bridges the word representation learning from big data to small text, will be a building block of that ideal architecture.

The primary contribution of this work is a memory augmented word embedding model with a fast adaptation mechanism, capable of learning representations efficiently from tiny data. Experimental results show that the proposed Mem2Vec learns high quality target word representation with both single informative sentence and a few casual sentences as contexts. To show its performance in downstream applications, Mem2Vec is used to pre-train embeddings for three NER tasks and also surpasses strong baselines. Since our model transfers from general domain corpus to a target small text, it is highly possible to face the problem of domain shift. Mem2vec is impressively competent in tackling domain shift, as demonstrated in a series of cross-domain sentiment classification tasks.

2 Related Work

Rare Word Embedding Acquiring representations for rare words has long been a well-known challenge of natural language understanding (Herbelot and Baroni, 2017; Wang and Zong, 2017). Khodak et al. (2018) learn a linear transformation with pretrained word vectors and linear regression, which can be efficient adapted for novel words. Lazaridou et al. (2017) directly sum the context embedding of a novel word as its representation, based on a pre-trained embedding space. Though not explicitly stated, their idea actually matches the HC theory. They constrain the hypothesis solely within the current context of the target word which we think is not enough. We constrain the hypothesis with memory and the context. Another strand of solutions rely on auxiliary information, such as morphological structure (Luong et al., 2013; Kisselew et al., 2015) and external knowledge (Long et al., 2017). Lazaridou et al. (2013) derive morphologically complex words from sub-word parts with phrase composition methods. Ling et al. (2015) read characters of the rare word with a bidirectional LSTM to deal with open vocabulary problem in language modeling and NER. Hill et al. (2016) learn an embedding of a dictionary definition to match the pre-trained headword vector, while Weissenborn (2017) refines the word embeddings with explicit background knowledge from a commonsense knowledge base. Different from this strand of work, our method doesn't fall back on auxiliary information. We acquire knowledge from a large unlabeled general domain corpora which is widely available.

Cross Domain Word Embedding The knowledge accumulation phase of our model aims to learn an embedding space from a large general domain corpora. This is partially in line with cross domain word embedding work. Among these work, a strand of approach hypothesizes that a word frequent in multiple domains should mean nearly across these domains. Bollegala et al. (2015) call such word pivot, share its embeddings across domains and use them to predict the surrounding non-pivots. Yang et al. (2017) selectively incorporate source domain information to target domain word embeddings with a word-frequency-based regularization. These pivot-based methods have delivered improvements on sentiment analysis and NER. However, they have a defect that only limited target domain words benefit from the knowledge transfer.

Memory based Meta Learning Memory augmented neural networks (MANN) are widely used in different tasks for efficient recall of experience and fast adaptation to new knowledge (Bahdanau et al., 2014; Merity et al., 2017; Miller et al., 2016; Grave et al., 2017; Sprechmann et al., 2018; Wang et al., 2017). Intuitively, Meta-learning, which aims to train a model that quickly adapts to a new task, should benefit from memory architecture, and empirically it does do (Santoro et al., 2016; Duan et al., 2016; Wang et al., 2016; Munkhdalai and Yu, 2017; Kaiser et al., 2017). The memory we use is closely related to (Kaiser et al., 2017), but still get three major differences. First,they only retrieve the single nearest neighbor from the memory while we retrieve an average of the K nearest neighbors weighted by how they match the current context. Second, they focus on supervised learn-

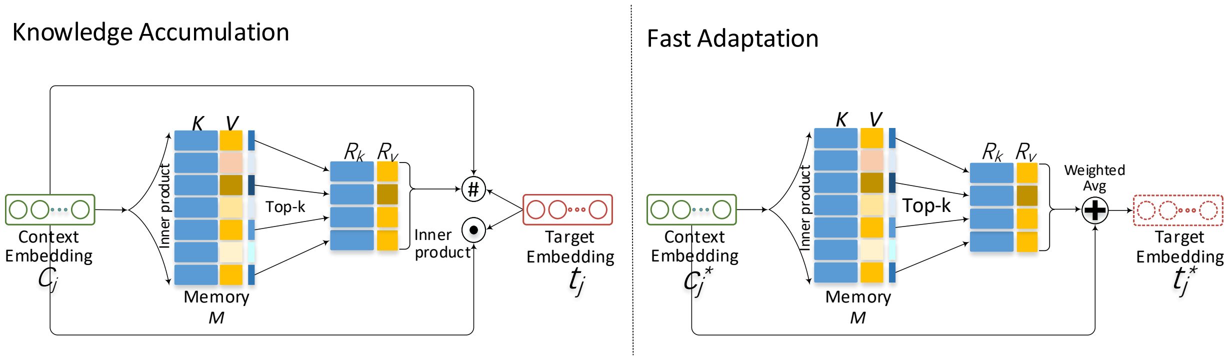

Figure 1: The proposed model architecture. *K* and *V* respectively denotes the key and value vector of the memory. # refers to equation(3). Left: Knowledge accumulation phase. The model learns word embeddings and store prototypes in memory. Right: Fast Adaptation phase. Prototypes retrieved from memory with the given context are combined with the context embedding to form the target word representation.

ing and don't have a fast adaptation mechanism for acquiring representation. Third, they update the memory according to whether the returned value is strictly the same as the target. However, synonyms are common in natural language text. We thus take a softer criterion and update the memory according to vector similarity between the addressed value and the target word embedding.

3 Methods

Our model in brief is a neural network based DSM augmented by a longterm memory. As showed in Fig.1, it operates in two consecutive phases, first accumulating knowledge and then doing fast adaptation on new words, just as the human learning process goes. In the knowledge acquisition phase, we train the memory augmented DSM to learn a semantic space. We also accumulate similar contexts of target words in the memory and gradually form "prototype" representations. The pre-trained embedding space and the saved prototypes are just the knowledge acquired. The fast adaption phase occurs when we need to learn a new word from minimal context. In this phase, we directly combine the context embedding and retrieve content from the memory to form the target word representation.

In the following sections, we will first introduce the memory architecture and the content based addressing. We then detail how exactly our model runs respectively in the knowledge accumulation and fast adaption phase.

3.1 Memory Addressing

M is a non-parametric key-value memory which stores a key-value pair (k_i, v_i) in each memory slot i. Inspired by (Kaiser et al., 2017), we keep an additional vector A tracking the age of slots. The initial age of all is zero. So the whole memory M looks like $(K_{m\times ks}, V_m, A_m)$ where m denotes memory size and ks denotes key vector size. Given a normalized query q, its nearest neighbor in M is defined as any of the keys that maximize the cosine similarity with q:

$$\mathrm{NN}(q, M) = \arg\max_i \; q \cdot K_i. \tag{1}$$

During training, a query to the memory M searches k nearest neighbors which is a natural extension to (1):

$$(n_1, ..., n_k) = \mathrm{NN_k}(q, M). \tag{2}$$

We take an average weighted by how the addressed memory slots match the query:

$$R_K, R_V = \sum_{k=i}^{K} \mathrm{softmax}\left(\frac{q \cdot M[n_k]}{\sqrt{d_k}}\right) \cdot M[n_k]. \tag{3}$$

This is actually a dot-product attention on the k nearest neighbors. R_K, R_V are the final output of the memory. Note that here we use softmax with temperature T:

$$softmax(a) = \frac{\frac{e^a}{T}}{\Sigma_{i=1}^{n}\frac{e^i}{T}}. \tag{4}$$

T is normally set to 1. Using a higher value for T produces a softer probability distribution. We set different temperatures in the knowledge accumulation and fast adaptation phase, which will be detailed in the following subsections.

3.2 Knowledge Accumulation

Given a target word embedding t_j with its context embedding c_j as input, we query the memory with c_j as (1)-(3) and retrieve R_k, R_V. The semantic relation between the current example and the retrieved content from memory is hoped to be consistent from context to target words, so we derive the following loss:

$$\mathcal{L}_m = \sum_{t_j, c_j \in D} log\sigma\left((R_K - R_V) \cdot (c_j - t_j)\right) \quad (5)$$

We also hope the target word representation fully incorporates context information and stay far from negative examples, so we also inherit the loss from (Mikolov et al., 2013):

$$\begin{aligned} \mathcal{L}_s = \sum_{t_j, c_j \in D} \#(t_j, c_j)\Big(log\sigma(t_j \cdot c_j) \\ + \sum_{i=1}^{k} \mathbb{E}_{p_i \sim P(t_j)}[log\sigma\ (t_j \cdot -p_i)]\Big), \end{aligned} \quad (6)$$

where D denotes the whole corpora, and $\#(t_j, c_j)$ means times the target and the context word cooccur. The word p_i is a negative sample sampled from the distribution $P(t_j)$, as Mikolov et al. (2013) do. We minimize the sum of $\mathcal{L}_m$ and $\mathcal{L}_s$:

$$\mathcal{L} = \mathcal{L}_m + \mathcal{L}_s \quad (7)$$

Memory Update. After each query, we update a memory slot according to how frequently the key is addressed and how useful the addressed value is. The update is done piecewise according to similarity between the addressed values $(V_{n_1}, ..., V_{n_k})$ and the target word. For all the addressed values V_{n_i} whose similarity to the target word is higher than the threshold β, we only update its corresponding key by taking a weighted average of the current key and the query:

$$K[n_i] \leftarrow \frac{q + K[n_i]}{||q + K[n_i]||}. \quad (8)$$

Otherwise, it means no addressed value correlates enough with the target, we then choose memory slots n' with maximum age and rewrite the stored items in it:

$$K[n'] \leftarrow q, V[n'] \leftarrow t_j. \quad (9)$$

The age of each updated slot will be reset to zero while all other non-updated slots get incremented by 1 in age. Memory updated in this way gradually accumulates similar contexts of a word into the same slot, which in another word, forms the prototype representation of a word.

3.3 Fast Adaptation

Now we show how to poll the memory to efficiently learn a new word representation from limited context. This is where the hypothesis constraint takes place. To be specific, given a new word embedding t_j^* to be learned and its context embedding c_j^*, we retrieve memory relevant to c_j^* as (2)-(3) and get R_K^*. Then we adapt context embedding with the retrieved memory to form the target word representation:

$$t_j^* = \alpha R_K^* + (1 - \alpha) c_j^*, \quad (10)$$

where α can be tuned a hyper-parameter or learned with regression models. Actually we also try to incorporate R_V^*, but the aggregated prototype R_K^* seems to continuously perform better.

We here pay additional attention to the softmax temperature T. T is emphasized since it conditions how the model "treats" the retrieved memory. Contexts are fairly limited in the few-shot case, so how the retrieved memory is treated crucially affects the quality of the learned representation. A higher temperature leads to a softer attention distribution , which means the model will be more likely to sample from all retrieved contents. A lower temperature makes the model focus more on the memory with highest similarity to the query. We predict a slightly higher temperature will generally be better in the fast adaptation phase. Since the HC theory points out that hypotheses are not in strict mutual-exclusions, they overlap with each other which corresponds to the higher-temperature condition. We will test this in the experiments.

4 Few-shot Word Similarity Tasks

We test the proposed method on two few-shot word similarity tasks. Fig.2 gives examples of the two tasks. In the following subsections we will introduce these datasets in detail and show the performance of tested methods on these tasks.

4.1 Tasks and Datasets

Definitional Nonce Task We evaluate on the Definitional Nonce dataset (Herbelot and Baroni,

Nonce Definition
Provided Context :
___ international inc is an american multinational conglomerate company that produces a variety of commercial and consumer products engineering services and aerospace systems for a wide variety of customers from private consumers to major corporations and governments
Ground Truth Word: Honeywell

Chimera-l2
Provided Context :
1. Canned sardines and ____ between two slices of whole meal bread and thinly spread Flora Original.
2. Erm, ____, low fat dairy products, incidents of heart disease for those who have an olive oil rich diet.

Probe Words: rhubarb, onion, pear, strawberry, limousine, cushion
Human Response: 2.57, 4.43 , 3.86, 3.71, 1.43, 2.14

Figure 2: Examples of the Nonce Definition and Chimera Task

2017) to simulate the process where a competent speaker learns a novel word from one informative sentence. 1000 words are included in the dataset as targets, with 700 for training and 300 for testing. Each target word corresponds to only one sentence extracted from its Wikipedia definition as context. All context sentences have been manually checked to be definitional enough to describe the corresponding target words. After tuning parameters on training data, the model is required to learn the target word representation with the provided context in test set. Learned representations are assessed by similarity to ground truth vectors produced in exposure to the whole corpora. We use the Reciprocal Rank (RR) of the ground vector in all nearest neighbors to the learnt representation for fair comparison of different methods, following Herbelot and Baroni (2017)'s settings. The mean value of RR over all test instances in the dataset is calculated as the final score.

Chimera Task Our second evaluation on the Chimera dataset (Lazaridou et al., 2017) means to simulate the case where a speaker learns the new word in a more casual multi-sentence context, not as highly informative as definitions in the Nonce dataset. There are 3 sub-tasks in Chimera:L2, L4 and L6, respectively providing 2, 4, 6 sentences as context to for each of the 330 instances in the dataset. The tested model needs to learn target word representation from the provided contexts. The similarity between learned embeddings and each of the probe words is measured and compared to human judgments by Spearman correlation. The final score is the average Spearman across all test pairs.

4.2 Baselines

Our model is compared to several baselines, including Word2Vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014), SUM (Lazaridou et al., 2017) and N2V (Herbelot and Baroni, 2017). Glove and Word2Vec are representatives of traditional DSMs. With them we want to test how exactly traditional DSMs perform in the few shot representation learning without any additional mechanism for small data. SUM and N2V are proposed especially for learning on small corpus. They adapt Word2Vec's skip-gram structure for incremental learning and show improvements on the Chimera dataset. They partially match the HC theory which Mem2Vec is based on. Note that several rare word learning methods (Long et al., 2017; Xu et al., 2014; Lazaridou et al., 2013) that rely on auxiliary information don't apply with most of our task settings. In the Nonce and Chimera task, context for target word learning is strictly limited for fair comparison, so external knowledge is banned. And the target word, as showed in Fig.2, is just a slot which doesn't provide any morphological hints, so sub-word methods are also excluded.

Both the above baselines and the proposed Mem2Vec use a dump of Wikipedia to learn a fundamental semantic space. To be specific, N2V and SUM use embeddings pre-trained by Word2Vec, while Mem2Vec acquires prior-knowledge, all from that Wiki corpora. We calculate correlation with the similarity ratings in the MEN and SIMLEX dataset to verify if the pre-trained semantic space is ready for use.

Task / Model	Nonce		Chimera		
	MRR	Med. Rank	L2 ρ	L4 ρ	L6 ρ
Word2Vec	0.00007	111012	0.1459	0.2457	0.2498
GloVe	0.00008	108002	0.1402	0.2397	0.2533
SUM	0.03686	861	0.3176	0.3534	0.3880
N2V	0.04907	623	0.3120	0.3628	0.3790
Mem2Vec	**0.05416**	**518**	**0.3301**	**0.3717**	**0.3897**

Table 1: Results of Nonce Definition and Chimera task. MRR and Med Rank respectively denotes mean reciprocal rank and median rank of the ground truth word. ρ denotes precision.

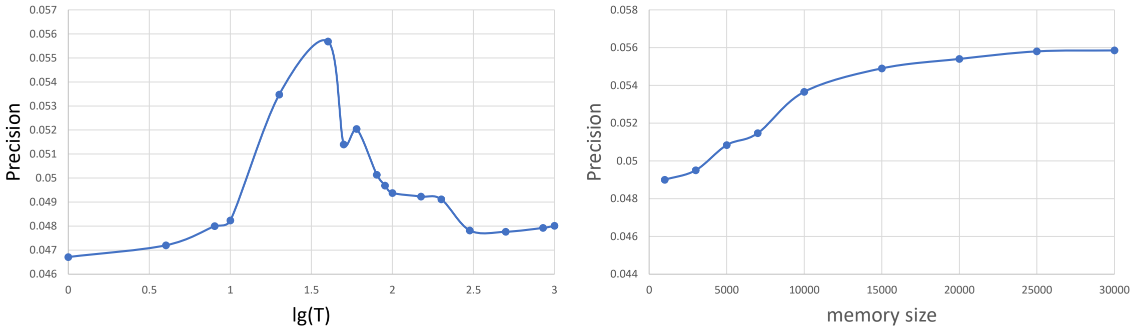

Figure 3: Performance of Nonce Definitional Task under different softmax temperature (left) and memory size (right). The left figure is in semilog coordinate.

4.3 Results

Nonce Definition Task We show the results of Nonce Definition Task in Table 1. Before analyzing the results we need to explain that MRR achieved by the tested models seems pretty low. This is no odd since matching the ground truth word in a vocabulary of 210,512 sets a potentially very large denominator in the reciprocal rank calculation. Our model achieves an MRR of 0.05416, which means the median rank of the true vector is 518 in the challenging two hundred thousand neighbors, surpassing all the baselines. N2V and SUM also deliver satisfactory performance with N2V working better. We are sorry to find that the naive Word2Vec and GloVe totally fail in the Nonce task, supporting the importance of adapting traditional DSMs for few-shot word representation learning.

Chimera Task The results on 3 chimera tasks are shown in Table 1, too. Mem2vec out-performs baselines in all the 3 context length settings. SUM performs steadily well from Nonce to the Chimera task, suggesting the effectiveness of constraining hypothesis space with contexts. But the continuous improvement of Mem2Vec over SUM confirms the advantage of our model, which incorporates “global” semantic information from the memory with the local contexts. N2V also works here but not as well as in the Nonce task, probably because the contexts in chimera are not as informative. Such performance drop may indicate N2V’s limited scalability to downstream NLP tasks since not all real world texts are as informative as in Nonce Definition Task. We will test this speculation with NER tasks in section 5.

4.4 Memory Parameter Analysis

We are interested to know how the two key parameters of memory, the softmax temperature T, and the memory size influence the quality of learned representations. We use the Nonce Definition task as the testbed. While studying the influence of one parameter, the other parameters are fixed. We run the model for 3 times with each candidate parameter and calculate the average precision as the final score.

Softmax Temperature Fig.3 (left) shows task performance under different softmax temperatures in semilog coordinate. We are a little bit surprised to find that it roughly fits a normal distribution and a mid-high temperature leads to best performance. A mid-high T means the model doesn’t give too large or too small weights to certain retrieved memory. This meets the HC theory about how humans weight the constrained hypothesis. We don't just trust a single hypothesis, nor do we treat all the hypotheses equally. The experiments shows similar principle also applies to our model.

Memory Size Fig.3 (right) shows task performance under different memory size. We find that increasing the memory size does lead to improved performance . But the improvements tend to be minor after the memory size is larger than 20,000. We owe it to the fact that we does not save specific examples, we accumulate similar contexts together in the memory to form prototypes. While we retrieve the memory, prototypes can be combined in different ways to represent multiple examples, thus a smaller memory can also work as well as the bigger one.

5 Extrinsic Tasks

We hope that the learned representations not only perform well on word similarity tasks but also apply to downstream NLP tasks. NER on domain specific datasets is an ideal benchmark. Named entities in these datasets are relatively low in frequency and not well covered by general domain corpus, tough for a traditional DSM to learn. Besides, while transferring from general domain corpus to a target small text, domain shift is a highly possible issue. We test if Mem2Vec could tackle the domain shift with a series of cross-domain sentiment analysis tasks.

5.1 Tasks and datasets

Domain Specific NER We use BioNLP11-species (Kim et al., 2011), AnatEMs (Pyysalo and Ananiadou, 2013) and NCBI-disease (Doğan et al., 2014) dataset, respectively from taxonomy, anatomy and pathology literatures. We train embeddings with tested methods to initialize the recognizer, whose performance then demonstrates whether the tested models learn representations well for rare words.

Cross Domain Sentiment Classification cross domain sentiment classification on Amazon Review dataset (Blitzer et al., 2007) is chosen as a benchmark. This dataset includes reviews from 4 product categories: books, DVDs, kitchens and electronics, suitable for the cross-domain setting. Using one as source domain and one as the target, we get 16 pairs for experiments. We train the classifier with source domain data and directly test it on the target domain, using the pre-trained embeddings as input feature. Note that through this task we also test how Mem2Vec performs when transferring from a small text, since in all the above experiments we learn prior knowledge from a large corpora.

5.2 Baselines

Except for the four baselines considered in word similarity tasks, we also compare with DAREP (Bollegala et al., 2015) and CRE (Yang et al., 2017) in the NER and sentiment classification tasks. They are both pivot-based methods for cross domain embedding learning which fare well in some downstream tasks. Besides we introduce SCL(Blitzer et al., 2006), a well-cited cross-domain sentiment analyser, as a baseline only for the sentiment classification task.

For NER, we use pre-trained embeddings by the tested methods as only input features for a LSTM-CRF recognition model (Lample et al., 2016). We simply mix the Wikipedia corpora with a dump of PubMed as our source corpora. Note that N2V and SUM can't be directly used to pre-train embeddings for downstream tasks since they focus on novel word learning. We thus explicitly divide words which occur less than 5 times as rare words while others as frequent words. N2V and SUM learn the frequent words with Word2Vec and learn the rare words in their own way. This setting also applies to the sentiment classification task.

For sentiment classification, we use a multi-layer perceptron (MLP) as the classifier, with one hidden layer of 400 nodes, ReLu activation and softmax output function.

5.3 Results

Named Entity Recognition Table 2 shows the results of domain specific named entity recognition. Used for pre-training embeddings, Mem2Vec achieves higher F1-score than all the baselines. It first surpasses CRE and DAREP that only bring slight improvements over Word2Vec. CRE and DAREP are both methods which relies on words with cooccurance patterns in source and target domain as the pivots for cross-domain transfer. This indicates the advantage of Mem2Vec over the traditional word frequency based methods in fast mapping cases where word cooccurrence pattern is not clear.

Our improvements over the N2V and SUM are more obvious than in the two word similarity

Task Model	AnatEM			BioNLP			NCBI		
	P	R	F1	P	R	F1	P	R	F1
Word2Vec	76.12	69.80	72.82	73.13	54.79	62.64	75.22	75.37	74.39
GloVe	75.83	67.04	71.14	72.58	53.35	61.50	75.76	72.33	74.01
N2V	76.81	66.8	71.46	73.91	54.21	62.54	72.45	74.37	73.30
SUM	77.06	69.01	72.81	74.36	58.58	62.25	74.89	74.02	74.45
DAREP	79.03	**67.95**	73.07	**77.18**	54.19	63.67	78.76	75.60	77.15
CRE	80.04	67.90	73.47	76.74	56.98	65.40	78.98	**76.63**	77.79
Mem2Vec	**81.23**	67.90	**73.96**	76.70	**57.81**	**65.92**	**79.56**	**76.63**	**78.06**

Table 2: Results of domain specific Named Entity Recognition. P, R, F1 respectively denotes precision, recall and F1 score

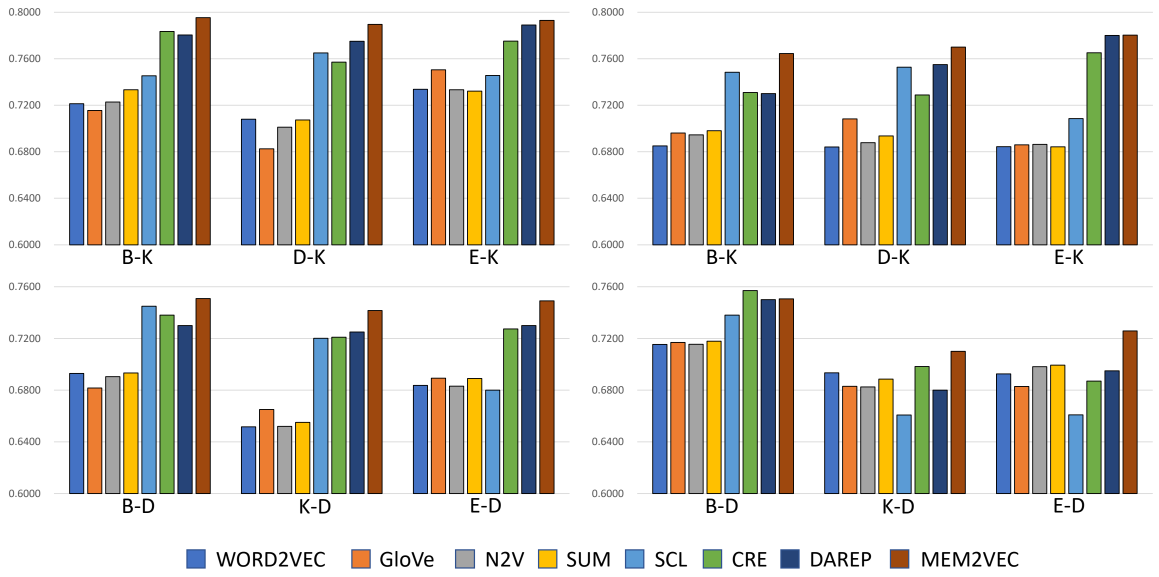

Figure 4: Results of cross domain sentiment classification on Amazon Review dataset. B denotes books, D for DVD, E for electronics, K for kitchen. B-K means B is the source domain and K is the target domain.

tasks. This again affirms our speculation that constraining hypothesis solely with the context is not enough. In the setting of NER, the context of one named entity is likely to be filled with other named entities which are also low in frequency. Directly summing the context as SUM does or taking risk to enlarge the window size as N2V may lead to over-fitting. While every training step of our method incorporates relative information from all the experienced examples stored in the memory, alleviating the danger of learn representations that over fits the local contexts.

In addition, it's worth noting that parameter tuning for N2V is no picnic. In our experiments, the original settings: high learning rate, large window size and short iteration span don't lead to satisfactory performance. More conservative parameter selection gets N2V back in track but departs from its fast mapping intention.

Sentiment Classification Fig.4 shows the results of Amazon Review sentiment classification. Mem2Vec delivers impressive performance, beating all the baselines in 10 of the total 12 pairs, including CRE and DAREP. This demonstrates the advantage of the memory as a transfer medium over the word- frequency based transfer of CRE and DAREP. But CRE and DAREP are still strong baselines in the cross domain task, surpassing SCL by a large margin. N2V and SUM are built for learning representation from small data, but they don't consider the possible domain discrepancy when using pre-trained embeddings on the target small text. So they don't bring much improvements over Word2Vec and GloVe. This also reminds us that to get the few-shot word representation learning methods in practical use, domain shift should be properly addressed.

6 Conclusion

We presented an integrated representation learning scheme which gradually learns from a big corpora and quickly adapt on tiny data. It accumulates knowledge with a long-term memory to adapt the representation learning of a novel word, in the few-shot learning case. Such adaptation means to constrain the "guess" of a DSM for the novel word according to the most relevant representation learning experience, inspired by hypothesis constraint theory for fast mapping. Experiments show the proposed method learns high quality representation from both highly informative and less definitional contexts in limited size. Pre-trained embeddings with our model also lead to improvements in Named Entity Recognition and sentiment analysis.

This work is our effort towards an ideal word representation learning scheme which learns from any amount of data. In the future work, we will explore more effective memory addressing and updating approaches to boost the few-shot representation learning. We believe not all examples are equally important and worth memorizing. Learning to memorize core examples should alleviate the data-hungry of representation learning methods.

Abstract

We present *disambiguated skip-gram*: a neural-probabilistic model for learning multi-sense distributed representations of words. Disambiguated skip-gram jointly estimates a skip-gram-like context word prediction model and a word sense disambiguation model. Unlike previous probabilistic models for learning multi-sense word embeddings, disambiguated skip-gram is end-to-end differentiable and can be interpreted as a simple feed-forward neural network. We also introduce an effective pruning strategy for the embeddings learned by disambiguated skip-gram. This allows us to control the granularity of representations learned by our model. In experimental evaluation disambiguated skip-gram improves state-of-the are results in several word sense induction benchmarks.

1 Introduction

Distributed representations of words find applications in a broad range of tasks, from natural language parsing (Socher et al., 2013) to image captioning (Karpathy and Fei-Fei, 2015). Their usefulness led to a renewed interest in word embedding algorithms. The most popular algorithms of this kind learn word vectors in an unsupervised manner, e.g., from word contexts (Mikolov et al., 2013a) or from statistics of word co-occurrence (Pennington et al., 2014). Unsupervised learning of word embeddings has a clear advantage: both general and domain-specific text corpora are available for a number of languages, which greatly reduces the cost of training. That said, unsupervised learning of word embeddings comes with its own challenges. One of the most important is word ambiguity: words in a natural language often have more than one meaning. The word *mouse*, for example, may mean a pointing device or an animal. Word embedding algorithms often do not recognize this language feature and estimate only one vector representation per word. This may lead to suboptimal word representations.

The main contribution of this work is *disambiguated skip-gram*: a neural-probabilistic model for learning distributed representations of words that capture word ambiguity. Disambiguated skip-gram builds upon the *skip-gram* model introduced by Mikolov et al. (2013a,b). Skip-gram constructs word embeddings via an auxiliary prediction task: given a word in a sentence, skip-gram attempts to predict the surrounding words. To this end, skip-gram defines a simple softmax model for the conditional probability of observing a context word c given the center word w:

$$p\left(c \mid w\right) = \frac{\mathrm{e}^{\mathbf{v}_w^{\mathrm{T}}\mathbf{u}_c}}{\sum_{c' \in D} \mathrm{e}^{\mathbf{v}_w^{\mathrm{T}}\mathbf{u}_{c'}}}, \qquad (1)$$

where D is the vocabulary. This log-bilinear model assigns two embedding vectors to every word $w \in D$: an *input embedding vector* $\mathbf{v}_w$ and an *output embedding vector* $\mathbf{u}_w$. Skip-gram defines the training objective for a single example as the log-probability: $\log p\left(c \mid w\right)$. By maximizing this objective, skip-gram estimates input and output vectors that reflect semantic relations between words that occur in similar contexts. The input vectors are then used as word embeddings.

The main idea behind disambiguated skip-gram is to jointly learn to disambiguate words and predict their contexts. We therefore extend skip-gram with a parametric word sense disambiguation model. This allows us to discover word senses in an unsupervised manner, while preserving the simplicity of the skip-gram approach. In particular, unlike previous probabilistic models for multi-sense word embeddings, disambiguated skip-gram can be seen as a simple feed-forward neural network amendable to end-to-end training with back-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1445–1454
Brussels, Belgium, October 31 - November 4, 2018.

propagation. Furthermore, disambiguated skip-gram admits an effective pruning strategy for the learned word sense embeddings. In particular, we control the granularity of the learned representations by penalizing the entropy of the probability distributions learned by the disambiguation model. We then marginalize word sense probabilities over the training examples and prune embeddings with low marginal probability.

We have carried out an extensive experimental evaluation of disambiguated skip-gram. Our results demonstrate that the multi-sense word embeddings learned by disambiguated skip-gram improve state-of-the-art results in the word sense induction task.

2 Disambiguated skip-gram model

Let $X = [w_1, \ldots, w_n]$, where each $w_i \in D$, be a sequence of words from a vocabulary D. By $\mathcal{C}_{w_i}$ we denote the context of the word w_i in X. For example, $\mathcal{C}_{w_i}$ can be a set of words that are no further than l positions from w_i and are in the same sentence as w_i. To simplify notation we will usually omit the sequence index i and write $w \in X$ for an element of the input sequence X and $\mathcal{C}_w$ for its context. We will also use notation $\mathbf{y}_w$ for a vector $\mathbf{y}$ (from some set of vectors indexed by the vocabulary words) corresponding to the word w. Note that in this case we disregard the position of w in X and use just the word as the index. In particular, if some word w occurs multiple times in X, all occurrences share a single vector $\mathbf{y}_w$.

Similarly to skip-gram, the disambiguated skip-gram model constructs word embeddings by learning to predict context words $c \in \mathcal{C}_w$ given the center word $w \in X$. However, disambiguated skip-gram explicitly accounts for word ambiguity. To this end, we represent each word $d \in D$ by a set of k *sense embedding vectors* $\mathbf{v}_{dz}$, indexed by $z \in \{1, \ldots k\}$, and an *output embedding vector* $\mathbf{u}_d$. We then parametrize the conditional probability $p\,(c \mid w, z = j)$ of observing a word c in the context of the word w in its j-th sense with a softmax model similar to the original skip-gram parametrization:

$$p\,(c \mid w, z = j) = \frac{\mathrm{e}^{\mathbf{v}_{wj}^{\mathrm{T}} \mathbf{u}_c}}{\sum_{c' \in D} \mathrm{e}^{\mathbf{v}_{wj}^{\mathrm{T}} \mathbf{u}_{c'}}}. \qquad (2)$$

Furthermore, in this work we assume that a sense of the word $w \in X$ can be guessed from its context $\mathcal{C}_w$[1], i.e. that:

$$z_w \sim p\,(z = j \mid w, \mathcal{C}_w)\,, \quad j = 1, \ldots, k, \qquad (3)$$

where z_w is an index of the sense of the word $w \in X$. Given this assumption, we parametrize the probability distribution for z_w using a softmax model similar to Eq. 2. That is, for each word $d \in D$ we introduce k *sense disambiguation vectors* $\mathbf{q}_{ds}$, $s \in \{1, \ldots, k\}$, and a *context embedding vector* $\mathbf{r}_d$. The conditional probability that the word $w \in X$ occurs in its j-th sense is then modelled as:

$$p\,(z = j \mid w, \mathcal{C}_w) = \frac{\mathrm{e}^{\mathbf{q}_{wj}^{\mathrm{T}} \bar{\mathbf{r}}_w}}{\sum_{s=1,\ldots,k} \mathrm{e}^{\mathbf{q}_{ws}^{\mathrm{T}} \bar{\mathbf{r}}_w}}, \qquad (4)$$

where $\bar{\mathbf{r}}_w$ is a vector representation of $\mathcal{C}_w$. We represent $\mathcal{C}_w$ by an average of context embedding vectors:

$$\bar{\mathbf{r}}_w = \frac{1}{\#\mathcal{C}_w} \sum_{c \in \mathcal{C}_w} \mathbf{r}_c. \qquad (5)$$

We can now define the training objective for a single word $w \in X$ as the expected negative log-likelihood of observing the context $\mathcal{C}_w$ under the distribution of senses of the center word w:

$$\mathcal{L}\,(\boldsymbol{\phi}, w) = \mathbb{E}_{z_w \sim p(z=j \mid w, \mathcal{C}_w)} \left[-\log \prod_{c \in \mathcal{C}_w} p\,(c \mid w, z = z_w) \right], \qquad (6)$$

with the parameters: $\boldsymbol{\phi} = \{\mathbf{v}_{dz}, \mathbf{u}_d, \mathbf{q}_{dz}, \mathbf{r}_d \mid d \in D, z = 1, \ldots, k\}$.

The objective in Eq. 6 is inconvenient for gradient-based optimization, because the expectation is taken with respect to a probability distribution that is a function of model parameters. In principle, we can estimate the gradient of this objective with the score function estimator (Glynn, 1990; Williams, 1992). Unfortunately, the score function estimator suffers from a high variance, even when used with a control variate. One can also derive a low-variance unbiased gradient estimator for certain probability distributions, by expressing the samples as a differentiable function of model parameters and a random variable from some independent fixed distribution (Kingma and Welling, 2013). This approach is not directly applicable to our case, because categorical distribution do not admit reparametrization with a differentiable function. That said, a simple and effective

---

[1] This assumption follows from an observation that two different meanings of a given word will often have vastly different contexts.

biased gradient estimator for an expectation with respect to a categorical distribution was recently proposed by Jang et al. (2016) and Maddison et al. (2016). The basic idea is to reparametrize the samples from the categorical distribution with the *Gumbel-Max trick* (Gumbel, 1954) and then approximate the non-differentiable max operator with a softmax function with temperature hyper-parameter. This can be seen as a reparametrization trick for a continuous relaxation to discrete samples from the categorical distribution.

In our case, the samples from $p(z = j \mid w, \mathcal{C}_w)$ take the form:

$$z_{wj} = \begin{cases} 1 & \text{if } j = \arg\max_{s}(\xi_s + \log p(z = s \mid w, \mathcal{C}_w)), \\ 0 & \text{otherwise,} \end{cases}$$

where ξ_s are i.i.d. samples from the standard Gumbel distribution $f(0,1)$. Note that the samples $\mathbf{z}_w = [z_{w1}, \ldots, z_{wk}]$ are now one-hot encoded. The continuous relaxation to $\mathbf{z}_w$ is:

$$\begin{aligned} \tilde{\mathbf{z}}_w &= [\tilde{z}_{wj}(\xi_1, \ldots, \xi_k, \mathcal{C}_w) \mid j = 1 \ldots k], \\ \tilde{z}_{wj}(\xi_1, \ldots, \xi_k, \mathcal{C}_w) &= \\ &\frac{\mathrm{e}^{[\xi_j + \log p(z=j \mid w, \mathcal{C}_w)]/\tau}}{\sum_{s=1,\ldots,k} \mathrm{e}^{[\xi_s + \log p(z=s \mid w, \mathcal{C}_w)]/\tau}}, \end{aligned} \quad (7)$$

where τ is the temperature hyper-parameter. When $\tau \to 0$, we recover the samples from $p(z = j \mid w, \mathcal{C}_w)$. However, for $\tau > 0$ the samples $\tilde{\mathbf{z}}_w$ are no longer discrete. In this case we consider a relaxed sense embedding vector:

$$\tilde{\mathbf{v}}_w = \sum_{j=1,\ldots,k} \tilde{z}_{wj}(\xi_1, \ldots, \xi_k, \mathcal{C}_w)\, \mathbf{v}_{wj} \quad (8)$$

and model the conditional probability of observing a word c in the context of the word w as:

$$p(c \mid w, \tilde{\mathbf{v}}_w) = \frac{\mathrm{e}^{\tilde{\mathbf{v}}_w^{\mathrm{T}} \mathbf{u}_c}}{\sum_{c' \in D} \mathrm{e}^{\tilde{\mathbf{v}}_w^{\mathrm{T}} \mathbf{u}_{c'}}}. \quad (9)$$

Our training objective for a single word $w \in X$ then takes the form:

$$\begin{aligned} \mathcal{L}(\boldsymbol{\phi}, w) = &\mathbb{E}_{\xi_1, \ldots, \xi_k \sim f(0,1)} \\ &\left[-\log \prod_{c \in \mathcal{C}_w} p(c \mid w, \tilde{\mathbf{v}}_w) \right]. \end{aligned} \quad (10)$$

The relaxed objective in Eq. 10 is tractable and differentiable with respect to the parameters $\boldsymbol{\phi}$.

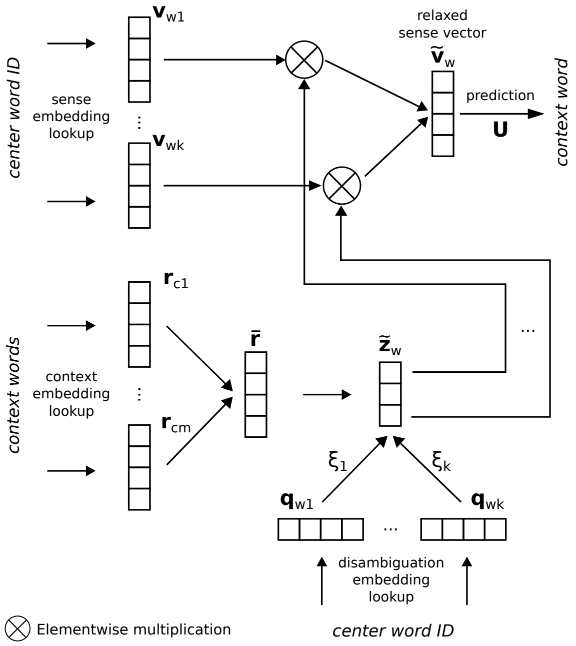

Figure 1: Disambiguated skip-gram model.

When $\tau \to 0$, it becomes equivalent to the objective in Eq. 6. In practice, we approximate the expectation in Eq. 10 with a one-sample Monte Carlo estimator. In these settings disambiguated skip-gram can be seen as a simple feed-forward neural network pictured in Fig. 1. During training, the network jointly estimates a sense disambiguation model (Eq. 4) and a context word prediction model (Eq. 2), which we use to construct multi-sense word embeddings.

2.1 Pruning word senses

The disambiguated skip-gram model is parametric, i.e. it allocates a fixed number of sense embedding vectors to each word, even though different words have different number of discernible senses. That said, we can prune the sense embedding vectors by considering their probabilities according to the learned disambiguation model. In particular, after training we estimate the marginal probability:

$$p(d, j) = \frac{1}{m_d} \sum_{\substack{w_i \in X, \\ w_i = d}} p(z = j \mid w_i, \mathcal{C}_{w_i}) \quad (11)$$

for each word $d \in D$ and each sense index $j \in \{1, \ldots, k\}$. We then prune sense embedding vectors with low marginal probability, e.g., $p(d, j) < 0.05$. The normalizing factor m_d in Eq. 11 is the number of occurrences of the word d in X.

The above pruning technique can be extended to allow for an explicit control over the granularity of the learned sense representations. To this end, we use an entropy regularization term similar to the one studied by Pereyra et al. (2017) in classification networks. In disambiguated skip-gram the granularity of the learned representations is controlled by the disambiguation model (Eq. 4). Therefore, we extend the objective of our model (Eq. 10) by adding to it an entropy S of the probability distribution $p\left(z=j \mid w, \mathcal{C}_w\right)$:

$$\mathcal{L}_r\left(\boldsymbol{\phi}, w\right)=\mathcal{L}\left(\boldsymbol{\phi}, w\right)+\gamma S\left(\boldsymbol{\phi}, w\right), \qquad (12)$$

where:

$$S\left(\boldsymbol{\phi}, w\right)= -\sum_{j=1}^{k} p\left(z=j \mid w, \mathcal{C}_w\right) \log p\left(z=j \mid w, \mathcal{C}_w\right).$$

The hyper-parameter γ, which we further call *entropy cost*, controls the strength of the regularization and, in turn, the granularity of the learned sense representations. In particular, $\gamma > 0$ encourages the model to learn more coarse-grained sense representations, whereas $\gamma < 0$ increases the granularity of the learned senses.

3 Related work

Algorithms for learning distributed multi-sense representations of words have been a focus of several recent works. Initial approaches to this task relied on clustering word contexts. One of the first algorithms of this kind was proposed by Huang et al. (2012). They learn multi-sense word representations in three steps. First, they estimate vector representations of words using a feed-forward neural language model. Next, they calculate average word vector for each context in the training corpus, cluster these context representations and relabel each word in the corpus to a word sense represented by the nearest cluster. Finally, they train the language model on the relabelled corpus and obtain vector representations for word senses.

Neelakantan et al. (2014) proposed the Multi-Sense Skip-gram (MSSG) model, that jointly learns context cluster prototypes and word sense embeddings. Their model extends skip-gram by maintaining context clusters for every word in the vocabulary. Given a training example with a center word w and its context representation c, they infer the word sense for w by a hard assignment of the context representation c to the cluster with the nearest centroid. Afterwards, they perform a skip-gram-like update on the vector representation of the selected word sense and the output vectors of the context words. Neelakantan et al. also proposed a non-parametric version of MSSG (NP-MSSG), in which the number of clusters, and in turn the number of word senses, increases during training. They use a simple heuristic to determine the number of word senses: NP-MSSG allocates a new sense for the center word w when the similarity between the context representation c and the nearest cluster centroid falls below some predefined threshold. Neelakantan et al. demonstrated that MSSG and NP-MSSG outperform the Huang et al. algorithm on a contextual word similarity task.

A disadvantage of the Huang et al. and Neelakantan et al. algorithms is that they do not follow a principled statistical approach, but instead rely on hard clustering of context vectors. This has been addressed in more recent algorithms, which learn multi-sense word representations in a probabilistic framework. Concurrent to Neelakantan et al. work, Tian et al. (2014) proposed a probabilistic Multi-Prototype Skip-Gram (MPSG) model. MPSG extends the skip-gram model by adding to each position in the input text a latent variable that encodes the index of the word sense at that position. Furthermore, for each word in the vocabulary MPSG maintains a fixed number of sense embedding vectors and a single output vector. These parameters define a softmax model for the conditional probability of observing a context word given the center word and the latent sense index. Finally, MPSG models the conditional probability of observing a context word given the center word with a mixture model whose components correspond to the senses of the center word. Tian et al. derived an expectation maximization algorithm for estimation of softmax parameters and prior sense probabilities in their model. MPSG was evaluated in a contextual word similarity task, where its performance was similar to that of the Huang et al. algorithm.

Bartunov et al. (2016) proposed the AdaGram model, which can be seen as a non-parametric version of MPSG. Similarly to MPSG, AdaGram introduces latent variables for word sense indexes in the input text. However, unlike MPSG, AdaGram does not assume a fixed number of word senses.

Instead, it defines the prior over word senses via a Dirichlet process. As a result, AdaGram automatically learns the number of senses for all words in the vocabulary. Unfortunately, defining the prior over word senses via a Dirichlet process gives an intractable model likelihood. Bartunov et al. therefore optimize variational lower bound of the AdaGram model likelihood using a stochastic variational inference algorithm. Bartunov et al. evaluated AdaGram performance on several word sense induction benchmarks. They demonstrated that AdaGram consistently outperforms MSSG, NP-MSSG and MPSG models in these benchmarks. AdaGram has been recently extended to handle parallel multilingual text corpora (Upadhyay et al., 2017).

For the prediction of context words (Eq. 2) disambiguated skip-gram adopts the softmax model used in MPSG. However, in contrast to the previous works, disambiguated skip-gram learns a parametric model for the conditional probability distribution over senses of the center word given the context words (Eq. 4). This allows us to define the training objective for disambiguated skip-gram as the expected negative log-likelihood of observing the context words under the distribution of senses of the center word. We use a biased low-variance gradient estimator for this objective, which enables stable end-to-end training with backpropagation.

The main goal of the AdaGram model is to automatically discover the number of word senses for the vocabulary words. This does not mean, however, that the number of senses learned by AdaGram is independent of model hyper-parameters. On the contrary, the number of senses learned by AdaGram is directly controlled by the hyper parameter α in the Dirichlet process used to define the prior over word meanings (Bartunov et al., 2016). Disambiguated skip-gram controls the number of learned senses by penalizing the entropy of the conditional probability distribution in the sense disambiguation model (Eq. 12). The entropy cost γ in this approach performs a function similar to the hyper-parameter α in AdaGram.

In addition to the works discussed above, word ambiguity was also modelled using topic models (Liu et al., 2015), large bi-directional language models (Peters et al., 2018) or subword information (Athiwaratkun et al., 2018). Also, Li and Jurafsky (2015) evaluated multi-sense embeddings in several downstream tasks. They found that multi-sense embeddings improve performance in tasks such as POS tagging or identification of semantic relations. They also identify downstream tasks which do not benefit from sense disambiguation. In sentiment analysis, for example, word sentiment usually does not depend on the inferred sense.

4 Experiments

We conducted a number of experiments to evaluate the quality of multi-sense word embeddings learned by disambiguated skip-gram. This section reports results from our evaluation. First, we report qualitative results from our model for several polysemous words. We then compare the performance of disambiguated skip-gram with several competing algorithms on a set of word sense induction tasks. Finally, we evaluate the effect of the entropy cost on the learned representations.

It is worth noting that the quality of multi-sense word embeddings was formerly assessed in contextual word similarity experiments. However, Bartunov et al. (2016) demonstrated that contextual word similarity experiments do not reflect the quality of multi-sense representations. In particular, the best performance in contextual word similarity task is often achieved by the baseline skip-gram model, which does not recognize word senses. This can be attributed to the fact that skip-gram objective directly optimizes similarity of vector representations of words that appear in similar contexts. Multi-sense models, on the other hand, solve a harder task: they disambiguate words in contexts and then model the similarities between the discovered senses. Bartunov et al. focus, therefore, on the performance of multi-sense embeddings in the word sense induction task. We adopt their evaluation methodology in this work.

We trained our disambiguated skip-gram models on the Westbury Lab Wikipedia corpus (Shaoul and Westbury, 2010). We optimized the models using mini-batch stochastic gradient descend with momentum.

4.1 Qualitative results

We begin our evaluation by presenting senses discovered by disambiguated skip-gram for several ambiguous words. For the demonstration we trained four 300-dimensional models with three sense embedding vectors allocated to each word

Table 1: Nearest neighbors and marginal probabilities p of word sense embedding vectors discovered by the disambiguated skip-gram model for several ambiguous words. Sense embedding vectors with a marginal probability $p < 0.05$ are pruned from the learned model.

and the entropy cost γ ranging from 0.0 to 0.5. For each of the evaluated words sense embeddings we calculated the cosine similarity to the remaining words and selected 5 nearest neighbours. The results are reported in Tab. 1.

Disambiguated skip-gram discovered main meanings of our test words. For example, the meanings discovered for the word *fox* correspond to a broadcasting company, an animal and a family name. The meanings discovered for the word *mouse* correspond to a cartoon character, a computer mouse and an animal.

Results in Tab. 1 also demonstrate that disambiguated skip-gram will often expose an internal structure in a word meaning, if that meaning appears in different contexts. For example, disambiguated skip-gram learned two embeddings for the word *plant* corresponding to its *factory* meaning: one related to heavy industry and one related to a farm or a plant nursery. This is a consequence of the fact that disambiguated skip-gram discovers word senses using only the information about the contexts in which these words occur. In particular, it does not employ any supervision from an external knowledge base. Bartunov et al. (2016) refer to a related phenomenon in the AdaGram embeddings as the semantic resolution of the model.

4.2 Word-sense induction experiments

To compare disambiguated skip-gram with state-of-the-art competing algorithms we assessed its performance in a set of word sense induction tasks. In this evaluation we follow the experimental setup from (Bartunov et al., 2016), allowing for direct comparison with the results reported therein. In particular, we evaluated disambiguated skip-gram on the datasets from the SemEval-2007 Task 2 competition (SE-2007), SemEval-2010 Task 14 competition (SE-2010), SemEval-2013 Task 13 competition (SE-2013) and the Wikipedia Word-sense Induction (WWSI) dataset introduced by Bartunov et al. The test datasets consist of between 4664 and 36354 examples. Each example provides a ground truth sense of a center word and the context in which this sense appeared. The goal is to recognize the sense of the center word given the context. We use the preprocessed versions of SE-2007, SE-2010 and WWSI datasets made available by Bartunov et al. For the SemEval-2013 Task 13 we use the original competition dataset (Jurgens and Klapaftis, 2013) and follow the preprocessing steps reported in (Bartunov et al., 2016).

We use a simple procedure for resolving word senses. That is, we average all sense embedding vectors of all context words and select the sense z_w of the center word w whose embedding vector is most similar to the average vector:

$$z_w = \arg\max_j \cos\left(\mathbf{v}_{wj}, \bar{\mathbf{c}}_w\right), \tag{13}$$

where:

$$\bar{\mathbf{c}}_w = \left(k \cdot \#\mathcal{C}_w\right)^{-1} \sum_{c \in \mathcal{C}_w} \sum_{s=1}^{k} \mathbf{v}_{cs}. \tag{14}$$

The intuition behind this procedure is that we expect the average to preserve a shared component in the embedding vectors, namely embeddings for senses related to the sense of the center word, and cancel out embeddings of unrelated senses. In addition to averaging sense embedding vectors we also experimented with averaging output vectors of context words. However, this approach usually gave slightly worse results.

Following Bartunov et al. (2016), we use adjusted rand index (Hubert and Arabie, 1985) to compare ground truth senses for a given word with the senses inferred from disambiguated skip-gram embeddings. The final performance on a benchmark task is the average of adjusted rand index values over all test words in the task.

For this evaluation we trained a 300-dimensional disambiguated skip-gram model with 5 sense embedding vectors allocated to each word and no entropy cost ($\gamma = 0.0$). The comparison between our model and MSSG, NP-MSSG, MPSG and AdaGram is reported in Tab. 2. The results for MSSG, NP-MSSG, MPSG and AdaGram are taken from Bartunov et al. (2016). Multi-sense embedding vectors learned by disambiguated skip-gram outperform baseline methods on the SE-2007, SE-2010 and WWSI benchmarks, and achieve the second best result on the SE-2013 benchmark.

	SE-2007	SE-2010	SE-2013	WWSI
MSSG	0.048	0.085	0.033	0.194
NP-MSSG	0.033	0.044	0.033	0.110
MPSG	0.044	0.077	0.014	0.160
AdaGram	0.069	0.097	**0.061**	0.286
Disamb. skip-gram	**0.077**	**0.117**	0.045	**0.292**

Table 2: Performance of multi-sense word embedding methods in word sense induction tasks. The reported performance metric is the adjusted rand index averaged over all test words in the benchmark task. Results for all models except the disambiguated skip-gram (Disamb. skip-gram) are taken from (Bartunov et al., 2016).

4.3 Effect of the entropy cost

Results reported in Tab. 1 demonstrate that the entropy cost γ (Eq. 12) indeed allows for pruning senses learned by disambiguated skip-gram. In particular, when the entropy cost increases, disambiguated skip-gram allocates more of the marginal probability mass (Eq. 11) to the frequent meanings of the modelled words and, in effect, learns coarser representations.

For a quantitative evaluation of the effect of entropy cost on the learned representations we trained 50-dimensional disambiguated skip-gram models with γ ranging from 0.0 to 1.0. All models allocate 5 sense embedding vectors to every word in the vocabulary. In Tab. 3 we report an average number of senses per word with marginal probability $p \geq 0.05$, depending on the value of the entropy cost. In Fig. 2 we also report histograms of marginal probabilities for selected entropy cost values.

Entropy cost	0.0	0.1	0.25	0.5	0.75	1.0
Avg. sense num.	4.7	4.3	3.7	3.2	2.8	2.5

Table 3: Average number of senses per word with marginal probability $p \geq 0.05$, learned by disambiguated skip-gram models with different values of the entropy cost.

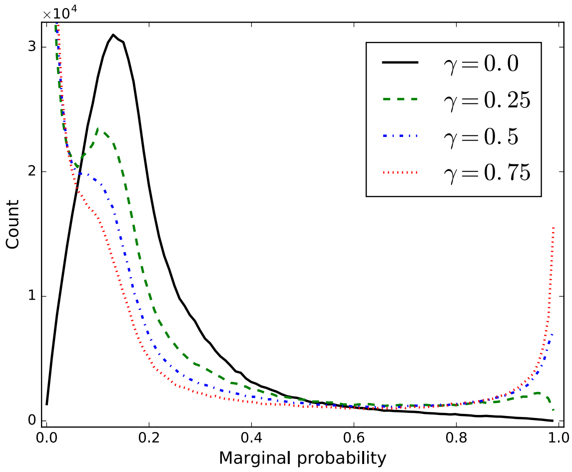

Figure 2: Histograms of marginal probabilities of word senses learned by disambiguated skip-gram models with different values of the entropy cost.

Histograms in Fig. 2 confirm our observation from the qualitative evaluation: when the entropy cost increases, disambiguated skip-gram learns more peaked distributions for the conditional sense probability $p(z = j \mid w, \mathcal{C}_w)$. This translates to coarser sense representations. In particular, the model with no entropy cost learned an average of 4.7 senses per word with marginal probability $p \geq 0.05$ (Tab. 3). This number decreases with an increasing entropy cost, reaching an average of 2.5 senses per word for $\gamma = 1.0$.

We also evaluated 50- and 300-dimensional models with different entropy costs in the word sense induction tasks. In each case we pruned senses with marginal probability $p < 0.05$. Results from this evaluation (Tab. 4) indicate that the desired granularity of the learned sense representations depends on the underlying task. In the WWSI benchmark the best performing models had no entropy cost, while in the SemEval tasks small entropy cost usually improved results. The results agree for both model dimensionalities.

Dim.	Entropy Cost	SE 2007	SE 2010	SE 2013	WWSI
50	No	0.064	0.107	0.040	**0.304**
	0.25	**0.083**	**0.116**	0.043	0.244
	0.5	0.064	0.091	**0.045**	0.182
300	No	0.077	**0.117**	0.045	**0.292**
	0.25	**0.079**	0.113	0.045	0.259
	0.5	0.065	0.091	**0.049**	0.183

Table 4: Performance of disambiguated skip-gram models with different entropy costs in the word sense induction tasks. The reported performance metric is the adjusted rand index averaged over all test words in the benchmark task.

5 Conclusions

In this work we developed disambiguated skip-gram: a novel neural-probabilistic model for learning multi-sense distributed representations of words. Unlike previous probabilistic models for multi-sense word embeddings, disambiguated skip-gram is a simple feed-forward neural network and can be trained end-to-end with backpropagation. In experimental evaluation disambiguated skip-gram improved over the state-of-the-art results in three out of four benchmark datasets and ranked second the fourth.

Disambiguated skip-gram optimizes expected log-likelihood of the context prediction model under the distribution of word senses parametrized by the disambiguation model. We choose to optimize this objective with a biased but low-variance gradient estimator. However, parallel to this work there has been a significant progress in gradient-based training of models with discrete latent variables. Specifically, Tucker et al. (2017) proposed an unbiased low-variance gradient estimator, called REBAR, that is applicable to models with categorical latent variables. REBAR may allow to efficiently optimize the original disambiguated skip-gram objective (Eq. 6), instead of the relaxed objective (Eq. 10). This may further improve the quality of embeddings learned with our approach.

Abstract

During natural disasters and conflicts, information about what happened is often confusing, messy, and distributed across many sources. We would like to be able to automatically identify relevant information and assemble it into coherent narratives of what happened. To make this task accessible to neural models, we introduce *Story Salads*, mixtures of multiple documents that can be generated at scale. By exploiting the Wikipedia hierarchy, we can generate salads that exhibit challenging inference problems. Story salads give rise to a novel, challenging clustering task, where the objective is to group sentences from the same narratives. We demonstrate that simple bag-of-words similarity clustering falls short on this task and that it is necessary to take into account global context and coherence.

1 Introduction

When a natural disaster strikes or a conflict arises, it is often hard to determine what happened. Information is messy and confusing, spread out over many messages, buried in irrelevant text, and even conflicting. For example, when flight MH-17 crashed in Ukraine in 2014, there were initially many theories of what happened, including a missile strike initiated by Russia-affiliated militants, a missile strike by the Ukrainian military, and a terrorist attack. There was no single coherent interpretation of what happened, but multiple, messy narratives, a *story salad*. We would like to be able to automatically identify relevant information and assemble it into coherent narratives of what happened. This task is also the subject of an upcoming task at the Text Analysis Conference.[1]

Picking apart a story salad is a hard task that could in principle make use of arbitrary amounts of inference. But it is also a task in which coherence judgments could play a large role, the simplest being topical coherence, but also narrative coherence (Chambers and Jurafsky, 2008, 2009; Pichotta and Mooney, 2016; Mostafazadeh et al., 2017), overall textual coherence (Barzilay and Lapata, 2008; Logeswaran et al., 2018), and coherence in the description of entities. This makes it an attractive task for neural models.

(A) Some of the prisoners were survivors of the Battle of Qala-i-Jangi in Mazar-i-Sharif. (A) Chechnya came under the influence of warlords. (B) The U.S. invaded Afghanistan the same year when several Taliban prisoners were shot. (A) Russian federal troops entered Chechnya and ended its independence. (A) The Russian casualties included at least two commandos killed and 11 wounded. (B) The dead were buried in the same grave under the authority of Commander Kamal.

Figure 1: A story salad involving two articles, about a Russian military operation in Chechnya (A) and about a U.S. operation in Afghanistan (B). These two articles are topically similar but their mixture can still be disentangled based on narrative coherence.

To make the task accessible to neural models, we propose a simple method for creating simulated story salad data at scale: we mix together sentences from different documents. Figure 1 shows an example mixture of two articles from Wikipedia, one on the Russia-Chechnya conflict and one on a conflict between the U.S. and Afghanistan. By controlling how similar the source documents are, we can flexibly adjust the difficulty of the task. In particular, as we show below, we can generate data that exhibits challenging inference problems by exploiting the Wikipedia category structure.[2] While this data is still simpler than story salads arising naturally, it approximates the task, is sufficiently challenging for modeling, and can be generated in large amounts.[3]

---

[1] https://tac.nist.gov/2018/SM-KBP/index.html

[2] In particular, while we do not focus on creating mixtures with conflicting information, it can often be found in mixtures created based on Wikipedia categories, as shown in Figure 2.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1455–1465
Brussels, Belgium, October 31 - November 4, 2018.

We explore some initial models for our Story Salad task. As the aim of the task is to group story pieces into stories, we start with straightforward clustering based on topic similarity. But topic similarity is clearly not enough to group the right pieces together. For example, the two articles in Figure 1 are both about armed conflicts, but the Russia-Chechnya sentences in the example form a group *in contrast to* the U.S.-Afghanistan sentences. To model this, we learn sentence embeddings adapted to the clustering task and with access to global information about the salad at hand. We also test an extension where to decide whether to group two sentences together, the model mutually attends to the sentences during encoding in order to better focus on the commonalities and differences of these two sentences. Both extensions lead to better models (6-13% improvement in accuracy with a model incorporating both), confirming that the task requires more than just general topical similarity. But there is much room for improvement, in particular on salads generated to be more difficult, where performance is around 15 points lower than on arbitrary mixtures.

2 Related Work

Building on early work in *script learning* (Schank and Abelson, 1977), Chambers and Jurafsky (2008) introduce *narrative schema* and propose the "narrative cloze" task where the modeling objective is to predict the event happening next. The topic has since seen many extensions and variants coupled with increasingly sophisticated models (Chambers and Jurafsky, 2009) including neural networks (Granroth-Wilding and Clark, 2016; Pichotta and Mooney, 2016; Mostafazadeh et al., 2017). This line of work is related to story salads in that our aim of separating entangled narratives in a document mixture also leverages within-narrative coherence. Our work, however, is very different from narrative cloze: (i) we group sentences/events rather than predicting what happens next; (ii) crucially, the narrative coherence in story salads is *in context*, in that a narrative clustering is only meaningful with respect to a particular document mixture (see Section 5, 6), while in narrative cloze the next event is predicted on a "global" level.[4]

Working with labeled story salad examples, we draw inspiration from previous work on supervised clustering (Bilenko et al., 2004; Finley and Joachim, 2005). We also take advantage of the recent success of deep learning in leveraging a continuous semantic space (Pennington et al., 2014; Kiros et al., 2015; Mekala et al., 2017; Wieting and Gimpel, 2017; Wieting et al., 2017) for word/sentence/event encoding; neural components for enhanced supervised clustering (Bilenko et al., 2004), in particular LSTMs (Hochreiter and Schmidhuber, 1997; Dai and Le, 2015), CNNs (Kim, 2014; Conneau et al., 2017), and attention mechanisms (Bahdanau et al., 2015; Hermann et al., 2015; Lin et al., 2017). By exploring our ability to pick apart story salads with these state-of-the-art NLP modeling tools, we attempt to (i) show the value of the story salad task as a new NLP task that warrants extensive research; (ii) understand the nature of the task and the challenges it sets forth for NLP research in general.

The task of picking apart story salads is related to the task of conversation disentanglement (Elsner and Charniak, 2008; Wang and Oard, 2009; Jiang et al., 2018), which is a clustering task of dividing a transcript into a set of distinct conversations. While superficially similar to our Story Salad task, conversation disentanglement focuses on dialogues and has many types of metadata available, such as time stamps, discourse information, and chat handles. Existing systems draw heavily on this metadata. Another related task is the distinction of on-topic and off-topic documents (Bekkerman and Crammer, 2008), which is defined in terms of topical relatedness. In comparison, the story salad task offers opportunities for more in-depth reasoning, as we show below.

3 Data

Natural story salads arise when multiple messy narratives exist to describe the same event or outcome. Often this is because each contribution to the explanation only addresses a small aspect of the larger picture. We can directly simulate the confusion this kind of discourse creates by taking multiple narratives, cutting them into small pieces, and mixing them together.

---

salads are available for download directly and we have provided code to reconstruct the NYT salads from English Gigaword 5 (available as LDC2003T05).

[4] The story salad task is more similar to multichoice narrative cloze (Granroth-Wilding and Clark, 2016) in this regard, but formulated categorically differently.

Dataset	Salads	Total Words	μ Words/Salad	cos (test)
NYT	573,681	217,841,716	379.726	0.33
NYT-HARD	1,000	20,149	438.220	0.56
WIKI	500,000	197,175,135	394.350	0.35
WIKI-HARD	50,374	21,266,243	422.167	0.64

Table 1: Statistics of the datasets we present. The average topic cosine similarity scores (cos) between the two narratives in document mixtures are computed from the test sets. The NYT, WIKI and WIKI-HARD salads are divided into 80%/20% train/test splits, while the smaller NYT-HARD is treated entirely as test.

Data generation. Story salads are generated by combining content from source documents and randomizing the sentence order of the resulting mixture. In order to ensure appropriately sized salads, we require that each source document contain at least eight sentences. Furthermore, to avoid problematically large salads, we pull paragraphs from source documents one at a time until the eight sentence minimum is met. While this procedure can be used to mix any number of documents, we currently present mixtures of two documents.

We utilize two different corpora as sources for story salad generation: (i) the subset of New York Times articles presented within English Gigaword (Graff and Cieri, 2003) and (ii) English Wikipedia[5] (Wikipedia contributors, 2004). An overview of the datasets is available in Table 1.

Gigaword. From the New York Times subset of Gigaword, we compiled a set of 573,681 mixtures we call NYT. Each mixture in this set is constructed from source articles pulled from the same month and year. Because this temporal constraint is the only restriction put on what articles can be mixed, it is possible for a salad to be constructed from topically disparate source documents (e.g., a restaurant review and a political story). We intend NYT to be relatively easy on the whole as a result of this design choice.

However, it is also possible for articles about dominant news stories and trends (e.g., the OJ Simpson trial in the summer of 1994) to be mixed as a result of the same temporal constraint. We therefore pulled out a curated subset of NYT consisting only of salads generated from highly topically similar source documents which we call NYT-HARD. This subset consists of the 1,000 salads where the source documents are most topically similar. We calculate topic similarity scores by computing the cosine similarity between the average word embeddings for each source document (denoted cos hereafter)

$$\cos(d) = \frac{g(\omega_1) \cdot g(\omega_2)}{\| g(\omega_1) \| \| g(\omega_2) \|} \qquad (1)$$

where ω_1 and ω_2 are the source documents, g is a function that computes the average word embedding of a document, and d is the salad under evaluation. The cos scores on the test portion of the datasets are presented in Table 1.

Wikipedia. From Wikipedia, we present an additional set of 500k salads constructed by combining random articles which we call WIKI.

We also leverage Wikipedia category membership as a form of human-annotated topic information. We use this to create a set of 50,374 salads, henceforth called WIKI-HARD, by restricting the domain of articles to only those appearing in categories containing the words *conflict* and *war*. Each mixture in this set is generated from source articles from the same category in order to produce highly difficult mixtures. We intend this to be a challenge set in this domain as the constituent articles for a given mixture are intentionally selected to be closely related. While we have used the category information to construct an intentionally very difficult set for this paper, we note that this procedure can be used to create sets of varying difficulty.

The fact that WIKI-HARD is generated from human-annotated category labels differentiates it from NYT-HARD in the source of its difficulty. After manually reviewing 20 samples from each *-HARD dataset, we found that NYT-HARD more frequently contains salads that are impossible for humans to pick apart while WIKI-HARD more frequently contains salads that are possible, though challenging. In particular, in 9 out of 20 WIKI-HARD salads we found that access to world knowledge and inference would be beneficial. Nevertheless, the two *-HARD datasets are both high in topic similarity (Table 1).

In Figure 2 we present sentences from a sample WIKI-HARD salad that can be solved with world knowledge. In this salad, we learn about two individuals. We can tell that Randle, born in 1855, is unlikely to also have been enrolled in high school in 1913 at the age of 58. We also learn that Randle was a doctor, while Martins, the other individual, was involved in theater. From this, we can deduce that the individual who "also worked as a wrestler" is more likely to be Martins than Randle.

---

[5] Wikipedia dump pulled on January 20, 2018.

(A) John K. Randle was born on 1 February 1855, son of Thomas Randle, a liberated slave from an Oyo village in the west of what is now Nigeria. (B) In 1913 he was enrolled in Eko Boys High School but dropped out. (B) Martins joined the theatre and from there took on various theatre jobs to survive. (A) Born in Sierra Leone , he was one of the first West Africans to qualify as a doctor in the United Kingdom. (B) He also worked as a wrestler (known as "Black Butcher Johnson").

Figure 2: A story salad from WIKI-HARD, sourced from articles belonging to the *Nigerian people of World War I* category. The sentences from this salad have been rearranged for clearer presentation.

Event Representation. Finally, we explore a form of document representation that has been shown to be useful in narrative schema learning, a related task. We include variants of NYT and NYT-HARD with story salads consisting of event tuple representations instead of natural language sentence representations, as in Pichotta and Mooney (2016). We label these variants as NYT-EVENT and NYT-EVENT-HARD. Event tuples are in the form <VERB, SUBJ, DOBJ, PREP, POBJ>, where as many preposition and prepositional object pairs as necessary are allowed.[6]

Summary. The story salads we present here are, in the end, simpler than those that occur naturally in the news or on social media: for one thing, sentences drawn from a document written by a single author should exhibit a high degree of coherence. We have also shown that we can use Wikipedia category annotations to produce large-scale story salad datasets with customizable levels of difficulty, enabling us to increase the difficulty of the task as performance increases. In the following section, we see that both our standard and *-HARD mixtures are challenging for current models. Furthermore, our WIKI-HARD dataset contains salads featuring conflicting information and is an attractive setting for building models with deeper reasoning capabilities.

4 Models

We treat the story salad task as a narrative clustering task where, in our dataset, each salad is comprised of two clusters. Accordingly, the first baselines we consider are standard clustering approaches.

Baselines. Our first baseline is a simple *uniform baseline* (hereafter **UNIF**), where we assign all sentences in a document mixture to a single cluster. Under UNIF the clustering accuracy is the percentage of the majority-cluster sentences, e.g. if a mixture has 7 sentences from one narrative and 3 from the other, then the accuracy is 0.7.

Additionally, we explore a family of baselines that consist of clustering off-the-shelf sentence embeddings. We choose k-medoids[7] (hereafter **KM**) as our clustering algorithm. For sentence embeddings, we experimented with (i) averaged 300D GloVe embeddings (Pennington et al., 2014), which have been shown to produce surprisingly strong performance in a variety of text classification tasks (Iyyer et al., 2015; Coates and Bollegala, 2018); (ii) skip-thought embeddings (Kiros et al., 2015); and (iii) SCDV (Mekala et al., 2017), a multisense-aware sentence embedding algorithm which builds upon pretrained GloVe embeddings using a Gaussian mixture model. Averaged GloVe embeddings gave the best performance in our experiments; to avoid clutter, we only report those results henceforth.

Neural supervised clustering. Our baselines work directly on sentence embeddings and therefore ignore the task-specific supervision available in our labeled training data. Inspired by the work in Bilenko et al. (2004) and Finley and Joachim (2005) on supervised clustering, we aim to exploit this supervision using a learned distance metric in our clustering.[8]

Figure 3 shows our model, which produces a distribution $P(\texttt{same} \mid s_1, s_2, d)$: the probability that two sentences s_1 and s_2 taken from document mixture d are in the same cluster. We train this model as a binary classifier on sampled pairs of sentences to distinguish same-narrative sentence pairs (positive examples) from different-narrative pairs (negative examples). $1-P(\texttt{same} \mid s_1, s_2, d)$ is then used by the clusterer as the pairwise distance metric. Given the pairwise distance between all sentence pairs in a mixture, the KM algorithm

---

[6] Event tuples are extracted via the extractor presented in Cheng and Erk (2018), and copular verbs are not treated as events, meaning that some sentences translate to null events.

[7] K-medoids is chosen as a substitute for k-means because the latter does not extend easily to our classifier-aided neural models: it does not work when only pairwise distances are available. In empirical evaluation we found k-means and k-medoids to produce very similar accuracy scores when using off-the-shelf embeddings. Experiments with hierarchical agglomerative clustering (not reported here) showed it to perform worse than either method.

[8] In early experiments, another strong candidate we tried is a joint model of a sentence autoencoder and a clustering algorithm (Yang et al., 2017). However, this produces subpar performance (weaker than the strongest baseline), due partially to scalability issues in learning these jointly.

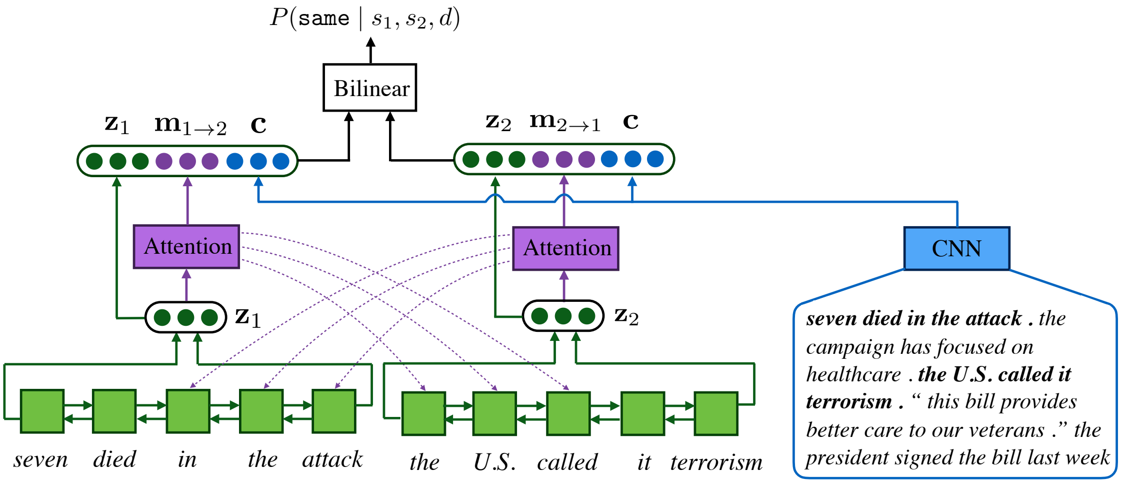

Figure 3: BiLSTM sentence pair classifier to determine whether s_1 and s_2 are from the same narrative, augmented with a mutual attention and a context reader. The three subcomponents — the BiLSTM, the mutual attention mechanism, and the context reader — each produce vectors, denoted as $\boldsymbol{z}, \boldsymbol{m}, \boldsymbol{c}$ respectively. In the basic BILSTM model, only $\boldsymbol{z}$ is fed to the bilinear layer (Eq. 2), while more sophisticated models incorporate the additional mutual attention and context vectors.

can then be applied to cluster sentences into two narratives.

Our classifier is a neural network model built on top of LSTM sentence encoders, which perform well at similar text classification tasks (Dai and Le, 2015; Liu et al., 2016).[9] Denoting a sentence as the list of embeddings of its constituent words: $s = \{\boldsymbol{w}_1, \ldots, \boldsymbol{w}_M\}$, we first encode it as a sentence embedding $\boldsymbol{z}$ with a bidirectional LSTM $\boldsymbol{z} = \texttt{BiLSTM}(s)$ and then compute the probability score with a bilinear layer:

$$P(\texttt{same} \mid s_1, s_2) = \sigma(\boldsymbol{z}_1^T W \boldsymbol{z}_2) \tag{2}$$

This model corresponds to the green subset of Figure 3.

Stronger models. There are two additional effects we might want our model to capture. First, whether two sentences are from the same narrative cannot be determined globally: there aren't two "globally-contrasted"[10] narratives (or bag-of-words based topics) from which sentences are sampled. In other words, sentences are always (pairwise) compared *in the context* of the document mixture from which they are drawn. Second, we want to capture more in-depth interactions between sentences: our sentence embedding scheme for a sentence s_1 should exploit its point of comparison s_2 and encode s_1 with a view of similarities to and differences with s_2. This type of technique has been useful in tasks like natural language inference (NLI) (Bowman et al., 2015; Peters et al., 2018).

To improve contextualization, we add a CNN-based context encoder to the BiLSTM classifier: the reader embeds the whole document salad at hand into a vector. Formally, we compute $\boldsymbol{c} = \text{CNN}(d)$, where in this case CNN denotes a single convolution layer with max pooling in the style of Kim (2014) and d is the concatenation of all sentences in the mixture. This component is shown in blue in Figure 3. The context vector $\boldsymbol{c}$ is then appended to $\boldsymbol{z}$ and fed into the bilinear layer.

To capture the interaction between two sentences in a pair, we employ a *mutual attention* mechanism, which is similar to the attentive reader (Hermann et al., 2015). Let $\boldsymbol{e}_{i,1\ldots n}$ denote the BiLSTM outputs for the tokens of sentence i. Given the encoding $\boldsymbol{z}_1$ of sentence s_1, we compute attention weights and a representation of s_2 as follows:

$$\boldsymbol{\alpha}_{1\to2} = \text{softmax}_j(\boldsymbol{z}_1^\top \boldsymbol{e}_{2,j})$$
$$\boldsymbol{m}_{1\to2} = \sum_j \alpha_{1\to2,j}\, \boldsymbol{e}_{2,j}$$

We compute $\boldsymbol{m}_{2\to1}$ analogously. This process is shown in purple in Figure 3. The $\boldsymbol{m}$ vectors are used as additional inputs to the bilinear layer.

For comprehensive ablation, we experiment with four variants of neural classifiers: (i) BiL-

---

[9] Experiments with convolutional encoders here yielded somewhat worse results.

[10] Two stories may be on the same topic and still form clearly different narratives. For example, both narratives in Figure 1 are regarding military conflict.

STM alone (**BILSTM**); (ii) BiLSTM + mutual attention (**BILSTM-MT**); (iii) BiLSTM + context (**BILSTM-CTX**); and (iv) BiLSTM + mutual attention and context (**BILSTM-MT-CTX**).

Event-based models. For the event-based variants of the datasets, NYT-EVENT and NYT-EVENT-HARD, we build three models: (i) FFNN-BILSTM: we input a sentence as a sequence of event embeddings rather than word embeddings as in BILSTM, where a feedforward layer maps the words in an event tuple to an event embedding; (ii) FFNN-BILSTM-MT-CTX: replacing the base BILSTM in (i) with our best model which is enhanced with mutual attention and contextualization; (iii) FFNN-BILSTM-MT-CTX-PRETRAIN: a variant of (ii) that is based on the event embedding pretraining method[11] described in Weber et al. (2018), where events are encoded with a feedforward net (same as (i)) and trained with a word2Vec-like objective, encouraging events that co-occur in the same narrative to have more similar embeddings.

5 Experiments and Analysis

Experimental setup. To stave off sparsity, we impose a vocabulary cut by using only the 100k most frequent lemmas. To evaluate on NYT, NYT-EVENT, WIKI and WIKI-HARD, we sample 20k unique salads (from their respective test portions[12]) to use for both the sentence and event versions of the experiments. For WIKI-HARD, the training combines the training portions of both WIKI and WIKI-HARD. For NYT-HARD, we train on the training portion of NYT and evaluate on NYT-HARD in full as a test set.

All the neural components are constructed with TensorFlow and use the same hyperparameters across variants: a 2-layer BiLSTM, learning rate 1e-5 with Adam (Kingma and Ba, 2014), dropout (Srivastava et al., 2014) rate 0.3 on all layers, and Xavier initialization (Glorot and Bengio, 2010). To create training pairs for the neural classifiers, we randomly sample sentence pairs balanced between same-narrative and different-narrative pairs. We train with a batch size of 32 and stop when an epoch yields less than 0.001% accuracy improvement on the validation set, which is 5% of mixtures sampled from the training data beforehand (the models are not trained on the validation sample). For KM we use the default configurations of off-the-shelf software.[13]

Model	NYT	WIKI	NYT-HARD	WIKI-HARD
UNIF	52.7	50.9	52.5	51.2
KM	76.4	74.9	59.8	60.4
BILSTM	78.5	76.2	55.3	59.8
BILSTM-MT	80.8	78.8	56.7	61.3
BILSTM-CTX	82.6	78.9	63.8	63.7
BILSTM-MT-CTX	**84.9**	**81.8**	**68.0**	**66.6**

Table 2: Clustering accuracy (CA) results from the sentence based experiments. More sophisticated models do better across all datasets, particularly on *-HARD tasks, which are substantially more challenging.

Evaluation. We evaluate all models in terms of a *clustering accuracy* metric (hereafter CA), which is a simple extension from the conventional accuracy metric: we calculate the ratio of correctly clustered sentences in a document mixture, averaged over test mixtures. Given a document mixture d_i, we call its component documents A and B. Let `pred` be a function that does the clustering by mapping each sentence $s_{i,n}$ of mixture d_i to either A or B, and $\texttt{true}_{AB}$ a function that returns the original pseudo-labels (i.e. $\{A, B\}$) as they are, and $\texttt{true}_{BA}$ flips the pseudo-labels, i.e. $A \rightarrow B$ and $B \rightarrow A$. Then the clustering accuracy for document d_i by `pred` is

$$\begin{aligned} \text{CA}(d_i, \texttt{pred}, \texttt{true}) = \max\{&\text{C}(d_i, \texttt{pred}, \texttt{true}_{AB}), \\ &\text{C}(d_i, \texttt{pred}, \texttt{true}_{BA})\} \end{aligned}$$

$$\text{C}(d_i, \texttt{pred}, \texttt{true}) = \frac{1}{N_i} \sum_n \mathbb{1}[\texttt{pred}(s_{i,n}) = \texttt{true}(s_{i,n})]$$

where $s_{i,n}$ is the n-th sentence of mixture d_i.

Sentence based models. First we evaluate the sentence based models. We first run the UNIF baseline on all our datasets, where we obtain near-50% clustering accuracy. This indicates that the data are all balanced in the number of sentences in the two narratives of the mixtures. We then run k-medoids (KM) on sentence embeddings as a baseline to compare to the classifier-aided models. The results are summarized in Table 2.

We first observe that the KM is a strong baseline and outperforms the supervised BILSTM system in the harder settings. Adding the mutual attention mechanism and contextualization, however, im-

---

[11] In Weber et al. (2018), a more complex tensor-based model is applied. Using exactly same method in our experiments we obtain weaker results.

[12] Test sets available with data release.

(a) from same narrative

(b) from different narratives

Figure 4: Attention weight heatmaps for a random sample with BILSTM-MT-CTX. Lighter color indicates higher attention weights. The two heatmaps in the same block are for the attention weights of one sentence attending to the other. In (a), we see related concepts being identified (*video game* and *sega*), while in (b), we see a contrast (*family station wagon* and *sega group*).

prove BILSTM substantially. In addition, the performance boost from the two components seems more or less orthogonal, as shown by the much stronger accuracy of the combined model (i.e. BILSTM-MT-CTX) than the models with a single component (i.e. BILSTM-MT and BILSTM-CTX). Overall, the large margin of KM and classifier-aided models above the UNIF baseline indicates that separating story salads is a valid task where generalizable patterns can be exploited by machine learning techniques.

Why would the mutual attention mechanism help? Plotting the attention weights of randomly selected samples, we see distributionally similar words being attended to in Figure 4a. Intuitively, a BiLSTM compresses a sentence into a single vector, leading to information loss (Conneau et al., 2018). Mutual attention enriches this representation by allowing us access to detailed information in sentences at word-level resolution by capturing lexical similarity. Even more interestingly, we observe a synergistic effect between mutual attention and contextualization: with the context reader added, we see high attention weights on words/phrases which bear little distributional similarity but are important for connecting/contrasting different narratives. For example, in Figure 4b, *sega group* and *family station wagon* are selected by the attention, despite not having similar words in the other sentences. These words are crucial in identifying the two narratives in this mixture: one is about a Japanese video game company, the other is on vehicle manufacturing in the U.S.

Type	Model	NYT	WIKI
-CONTEXT	BILSTM	-0.40^*	-0.43^*
	BILSTM-MT	-0.38^*	-0.40^*
+CONTEXT	BILSTM-CTX	-0.31^*	-0.30^*
	BILSTM-MT-CTX	-0.27^*	-0.25^*

Table 3: Spearman's ρ correlation between clustering accuracy (CA) and topic similarity (COS) in the evaluation with NYT and WIKI. The p-values are all below 0.01 (indicated by *). Contextualized models (+CONTEXT) are more robust to high topic similarity than their uncontextualized counterparts (-CONTEXT), indicated by the lower negative correlation between their accuracy and topic similarity.

Another observation is that all models see drastic reduction in accuracy in the *-HARD version of the data. In fact, the clustering accuracy corresponds well with our topic similarity metric (COS, Eq. 1; Table 1) across models. In addition, COS is negatively correlated with clustering accuracy for all mixtures (Table 3).

From the results we also see that contextualization brings clear performance improvement. This supports our hypothesis that the Story Salad task is a nonstandard clustering task where the contrast of two narratives is only meaningful *in the context* of the particular mixture where they reside, rather than on a corpus-general level. Taking the example in Figure 1, the Russian-Chechnya and the U.S.-Afghanistan narratives are contrasted in that mixture, but one can easily imagine a mixture where they are in the same narrative and are contrasted to another narrative on business affairs. Further, contextualized models are less vulnerable to the performance reduction on mixtures with high topic similarity: for one thing, contextualization improves performance over the base BILSTM on both regular and *-HARD datasets. Secondly, computing the correlation between clustering accuracy and topic similarity, we see a lower negative correlation for contextualized models, true for both NYT and WIKI datasets (Table 3).

Event based models. While the accuracy scores in the event based experiments are in general lower than those in the sentence based (Table 4), overall we observe the same pattern that

Model	NYT-EVENT	NYT-EVENT-HARD
KM	64.7	55.3
FFNN-BILSTM	64.9	54.8
*-MT-CTX	66.8	59.1
*-MT-CTX-PRETRAIN	**70.2**	**61.4**

Table 4: Clustering accuracy (CA) results from the event based experiments. *-MT-CTX is a short hand for FFNN-BILSTM-MT-CTX. The same notation applies for the following models.

mutual attention and contextualization contribute substantially to the performance. More interestingly, the performance reduction on the topically highly similar *-HARD is more mild compared to the sentence based experiments, which provides initial evidence that event-based narrative encoding allows the models to be more robust to distraction by lexical overlap in topically similar narratives. Finally we see that the event pretraining with Weber et al. (2018)'s technique brings additional improvement over a contextualized system.

The results open up a door for future work: (i) our simple models do not make use of coreference, narrative schema or world knowledge, which are intuitively promising components to introduce (see, e.g., the salad in Figure 2); (ii) more sophisticated model architectures may help capture the information missed by our models: moving from the sentence version to the event version, we lose many words which may have provided crucial cues in the sentence-based experiments.

Error analysis. In order to understand the errors made by each model, we performed a manual analysis of a small sample of bad clusterings. In a sample of 60 mixtures from NYT (test set), we considered all clusterings for which accuracy was less than 0.65. Among the 60 mixtures, the base model had an accuracy this low for 27 mixtures, the BILSTM-MT and BILSTM-CTX model had 13 low-accuracy mixtures each, and BILSTM-MT-CTX had 3. Each mixture was manually annotated by 2 annotators as being sourced from (i) thematically closely related documents (e.g., two stories on the same political event), (ii) thematically distinct documents (e.g., a political story and a sports story), or (iii) cannot tell.

(A) lehman brothers be one of several investment bank eager to get UNK hand on state asset, across the nation and in massachusetts (A) former massachusetts governor william f. weld, a staunch supporter of privatization during UNK administration, have UNK in the hall of the state house, now as a corporate lawyer try to drum up support for the sale of lucrative state asset. (B) officially, the rays option dukes, 22, to class a vero beach and place UNK on the temporary inactive list, where UNK will remain for an undetermined amount of time as UNK undergo counseling. (B) UNK apparently will receive UNK $ 380,000 major-league salary .

Figure 5: An example of (preprocessed) sentences from two unrelated documents being that have been clustered into a single cluster by the base model. Document (A) is an article about proposed privatization of public assets, while Document (B) is an article about happenings in Major League Baseball.

Our analysis showed that the base BILSTM model has difficulty even in cases where the source documents for the salad are thematically distinct. This was the case in 9 of 27 bad clusterings. The BILSTM-MT, BILSTM-CTX and BILSTM-MT-CTX models not only have many fewer bad clusterings, they also show low accuracy almost exclusively in mixtures of related documents (2 cases of distinct documents for BILSTM-CTX, none for BILSTM-MT or BILSTM-MT-CTX). Figure 5 shows an example of a bad clustering of two unrelated documents, produced by the base BILSTM model.

In a second study, we rated the same 60 samples by their difficulty for a human, focusing in particular on mixtures that went from low performance (0.5-0.65) in the BILSTM model to high performance (0.8-1.0) in another model. For BILSTM-CTX we find that only 2 out of 11 mixtures with such marked improvement over BILSTM were hard for humans; for BILSTM-MT only 1 out of 9 markedly improved mixtures was hard for humans. But for BILSTM-MT-CTX, 8 out of 17 markedly improved mixtures were hard for humans, indicating that more sophisticated models do better not only on easy but also on hard cases.

In a third small study, we compare NYT-HARD and WIKI-HARD for their difficulty for humans, looking at 20 mixtures each. Here, very interestingly, we find more mixtures that are impossible for humans in NYT-HARD (10 cases, example in Figure 6) than WIKI-HARD (3 cases). This presents a clear discrepancy between difficulty for humans and difficulty for models: the models do better on NYT-HARD which is harder for us. While we would not want to draw strong conclusions from a small sample, this hints at possibilities of future work where world knowledge, which is likely to be orthogonal to the information picked up by the models, can be introduced to improve performance (e.g. Wang et al. (2018)).

Note that unlike many other NLP tasks where

(A) The most basic question face the country on energy be how to keep supply and demand in line. The Democrats would say : “what can UNK do to make good use of what UNK have get?” (B) Oil price dominate the 31-minute news conference, hold here near pittsburgh. (B) Vice President Al Gore hold UNK first news conference in 67 day on Friday, defend UNK call for the release of oil from the government’s stockpile and and vow that UNK would “confront friend and foe alike” over the marketing of violent entertainment to child, despite the million in donation UNK receive from Hollywood. (A) With oil price up, consumer agitate and the winter heating season loom, Vice President Al Gore and Gov. George W. Bush be go at UNK on energy policy, seek to draw sharp distinction over an issue on which both candidate have political vulnerability. (B) On other topic, Gore say UNK be not nervous about the upcoming debate, but be incredulous when a reporter ask whether UNK be confident UNK have the election lock up. (A) Bush, who criticize the decision as a political ploy to drive down price just ahead of election day, be schedule to discuss energy policy in a speech on Friday. (B) On Friday, Bush call Gore a “flip-flopper”, say UNK proposal to tap into the reserve be a political ploy.

Figure 6: Part of a story salad that is impossible for a human to pick apart (source: NYT-HARD). “UNK” represents out-of-vocabulary tokens, and all the words are lemmatized. Both narratives, i.e. (A) and (B) involve the characters Al Gore and George Bush, and both are on the topic of energy, with strongly overlapping vocabulary.

human performance sets the ceiling for the best achievable results (e.g. span-prediction based question answering (Rajpurkar et al., 2016), where all the information needed for the correct answer is available in the input), successfully picking apart narratives in a story salad may require consulting an external knowledge base, which affords machine learning models a clear advantage over humans. For example, recognizing that *Commander Kamal* is likely to be Afghani based on his name, which is not knowledge every reader possesses, would allow us to successfully cluster the sentence with the U.S.-Afghanistan narrative rather than the Russian-Chechnya narrative.

6 Conclusion

We have presented a technique to generate *Story Salads*, mixtures of multiple narratives, at scale. We have demonstrated that the difficulty of these mixtures can be manipulated either based on document similarity or based on human-created document categories. This data gives rise to a challenging binary clustering task (but easily extended to n-ary), where the aim is to group sentences that come from the same original narrative. As coherence plays an important role in this task, the task is related to work on narrative schemas (Chambers and Jurafsky, 2008; Pichotta and Mooney, 2016) and textual coherence (Barzilay and Lapata, 2008; Logeswaran et al., 2018). The automated and scalable data generation technique allows for the use of neural models, which need large amounts of training data.

Conducting a series of preliminary experiments on the data with common unsupervised clustering algorithms (Cao and Yang, 2010) and variants of neural network-based (Kim, 2014; Dai and Le, 2015; Liu et al., 2016) supervised clustering (Bilenko et al., 2004; Finley and Joachim, 2005) models, we have (i) verified the validity of the task where generalizable patterns can be learned through machine learning techniques; (ii) shown that this is a nonstandard clustering task in which the contrast between narratives is *in context* as opposed to global; (iii) found that there is a class of mixtures that are doable for humans but very difficult for our current models, and that in particular the category-based method creates a high proportion of such mixtures.

Our work opens up a large number of directions for future research. First, while our models obtain strong results on simpler story salads, they have low performance on more difficult mixtures with high topical similarity. Second, there are many intuitively promising sources of information that we have not explored, such as coreference. And third, our models rely on pairwise similarity-based coherence learning, which leads to the natural question of whether structured prediction would improve performance.

Abstract

While one of the first steps in many NLP systems is selecting what pre-trained word embeddings to use, we argue that such a step is better left for neural networks to figure out by themselves. To that end, we introduce dynamic meta-embeddings, a simple yet effective method for the supervised learning of embedding ensembles, which leads to state-of-the-art performance within the same model class on a variety of tasks. We subsequently show how the technique can be used to shed new light on the usage of word embeddings in NLP systems.

1 Introduction

It is no exaggeration to say that word embeddings have revolutionized NLP. From early distributional semantic models (Turney and Pantel, 2010; Erk, 2012; Clark, 2015) to deep learning-based word embeddings (Bengio et al., 2003; Collobert and Weston, 2008; Mikolov et al., 2013; Pennington et al., 2014; Bojanowski et al., 2016), word-level meaning representations have found applications in a wide variety of core NLP tasks, to the extent that they are now ubiquitous in the field (Goldberg, 2016).

A sprawling literature has emerged about what types of embeddings are most useful for which tasks. For instance, there has been extensive work on understanding what word embeddings learn (Levy and Goldberg, 2014b), evaluating their performance (Milajevs et al., 2014; Schnabel et al., 2015; Bakarov, 2017), specializing them for certain tasks (Maas et al., 2011; Faruqui et al., 2014; Kiela et al., 2015; Mrkšić et al., 2016; Vulić and Mrkšić, 2017), learning sub-word level representations (Wieting et al., 2016; Bojanowski et al., 2016; Lee et al., 2016), et cetera.

One of the first steps in designing many NLP systems is selecting what kinds of word embeddings to use, with people often resorting to freely available pre-trained embeddings. While this is often a sensible thing to do, the usefulness of word embeddings for downstream tasks tends to be hard to predict, as downstream tasks can be poorly correlated with word-level benchmarks. An alternative is to try to combine the strengths of different word embeddings. Recent work in so-called "meta-embeddings", which ensembles embedding sets, has been gaining traction (Yin and Schütze, 2015; Bollegala et al., 2017; Muromägi et al., 2017; Coates and Bollegala, 2018). Meta-embeddings are usually created in a separate preprocessing step, rather than in a process that is dynamically adapted to the task. In this work, we explore the supervised learning of task-specific, dynamic meta-embeddings, and apply the technique to sentence representations.

The proposed approach turns out to be highly effective, leading to state-of-the-art performance within the same model class on a variety of tasks, opening up new areas for exploration and yielding insights into the usage of word embeddings.

Why Is This a Good Idea? Our technique brings several important benefits to NLP applications. First, it is embedding-agnostic, meaning that one of the main (and perhaps most important) hyperparameters in NLP pipelines is made obsolete. Second, as we will show, it leads to improved performance on a variety of tasks. Third, and perhaps most importantly, it allows us to overcome common pitfalls with current systems:

- **Coverage** One of the main problems with NLP systems is dealing with out-of-vocabulary words: our method increases lexical coverage by allowing systems to take the union over different embeddings.
- **Multi-domain** Standard word embeddings

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1466–1477
Brussels, Belgium, October 31 - November 4, 2018.

are often trained on a single domain, such as Wikipedia or newswire. With our method, embeddings from different domains can be combined, optionally while taking into account contextual information.

- **Multi-modality** Multi-modal information has proven useful in many tasks (Baroni, 2016; Baltrušaitis et al., 2018), yet the question of multi-modal fusion remains an open problem. Our method offers a straightforward solution for combining information from different modalities.
- **Evaluation** While it is often unclear how to evaluate word embedding performance, our method allows for inspecting the weights that networks assign to different embeddings, providing a direct, task-specific, evaluation method for word embeddings.
- **Interpretability and Linguistic Analysis** Different word embeddings work well on different tasks. This is well-known in the field, but knowing *why* this happens is less well-understood. Our method sheds light on which embeddings are preferred in which linguistic contexts, for different tasks, and allows us to speculate as to why that is the case.

Outline In what follows, we explore dynamic meta-embeddings and show that this method outperforms the naive concatenation of various word embeddings, while being more efficient. We apply the technique in a BiLSTM-max sentence encoder (Conneau et al., 2017) and evaluate it on well-known tasks in the field: natural language inference (SNLI and MultiNLI; §4), sentiment analysis (SST; §5), and image-caption retrieval (Flickr30k; §6). In each case we show state-of-the-art performance within the class of single sentence encoder models. Furthermore, we include an extensive analysis (§7) to highlight the general usefulness of our technique and to illustrate how it can lead to new insights.

2 Related Work

Thanks to their widespread popularity in NLP, a sprawling literature has emerged about learning and applying word embeddings—much too large to fully cover here, so we focus on previous work that combines multiple embeddings for downstream tasks.

Maas et al. (2011) combine unsupervised embeddings with supervised ones for sentiment classification. Yang et al. (2016) and Miyamoto and Cho (2016) learn to combine word-level and character-level embeddings. Contextual representations have been used in neural machine translation as well, e.g. for learning contextual word vectors and applying them in other tasks (McCann et al., 2017) or for learning context-dependent representations to solve disambiguation problems in machine translation Choi et al. (2016).

Neural tensor skip-gram models learn to combine word, topic and context embeddings (Liu et al., 2015); context2vec (Melamud et al., 2016) learns a more sophisticated context representation separately from target embeddings; and Li et al. (2016) learn word representations with distributed word representation with multi-contextual mixed embedding. Recent work in "meta-embeddings", which ensembles embedding sets, has been gaining traction (Yin and Schütze, 2015; Bollegala et al., 2017; Muromägi et al., 2017; Coates and Bollegala, 2018)—here, we show that the idea can be applied in context, and to sentence representations. Furthermore, these works obtain meta-embeddings as a preprocessing step, rather than learning them dynamically in a supervised setting, as we do here. Similarly to Peters et al. (2018), who proposed deep contextualized word representations derived from language models and which led to impressive performance on a variety of tasks, our method allows for contextualization, in this case of embedding set weights.

There has also been work on learning multiple embeddings per word (Chen et al., 2014; Neelakantan et al., 2015; Vu and Parker, 2016), including a lot of work in sense embeddings where the senses of a word have their own individual embeddings (Iacobacci et al., 2015; Qiu et al., 2016), as well as on how to apply such sense embeddings in downstream NLP tasks (Pilehvar et al., 2017).

The question of combining multiple word embeddings is related to multi-modal and multi-view learning. For instance, combining visual features from convolutional neural networks with word embeddings has been examined (Kiela and Bottou, 2014; Lazaridou et al., 2015), see Baltrušaitis et al. (2018) for an overview. In multi-modal semantics, for instance, word-level embeddings from different modalities are often mixed via concatenation $\mathbf{r} = [\alpha\mathbf{u}, (1-\alpha)\mathbf{v}]$ (Bruni et al., 2014). Here, we dynamically learn the weights to combine representations. Recently, related dynamic multi-modal fusion methods have also been explored (Wang et al., 2018; Kiros et al., 2018). There has also been work on unifying multi-view embeddings from different data sources (Luo et al., 2014).

The usefulness of different embeddings as initialization has been explored (Kocmi and Bojar, 2017), and different architectures and hyperparameters have been extensively examined (Levy et al., 2015). Problems with evaluating word embeddings intrinsically are well known (Faruqui et al., 2016), and various alternatives for evaluating word embeddings in downstream tasks have been proposed (e.g., Tsvetkov et al., 2015; Schnabel et al., 2015; Ettinger et al., 2016). For more related work with regard to word embeddings and their evaluation, see Bakarov (2017).

Our work can be seen as an instance of the well-known attention mechanism (Bahdanau et al., 2014), and its recent sentence-level incarnations of self-attention (Lin et al., 2017) and inner-attention (Cheng et al., 2016; Liu et al., 2016), where the attention mechanism is applied within the same sentence instead of for aligning multiple sentences. Here, we learn (optionally contextualized) attention weights for different embedding sets and apply the technique in sentence representations (Kiros et al., 2015; Wieting et al., 2015; Hill et al., 2016; Conneau et al., 2017).

3 Dynamic Meta-Embeddings

Commonly, NLP systems use a single type of word embedding, e.g., word2vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014) or FastText (Bojanowski et al., 2016). We propose giving networks access to multiple types of embeddings, allowing a network to learn which embeddings it prefers by predicting a weight for each embedding type, optionally depending on the context.

For a sentence of s tokens $\{\mathbf{t}_j\}_{j=1}^{s}$, we have n word embedding types, leading to sequences $\{\mathbf{w}_{i,j}\}_{j=1}^{s} \in \mathbb{R}^{d_i}$ $(i = 1, 2, \ldots, n)$. We center each type of word embedding to zero mean.

Naive baseline We compare to naive concatenation as a baseline. Concatenation is a sensible strategy for combining different embedding sets, because it provides the sentence encoder with all of the information in the individual embeddings:

$$\mathbf{w}_j^{CAT} = [\mathbf{w}_{1,j}, \mathbf{w}_{2,j}, \ldots, \mathbf{w}_{n,j}].$$

The downside of concatenating embeddings and giving that as input to an RNN encoder, however, is that the network then quickly becomes inefficient as we combine more and more embeddings.

DME For dynamic meta-embeddings, we project the embeddings into a common d'-dimensional space by learned linear functions $\mathbf{w}'_{i,j} = \mathbf{P}_i \mathbf{w}_{i,j} + \mathbf{b}_i$ $(i = 1, 2, \ldots, n)$ where $\mathbf{P}_i \in \mathbb{R}^{d' \times d_i}$ and $\mathbf{b}_i \in \mathbb{R}^{d'}$. We then combine the projected embeddings by taking the weighted sum

$$\mathbf{w}_j^{DME} = \sum_{i=1}^{n} \alpha_{i,j} \mathbf{w}'_{i,j}$$

where $\alpha_{i,j} = g(\{\mathbf{w}'_{i,j}\}_{j=1}^{s})$ are scalar weights from a self-attention mechanism:

$$\alpha_{i,j} = g(\mathbf{w}'_{i,j}) = \phi(\mathbf{a} \cdot \mathbf{w}'_{i,j} + b) \qquad (1)$$

where $\mathbf{a} \in \mathbb{R}^{d'}$ and $b \in \mathbb{R}$ are learned parameters and ϕ is a softmax (or could be a sigmoid or tanh, for gating). We also experiment with an **Unweighted** variant of this approach, that just sums up the projections.

CDME Alternatively, we can make the self-attention mechanism context-dependent, leading to contextualized DME (CDME):

$$\alpha_{i,j} = g(\{\mathbf{w}'_{i,j}\}_{j=1}^{s}) = \phi(\mathbf{a} \cdot \mathbf{h}_j + b) \qquad (2)$$

where $\mathbf{h}_j \in \mathbb{R}^{2m}$ is the j^{th} hidden state of a BiLSTM taking $\{\mathbf{w}'_{i,j}\}_{j=1}^{s}$ as input, $\mathbf{a} \in \mathbb{R}^{2m}$ and $b \in \mathbb{R}$. We set $m = 2$, which makes the contextualization very efficient.

Sentence encoder We use a standard bidirectional LSTM encoder with max-pooling (BiLSTM-Max), which computes two sets of s hidden states, one for each direction:

$$\overrightarrow{\mathbf{h}_j} = \overrightarrow{\mathrm{LSTM}_j}(\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_j)$$
$$\overleftarrow{\mathbf{h}_j} = \overleftarrow{\mathrm{LSTM}_j}(\mathbf{w}_j, \mathbf{w}_{j+1}, \ldots, \mathbf{w}_s)$$

The hidden states are subsequently concatenated for each timestep to obtain the final hidden states, after which a max-pooling operation is applied over their components to get the final sentence representation:

$$\mathbf{h} = \max(\{[\overrightarrow{\mathbf{h}_j}, \overleftarrow{\mathbf{h}_j}]\}_{j=1,2,\ldots,s})$$

Results averaged over five runs with different random seeds, using a BiLSTM-Max sentence encoder.

4 Natural Language Inference

Natural language inference, also known as recognizing textual entailment (RTE), is the task of classifying pairs of sentences according to whether they are neutral, entailing or contradictive. Inference about entailment and contradiction is fundamental to understanding natural language, and there are two established datasets to evaluate semantic representations in that setting: SNLI (Bowman et al., 2015) and the more recent MultiNLI (Williams et al., 2017).

The SNLI dataset consists of 570k human-generated English sentence pairs, manually labeled for entailment, contradiction and neutral. The MultiNLI dataset can be seen as an extension of SNLI: it contains 433k sentence pairs, taken from ten different genres (e.g. fiction, government text or spoken telephone conversations), with the same entailment labeling scheme.

We train sentence encoders with dynamic meta-embeddings using two well-known and often-used embedding types: FastText (Mikolov et al., 2018; Bojanowski et al., 2016) and GloVe (Pennington et al., 2014). Specifically, we make use of the 300-dimensional embeddings trained on a similar WebCrawl corpus, and compare three scenarios: when used individually, when naively concatenated or in the dynamic meta-embedding setting (unweighted, context-independent DME and contextualized CDME). We also compare our approach against other models in the same class—in this case, models that encode sentences individually and do not allow attention *across* the two sentences.[1] We include InferSent (Conneau et al., 2017), which also makes use of a BiLSTM-Max sentence encoder.

In addition, we include a setting where we combine not two, but six different embedding types, adding FastText wiki-news embeddings[2], English-German and English-French embeddings from Hill et al. (2014), as well as the BOW2 embeddings from Levy and Goldberg (2014a) trained on Wikipedia.

4.1 Implementation Details

The two sentences are represented individually using the sentence encoder. As is standard in the literature, the sentence representations are subsequently combined using $\mathbf{m} = [\mathbf{u}, \mathbf{v}, \mathbf{u} * \mathbf{v}, |\mathbf{u} - \mathbf{v}|]$. We train a two-layer classifier with rectifiers on top of the combined representation. Notice that there is no interaction (e.g., attention) between the representations of $\mathbf{u}$ and $\mathbf{v}$ for this class of model.

We use 256-dimensional embedding projections, 512-dimensional BiLSTM encoders and an MLP with 1024-dimensional hidden layer in the classifier. The initial learning rate is set to 0.0004 and dropped by a factor of 0.2 when dev accuracy stops improving, dropout to 0.2, and we use Adam for optimization (Kingma and Ba, 2014). The loss is standard cross-entropy.

For MultiNLI, which has no designated validation set, we use the in-domain *matched* set for validation and report results on the out-of-domain *mismatched* set.

4.2 Results

Table 1 shows the results. We report accuracy scores averaged over five runs with different random seeds, together with their standard deviation, for the SNLI and MultiNLI datasets. We include two versions of the naive baseline: one with a 512-dimensional BiLSTM encoder; and a bigger one with 2048 dimensions. Both naive baseline models outperform the single encoders that have only GloVe or FastText embeddings. This shows how

---

[1] This is a common distinction, see e.g. the SNLI leaderboard at `https://nlp.stanford.edu/projects/snli/`.

Table 2: Sentiment classification accuracy results on the binary SST task. For DCG we compare against their best single sentence model (Looks et al., 2017). *=multiple different embedding sets (see Section 4). Number of parameters included in parenthesis. Results averaged over ten runs with different random seeds.

including more than one embeddings can help performance. Next, we observe that the DME embeddings outperform the naive concatenation baselines, while having fewer parameters. Differences between the three DME variants are small and not significant, although we do note that we found the highest maximum performance for the contextualized version, which adds very few additional parameters. It is important to note that the imposition of weighting thus is not detrimental to performance, which means that DME and CDME provide additional interpretability without sacrificing performance.

Finally, we obtain results for using the six different embedding types (marked *), and show that adding in more embeddings increases performance further. To our knowledge, these numbers constitute the state of the art within the model class of single sentence encoders on these tasks.

5 Sentiment

To showcase the general applicability of the proposed approach, we also apply it to a case where we have to classify a single sentence, namely, sentiment classification. Sentiment analysis and opinion mining have become important applications for NLP research. We evaluate on the binary SST task (Socher et al., 2013), consisting of 70k sentences with a corresponding binary (positive or negative) sentiment label.

	Image		Caption	
Model | R@:	1	10	1	10

CDME (15M)	36.5	75.6	49.0	83.8

Table 3: Image and caption retrieval results (R@1 and R@10) on Flickr30k dataset, compared to VSE++ baseline (Faghri et al., 2017). VSE++ numbers in the table are with ResNet features and random cropping, but no fine-tuning. Number of parameters included in parenthesis; averaged over five runs with std omitted for brevity.

5.1 Implementation Details

We use 256-dimensional embedding projections, 512-dimensional BiLSTM encoders and an MLP with 512-dimensional hidden layer in the classifier. The initial learning rate is set to 0.0004 and dropped by a factor of 0.2 when dev accuracy stops improving, dropout to 0.5, and we use Adam for optimization. The loss is standard cross-entropy. We calculate the mean accuracy and standard deviation based on ten random seeds.

5.2 Results

Table 2 shows a similar pattern as we observed with NLI: the naive baseline outperforms the single-embedding encoders; the DME methods outperform the naive baseline, with the contextualized version appearing to work best. Finally, we experiment with replacing ϕ in Eq. 1 and 2 with a sigmoid gate instead of a softmax, and observe improved performance on this task, outperforming the comparable models listed in the table. These results further strengthen the point that having multiple different embeddings helps, and that we can learn to combine those different embeddings efficiently, in interpretable ways.

6 Image-Caption Retrieval

An advantage of the proposed approach is that it is inherently capable of dealing with multi-modal information. Multi-modal semantics (Bruni et al., 2014) often combines linguistic and visual representations via concatenation with a global weight

α, i.e., $\mathbf{v} = [\alpha\mathbf{v}_{ling}, (1-\alpha)\mathbf{v}_{vis}]$. In DME we instead learn to combine embeddings dynamically, optionally based on context. The representation for a word then becomes grounded in the visual modality, and we encode on the word-level *what things look like*.

We evaluate this idea on the Flickr30k image-caption retrieval task: given an image, retrieve the correct caption; and vice versa. The intuition is that knowing what something looks like makes it easier to retrieve the correct image/caption. While this work was under review, a related method was published by Kiros et al. (2018), which takes a similar approach but evaluates its effectiveness on COCO and uses Google images. We obtain word-level *visual embeddings* by retrieving relevant images for a given label from ImageNet in the same manner as Kiela and Bottou (2014), taking the images' ResNet-152 features (He et al., 2016) and subsequently averaging those. We then learn to combine textual (FastText) and visual (ImageNet) word representations in the caption encoder used for retrieving relevant images.

6.1 Implementation Details

Our loss is a max-margin rank loss as in VSE++ (Faghri et al., 2017), a state-of-the-art method on this task. The network architecture is almost identical to that system, except that we use DME (with 256-dimensional embedding projection) and a 1024-dimensional caption encoder. For the Flickr30k images that we do retrieval over, we use random cropping during training for data augmentation and use a ResNet-152 for feature extraction. We tune the sizes of the encoders and use a learning rate of 0.0003 and a dropout rate of 0.1.

6.2 Results

Table 3 shows the results, comparing against VSE++. First, note that the ImageNet-only embeddings don't work as well as the FastText ones, which is most likely due to poorer coverage. We observe that DME outperforms naive and FastText-only, and outperforms VSE++ by a large margin. These findings confirm the intuition that knowing what things look like (i.e., having a word-level visual representation) improves performance in visual retrieval tasks (i.e., where we need to find relevant images for phrases or sentences)—something that sounds obvious but has not really been explored before, to our knowledge. This showcases DME's usefulness for fusing embeddings in multi-modal tasks.

7 Discussion & Analysis

Aside from improved performance, an additional benefit of learning dynamic meta-embeddings is that they enable inspection of the weights that the network has learned to assign to the respective embeddings. In this section, we perform a variety of smaller experiments in order to highlight the usefulness of the technique for studying linguistic phenomena, determining appropriate training domains and evaluating word embeddings. We compute the contribution of each word embedding type as follows:

$$\beta_{i,j} = \frac{\|\alpha_{i,j}\mathbf{w'}_{i,j}\|_2}{\sum_{k=1}^{n}\|\alpha_{k,j}\mathbf{w'}_{k,j}\|_2}$$

7.1 Visualizing Attention

Figure 1 shows the attention weights for a CDME model trained on SNLI, using the aforementioned six embedding sets. The sentence is from the SNLI validation set. We observe that different embeddings are preferred for different words. The figure is meant to illustrate possibilities for analysis, which we turn to in the next section.

7.2 Linguistic Analysis

We perform a fine-grained analysis of the behavior of DME on the validation set of SNLI. Figure 3 shows a breakdown of the average attention weights per part of speech. Figure 4 shows a similar breakdown for open versus closed class. The analysis allows us to make several interesting observations: it appears that this model prefers GloVe embeddings, followed by the two FastText embeddings (trained on Wikipedia and Common Crawl). For open class words (e.g., nouns, verbs, adjectives and adverbs), those three embedding types are strongly preferred, while closed class words get more evenly divided attention. The embeddings from Levy and Goldberg (2014a) get low weights, possibly because the method is complementary with FastText-wiki, which was trained on a more recent version of Wikipedia.

We can further examine the attention weights by analyzing them in terms of frequency and concreteness. We use Norvig's Google N-grams corpus frequency counts[3] to divide the words into fre-

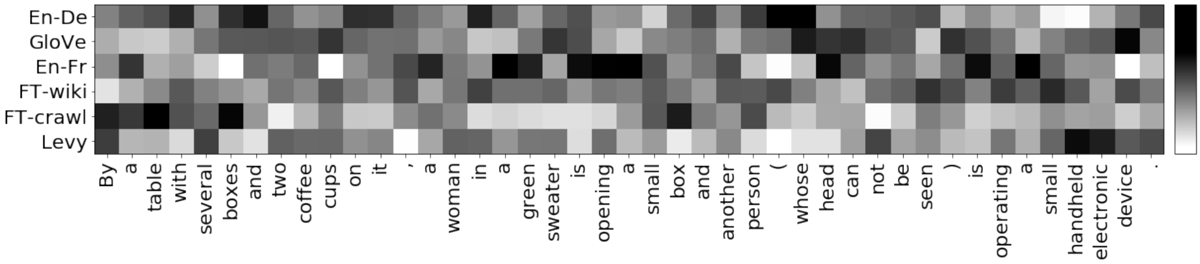

Figure 1: Example visualization of a sentence from the SNLI dev set.

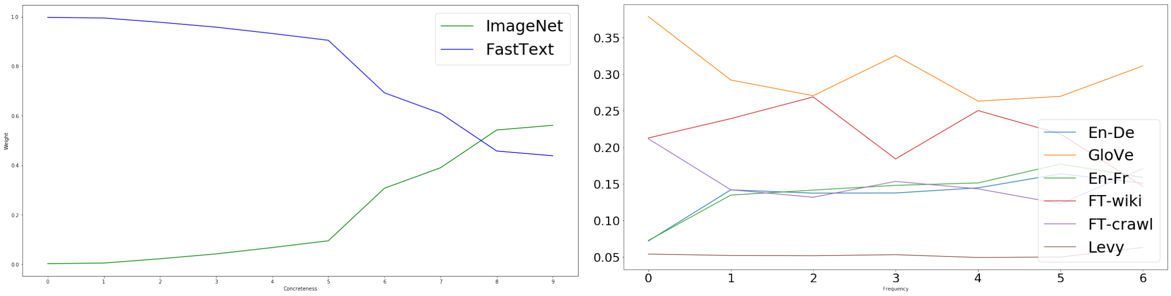

Figure 2: Concreteness weights (left) for Flickr30k model and Frequency weights (right) for SNLI model with multiple embeddings. Visual ImageNet embeddings are preferred for more concrete words. GloVe is strongly preferred for low-frequency words.

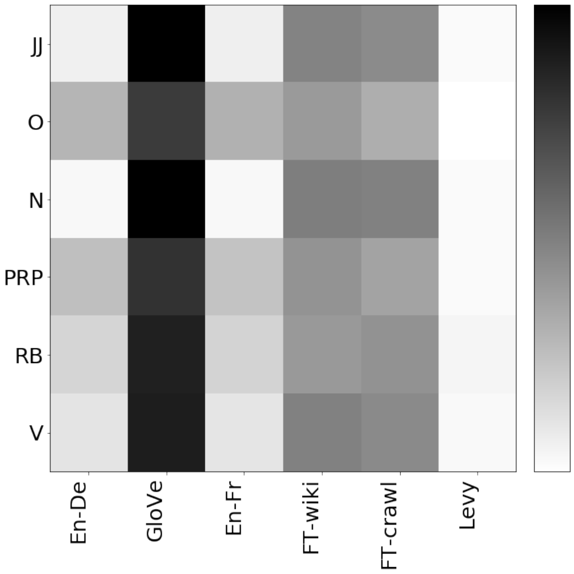

Figure 3: Pos tags and weights by embedding type.

quency bins. Figure 2 (right) shows the average attention weights per frequency bin, ranging from low to high. We observe a clear preference for GloVe, in particular for low-frequency words. For concreteness, we use the concreteness ratings from Brysbaert et al. (2014). Figure 2 (left) shows the average weights per concreteness bin for a model trained on Flickr30k. We can clearly see that visual embeddings get higher weights as the words become more and more concrete.

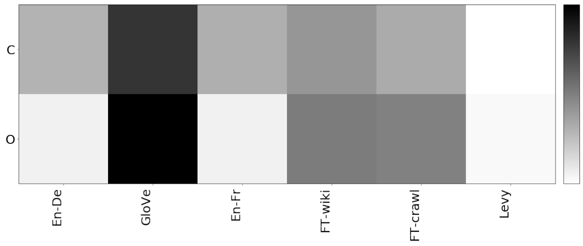

Figure 4: Weights for open/closed class words.

There are of course intricate relationships between concreteness, frequency, POS tags and open/closed class words: closed class words are often frequent and abstract, while open class words could be more concrete, etc. It is beyond the scope of the current work to explore these further, but we hope that others will pursue this direction in future work.

7.3 Multi-domain Embeddings

The MultiNLI dataset consists of various genres. This allows us to inspect the applicability of source domain data for a specific genre. We train embeddings on three kinds of data: Wikipedia, the Toronto Books Corpus (Zhu et al., 2015) and the English OpenSubtitles[4]. We examine the atten-

---

[4] `http://opus.nlpl.eu/OpenSubtitles.php`

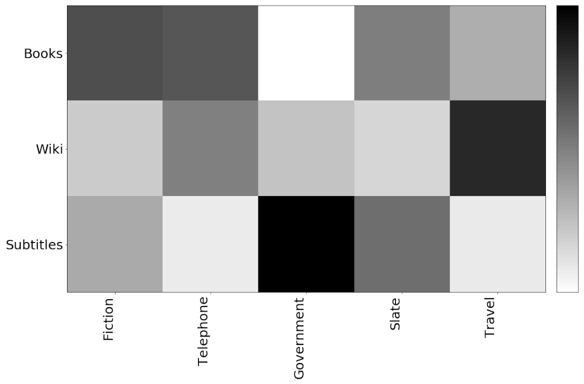

Figure 5: Multi-domain weights on MultiNLI.

Model	Levy	LEAR	SNLI
CDME	0.33	0.67	85.3±.9
Model	GloVe	Refined	SST
CDME	0.59	0.41	89.0±.4

Table 4: Accuracy and learned weights on SNLI using LEAR (Vulić and Mrkšić, 2017) or SST using sentiment-refined embeddings using the specialization method from Yu et al. (2017).

tion weights on the five genres in the in-domain (matched) set, consisting of fiction; transcriptions of spoken telephone conversations; government reports, speeches, letters and press releases; popular culture articles from the Slate Magazine archive; and travel guides.

Figure 5 shows the average attention weights for the three embedding types over the five genres. We observe that Toronto Books, which consists of fiction, is very appropriate for the fiction genre, while Wikipedia is highly preferred for the travel genre, perhaps because it contains a lot of factual information about geographical locations. The government genre makes more use of OpenSubtitles. The spoken telephone genre does not appear to prefer OpenSubtitles, which we might have expected given that that corpus would contain spoken dialogue, but Toronto books, which does include written dialogue.

7.4 Specialization

The above shows that we can use DME to analyze different embeddings on a task. Given the recent interest in the community in specializing, retro-fitting and counter-fitting word embeddings for given tasks, we examine whether the lexical-level benefits of specialization extend to sentence-level downstream tasks. After all, one of the main motivations behind work on lexical entailment is that it allows for better downstream textual entailment. Hence, we take the LEAR embeddings by Vulić and Mrkšić (2017), which do very well on the HyperLex lexical entailment evaluation dataset (Vulić et al., 2017). We compare their best-performing embeddings against the original embeddings that were used for specialization, derived from the BOW2 embeddings of Levy and Goldberg (2014a). Similarly, we use the technique of Yu et al. (2017) for refining GloVe embeddings for sentiment, and evaluate model performance on the SST task.

Table 4 shows that LEAR embeddings get high weights compared to the original source embeddings ("Levy" in the table). Our analysis showed that LEAR was particularly favored for verbs (with average weights of 0.75). The sentiment-refined embeddings were less useful, with the original GloVe embeddings receiving higher weights. These preliminary experiments show how DME models can be used for analyzing the performance of specialized embeddings in downstream tasks.

Note that different weighting mechanisms might give different results—we found that the normalization strategy and the depth of the network significantly influenced weight assignments in our experiments with specialized embeddings.

7.5 Examining Contextualization

We examined models trained on SNLI and looked at the variance of the attention weights per word in the dev set. If contextualization is important for getting the classification decision correct, then we would expect big differences in the attention weights per word depending on the context. Upon examination, we only found relatively few differences. In part, this may be explained by the small size of the dev set, but for the Glove+FastText model we inspected there were only around twenty words with any variance at all, which suggests that the field needs to work on more difficult semantic benchmark tasks. The words, however, where characterized by their polysemy, in particular by having both noun and verb senses. The following words were all in the top 20 most context-dependent words: *mob*, *boards*, *winds*, *trains*, *pitches*, *camp*.

8 Conclusion

We argue that the decision of which word embeddings to use in what setting should be left to the neural network. While people usually pick one type of word embeddings for their NLP systems and then stick with it, we find that dynamically learned meta-embeddings lead to improved results. In addition, we showed that the proposed mechanism leads to better interpretability and insightful linguistic analysis. We showed that the network learns to select different embeddings for different data, different domains and different tasks. We also investigated embedding specialization and examined more closely whether contextualization helps. To our knowledge, this work constitutes the first effort to incorporate multi-modal information on the language side of image-caption retrieval models; and the first attempt at incorporating meta-embeddings into large-scale sentence-level NLP tasks.

In future work, it would be interesting to apply this idea to different tasks, in order to explore what kinds of embeddings are most useful for core NLP tasks, such as tagging, chunking, named entity recognition, parsing and generation. It would also be interesting to further examine specialization and how it transfers to downstream tasks. Using this method for evaluating word embeddings in general, and how they relate to sentence representations in particular, seems a fruitful direction for further exploration. In addition, it would be interesting to explore how the attention weights change during training, and if, e.g., introducing entropy regularization (or even negative entropy) might improve results or interpretability further.

Acknowledgments

We thank the anonymous reviewers for their comments. We also thank Marcus Rohrbach, Laurens van der Maaten, Ivan Vulić, Edouard Grave, Tomas Mikolov and Maximilian Nickel for helpful suggestions and discussions with regard to this work.

Abstract

Several recent studies have shown the benefits of combining language and perception to infer word embeddings. These multimodal approaches either simply combine pre-trained textual and visual representations (e.g. features extracted from convolutional neural networks), or use the latter to bias the learning of textual word embeddings. In this work, we propose a novel probabilistic model to formalize how linguistic and perceptual inputs can work in concert to explain the observed word-context pairs in a text corpus. Our approach learns textual and visual representations jointly: latent visual factors couple together a skip-gram model for co-occurrence in linguistic data and a generative latent variable model for visual data. Extensive experimental studies validate the proposed model. Concretely, on the tasks of assessing pairwise word similarity and image/caption retrieval, our approach attains equally competitive or stronger results when compared to other state-of-the-art multimodal models.

1 Introduction

Continuous-valued vector representation of words has been one of the key components in neural architectures for natural language processing (Mikolov et al., 2013; Pennington et al., 2014; Levy and Goldberg, 2014). The main idea is based on the distributional hypothesis (Harris, 1954), which states that words used in similar contexts have similar semantic meanings. To this end, words are mapped to points in an Euclidean space such that the displacement between their coordinates (i.e., embeddings) reflects similarity and difference in semantics (Pennington et al., 2014). As such, word embeddings have been shown to be useful in determining semantic and syntactic similarity between individual words (Mikolov et al., 2013; Baroni et al., 2014; Levy et al., 2015), as well as in downstream NLP tasks, e.g., sentiment analysis, question answering, and coreference resolution, just to name a few.

Most existing approaches rely solely on text corpora to infer word representations. While successful, the embeddings produced by such models do not necessarily reflect all inherent aspects of human semantic knowledge, such as the perceptual aspect (Feng and Lapata, 2010). This has motivated many researchers to explore different ways to infuse visual information, often represented in the form of pre-computed visual features, into word embeddings (Kiela and Bottou, 2014; Silberer et al., 2017; Collell et al., 2017; Lazaridou et al., 2015). The main theme is to take either the text embeddings, or the visual features or both *as such* to derive multimodal embeddings: through concatenation (Kiela and Bottou, 2014), or by treating visual features as regression targets (Lazaridou et al., 2015; Collell et al., 2017).

Despite the success of these prior efforts in yielding multimodal embeddings and applying them to downstream NLP tasks, there are still several deficiencies. In particular, the visual features (as such) are not guaranteed to be suitable for the word embedding task since they are typically optimized independently for another objective (e.g., image classification). Hence, fusing *pre-computed* word representations and visual features may not be a good strategy.

To address the above issues, we explore a new way to integrate linguistic and perceptual information. We develop a new model which jointly learns word embeddings from text and extracts latent visual information, from pre-computed visual features, that could supplement the linguistic embeddings in modeling the co-occurrence of words

Brussels, Belgium, October 31 - November 4, 2018.

and their contexts in a corpus. Instead of using pre-trained visual features as it is or as regression targets, we posit that they contain latent perceptual information that could complement text in representing words.

More specifically, the proposed model consists of two components. The visual component is an unsupervised probabilistic model for learning latent factors that generates the visual data. The linguistic component is a revised SKIP-GRAM model in which the text embeddings work *in concert* with the latent visual factors to explain the occurrence of word-context pairs in a corpus. One advantage of our joint modeling is that it allows two-way interaction. On one hand, the linguistic information can guide the extraction of latent visual factors. On the other hand, the extracted visual factors can improve the modeling of word-context co-occurrences in text data. Another appealing property of our model is its natural ability to propagate perceptual information to the embeddings of words lacking visual features (e.g., abstract words) during learning.

We conduct extensive quantitative and qualitative experiments to examine and understand the effectiveness of our approach, on the tasks of word similarity and image/caption retrieval. We show its matching or stronger performance when compared to other state-of-the-art approaches for learning multimodal embeddings.

2 Our Approach

We start by introducing the problem setup and notations. We then describe our model, namely PIXIE (ProbabIlistic teXtual Image Embeddings), for joint learning of word representations from text and perceptual information.

2.1 Setup and Background

We are given a corpus of H tokens (words): $w_1, \ldots, w_i, \ldots, w_H$. From the corpus, we form a collection of word-context pairs $\delta_{w,c} = (w, c)$, such that $w \in V_w$, $c \in V_c$, with V_w and V_c denoting respectively the word and context vocabularies. As in most previous work, the contexts for word w_i are the words that surround it in a L-sized window. We introduce the binary indicator variables y_{wc}, such that $y_{wc} = 1$ if $\delta_{w,c}$ appears in our collection, and $y_{wc} = 0$ otherwise.

For some words with visual grounding (we will refer to them as *visual words*), we have access to a visual representation $\boldsymbol{x}_w$. In practice, we use convolutional net features (see Section 4 for details).

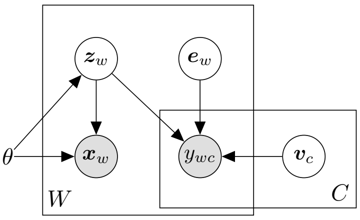

Figure 1: Plate representation of our model PIXIE. The model consists of a generative model for visual data and a conditional model for text data. The latent visual factors $\boldsymbol{z}$ and text embedding $\boldsymbol{e}$ jointly predict the word-context pair's label y.

SKIP-GRAM WITH NEGATIVE SAMPLING (SGNS) The SGNS's objective is to learn word representations that are good at distinguishing the observed pairs ($y_{wc} = 1$) from non-observed or "negative" pairs ($y_{wc} = 0$), using logistic regression. Formally, SGNS maximizes the following log-likelihood:

$$\sum_{w,c} [y_{wc} \log \sigma(\boldsymbol{v}_c^\top \boldsymbol{e}_w) + (1 - y_{wc}) \log \sigma(-\boldsymbol{v}_c^\top \boldsymbol{e}_w)], \quad (1)$$

where $\sigma(\cdot)$ is the sigmoid function, $\boldsymbol{v}_c$, $\boldsymbol{e}_w$ denote respectively the vectors for the context c and target word w. The second term in (1) is intractable due to the large number of possible negative pairs, and is approximated by sampling N negative examples $\{c'_i\}_{i=1}^N$ for every observed pair of words and their contexts. This gives rise to the following objective function for each observed pair:

$$\log \sigma(\boldsymbol{v}_c^\top \boldsymbol{e}_w) + \sum_{i=1}^{N} \log \sigma(-\boldsymbol{v}_{c'_i}^\top \boldsymbol{e}_w), \qquad (2)$$

where c'_i is a (negative) context that does not appear in the context of w (Mikolov et al., 2013). In practice, criterion (2) is optimized in an online fashion, by using Stochastic Gradient Descent (SGD) over the observed pairs δ_{wc} in the corpus. Each observed pair δ_{wc} typically occurs several times in the corpus, therefore performing SGD over the corpus amounts to weighting equation (2) by the number of occurrence of each pair.

2.2 Joint Visual and Text Modeling

We now describe our model, namely PIXIE (ProbabIlistic teXtual Image Embeddings) illustrated in Fig. 1, for joint learning of word representations from textual and perceptual information.

Formally, PIXIE is a probabilistic model of image features $\boldsymbol{x}$ and word-context pairs' labels $\boldsymbol{y}$. Similar to SKIP-GRAM, PIXIE represents each word w and context c with low dimensional embeddings noted respectively $\boldsymbol{e}_w \in \mathbb{R}^K$ and $\boldsymbol{v}_c \in \mathbb{R}^K$. PIXIE further assumes latent visual factors, $\boldsymbol{z}_w \in \mathbb{R}^K$, for each word's visual representation $\boldsymbol{x}_w$. Next we describe the two main components of PIXIE, namely *textual* and *perceptual*, in more details.

Perceptual Component Each visual vector $\boldsymbol{x}_w$ is drawn conditional on its latent representation $\boldsymbol{z}_w$, i.e., $\boldsymbol{x}_w \sim p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z}_w)$, with $p_{\boldsymbol{\theta}}(\boldsymbol{z}) = \mathcal{N}(0, \mathbf{I})$. Since $\boldsymbol{x}_w$ is real valued, we let $p_{\boldsymbol{\theta}}(\boldsymbol{x}_w|\boldsymbol{z}_w)$ be a Gaussian parameterized by a *generative neural network* (or decoder). That is,

$$p_{\boldsymbol{\theta}}(\boldsymbol{x}_w|\boldsymbol{z}_w) = \mathcal{N}(\boldsymbol{x}_w|\boldsymbol{\mu}_{\boldsymbol{\theta}}(\boldsymbol{z}_w), \boldsymbol{\Sigma}_{\boldsymbol{\theta}}(\boldsymbol{z}_w)). \quad (3)$$

For tractability purposes, $\boldsymbol{\Sigma}_{\boldsymbol{\theta}}$ is restricted to be diagonal. Moreover, both the co-variance $\boldsymbol{\Sigma}_{\boldsymbol{\theta}}(\boldsymbol{z}_w)$ (its diagonal) and the mean $\boldsymbol{\mu}_{\boldsymbol{\theta}}$ are the outputs of a decoder network with parameters $\boldsymbol{\theta}$ and input $\boldsymbol{z}_w$.

Textual Component To model the occurrence/absence of word-context pair δ_{wc} in the linguistic corpus, we adopt a Bernoulli (Ber) model:

$$p(y_{wc}|\,\boldsymbol{e}_w, \boldsymbol{v}_c, \boldsymbol{z}_w) = \text{Ber}(\sigma[f(\boldsymbol{e}_w, \boldsymbol{v}_c, \boldsymbol{z}_w)]) \quad (4)$$

The function $f(\cdot)$ defines how multimodal embeddings are fused. While many choices can be experimented, we use the simple additive model:

$$f(\boldsymbol{e}_w, \boldsymbol{v}_c, \boldsymbol{z}_w) = \boldsymbol{v}_c^{\mathsf{T}}(\boldsymbol{e}_w + \boldsymbol{z}_w). \quad (5)$$

For words without visual representation, we simply set the corresponding latent factors $\boldsymbol{z}_w$ to the zero vector. Note that, without the visual factors $\boldsymbol{z}_w$, equation (4) reduces to the Skip-Gram with negative sampling objective (1).

Joint Model The perceptual and the textual information interact through the shared latent $\boldsymbol{z}_w$. The joint model of the above two sources of information takes the following form:

$$p(\boldsymbol{x}_w, y_{wc}|\,\boldsymbol{e}_w, \boldsymbol{v}_c) = \int p_{\boldsymbol{\theta}}(\boldsymbol{z}_w) p_{\boldsymbol{\theta}}(\boldsymbol{x}_w|\boldsymbol{z}_w) p(y_{wc}|\,\boldsymbol{e}_w, \boldsymbol{v}_c, \boldsymbol{z}_w) d\boldsymbol{z}_w \quad (6)$$

The intuition behind our joint formulation is to let the textual information guide the extraction of latent visual factors $\boldsymbol{z}_w$. Through equations (4) and (5), the model will put high probability on factors $\boldsymbol{z}_w$ reflecting patterns that can supplement the linguistic embeddings $\boldsymbol{e}_w$ in explaining the word-context co-occurrences. Thus, the extracted latent visual factors can contribute to improve the performance on predicting the occurrence of a word and its contexts in the linguistic corpus, which would encourage the model to leverage the perceptual information. The underlying assumption here is to infer visual and textual embeddings that can work in concert to represent words.

Visual Information Propagation Equation (5) implies that the embeddings $\boldsymbol{z}$, $\boldsymbol{e}$ and $\boldsymbol{v}$ will affect each other during the learning process. Interestingly, if a non-visual word w_1 shares a similar context c with a visual word w_2, then the factor $\boldsymbol{z}_{w_2}$ will affect $\boldsymbol{e}_{w_1}$ via $\boldsymbol{v}_c$. In other words, our formulation makes it possible to implicitly propagate perceptual information from one word to another through shared contexts. We illustrate this aspect in our experiments.

2.3 Approximate Inference and Learning

Training PIXIE amounts to inferring the posterior over the visual latent factors, $p_{\boldsymbol{\theta}}(\boldsymbol{z}|\boldsymbol{x}, y)$, as well as finding the decoder's parameters $\boldsymbol{\theta}$, the word and context embeddings, $\boldsymbol{e}$ and $\boldsymbol{v}$, that maximize the likelihood (6). However, as in many complex probabilistic models, the likelihood (due to the integral over $\boldsymbol{z}$) and the posterior are intractable. We therefore resort to approximation techniques. More precisely, we rely on Variational Inference (VI) (Blei et al., 2017). The idea of VI is to introduce a tractable approximate posterior distribution $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$ (the variational distribution) and optimize a lower bound on the likelihood, known as Evidence Lower BOund (ELBO). The latter can be written for each word w as follows:

$$\mathcal{L}_w = \mathbb{E}_q[\log p_{\boldsymbol{\theta}}(\boldsymbol{x}_w|\boldsymbol{z}_w) + \sum_c \log p(y_{wc}|\boldsymbol{e}_w, \boldsymbol{v}_c, \boldsymbol{z}_w)] - \text{KL}(q_{\boldsymbol{\phi}}(\boldsymbol{z}_w|\boldsymbol{x}_w)\|p_{\boldsymbol{\theta}}(\boldsymbol{z}_w)) \quad (7)$$

where $\text{KL}(\cdot\|\cdot)$ is the Kullback-Leibler divergence. The variational distribution is chosen to be a multivariate Gaussian parameterized by an *inference network* (or encoder) which takes $\boldsymbol{x}$ as input, namely

$$q_{\boldsymbol{\phi}}(\boldsymbol{z}_w|\boldsymbol{x}_w) = \mathcal{N}(\boldsymbol{z}_w|\boldsymbol{\mu}_{\boldsymbol{\phi}}(\boldsymbol{x}_w), \boldsymbol{\Sigma}_{\boldsymbol{\phi}}(\boldsymbol{x}_w)), \quad (8)$$

where we drop the dependency on all y_{wc} variables to be computationally tractable. The pair of encoder and decoder neural networks gives rise to the interpretation of PIXIE's visual component (formed by $\boldsymbol{z}$ and $\boldsymbol{x}$) as a probabilistic autoencoder. In fact, if we drop the textual part in PIXIE, namely y, $\boldsymbol{e}$ and $\boldsymbol{v}$, then we recover the Variational Auto-Encoder (VAE) (Kingma and Welling, 2013).

Lastly, we approximate the intractable (i) expectation with respect to $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$ and the (ii) sum over the negative pairs in (7), by relying on a Monte Carlo estimator of $\mathcal{L}$. Concretely, for (ii) we use negative sampling as in (2). Concerning (i), for every observed $\boldsymbol{x}_w$, we sample $\{\boldsymbol{z}_w^{(j)}\}_{j=1}^J$ from $q_{\boldsymbol{\phi}}(\boldsymbol{z}_w|\boldsymbol{x}_w)$ using the *reparameterization trick* (Kingma and Welling, 2013), i.e., $\boldsymbol{z}_w^{(j)} = \boldsymbol{\mu}_{\boldsymbol{\phi}}(\boldsymbol{x}_w) + \boldsymbol{\Sigma}_{\boldsymbol{\phi}}(\boldsymbol{x}_w)\boldsymbol{\epsilon}$, with $\boldsymbol{\epsilon} \sim \mathcal{N}(0, \mathbf{I})$. Then we approximate $\mathcal{L}$ with:

$$\begin{aligned}
&\widetilde{\mathcal{L}}_w = \\
&\tfrac{1}{J}\sum_j \log p_{\boldsymbol{\theta}}(\boldsymbol{x}_w|\boldsymbol{z}_w^{(j)}) - \mathrm{KL}(q_{\boldsymbol{\phi}}(\boldsymbol{z}_w|\boldsymbol{x}_w)\|p_{\boldsymbol{\theta}}(\boldsymbol{z}_w)) \\
&+ \tfrac{1}{J}\sum_{c,j} y_{wc} \log \sigma[\boldsymbol{v}_c^{\mathsf{T}}(\boldsymbol{e}_w + \boldsymbol{z}_w^{(j)})] \\
&+ \tfrac{1}{J}\sum_{c,j}\sum_{i=1}^{N} y_{wc} \log(\sigma[-\boldsymbol{v}_{c'_i}^{\mathsf{T}}(\boldsymbol{e}_w + \boldsymbol{z}_w^{(j)})]). \qquad (9)
\end{aligned}$$

The last two summands correspond to the familiar conditional likelihood term in the SGNS model, augmented with latent visual factors.

We optimize the objective (9) via SGD with respect to both the encoder/decoder networks parameters ($\boldsymbol{\theta}$ and $\boldsymbol{\phi}$) and the embeddings ($\boldsymbol{e}$ and $\boldsymbol{v}$). We evaluate the gradients of $\widetilde{\mathcal{L}}$, with respect to $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$ using backpropagation. Similarly, the gradient with respect to $\boldsymbol{e}$ and $\boldsymbol{v}$ can be easily carried out using automatic differentiation tools. Our learning procedure is summarized in Algorithm 1.

Algorithm 1 Variational PIXIE

```
Input: $\boldsymbol{x}$, $y$, sample sizes B and J
Steps:
Randomly initialize $\boldsymbol{\theta}$, $\boldsymbol{\phi}$, $\boldsymbol{e}$ and $\boldsymbol{v}$
repeat
    • Draw a minibatch $W^B$ of words: $w^{(1)}, \ldots, w^{(B)}$
    • For each $\boldsymbol{x}_w$ with $w \in W^B$, sample $\{\boldsymbol{z}_w^{(j)}\}_{j=1}^J$ from
      $q_{\boldsymbol{\phi}}(\boldsymbol{z}_w|\boldsymbol{x}_w)$ using the reparameterization trick. For each
      observed pair $\delta_{wc}$ draw $N$ negative examples $\{c'_i\}_{i=1}^N$.
    • Compute the estimator $\widetilde{\mathcal{L}}_{W^B} \leftarrow \sum_{w \in W^B} \widetilde{\mathcal{L}}_w$
    • Compute the gradient: $\mathbf{G} \leftarrow \nabla_{\boldsymbol{\theta},\boldsymbol{\phi},\boldsymbol{e},\boldsymbol{v}} \widetilde{\mathcal{L}}_{W^B}$
    • Use $\mathbf{G}$ to update $\boldsymbol{\theta}$, $\boldsymbol{\phi}$, $\boldsymbol{e}$ and $\boldsymbol{v}$ (e.g., with ADAM)
until convergence
return $\boldsymbol{\theta}$, $\boldsymbol{\phi}$, $\boldsymbol{e}$ and $\boldsymbol{v}$
```

Inference Once the parameters of the model are learned, for any given word with or without visual representation, we can compute its multimodal embedding. As a short hand, let the binary variable m_w denote whether or not the word w has a visual representation. The multimodal embedding for w can be written as

$$\boldsymbol{s}_w = \boldsymbol{e}_w + m_w \boldsymbol{\mu}(\boldsymbol{x}_w), \qquad (10)$$

where $\boldsymbol{\mu}(\boldsymbol{x}_w) = \mathbb{E}_q(\boldsymbol{z}_w)$ is the output of the encoding neural network, cf. Eq. (8).

In our experiments, we have also studied an alternative way to compose multimodal embeddings by concatenating the two vectors $\boldsymbol{e}_w$ and $\boldsymbol{\mu}(\boldsymbol{x}_w)$

$$\boldsymbol{t}_w = [\boldsymbol{e}_w \;\; m_w \boldsymbol{\mu}(\boldsymbol{x}_w)]. \qquad (11)$$

Note that for non-visual words, only zeros are appended to $\boldsymbol{e}_w$. One advantage of $\boldsymbol{t}$ over $\boldsymbol{s}$ is that if one uses distances to measure similarity, $\boldsymbol{t}$ can be seen as a simple summation of distances in two different spaces (in terms of $\boldsymbol{e}$ and $\boldsymbol{\mu}$ respectively).

3 Related Work

Combining language and perception has been recently considered in various NLP tasks such as machine translation (Calixto and Liu, 2017), visual question generation (Mostafazadeh et al., 2016), image captioning (Klein et al., 2015), etc. In this work, we focus on learning word embeddings from images and texts.

Multimodal embeddings have been studied in several recent research work. One strategy is to obtain word embeddings from linguistic data and visual data *independently* and then proceed with some kind of fusion steps. Kiela and Bottou (2014) simply concatenates pre-trained linguistic word embeddings and visual features computed by convolutional nets. Bruni et al. (2014) performs an additional step of dimensionality reduction via singular value decomposition. Silberer et al. (2017) extend on this work by feeding the linguistic embedding and visual features into a stacked auto-encoder for nonlinear dimensionality reduction. The above-mentioned approaches perform a two-stage process to derive multimodal representations (unimodal inference followed by fusion) and have been evaluated only on words for which both perceptual and textual representations are available.

A standing question is how to propagate visual information from words with visual features to words lacking them (for instance, abstract words). While the previous methods fall short on that, the recent work by Collell et al. (2017) addresses this challenge by learning a mapping from language to vision, using a set of words with known linguistic embeddings and visual features. This mapping can then be used to infer visual representations for new words from their textual embeddings.

All the aforementioned methods rely on independently pre-trained linguistic embeddings and visual features. In this work, we propose a different strategy, which consists in adapting those representations so that the information can be fused in earlier stages. In this respect, the closest work to ours is (Lazaridou et al., 2015), which proposes to augment the SKIP-GRAM objective function with a term mapping the textual embeddings to the visual features. Crudely, the linguistic embeddings must therefore predict both the text co-occurrences and (pre-trained) visual features. We emphasize two key differences with our approach. First, instead of performing a regression or mapping from the textual embeddings to the visual features, our model learns to infer perceptual latent factors to retain only the portion of visual information that can supplement the linguistic embeddings in representing words. Second, while Lazaridou et al. (2015) combines two objectives, we use a joint probabilistic model integrating both visual and text information in a principled way. Specifically, our model seeks latent factors that are good at explaining the word-context co-occurrences. For instance, a visual feature of (an image of) OCEAN often contains information about SKY and BLUE — such visual information could be beneficial to predict co-occurrence of tokens in the context of OCEAN. This desiderata further strengthens the learned embeddings to be visually grounded. In our experiments, we show that our approach tends to group concrete visually similar concepts together.

4 Experiments

In this section, we evaluate our model and contrast it to other competing approaches on two different tasks: word similarity and image/caption retrieval.

4.1 Setup

Text corpus We use the Text8 WIKIPEDIA corpus[1] containing over 17 million tokens. Text8 was pre-processed to contain only letters and nonconsecutive spaces. After removing infrequent words, we obtain a vocabulary of $50,000$ unique words.

Image features We use the ImageNet dataset (Russakovsky et al., 2015), including the fall ImageNet 2011 release (Deng et al., 2009). It contains $14,188,125$ images organized according to $21,842$ synsets of WordNet (Fellbaum, 1998). Each synset contains 600 images on average. To extract image features, we rely on the Caffe toolkit (Jia et al., 2014) and use the GoogLeNet convolutional neural nets (Szegedy et al., 2015) pre-trained on the 1000 synsets of ILSVRC 2012. The 1024-dimensional activation of the pooling units (before the softmax layer) are then taken as our image features.

Visual representation of words For each word in the vocabulary, we recover all the synsets that it belongs to using the WordNet interface of the NLTK module (Python) (Bird et al., 2009). We then remove the synsets not covered by our ImageNet dataset. This results in 9,713 words, out of the 50,000 words in the vocabulary. For each visual word, we randomly draw 1,000 distinct images in ImageNet. If the number of images for a word is less than 1,000, we increase the coverage using images belonging to the hypernyms of the considered word's synsets, as in (Kiela and Bottou, 2014). We then take the average of these features as the word's visual representation $\boldsymbol{x}$.

Hyper-parameter setting For all models, we set the dimension of linguistic and visual embeddings, $\boldsymbol{e}$ and $\boldsymbol{z}$, to 100, following many previous works. In our model, the encoder/decoder neural networks are implemented as one-hidden-layer neural nets with 500 hidden units each. The dimensions of the inputs and the outputs of the decoder neural networks are 100 and $1,024$ respectively ($1,024$ and 100 for the encoder). For the encoder, the hidden units are hyperbolic tangent, and the output units are linear. For the decoder, the hidden units are hyperbolic while the outputs are sigmoid. For SGNS, we set the window size L to 10 and the number of negative samples to 64. Our model is learned by Stochastic Gradient Descent using the ADAM optimizer (Kingma and Ba, 2014) with a learning rate set to 0.001.

Table 1: Datasets for the task of word similarity.

Datasets	#word pairs
MEN (Bruni et al., 2014)	3000
EN-MC (Miller and Charles, 1991)	31
EN-RG (Rubenstein and Goodenough, 1965)	65
SimLex (Hill et al., 2015)	999
MTurk (Radinsky et al., 2011; Halawi et al., 2012)	287
WORDSIM (Finkelstein et al., 2001)	350
REL (Agirre et al., 2009)	150
SIM (Agirre et al., 2009)	200
SEMSIM (Silberer and Lapata, 2014)	5494
VISSIM (Silberer and Lapata, 2014)	5494

4.2 Task 1: Word Similarity

Datasets Word similarity is a common type of evaluation task for measuring the effectiveness of word embeddings. To this end, we retain 10 benchmark datasets consisting of pairs of words associated with similarity scores given by human judges. Table 1 summarizes their basic properties. There are different types of similarities being assessed. SEMSIM, SimLex, SIM, EN-RG and EN-MC focus on *semantic or taxonomic similarity* — e.g. CAR is similar to AUTOMOBILE. MEN, REL and MTurk consider *general relatedness* — e.g. CAR is related to GARAGE. VISSIM is about *visual similarity* — e.g. GOOSE looks like SWAN. Note that SIM and REL are the similarity and relatedness subsets of the full WORDSIM dataset (Finkelstein et al., 2001) respectively. VISSIM contains the same word pairs as SEMSIM.

Competing models We benchmark our model PIXIE against several strong uni- and multi-modal models listed below:

- SGNS: Skip-Gram with Negative Sampling (Mikolov et al., 2013). Without the visual component, PIXIE reduces to SGNS. We can thus assess the impact of the perceptual information by comparing PIXIE to SGNS.
- VAE: Vatiational Auto-Encoder (Kingma and Welling, 2013), which corresponds to the visual-specific component of PIXIE.
- CNN: Visual features extracted from a convolutional neural net as described in Section 4.1.
- CNN⊕SGNS (Kiela and Bottou, 2014): Concatenation of CNN and SKIP-GRAM embeddings.
- VAE⊕SGNS: Concatenation of VAE and SKIP-GRAM embeddings.
- V-SGNS (Lazaridou et al., 2015): A multimodal approach which augments SGNS with a term that treats CNN visual features as regression targets. Comparisons with V-SGNS will allow us to evaluate the impact of our modeling assumptions.
- IV-SGNS (Collell et al., 2017): Learns a mapping from SGNS embeddings to CNN visual features.

Due to a large degree of discrepancies in experimental setups across previously published methods and results,[2] we re-implemented all the baselines and evaluate them under the same conditions.[3] For (Lazaridou et al., 2015), we implemented its model "A" as model "B" is comparable according to the original authors. For (Collell et al., 2017), we implemented both linear and nonlinear variants.

Evaluation metrics We use the cosine to measure the similarity between word representations. To assess the coherence between human ratings and models' predictions, we use the Spearman correlation coefficient.

4.2.1 Main results

The results across different datasets are shown in Table 2. We perform evaluations under two settings: by considering (i) word similarity between visual words only and (ii) between all words (column 100% in Table 2). For the models CNN, VAE and their concatenation with SGNS embeddings, the latter setting is not applicable. The two last rows correspond to the multimodal embeddings inferred from our model. In particular, PIXIE$_{+}$

---

[2] For instance, Lazaridou et al. (2015) reports only 5,100 visual words, nearly half of what we have defined. Collell et al. (2017) used pre-trained GloVe word vectors obtained from a different corpus.

[3] For each method we use the hyper-parameters recommended by the authors.

(resp. PIXIE$_{\oplus}$) represents the multimodal embeddings built using Eq. (10) (resp. Eq. (11)).

Overall, we note that PIXIE$_{\oplus}$ offers the best performance in almost all situations. This provides strong empirical support for the proposed model. Below, we discuss the above results in more depth to better understand them and characterize the circumstances in which our model performs better.

How relevant is our formulation? Except PIXIE and V-SGNS, most of the multimodal competing methods rely on independently pre-computed linguistic embeddings. As Table 2 shows, PIXIE and V-SGNS are often the best performing multimodal models, which provides empirical evidence that accounting for perceptual information while learning word embeddings from text is beneficial. Moreover, the superior performance of PIXIE$_{\oplus}$ over V-SGNS suggests that our model does a better job at combining perception and language to learn word representations.

Joint learning is beneficial PIXIE$_{\oplus}$ outperforms VAE⊕SGNS in almost all cases, which demonstrates the importance of joint learning.

Where does our approach perform better? On datasets that focus on *semantic/taxonomic similarity*, our approach dominates all other methods.

On datasets focusing on *general relatedness*, our approach obtains mixed results. While dominating other approaches on MEN, it tends to perform worst than SGNS on MTurk and REL (under the 100% setting). One possible explanation is that general relatedness tends to focus more on "extrapolating" from one word to another word (such as SWAN is related to LAKE), while our approach better models more concrete relationships (such as SWAN is related to GOOSE). The low performance of CNN and VAE confirms this hypothesis.

On the VISSIM dataset focusing on *visual similarity*, both CNN⊕SGNS and VAE⊕SGNS perform the best, strongly suggesting that visual and linguistic data are complementary. Our approach comes very close to these two methods. Note that our learning objective is to jointly explain visual features and word-context co-occurrences. Thus, two visually similar words, which never occur within the same context, could be mapped into slightly different directions in the latent space.

Visual Propagation Here we wish to evaluate the ability of our model to propagate perceptual information to words lacking visual features. To this end, we randomly select a subset of $2,000$ words for which we have visual features, and we train our model under two different settings: the visual features of the selected 2K words (i) are taken into account (PIXIE$_{\oplus}$), (ii) are ignored, i.e. set to zero (PIXIE$_{\oplus}^{(*)}$). We then perform evaluations, under the two settings, on the datasets of Table 1 considering only pairs composed of words in the above subset of 2K words. As baselines for this experiment, we consider SGNS and the multimodal approaches which can propagate perceptual information, namely V-SGNS and IV-SGNS, as well as their outputs when the 2K visual features are ignored (denoted by V-SGNS$^{(*)}$, and IV-SGNS$^{(*)}$).

Table 3: Spearman's score on subsets of visual words. The symbol $(*)$ indicates the visual features for the subset of 2K words have been ignored when training. Bold highlights the best performing method. Blue color highlights the best performing model under the $(*)$ setting.

	Semantic/taxonomic					Relatedness			Visual	REL +SIM
models	SEMSIM	SimLex	SIM	EN-RG	EN-MC	MEN	REL	MTurk	VISSIM	WORDSIM
SGNS	0.55	0.40	0.67	0.57	0.52	0.68	0.53	0.75	0.41	0.63
V-SGNS	0.61	0.32	**0.72**	0.71	0.69	0.69	0.52	0.75	0.44	**0.66**
IV-SGNS (LINEAR)	0.50	0.40	0.60	0.59	0.60	0.66	0.41	0.72	0.37	0.54
PIXIE$_{\oplus}$	**0.71**	**0.59**	**0.72**	**0.73**	**0.71**	**0.77**	**0.57**	0.74	**0.60**	0.62
V-SGNS$^{(*)}$	0.58	0.29	**0.72**	0.68	0.61	0.67	0.44	**0.76**	0.43	0.60
IV-SGNS$^{(*)}$	0.50	0.40	0.61	0.58	0.58	0.65	0.40	0.72	0.37	0.54
PIXIE$_{\oplus}^{(*)}$	0.60	0.43	**0.72**	0.65	0.60	0.70	0.56	**0.76**	0.45	0.63

The results are given in Table 3. We observe that PIXIE$_{\oplus}^{(*)}$ outperforms SGNS in almost all cases. Recall that, if we ignore the visual features for all words, PIXIE reduces to SGNS. We can therefore attribute the performance improvement of PIXIE$_{\oplus}^{(*)}$ over SGNS to the propagation of visual information to the subset of 2K words. Compared to multimodal methods, PIXIE$_{\oplus}^{(*)}$ (resp. PIXIE$_{\oplus}$) performs better than V-SGNS$^{(*)}$ (resp. V-SGNS) and IV-SGNS$^{(*)}$ (resp. IV-SGNS) in almost situations. This suggests that our formulation allows perceptual information to propagate better.

Table 4: Word pair cosine similarity computed based on SGNS and PIXIE$_{\oplus}^{(*)}$ embeddings.

Word pairs	SGNS	PIXIE$_{\oplus}^{(*)}$
(chicken, turkey)	0.35	0.55
(helicopter, jet)	0.63	0.76
(falcon, hawk)	0.49	0.70
(cathedral, chapel)	0.69	0.80
(cup, mug)	0.39	0.46

Table 5: 10 nearest neighboring words to the query words in different embedding spaces generated by different methods. Only "visual" words contain direct visual representations in our dataset. The concreteness score of each query word is reported between parenthesis (see text for details).

	Query word	SGNS	V-SGNS	PIXIE$_{\oplus}$
Visual	goose (4.81)	quail, pig, shark, gull, smoky, sooty, bald, owl, guppy, bird	fowl, quail, duck, bat, bulldog, puppy, warbler, blossom, wolfhound, crows	geese, duck, swans, swan, teal, loon, albatross, ostrich, gull, eider
	brave (1.26)	courageous, young, man, fearless, heroic, thief, horrible, adventures, carefree, cowardly	heroes, valiant, ominous, wondrous, fearless, wanton, sabers, beast, excalibur, carefree	bodyguard, wives, benefactors, womanizer, heroes, valiant, immortal, housewives, fearless, warrior
Non Visual	birthstone (4.25)	heaviest, yeti, koala, snowfall, intrusions, mourning, amalthea, gleaming, incidentally, dolly	emerald, lily, lavender, earthy, olive, delicacy, acacia, belladonna, flower, poppy	beryl, emerald, lily, sandalwood, hula, guinevere, pearls, holly, jasmine, jewels
	savagery (1.73)	swamp, man, crazy, madman, mysterious, thief, jeffrey, rage, mad, hardy	mad, zombies, beast, fabulous, mysterious, nightmare, ghosts, alien, mayhem, bandits	cannibals, evil, legends, werewolves, beast, haunting, ghosts, zombies, mayhem, thrillers

In Table 4, we report the cosine similarity between 5 semantically/visually coherent word pairs (from our subset of 2K words). Although the visual vectors of these words were removed during training, the PIXIE's word embeddings of each pair correlate better as compared to their SGNS counterparts, which provides further support to the propagation of visual information under PIXIE.

4.2.2 Qualitative analysis

Table 5 displays several qualitative examples of word similarity. We have selected 4 words: *goose*, *brave*, *birthstone* and *savagery*. The first two have visual feature representations in our training dataset and the last two do not. Furthermore, for each case, we chose one concrete and one abstract word.[4] For each word, we identify their nearest neighbors in the embedding space.

For the visual words, there is a noticeable difference between our method and others. For instance, for word *goose*, SGNS expresses more "general" relatedness and returns other animals like *pig* or *shark*, while our approach is more specific and tends to give visually similar neighbors by focusing on *goose* looks-like birds. V-SGNS's result is somewhat in between. On the abstract word *brave*, we observe that PIXIE$_{\oplus}$ tends to select more explicit embodiments of the adjective *brave* than SGNS and V-SGNS.

Moving towards the non-visual words, we do not seem to find a consistent discrepancy pattern between V-SGNS and PIXIE$_{\oplus}$, though, as for visual words, both methods seem to select more explicit exemplars compared to SGNS. For instance, for the abstract word *savagery*, both multimodal approaches suggest *cannibals* and *zombies*.

Table 6: Results for image (I) ↔ sentence (S) retrieval.

Models	I → S			S → I		
	K=1	K=5	K=10	K=1	K=5	K=10
SGNS	23.1	49.0	61.6	16.6	41.0	53.8
V-SGNS	21.9	51.7	64.2	16.2	42.0	54.8
IV-SGNS (LINEAR)	22.7	50.5	61.7	17.1	42.6	55.4
PIXIE$_{+}$	24.2	52.5	65.4	17.5	43.8	56.2
PIXIE$_{\oplus}$	**25.7**	**55.7**	**67.7**	**18.4**	**44.9**	**56.9**

4.3 Task 2: Image and Caption Retrieval

We now study the usefulness of the learned word embeddings for the tasks of image and caption retrieval. Our hypothesis is that multimodal word embeddings will perform better for downstream tasks involving multimodal information.

Experimental setup We use the Flickr30K dataset (Young et al., 2014) containing 31,000 images and 155,000 sentences (5 captions per image). The sentences describe the images. The task is to identify the best sentence describing an image or to identify the best image depicting a sentence. We follow the data split setting provided by Karpathy and Fei-Fei (2015), in which 1,000 images are used for validation and 1,000 for testing. The rest is used for training.

The retrieval models compute the proximity between the image features and the sentence embeddings. For image features, we use the precomputed features provided by Faghri et al. (2017), which are extracted from the FC7 layer of VGG-19 (Simonyan and Zisserman, 2014). These 4,096-dimensional features are then linearly mapped to 1,024-dimensional features. For sentences, we use an one GRU-layer over the sequences of the word embeddings, resulting in 1,024-dimensional sentence embeddings.

We use a triplet loss to train the retrieval model such that the inner product between the corresponding image feature and the sentence is greater than the inner products with incorrect sentences (or im-

---

[4] We rely on the concreteness ratings made available by Brysbaert et al. (2014), ranging from 1 to 5.

ages) (Kiros et al., 2014). The linear mapping and the GRU layer are then optimized to minimize the loss. We use the ADAM optimizer with the learning rate of 0.0002 and divide it by 10 every 15 epochs and we train the model for 30 epochs. Note that we do not *fine-tune* either the original visual feature or the word embeddings.

Results Table 6 summarizes the results. The evaluation metrics are accuracies at top-K (K=1, 5, or 10) retrieved sentences or images. Our model consistently outperforms SGNS and other competing multimodal methods, which provides additional support for the benefits of our approach.

5 Conclusion

We propose PIXIE, a novel probabilistic model joining textual and perceptual information to infer multimodal word embeddings. In our model, both linguistic and visual latent factors work in concert to explain the co-occurrences of words and their contexts in a corpus. Empirical results show that our model achieves equally competitive or stronger results when compared to state-of-the-art methods for multimodal embeddings.

Currently our model relies on unsupervised learning to infer visual factors. Explicit knowledge of similar and dissimilar visual categories could potentially disentangle latent factors better for alignment with linguistic data. How to incorporate visual domain knowledge more explicitly into the model would be an interesting direction for future research. While we build on skip-gram, the idea of PIXIE could be extended to other word embedding models, e.g., Glove (Pennington et al., 2014), ELMO (Peters et al., 2018), etc.

Transfer and Multi-Task Learning for Noun–Noun Compound Interpretation

Murhaf Fares **Stephan Oepen** **Erik Velldal**

Department of Informatics
University of Oslo
murhaff|oe|erikve@ifi.uio.no

Abstract

In this paper, we empirically evaluate the utility of transfer and multi-task learning on a challenging semantic classification task: semantic interpretation of noun–noun compounds. Through a comprehensive series of experiments and in-depth error analysis, we show that transfer learning via parameter initialization and multi-task learning via parameter sharing can help a neural classification model generalize over a highly skewed distribution of relations. Further, we demonstrate how dual annotation with two distinct sets of relations over the same set of compounds can be exploited to improve the overall accuracy of a neural classifier and its F_1 scores on the less frequent, but more difficult relations.

1 Introduction

Noun–noun compound interpretation is the task of assigning semantic relations to pairs of nouns (or more generally, pairs of noun phrases in the case of multi-word compounds). For example, given the nominal compound *street protest*, the task of compound interpretation is to predict the semantic relation holding between *street* and *protest* (a locative relation in this example). Given the frequency of noun–noun compounds in natural language – e.g. 3% of the tokens in the British National Corpus (Burnard, 2000) are part of noun–noun compounds (Ó Séaghdha, 2008) – and its relevance to other natural language processing (NLP) tasks such as question answering and information retrieval (Nakov, 2008), noun–noun compound interpretation has been the focus of much work, in theoretical linguistics (Li, 1972; Downing, 1977; Levi, 1978; Finin, 1980; Ryder, 1994), psycholinguistics (Gagné and Shoben, 1997; Marelli et al., 2017), and computational linguistics (Lauer, 1995; Nakov, 2007; Ó Séaghdha and Copestake, 2009; Girju et al., 2009; Kim and Baldwin, 2013; Dima and Hinrichs, 2015). In computational linguistics, noun–noun compound interpretation is, by and large, approached as an automatic classification problem. Hence several machine learning (ML) algorithms and models have been used to learn the semantics of nominal compounds, including Maximum Entropy (Tratz and Hovy, 2010), Support Vector Machines (Ó Séaghdha and Copestake, 2013) and Neural Networks (Dima and Hinrichs, 2015; Vered and Waterson, 2018). These models use information from lexical semantics such as WordNet-based features and distributional semantics such as word embeddings. Nonetheless, noun–noun compound interpretation remains one of the more difficult NLP problems because: 1) noun–noun compounding, as a linguistic construction, is very productive and 2) the semantics of noun–noun compounds is not easily derivable from the compounds' constituents (Vered and Waterson, 2018). Our work, in part, contributes to advancing NLP research on noun–noun compound interpretation through the use of transfer and multi-task learning.

The interest in using transfer learning (TL) and multi-task learning (MTL) in NLP has surged over the past few years, showing 'mixed' results depending on the so-called main and auxiliary tasks involved, model architectures and datasets, among other things (Collobert and Weston, 2008; Mou et al., 2016; Søgaard and Goldberg, 2016; Martínez Alonso and Plank, 2017; Bingel and Søgaard, 2017). These 'mixed' results, coupled with the fact that neither TL nor MTL has been applied to noun–noun compounds interpretation before, motivate our extensive empirical study on the use of TL and MTL for compound interpretation, not only to supplement existing research on the utility of TL and MTL for semantic NLP tasks in general, but also to determine their benefits for compound interpretation in particular.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1488–1498
Brussels, Belgium, October 31 - November 4, 2018.

One of the primary motivations for using multi-task learning is to improve generalization by "leveraging the domain-specific information contained in the training signals of *related* tasks" Caruana (1997). In this work, we show that TL and MTL can indeed be used as a kind of *regularizer* to learn to predict infrequent relations given a highly skewed distribution of relations from the noun–noun compound dataset of Fares (2016) which is especially well suited for TL and MTL experimentation as detailed in Section 3.

Our contributions can be summarized as:

1. Through careful result analysis, we find that TL and MTL (mainly on the embedding layer) do improve the overall accuracy and the F_1 scores of the less frequent relations in a highly skewed dataset, in comparison to a strong single-task learning baseline.

2. Even though our work focuses on TL and MTL, to the best of our knowledge, we are the first to report experimental results on the comparatively recent dataset of Fares (2016).

2 Related Work

Noun–Noun Compound Interpretation Existing approaches to noun–noun compound interpretation vary depending on the taxonomy of compound relations as well as the machine learning models and features used to learn those relations. For example, Ó Séaghdha (2007) defines a coarse-grained set of relations (viz. six relations based on theoretical work by Levi (1978)), whereas Tratz and Hovy (2010) assume a considerably more fine-grained taxonomy of 43 relations. Others question the very assumption that noun–noun compounds are interpretable using a finite, predefined set of relations (Downing, 1977; Finin, 1980) and propose alternative paraphrasing-based approaches (Nakov, 2007; Shwartz and Dagan, 2018). We here focus on the approaches that cast the interpretation problem as a classification task over a finite predefined set of relations. A wide variety of machine learning models have been already applied to learn this task, including nearest neighbor classifiers using semantic similarity based on lexical resources (Kim and Baldwin, 2005), kernel-based methods like SVMs using lexical and relational features (Ó Séaghdha and Copestake, 2009), Maximum Entropy models with a relatively large selection of lexical and surface form features such as synonyms and affixes (Tratz and Hovy, 2010) and, most recently, neural networks either solely relying on word embeddings to represent noun–noun compounds (Dima and Hinrichs, 2015) or word embeddings and so-called path embeddings (which encode information about lemmas and part-of-speech tags, inter alia) in a combined paraphrasing and classification approach (Vered and Waterson, 2018). Of the aforementioned studies, Tratz and Hovy (2010); Dima and Hinrichs (2015); Vered and Waterson (2018) have all used the same dataset by Tratz and Hovy (2010). To the best of our knowledge, TL and MTL have never been applied to compound interpretation before, and in the following we therefore review some of the previous work on TL and MTL on other NLP tasks.

Transfer and Multi-Task Learning A number of recent studies have presented comprehensive experiments on the use of TL and MTL for a variety of NLP tasks including named entity recognition and semantic labeling (Martínez Alonso and Plank, 2017), sentence-level sentiment classification (Mou et al., 2016), super-tagging and chunking (Bingel and Søgaard, 2017) and semantic dependency parsing (Peng et al., 2017). The common thread among the findings of these studies is that the benefits of TL and MTL largely depend on the properties of the tasks at hand, such as the skewedness of the data distribution (Martínez Alonso and Plank, 2017), the semantic similarity between the source and target tasks (Mou et al., 2016), the learning pattern of the auxiliary and main tasks where "target tasks that quickly plateau" benefit most from "non-plateauing auxiliary tasks" (Bingel and Søgaard, 2017) and the "structural similarity" between the tasks (Peng et al., 2017). In addition to the difference in the NLP tasks they experiment with, the aforementioned studies assume slightly different definitions of TL and MTL (cf. Section 4). Our work is similar in spirit to that of Peng et al. (2017) in the sense that we use TL and MTL to learn different 'formalisms' (semantic annotations of noun–noun compounds in our case) on the *same* dataset. However, our experimental setup is more similar to the work by Mou et al. (2016) in that we experiment with parameter initialization on all the layers of the neural model and simultaneously train one MTL model on two sets of relations (cf. Section 5).

3 Task Definition and Dataset

Given a set of labeled pairs of nouns, each a noun–noun compound, the task is simply to learn to classify the semantic relations holding between each pair of compound constituents. The difficulty of this task, obviously, depends on the label set used and its distribution, among other things. For all the experiments presented in this paper, we adapt the noun–noun compounds dataset created by Fares (2016) which consists of compounds annotated with two different taxonomies of relations; in other words, for each noun–noun compound there are two distinct relations, drawing on different linguistic schools. The dataset was derived from existing linguistic resources, such as `NomBank` (Meyers et al., 2004) and the Prague Czech-English Dependency Treebank 2.0 (Hajič et al., 2012, `PCEDT`). Our motivation for using this dataset is twofold: first, dual annotation with relations over the same underlying set of compounds maximally enables TL and MTL perspectives; second, alignment of two distinct annotation frameworks over the same data facilitates contrastive analysis and comparison across frameworks.

More specifically, we use a subset of the dataset created by Fares (2016), by focusing on type-based instances of so-called two-word compounds.[1] The original dataset by Fares (2016) also includes multi-word compounds (i.e. compounds consisting of more than two nouns) and more than just one instance per compound type. Furthermore, we define a three-way split of the dataset; Table 1 presents the number of compound types per split and the vocabulary size of each split (i.e. the number of unique words in each split); the latter is also broken down in terms of words occurring in the right-most position (right constituents) and the left-most position (left constituents).[2] Overall, the two label sets consists of 35 so-called `PCEDT` functors and 18 `NomBank` argument and adjunct relations. As detailed in Section 7.1, these label sets are far from being uniformly distributed.

	Train	Dev	Test
Compounds	6932	920	1759
Vocab size	4102	1163	1772
Right constituents	2304	624	969
Left constituents	2405	618	985

Table 1: Characteristics of the noun–noun compound dataset used in our experiments. The numbers in this table correspond to a (sub)set of the dataset by Fares (2016), see Section 3.

Abstractly, many relations in `PCEDT` and `NomBank` describe similar semantic concepts, since they annotate the semantics of the same text. For example, Fares (2016) reports that the temporal and locative relations in `NomBank` (`ARGM-TMP` and `ARGM-LOC`, respectively) and their counterparts in `PCEDT` (`TWHEN` and `LOC`) exhibit a relatively consistent behavior across frameworks as they annotate many of the same compounds. However, Fares (2016) also points out that some abstractly similar relations do not align well in practice; for example, the functor `AIM` in `PCEDT` and the modifier argument `ARGM-PNC` in `NomBank` express a somewhat similar semantic concept (purpose) but the overlap between the sets of compounds they annotate in practice is rather small. Nonetheless, it is plausible to assume that the semantic similarity in the label sets—whenever it exists—can be exploited in the form of transfer and multi-task learning, not least because the overall distribution of the relations in the two frameworks is different.

4 Transfer vs. Multi-Task Learning

In this section, we use the notations and definitions by Pan and Yang (2010) to define our setup for transfer and multi-task learning.

Our classification task $\mathcal{T}$ can be defined in terms of all training pairs (X, Y) and a probability distribution $P(X)$, where $X = x_i, \ldots, x_N \in \mathcal{X}$ and $Y = y_i, \ldots, y_N \in \mathcal{Y}$; $\mathcal{X}$ is the input feature space, $\mathcal{Y}$ is the set of all labels and N is the size of the training data. A task's domain $\mathcal{D}$ is defined by $\{\mathcal{X}, P(X)\}$. Our goal is to learn a function $f(X)$ that predicts Y based on the input features X. Assuming two ML tasks, $\mathcal{T}_a$ and $\mathcal{T}_b$, we would train two models (i.e. learn two separate functions f_a and f_b) to predict Y_a and Y_b in a single-task learning setup. However, if $\mathcal{T}_a$ and $\mathcal{T}_b$ are related somehow, either explicitly or implicitly, TL and MTL can improve the generalization of either task or both (Caruana, 1997; Pan and Yang, 2010; Mou et al., 2016). Two tasks are considered related

---

[1] Two-word compounds consist of two whitespace-separated constituents. A single constituent, however, can be a 'simple' noun (e.g. *system*) or a hyphenated noun (e.g. *land-ownership*) leading to compounds like *land-ownership system*. The representation of compounds with hyphenated constituents is explained in Section 5.1

[2] We use the terms left and right constituents, instead of modifier and head nouns, because the dataset does not make explicit the notion of 'headedness'.

when their domains, $\mathcal{D}_a$ and $\mathcal{D}_b$, are similar but their label sets are different $\mathcal{Y}_a \neq \mathcal{Y}_b$ or when their domains are different but their label sets are identical, i.e. $\mathcal{Y}_a = \mathcal{Y}_b$ (Pan and Yang, 2010).[3] As such, noun–noun compound interpretation over the dataset of Fares (2016) is a well suited candidate for TL and MTL, because the training examples are identical, i.e. $X_{PCEDT} = X_{NomBank}$, but the label sets are different $\mathcal{Y}_{PCEDT} \neq \mathcal{Y}_{NomBank}$.

For the sake of clarity, we distinguish between transfer learning and multi-task learning in this paper, even though these two terms are at times used somewhat interchangeably in the literature. For example, what we call TL and MTL in this paper are both referred to as transfer learning by Mou et al. (2016). We define TL as using the parameters (i.e. weights in neural networks) of one model trained on $\mathcal{T}_a$ to initialize another model for $\mathcal{T}_b$. Mou et al. (2016) refer to this method as "parameter initialization".[4] MTL, on the other hand, here refers to training (parts of) the same model to learn $\mathcal{T}_a$ and $\mathcal{T}_b$, i.e. learning one set of parameters for both tasks. The idea is to train a single model simultaneously on the two tasks where one task is considered to introduce inductive bias which would help the model generalize over the main task. Note, however, that this does not necessarily mean that we eventually want to use a single model to predict both label sets in practice (cf. Section 5.3).

5 Neural Classification Models

Here we present the neural classification models used in our experiments. To isolate the effect of TL and MTL, we first present a single-task learning model, which serves as our baseline model, and then we use the same model to apply TL and MTL.

5.1 Single-Task Learning Model

In our single-task learning (STL) setup, we train and fine-tune a feed-forward neural network based on the neural classifier proposed by Dima and Hinrichs (2015), which consists of: 1) input layer, 2) embedding layer, 3) hidden layer, and 4) output layer. The input layer is simply two integers specifying the indices of a compound's constituents in the embedding layer where the word embedding vectors are stored; the selected word embedding vectors are then fed to a fully connected hidden layer whose size is the same as the number of dimensions of the word embedding vectors. Finally, a *softmax* function is applied on the output layer and the most likely relation is selected.

The compound's constituents are represented using a 300-dimensional word embedding model trained on an English Wikipedia dump (dated February 2017) and English Gigaword Fifth Edition (Parker et al., 2011) using GloVe (Pennington et al., 2014). The embedding model was trained by Fares et al. (2017) who provide more details on the hyperparameters used to train the embedding model.[5] When looking up a word in the embedding model, if the word is not found we check if the word is uppercased and look up the same word in lowercase. If a word is hyphenated and is not found in the embedding vocabulary, we split it on the hyphen and average the vectors of its parts (if they exist in the vocabulary). If after these steps the word is still not found, we use a designated vector for unknown words.

Architecture and Hyperparameters Our choice of hyperparameters is motivated by several rounds of experimentation on the single-task learning model as well as the choices made by Dima and Hinrichs (2015).

The weights of the embedding layer (i.e. the word embeddings) are updated during training in all the models. The optimization function we use in all the models is Adaptive Moment Estimation, known as *Adam* (Kingma and Ba, 2015) with $\eta = 0.001$ (the default learning rate). The loss function is negative-log likelihood (aka categorical cross-entropy). We use a *Sigmoid* activation function on the hidden layer units. All the models are trained using mini-batches of size five. The maximum number of epochs is set to 50, but we also use an early stopping criterion on the model's accuracy on the validation split (i.e. training is interrupted if the validation accuracy doesn't improve over five consecutive epochs). We implement all the models in *Keras* with *TensorFlow* as backend. All the TL and MTL models are trained with the same hyperparameters of the STL model.[6]

---

[3] When the label sets are identical, TL practically becomes a technique for *domain adaptation*. Though these two terms have also been used interchangeably (Chung et al., 2018).

[4] Using *pretrained* word embeddings as input representation is in a sense a form of unsupervised transfer learning, but in this work we focus on transfer learning based on supervised learning.

5.2 Transfer Learning Models

Transfer learning in our experiments amounts to training an STL model on `PCEDT` relations, for example, and then using (some of) its weights to initialize another model for `NomBank` relations. Given the architecture of the neural classifier described in Section 5.1, we identify three ways to implement TL: 1) **TL$_{\mathbf{E}}$**: Transfer of the embedding layer weights, 2) **TL$_{\mathbf{H}}$**: Transfer of the hidden layer weights, and 3) **TL$_{\mathbf{EH}}$**: Transfer of both the embedding and hidden layer weights. Furthermore, we distinguish between transfer learning from `PCEDT` to `NomBank` and vice versa; that is, either task can be used as main task or auxiliary task. Hence, we either start by training on `NomBank` and use the weights of the corresponding transfer layer to initialize the `PCEDT` model or the other way around. In total, this leads to six setups, as shown in Table 2. Note that we do not apply TL (or MTL) on the output layer because it is task- or dataset-specific (Mou et al., 2016).

5.3 Multi-Task Learning Models

In MTL, we train one model simultaneously to learn both `PCEDT` and `NomBank` relations, and therefore all the MTL models have two objective functions and two output layers. We implement two MTL setups: **MTL$_{\mathbf{E}}$**, which consists of a shared embedding layer but two task-specific hidden layers, and **MTL$_{\mathbf{F}}$**, which, apart from the output layer, does not have task-specific layers, i.e. both the embedding and hidden layers are shared. We distinguish between the auxiliary and main tasks based on which validation accuracy (`NomBank`'s or `PCEDT`'s) is monitored by the early stopping criterion. Hence we end up with a total of four MTL models as shown in Table 3.

Model	`NomBank`		`PCEDT`	
	Dev	Test	Dev	Test
STL	78.15	76.75	58.80	56.05
TL$_{\text{E}}$	78.37	**78.05**	59.57	**57.42**
TL$_{\text{H}}$	78.15	78.00	59.24	56.51
TL$_{\text{EH}}$	**78.48**	78.00	**59.89**	56.68

Table 2: Accuracy (%) of the transfer learning models.

Model	`NomBank`		`PCEDT`	
	Dev	Test	Dev	Test
STL	**78.15**	76.75	58.80	56.05
MTL$_{\text{E}}$	77.93	78.45	**59.89**	**56.96**
MTL$_{\text{F}}$	76.74	**78.51**	58.91	56.00

Table 3: Accuracy (%) of the MTL models.

6 Experimental Results

Tables 2 and 3 present the accuracies of the different TL and MTL models on the development and test splits in `NomBank` and `PCEDT`. The top row in both tables shows the accuracy of the STL model. All the models were trained on the training split only. There are several observations one can draw from these tables. First, the accuracy of the STL models drops when the models are evaluated on the test split, whether on `NomBank` or `PCEDT`. Second, all the TL models achieve better accuracy on the test split of `NomBank` even though transfer learning does not remarkably improve accuracy on the development split of the same dataset. The MTL models, especially MTL$_{\text{F}}$, have a negative effect on the development accuracy of `NomBank`, but we still see the same improvement, as in TL, on the test split. Third, both the TL and MTL models exhibit less consistent effects on `PCEDT` (on both the development and test splits) compared to `NomBank`; for example, all the TL models lead to about 1.25 points absolute improvement in accuracy on `NomBank`, whereas in `PCEDT` TL$_{\text{E}}$ is clearly better than the other two TL models (TL$_{\text{E}}$ improves over the STL accuracy by 1.37 points).

Overall, the accuracy of the STL models drops when evaluated on the test split of `NomBank` and `PCEDT` (in comparison to their accuracy on the development split); this might be an indicator of overfitting, especially because we select the model that performs best on the development split in our stopping criterion. Both TL and MTL, on the other hand, improve accuracy on the test splits, even though the same stopping criterion was used for STL, TL and MLT. We interpret this result as improvement in the models' generalization ability. However, given that these improvements are relatively small, we next take a closer look at the results to understand if and how TL and MTL help.

7 Results Analysis

This section presents a systematic analysis of the performance of the models based on insights from the dataset used in the experiments as well as the classification errors of the models. The discussion in the following sections is based on the results on the test split rather than the development split, primarily because the former is larger in size.[7]

---

[7] One can also argue that result analysis on the test split is stricter than on the validation split. While using an early stop-

7.1 Relation Distribution

To demonstrate the difficulty of the problem at hand, we plot the distribution of the most frequent relations in `NomBank` and `PCEDT` across the three data splits in Figure 1. We find that almost 71.18% of the relations in the `NomBank` training split are of type `ARG1` (proto-typical patient), and 52.20% of the `PCEDT` relations are of type `RSTR` (an underspecified adnominal modifier). Such highly skewed distributions of the relations makes learning some of the other relations more difficult, if not impossible in some cases. In fact, of the 15 `NomBank` relations observed in the test split, five relations are never predicted by any of the STL, TL and MTL models, and of the 26 `PCEDT` relations observed in the test split only six are predicted. That said, the non-predicted relations are extremely infrequent in the training split (e.g. 23 `PCEDT` functors occur less than 20 times in the training split), and it is therefore questionable if an ML model will be able to learn them under any circumstances.

From this imbalanced distribution of relations, it immediately follows that accuracy alone, as evaluation measure, is not sufficient to identify the best performing model. Therefore, in the following section we report, and analyze, the F_1 scores of the predicted `NomBank` and `PCEDT` relations across all the STL, TL and MTL models.

7.2 Per-Relation F_1 Scores

Tables 4 and 5 show the per-relation F_1 scores for `NomBank` and `PCEDT`, respectively. Note that we only include the results for the relations that are actually predicted by at least one of the models.

We observe several interesting patterns in Tables 4 and 5. First, the MTL_F model seems to be confusing for both datasets: it leads to substantially degraded F_1 scores on four `NomBank` relations, including the locative modifier `ARGM-LOC` and manner modifier `ARGM-MNR` (shortened to `LOC` and `MNR` in Table 4) which the model is no longer able to predict. The same model has the worst F_1 score, compared to all other models, for two `PCEDT` relations, `REG` (which expresses a circumstance) and `PAT` (patient). Given that the MTL_F model achieves the highest accuracy on the `NomBank` test split (cf. Table 3), it becomes all the more evident that mere accuracy scores are not enough to judge the utility of TL and MTL for this task (and dataset).

Second, with the exception of the MTL_F model, all the TL and MTL models consistently improve the F_1 score of all the `PCEDT` relations except `PAT`. Most notably, the F_1 scores of the relations `TWHEN` and `ACT` see a remarkable boost, compared to other `PCEDT` relations, when only the embedding layer's weights are shared (MTL_E) or transfered (TL_E). This result can be partly explained by looking at the correspondence matrices between `NomBank` arguments and `PCEDT` functors shown in Tables 7 and 6, which show how the `PCEDT` functors map to `NomBank` arguments in the training split (Table 6) and the other way around (Table 7). From Table 6, we see that 80% of the compounds annotated as `TWHEN` in `PCEDT` were annotated as `ARGM-TMP` in `NomBank`. In addition, 47% of `ACT` (Actor) relations map to `ARG0` (Proto-Agent) in `NomBank`, even though this mapping is not as clear as one would have hoped, it is still relatively high if we consider how other `PCEDT` relations map to `ARG0`. The correspondence matrices also show that the assumed theoretical similarities between the `NomBank` and `PCEDT` relations do not always hold. Nonetheless, even such 'imperfect' correspondence can provide a 'training signal' that help the TL and MTL models learn relations such as `TWHEN` and `ACT`.

Since the TL_E model outperforms STL on predicting `REG` by ten absolute points, we inspected

---

ping criterion based on the validation data can help prevent overfitting on the training data, we still choose a model that achieves the best accuracy on the validation split. In addition, it's unclear if early stopping helps when the validation split is not fully representative of the problem (Prechelt, 2012).

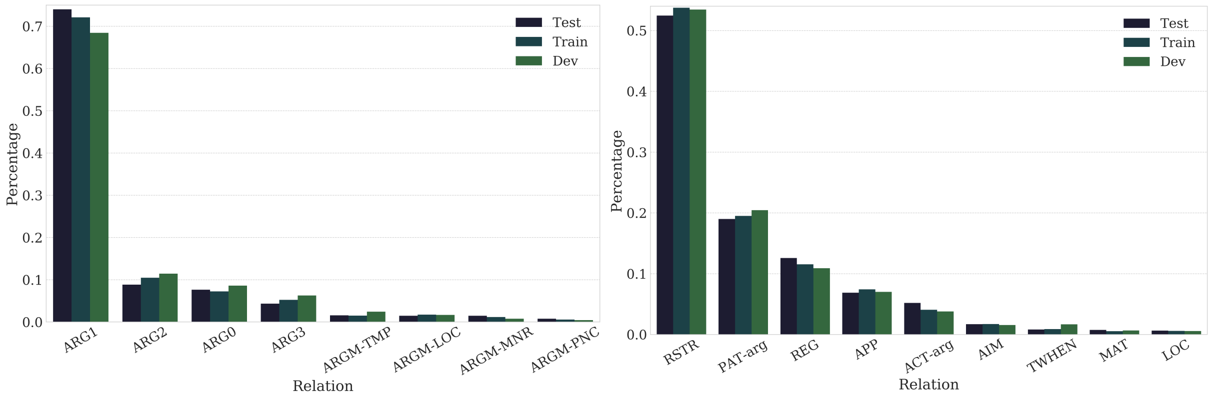

Figure 1: Distribution of NomBank relations (left) and PCEDT relations (right)

all the REG compounds that were correctly classified by the TL_E model but were misclassified by the STL model and found that the latter misclassified them as RSTR which indicates that TL from NomBank helps the TL_E model recover from the STL's over-generalization in RSTR prediction.

The two NomBank relations that receive the highest boost in F_1 score (about five absolute points) are ARG0 and ARGM-MNR, but the improvement in the latter relation corresponds to only one more compound which might well be predicted correctly by chance. Overall, TL and MTL from NomBank to PCEDT is more helpful than the other way around. One way to explain this is considering the first rows in Tables 6 and 7, where we see that five PCEDT relations (including the four most frequent ones) map to ARG1 in NomBank in more than 60% of the cases for each relation. This means that the weights learned to predict PCEDT relations offer little or no inductive bias for NomBank relations. Whereas if we consider the mapping from NomBank to PCEDT, we see that even though many NomBank arguments map to RSTR in PCEDT the percentages are lower, and hence the mapping is more 'diverse' (i.e. discriminative) which seems to help the TL and MTL models learn the less frequent PCEDT relations.

For completeness, we investigate why the PCEDT functor AIM is never predicted even though it is more frequent than TWHEN (cf. Figure 1). We find that AIM is almost always misclassifed as RSTR by all the models. Furthermore, we discover that AIM and RSTR have the highest lexical overlap in the training set among all other pairs of relations in PCEDT: 78.35% of the left constituents and 73.26% of the right constituents of the compounds annotated as AIM occur in other compounds annotated as RSTR. This explains why none of the models manage to learn the relation AIM but raises a question about the models' ability to learn relational representations; we pursue this question further in Section 7.3.

Table 7: Correspondence matrix between NomBank arguments and PCEDT functors.

Finally, to clearly demonstrate the benefits of TL and MTL for NomBank and PCEDT, we report the F_1 macro-average scores in Table 8 (which is arguably the appropriate evaluation measure for imbalanced classification problems). Note that the relations that are not predicted by any of the models are not included in computing the macro-average. From Table 8 it becomes crystal clear that TL and MTL on the embedding layer yield remarkable improvements for PCEDT with about 7–

Model	`NomBank`	`PCEDT`
STL	52.66	40.15
TL$_{\text{E}}$	52.83	**48.34**
TL$_{\text{H}}$	52.98	46.52
TL$_{\text{EH}}$	**53.31**	47.12
MTL$_{\text{E}}$	53.21	47.23
MTL$_{\text{F}}$	42.07	40.73

Table 9: Generalization error on the subset of unseen compounds in the test split. L: Left constituent. R: Right constituent. L&R: Completely unseen.

8 absolute points increase in macro-average F_1, in contrast to just 0.65 in the best case on `NomBank`.

7.3 Generalization on Unseen Compounds

Now we turn to analyze the models' ability to generalize over compounds unseen in the training split. Recent work by Dima (2016) and Vered and Waterson (2018) suggest that the gains achieved in noun–noun compound interpretation using word embeddings and somewhat similar neural classification models are in fact a by-product of *lexical memorization* (Levy et al., 2015); in other words, the classification models learn that a specific set of nouns is a strong indicator of a specific relation. Therefore, in order to gauge the role of lexical memorization in our models also, we quantify the number of unseen compounds that the STL, TL and MTL models predict correctly.

We distinguish between 'partly' and 'completely' unseen compounds. A compound is considered 'partly' unseen if one of its constituents (right or left) is not seen in the training data at all. A completely unseen compound is one whose left *and* right constituent are not seen in the training data (i.e. completely unseen compounds are the subset of compounds in the test split that have zero lexical overlap with the training split). Overall, almost 20% of the compounds in the test split have an unseen left constituent, about 16% of the compounds have unseen right constituent and 4% are completely unseen. In Table 9, we compare the performance of the different models on these three groups in terms of the proportion of compounds a model *misclassifies* in each group.

From Table 9 we see that TL and MTL reduce the `NomBank` generalization error in all cases, except TL$_{\text{H}}$ and TL$_{\text{EH}}$ on completely unseen compounds; the latter leads to higher generalization error. The MTL models lead to the biggest error reduction across the three types of unseen compounds; MTL$_{\text{E}}$ leads to about six points error reduction on compounds with unseen right constituent and eleven points on completely unseen ones, and MTL$_{\text{F}}$ reduces the error on unseen left constituent by five points. Note, however, that these results have to be read together with the *Count* row in Table 9 to get a complete picture. For instance, an eleven-point decrease in error on completely unseen compounds amounts to eight compounds. In `PCEDT`, the largest error reduction on unseen left constituents is 1.14 points which amounts to four compounds, 0.35 (just one compound) on unseen right constituents and 2.7 (or two compounds) on completely unseen compounds.

Since we see larger reductions in the generalization error in `NomBank`, we manually inspect the compounds that led to these reductions; i.e. we inspect the distribution of relations in the set of the correctly predicted unseen compounds. The MTL$_{\text{E}}$ model reduces the generalization error on completely unseen compounds by a total of eight compounds compared to the STL model, but seven of these compounds are annotated with `ARG1` which is the most frequent relation in `NomBank`. When it comes to the unseen right constituents, the 24 compounds MTL$_{\text{E}}$ improves on consist of 18 `ARG1` compounds, 5 `ARG0` compounds and one `ARG2` compound. We see a similar pattern upon inspecting the gains of the TL$_{\text{E}}$ model; where most of the improvement arises from predicting more `ARG1` and `ARG0` correctly.

The majority of the partly or completely unseen compounds that were misclassified by all models are *not* of type `ARG1` in `NomBank` or `RSTR` in `PCEDT`. This, together with the fact that the correctly predicted unseen compounds are annotated with the most frequent relations, indicate that the classification models rely on lexical memorization to learn the interpretation of compound relations.

Finally, to complement our understanding of the effect of lexical memorization, we plot the ratio of relation-specific constituents in `NomBank` and

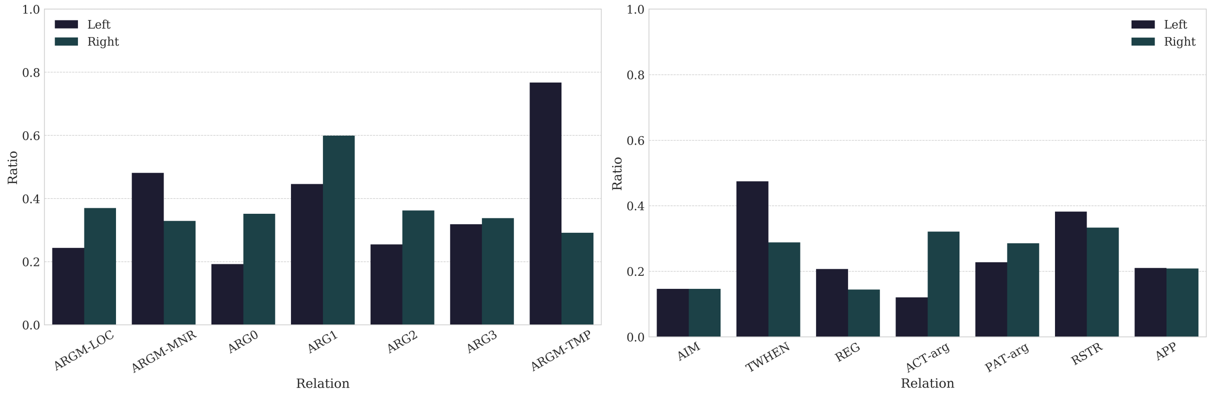

Figure 2: Ratio of relation-specific constituents in `NomBank` (left) and `PCEDT` (right).

`PCEDT` in Figure 2. We define relation-specific constituents as left or right constituents that only occur with one specific relation in the training split, and their ratio is simply their proportion in the overall set of left or right constituents per relation. Looking at Figure 2, we see that `NomBank` relations have higher ratios of relation-specific constituents in comparison to `PCEDT`, which arguably makes learning the former comparatively easier if the model is only to rely on lexical memorization. Furthermore, `ARGM-TMP` in `NomBank` and `TWHEN` in `PCEDT` stand out from other relations in Figure 2, which are also the two relations with the second highest F_1 score in their respective dataset—except in STL on `PCEDT` (cf. Tables 4 and 5). Lexical memorization is, therefore, the most likely explanation of such relatively high F_1 scores. We also observe some correlation between lower ratios of relation-specific constituents and relatively low F_1 scores, e.g. `APP` and `REG` in `PCEDT`. Based on these observations, we cannot rule out that our models exhibit some degree of lexical memorization effects, even though manual result analysis also reveals ‘counter-examples’ where the models generalize and make correct predictions where lexical memorization is impossible.

8 Conclusion

Transfer and multi-task learning for NLP currently receive a lot of attention, but for the time being there remains considerable uncertainty about which task properties and experimental settings actually are effective. In this work, we seek to shed light on the utility of TL and MTL perspectives on the semantic interpretation of noun–noun compounds. Through a comprehensive series of minimally contrasting experiments and in-depth analysis of results and prediction errors, we demonstrate the ability of both TL and MTL to mitigate the challenges of class imbalance and substantially improve prediction of low-frequency relations. In a nutshell, our TL and in particular MTL models make quantitatively and qualitatively better predictions, especially so on the ‘hardest’ inputs involving at least one constituent not seen in the training data—but clear indicators of remaining ‘lexical memorization’ effects arise from our error analysis of unseen compounds.

In general, transfer of representations or sharing across tasks is most effective at the embedding layers, i.e. the model-internal representation of the two compound constituents involved. In multi-task learning, full sharing of the model architecture across tasks worsens the model’s ability to generalize on the less frequent relations.

We experience the dataset by Fares (2016) as an interesting opportunity for innovative neural approaches to compound interpretation, as it relates this sub-problem to broad-coverage semantic role labeling or semantic dependency parsing in `PCEDT` and `NomBank`. In future work, we plan to incorporate other NLP tasks defined over these frameworks to learn noun–noun compound interpretation using TL and MTL. Such tasks include semantic role labeling of nominal predicates in `NomBank` annotations as well as verbal predicates in `PropBank` (Kingsbury and Palmer, 2002).

Abstract

Contextual word representations derived from pre-trained bidirectional language models (biLMs) have recently been shown to provide significant improvements to the state of the art for a wide range of NLP tasks. However, many questions remain as to how and why these models are so effective. In this paper, we present a detailed empirical study of how the choice of neural architecture (e.g. LSTM, CNN, or self attention) influences both end task accuracy and qualitative properties of the representations that are learned. We show there is a tradeoff between speed and accuracy, but all architectures learn high quality contextual representations that outperform word embeddings for four challenging NLP tasks. Additionally, all architectures learn representations that vary with network depth, from exclusively morphological based at the word embedding layer through local syntax based in the lower contextual layers to longer range semantics such coreference at the upper layers. Together, these results suggest that unsupervised biLMs, independent of architecture, are learning much more about the structure of language than previously appreciated.

1 Introduction

Contextualized word embeddings (Peters et al., 2018) derived from pre-trained bidirectional language models (biLMs) have been shown to substantially improve performance for many NLP tasks including question answering, entailment and sentiment classification (Peters et al., 2018), constituency parsing (Kitaev and Klein, 2018; Joshi et al., 2018), named entity recognition (Peters et al., 2017), and text classification (Howard and Ruder, 2018). Despite large gains (typical relative error reductions range from 10–25%), we do not yet fully understand why or how these models work in practice. In this paper, we take a step towards such understanding by empirically studying how the choice of neural architecture (e.g. LSTM, CNN, or self attention) influences both direct end-task accuracies and the types of neural representations that are induced (e.g. how do they encode notions of syntax and semantics).

Previous work on learning contextual representations has used LSTM-based biLMs, but there is no prior reason to believe this is the best possible architecture. More computationally efficient networks have been introduced for sequence modeling including including gated CNNs for language modeling (Dauphin et al., 2017) and feed forward self-attention based approaches for machine translation (Transformer; Vaswani et al., 2017). As RNNs are forced to compress the entire history into a hidden state vector before making predictions while CNNs with a large receptive field and the Transformer may directly reference previous tokens, each architecture will represent information in a different manner.

Given such differences, we study whether more efficient architectures can also be used to learn high quality contextual vectors. We show empirically that all three approaches provide large improvements over traditional word vectors when used in state-of-the-art models across four benchmark NLP tasks. We do see the expected tradeoff between speed and accuracy between LSTMs and the other alternatives, but the effect is relatively modest and all three networks work well in practice.

Given this result, it is important to better understand what the different networks learn. In a detailed quantitative evaluation, we probe the learned representations and show that, in every case, they represent a rich hierarchy of contextual information throughout the layers of the network in an analogous manner to how deep CNNs

---

Brussels, Belgium, October 31 - November 4, 2018.

trained for image classification learn a hierarchy of image features (Zeiler and Fergus, 2014). For example, we show that in contrast to traditional word vectors which encode some semantic information, the word embedding layer of deep biLMs focuses exclusively on word morphology. Moving upward in the network, the lowest contextual layers of biLMs focus on local syntax, while the upper layers can be used to induce more semantic content such as within-sentence pronominal coreferent clusters. We also show that the biLM activations can be used to form phrase representations useful for syntactic tasks. Together, these results suggest that large scale biLMs, independent of architecture, are learning much more about the structure of language than previous appreciated.

2 Contextual word representations from biLMs

To learn contextual word representations, we follow previous work by first training a biLM on a large text corpus (Sec. 2.1). Then, the internal layer activations from the biLM are transferred to downstream tasks (Sec. 2.3).

2.1 Bidirectional language models

Given a sequence of N tokens, $(t_1, t_2, ..., t_N)$, a biLM combines a forward and backward language model to jointly maximize the log likelihood of both directions:

$$\sum_{k=1}^{N} \big(\log p(t_k \mid t_1, \ldots, t_{k-1}; \overrightarrow{\Theta}) \\ + \log p(t_k \mid t_{k+1}, \ldots, t_N; \overleftarrow{\Theta}) \big) ,$$

where $\overrightarrow{\Theta}$ and $\overleftarrow{\Theta}$ are the parameters of the forward and backward LMs respectively.

To compute the probability of the next token, state-of-the-art neural LMs first produce a context-insensitive token representation or word embedding, $\mathbf{x}_k$, (with either an embedding lookup or in our case a character aware encoder, see below). Then, they compute L layers of context-dependent representations $\overrightarrow{\mathbf{h}}_{k,i}$ where $i \in [1, L]$ using a RNN, CNN or feed forward network (see Sec. 3). The top layer output $\overrightarrow{\mathbf{h}}_{k,L}$ is used to predict the next token using a Softmax layer. The backward LM operates in an analogous manner to the forward LM. Finally, we can concatenate the forward and backward states to form L layers of contextual representations, or context vectors, at each token position: $\mathbf{h}_{k,i} = [\overrightarrow{\mathbf{h}}_{k,i}; \overleftarrow{\mathbf{h}}_{k,i}]$. When training, we tie the weights of the word embedding layers and Softmax in each direction but maintain separate weights for the contextual layers.

2.2 Character based language models

Fully character aware models (Kim et al., 2015) are considerably more parameter efficient then word based models but more computationally expensive then word embedding based methods when training. During inference, these differences can be largely eliminated by pre-computing embeddings for a large vocabulary and only falling back to the full character based method for rare words. Overall, for a large English language news benchmark, character aware models have slightly better perplexities then word based ones, although the differences tend to be small (Józefowicz et al., 2016).

Similar to Kim et al. (2015), our character-to-word encoder is a five-layer sub-module that first embeds single characters with an embedding layer then passes them through 2048 character n-gram CNN filters with max pooling, two highway layers (Srivastava et al., 2015), and a linear projection down to the model dimension.

2.3 Deep contextual word representations

After pre-training on a large data set, the internal representations from the biLM can be transferred to a downstream model of interest as contextual word representations. To effectively use all of the biLM layers, Peters et al. (2018) introduced ELMo word representations, whereby all of the layers are combined with a weighted average pooling operation, $\mathbf{ELMo}_k = \gamma \sum_{j=0}^{L} s_j \mathbf{h}_{k,j}$. The parameters s are optimized as part of the task model so that it may preferentially mix different types of contextual information represented in different layers of the biLM. In Sec. 4 we evaluate the relative effectiveness of ELMo representations from three different biLM architectures vs. pre-trained word vectors in four different state-of-the-art models.

3 Architectures for deep biLMs

The primary design choice when training deep biLMs for learning context vectors is the choice of the architecture for the contextual layers. However, it is unknown if the architecture choice is important for the quality of learned representations. To study this question, we consider two alterna-

Architecture	# layers	Perplexity	# params. (M)	Inference (ms) 1 sentence	Inference (ms) 64 sentences
LSTM	2	39.7	76 / 94	44 / 46	66 / 85
LSTM	4	37.5	151 / 153	85 / 86	102 / 118
Transformer	6	40.7	38 / 56	12 / 13	22 / 44
Gated CNN	16	44.5	67 / 85	9 / 11	29 / 55

Table 1: Characteristics of the different biLMs in this study. For each model, the table shows the number of layers used for the contextual representations, the averaged forward and backward perplexities on the 1 Billion Word Benchmark, the number of parameters (in millions, excluding softmax) and the inference speed (in milliseconds with a Titan X GPU, for sentences with 20 tokens, excluding softmax). For the number of parameters and inference speeds we list both the values for just the contextual layers and all layers needed to compute context vectors.

tives to LSTMs as described below. See the appendix for the hyperparameter details.

3.1 LSTM

Among the RNN variants, LSTMs have been shown to provide state-of-the-art performance for several benchmark language modeling tasks (Józefowicz et al., 2016; Merity et al., 2018; Melis et al., 2018). In particular, the LSTM with projection introduced by Sak et al. (2014) allows the model to use a large hidden state while reducing the total number of parameters.This is the architecture adopted by Peters et al. (2018) for computing ELMo representations. In addition to the pre-trained 2-layer biLM from that work,[1] we also trained a deeper 4-layer model to examine the impact of depth using the publicly available training code.[2] To reduce the training time for this large 4-layer model, we reduced the number of parameters in the character encoder by first projecting the character CNN filters down to the model dimension before the two highway layers.

3.2 Transformer

The Transformer, introduced by Vaswani et al. (2017), is a feed forward self-attention based architecture. In addition to machine translation, it has also provided strong results for Penn Treebank constituency parsing (Kitaev and Klein, 2018) and semantic role labeling (Tan et al., 2018). Each identical layer in the encoder first computes a multi-headed attention between a given token and all other tokens in the history, then runs a position wise feed forward network.

To adapt the Transformer for bidirectional language modeling, we modified a PyTorch based re-implementation (Klein et al., 2017)[3] to mask out future tokens for the forward language model and previous tokens for the backward language model, in a similar manner to the decoder masking in the original implementation. We adopted hyper-parameters from the “base” configuration in Vaswani et al. (2017), providing six layers of 512 dimensional representations for each direction.

Concurrent with our work, Radford et al. (2018) trained a large forward Transformer LM and fine tuned it for a variety of NLP tasks.

3.3 Gated CNN

Convolutional architectures have also been shown to provide competitive results for sequence modeling including sequence-to-sequence machine translation (Gehring et al., 2017). Dauphin et al. (2017) showed that architectures using Gated Linear Units (GLU) that compute hidden representations as the element wise product of a convolution and sigmoid gate provide perplexities comparable to large LSTMs on large scale language modeling tasks.

To adapt the Gated CNN for bidirectional language modeling, we closely followed the publicly available ConvSeq2Seq implementation,[4] modified to support causal convolutions (van den Oord et al., 2016) for both the forward and backward directions. In order to model a wide receptive field at the top layer, we used a 16-layer deep model, where each layer is a $[4, 512]$ residual block.

3.4 Pre-trained biLMs

Table 1 compares the biLMs used in the remainder of this study. All models were trained on the 1

Billion Word Benchmark (Chelba et al., 2014) using a sampled softmax with 8192 negative samples per batch. Overall, the averaged forward and backward perplexities are comparable across the models with values ranging from 37.5 for the 4-layer LSTM to 44.5 for the Gated CNN. To our knowledge, this is the first time that the Transformer has been shown to provide competitive results for language modeling. While it is possible to reduce perplexities for all models by scaling up, our goal is to compare representations across architectures for biLMs of approximately equal skill, as measured by perplexity.

The Transformer and CNN based models are faster than the LSTM based ones for our hyperparameter choices, with speed ups of 3-5X for the contextual layers over the 2-layer LSTM model.[5] Speed ups are relatively faster in the single element batch scenario where the sequential LSTM is most disadvantaged, but are still 2.3-3X for a 64 sentence batch. As the inference speed for the character based word embeddings could be mostly eliminated in a production setting, the table lists timings for both the contextual layers and all layers of the biLM necessary to compute context vectors. We also note that the faster architectures will allow training to scale to large unlabeled corpora, which has been shown to improve the quality of biLM representations for syntactic tasks (Zhang and Bowman, 2018).

4 Evaluation as word representations

In this section, we evaluate the quality of the pre-trained biLM representations as ELMo-like contextual word vectors in state-of-the-art models across a suite of four benchmark NLP tasks. To do so, we ran a series of controlled trials by swapping out pre-trained GloVe vectors (Pennington et al., 2014) for contextualized word vectors from each biLM computed by applying the learned weighted average ELMo pooling from Peters et al. (2018).[6] Each task model only includes one type of pre-trained word representation, either GloVe or ELMo-like, this is a direct test of the transferability of the word representations. In addition, to isolate the general purpose LM representations from any task specific supervision, we did not fine tune the LM weights.

Table 2 shows the results. Across all tasks, the LSTM architectures perform the best. All architectures improve significantly over the GloVe only baseline, with relative improvements of 13% – 25% for most tasks and architectures. The gains for MultiNLI are more modest, with relative improvements over GloVe ranging from 6% for the Gated CNN to 13% for the 4-layer LSTM. The remainder of this section provides a description of the individual tasks and models with details in the Appendix.

4.1 MultiNLI

The MultiNLI dataset (Williams et al., 2018) contains crowd sourced textual entailment annotations across five diverse domains for training and an additional five domains for testing. Our model is a re-implementation of the ESIM sequence model (Chen et al., 2017). It first uses a biLSTM to encode the premise and hypothesis, then computes an attention matrix followed by a local inference layer, another biLSTM inference composition layer, and finally a pooling operation before

---

[5] While the CNN and Transformer implementations are reasonably well optimized, the LSTM biLM is not as it does not use an optimized CUDA kernel due to the use of the projection cell.

[6] Generally speaking, we found adding pre-trained GloVe vectors in addition to the biLM representations provided a small improvement across the tasks.

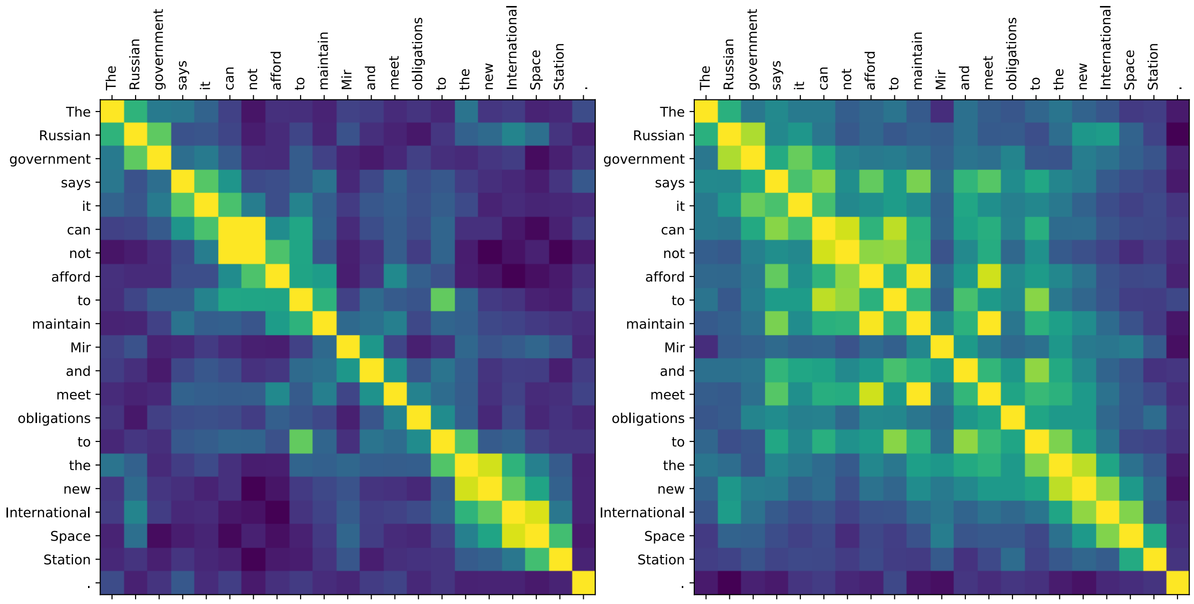

Figure 1: Visualization of contextual similarity between all word pairs in a single sentence using the 4-layer LSTM. The left panel uses context vectors from the bottom LSTM layer while the right panel uses the top LSTM layer. Lighter yellow-colored areas have higher contextual similarity.

the output layer. With the 2-layer LSTM ELMo representations, it is state-of-the-art for SNLI (Peters et al., 2018). As shown in Table 2, the LSTMs perform the best, with the Transformer accuracies 0.2% / 0.6% (matched/mismatched) less then the 2-layer LSTM. In addition, the contextual representations reduce the matched/mismatched performance differences showing that the biLMs can help mitigate domain effects. The ESIM model with the 4-layer LSTM ELMo-like embeddings sets a new state-of-the-art for this task, exceeding the highest previously published result by 1.3% matched and 1.9% mismatched from Gong et al. (2018).

4.2 Semantic Role Labeling

The Ontonotes 5.0 Dataset (Pradhan et al., 2013) contains predicate argument annotations for a variety of types of text, including conversation logs, web data, and biblical extracts. For our model, we use the deep biLSTM from He et al. (2017) who modeled SRL as a BIO tagging task. With ELMo representations, it is state-of-the-art for this task (Peters et al., 2018). For this task, the LSTM based word representations perform the best, with absolute improvements of 0.6% of the 4-layer LSTM over the Transformer and CNN.

4.3 Constituency parsing

The Penn Treebank (Marcus et al., 1993) contains phrase structure annotation for approximately 40k sentences sourced from the Wall Street Journal. Our model is the Reconciled Span Parser (RSP; Joshi et al., 2018), which, using ELMo representations, achieved state of the art performance for this task. As shown in Table 2, the LSTM based models demonstrate the best performance with a 0.2% and 1.0% improvement over the Transformer and CNN models, respectively. Whether the explicit recurrence structure modeled with the biLSTM in the RSP is important for parsing is explored in Sec. 5.3.

4.4 Named entity recognition

The CoNLL 2003 NER task (Sang and Meulder, 2003) provides entity annotations for approximately 20K sentences from the Reuters RCV1 news corpus. Our model is a re-implementation of the state-of-the-art system in Peters et al. (2018) with a character based CNN word representation, two biLSTM layers and a conditional random field (CRF) loss (Lafferty et al., 2001). For this task, the 2-layer LSTM performs the best, with averaged F_1 0.4% - 0.8% higher then the other biLMs averaged across five random seeds.

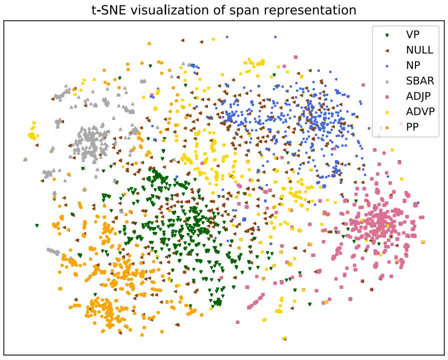

Figure 2: t-SNE visualization of 3K random chunks and 500 unlabeled spans ("NULL") from the CoNLL 2000 chunking dataset.

5 Properties of contextual vectors

In this section, we examine the intrinsic properties of contextual vectors learned with biLMs, focusing on those that are independent of the architecture details. In particular, we seek to understand how familiar types of linguistic information such as syntactic or coreferent relationships are represented throughout the depth of the network. Our experiments show that deep biLMs learn representations that vary with network depth, from morphology in the word embedding layer, to local syntax in the lowest contextual layers, to semantic relationships such as coreference in the upper layers.

We gain intuition and motivate our analysis by first considering the inter-sentence contextual similarity of words and phrases (Sec. 5.1). Then, we show that, in contrast to traditional word vectors, the biLM word embeddings capture little semantic information (Sec. 5.2) that is instead represented in the contextual layers (Sec. 5.3). Our analysis moves beyond single tokens by showing that a simple span representation based on the context vectors captures elements of phrasal syntax.

5.1 Contextual similarity

Nearest neighbors using cosine similarity are a popular way to visualize the relationships encoded in word vectors and we can apply a similar method to context vectors. As the biLMs use context vectors to pass information between layers in the network, this allows us to visualize how information is represented throughout the network.

Intra-sentence similarity Fig. 1 shows the intra-sentence contextual similarity between all pairs of words in single sentence using the 4-layer LSTM.[7] From the figure, we make several observations. First, the lower layer (left) captures mostly local information, while the top layer (right) represents longer range relationships. Second, at the lowest layer the biLM tends to place words from the same syntactic constituents in similar parts of the vector space. For example, the words in the noun phrase "the new international space station" are clustered together, similar to "can not" and "The Russian government".

In addition, we can see how the biLM is implicitly learning other linguistic information in the upper layer. For example, all of the verbs ("says", "can", "afford", "maintain", "meet") have high similarity suggesting the biLM is capturing part-of-speech information. We can also see some hints that the model is implicitly learning to perform coreference resolution by considering the high contextual similarity of "it" to "government", the head of "it"s antecedent span. Section 5.3 provides empirical support for these observations.

Span representations The observation that the biLM's context vectors abruptly change at syntactic boundaries suggests we can also use them to form representations of spans, or consecutive token sequences. To do so, given a span of S tokens from indices s_0 to s_1, we compute a span representation $\mathbf{s}_{(s_0,s_1),i}$ at layer i by concatenating the first and last context vectors with the element wise product and difference of the first and last vectors:

$$\mathbf{s}_{(s_0,s_1),i} = [\mathbf{h}_{s_0,i}; \mathbf{h}_{s_1,i}; \mathbf{h}_{s_0,i} \odot \mathbf{h}_{s_1,i}; \mathbf{h}_{s_0,i} - \mathbf{h}_{s_1,i}].$$

Figure 2 shows a t-SNE (Maaten and Hinton, 2008) visualization of span representations of 3,000 labeled chunks and 500 spans not labeled as chunks from the CoNLL 2000 chunking dataset (Sang and Buchholz, 2000), from the first layer of the 4-layer LSTM. As we can see, the spans are clustered by chunk type confirming our intuition that the span representations capture elements of syntax. Sec. 5.3 evaluates whether we can use these span representations for constituency parsing.

Unsupervised pronominal coref We hypothesize that the contextual similarity of coreferential mentions should be similar, as in many cases it is possible to replace them with their referent. If true, we should be able to use contextual similarity to perform unsupervised coreference reso-

---

[7] See appendix for visualizations of the other models.

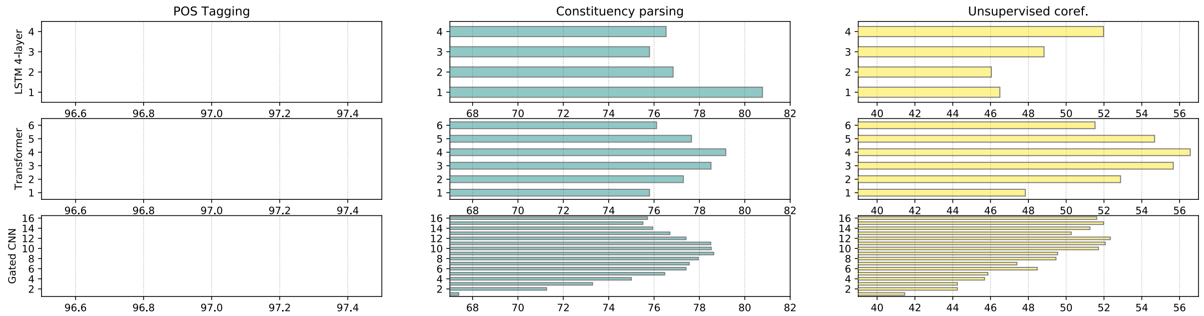

Figure 3: Various methods of probing the information stored in context vectors of deep biLMs. Each panel shows the results for all layers from a single biLM, with the first layer of contextual representations at the bottom and last layer at the top. From top to bottom, the figure shows results from the 4-layer LSTM, the Transformer and Gated CNN models. From left to right, the figure shows linear POS tagging accuracy (%; Sec. 5.3), linear constituency parsing (F_1; Sec. 5.3), and unsupervised pronominal coreference accuracy (%; Sec. 5.1).

Representation	**Syntactic**	**Semantic**
GloVe	77.9	**79.2**
n-gram hash	72.3	0.5
LSTM 4-layer	74.2	11.5
Transformer	**87.1**	48.8
Gated CNN	83.6	26.3

Table 3: Accuracy (%) for word vector analogies. In addition to the 300 dimension 840B GloVe vectors, the table contains results from a character n-gram hash and the context insensitive word embedding layer ($\mathbf{x}_k$) from the biLMs.

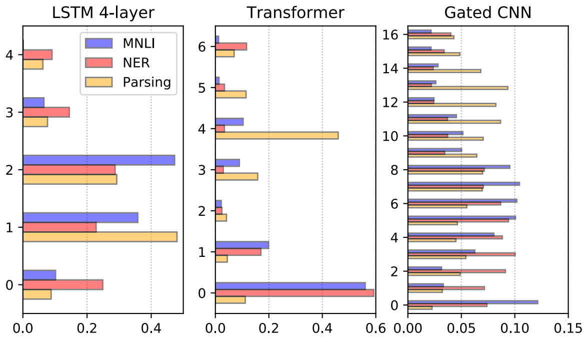

Figure 4: Normalized layer weights $\mathbf{s}$ for the tasks in Sec. 4. The vertical axis indexes the layer in the biLM, with layer 0 the word embedding $\mathbf{x}_k$.

lution. To test this, we designed an experiment as follows. To rule out trivially high mention-mention similarities due to lexical overlap, we restricted to pronominal coreference resolution. We took all sentences from the development set of the OntoNotes annotations in the CoNLL 2012 shared task (Pradhan et al., 2012) that had a third-person personal pronoun[8] and antecedent in the same sentence (904 sentences), and tested whether a system could identify the head word of the antecedent span given the pronoun location. In addition, by restricting to pronouns, systems are forced to rely on context to form their representation of the pronoun, as the surface form of the pronoun is uninformative. As an upper bound on performance, the state-of-the-art coreference model from Lee et al. (2017)[9] finds an antecedent span with the head word 64% of the time. As a lower bound on performance, a simple baseline that chooses the closest noun occurring before the pronoun has an accuracy of 27%, and one that chooses the first noun in the sentence has an accuracy of 35%. If we add an additional rule and further restrict to antecedent nouns matching the pronoun in number, the accuracies increase to 41% and 47% respectively.

To use contextual representations to solve this task, we first compute the mean context vector of the smallest constituent with more then one word containing the pronoun and subtract it from the pronoun's context vector. This step is motivated by the above observation that local syntax is the dominant signal in the contextualized word vectors, and removing it improves the accuracies of our method. Then, we choose the noun with the highest contextual similarity to the adjusted context vector that occurs before the pronoun and matches it in number.

The right hand column of Fig. 3 shows the results for all layers of the biLMs. Accuracies for the

---

[8] he, him, she, her, it, them, they

[9] `http://allennlp.org/models`

models peak between 52% and 57%, well above the baseline, with the Transformer overall having the highest accuracy. Interestingly, accuracies only drop 2-3% compared to 12-14% in the baseline if we remove the assumption of number agreement and simply consider all nouns, highlighting that the biLMs are to a large extent capturing number agreement across coreferent clusters. Finally, accuracies are highest at layers near the top of each model, showing that the upper layer representations are better at capturing longer range coreferent relationships then lower layers.

5.2 Context independent word representation

The word analogy task introduced in Mikolov et al. (2013) are commonly used as intrinsic evaluations of word vectors. Here, we use them to compare the word embedding layer from the biLMs to word vectors. The task has two types of analogies: syntactic with examples such as "bird:birds :: goat:goats", and semantic with examples such as "Athens:Greece :: Oslo:Norway". Traditional word vectors score highly on both sections. However, as shown in Table 3, the word embedding layer $\mathbf{x}_k$ from the biLMs is markedly different with syntactic accuracies on par or better then GloVe, but with very low semantic accuracies. To further highlight this distinction, we also computed a purely orthographically based word vector by hashing all character 1, 2, and 3-grams in a word into a sparse 300 dimensional vector. As expected, vectors from this method had near zero accuracy in the semantic portion, but scored well on the syntactic portion, showing that most of these analogies can be answered with morphology alone. As a result, we conclude that the word representation layer in deep biLMs is only faithfully encoding morphology with little semantics.

5.3 Probing contextual information

In this section, we quantify some of the anecdotal observations made in Sec. 5.1. To do so, we adopt a series of linear probes (Belinkov et al., 2017) with two NLP tasks to test the contextual representations in each model layer for each biLM architecture. In addition to examining single tokens, we also depart from previous work by examining to what extent the span representations capture phrasal syntax.

Our results show that all biLM architectures learn syntax, including span-based syntax; and part-of-speech information is captured at lower layers then constituent structure. When combined with the coreference accuracies in Sec. 5.1 that peak at even higher layers, this supports our claim that deep biLMs learn a hierarchy of contextual information.

POS tagging Peters et al. (2018) showed that the contextual vectors from the first layer of the 2-layer LSTM plus a linear classifier was near state-of-the-art for part-of-speech tagging. Here, we test whether this result holds for the other architectures. The second row of Fig. 3 shows tagging accuracies for all layers of the biLMs evaluated with the Wall Street Journal portion of Penn Treebank (Marcus et al., 1993). Accuracies for all of the models are high, ranging from 97.2 to 97.4, and follow a similar trend with maximum values at lower layers (bottom layer for LSTM, second layer for Transformer, and third layer for CNN).

Constituency parsing Here, we test whether the span representations introduced in Sec. 5.1 capture enough information to model constituent structure. Our linear model is a very simple and independently predicts the constituent type for all possible spans in a sentence using a linear classifier and the span representation. Then, a valid tree is built with a greedy decoding step that reconciles overlapping spans with an ILP, similar to Joshi et al. (2018).

The third row in Fig. 3 shows the results. Remarkably, predicting spans independently using the biLM representations alone has F_1 of near 80% for the best layers from each model. For comparison, a linear model using GloVe vectors performs very poorly, with F_1 of 18.1%. Across all architectures, the layers best suited for constituency parsing are at or above the layers with maximum POS accuracies as modeling phrasal syntactic structure requires a wider context then token level syntax. Similarity, the layers most transferable to parsing are at or below the layers with maximum pronominal coreference accuracy in all models, as constituent structure tends to be more local than coreference (Kuncoro et al., 2017).

5.4 Learned layer weights

Fig. 4 plots the softmax-normalized layer weights $\mathbf{s}$ from each biLM, learned as part of the tasks in Sec. 4. The SRL model weights are omitted as they close to constant since we had to regularize them to stabilize training. For constituency parsing, $\mathbf{s}$ mirrors the layer wise linear parsing results, with the largest weights near or at the same layers as maximum linear parsing. For both NER and MultiNLI, the Transformer focuses heavily on the word embedding layer, $\mathbf{x}_k$, and the first contextual layer. In all cases, the maximum layer weights occur below the top layers as the most transferable contextual representations tend to occur in the middle layers, while the top layers specialize for language modeling.

6 Related work

In addition to biLM-based representations, McCann et al. (2017) learned contextualized vectors with a neural machine translation system (CoVe). However, as Peters et al. (2018) showed the biLM based representations outperformed CoVe in all considered tasks, we focus exclusively on biLMs.

Liu et al. (2018) proposed using densely connected RNNs and layer pruning to speed up the use of context vectors for prediction. As their method is applicable to other architectures, it could also be combined with our approach.

Several prior studies have examined the learned representations in RNNs. Karpathy et al. (2015) trained a character LSTM language model on source code and showed that individual neurons in the hidden state track the beginning and end of code blocks. Linzen et al. (2016) assessed whether RNNs can learn number agreement in subject-verb dependencies. Our analysis in Sec. 5.1 showed that biLMs also learn number agreement for coreference. Kádár et al. (2017) attributed the activation patters of RNNs to input tokens and showed that a RNN language model is strongly sensitive to tokens with syntactic functions. Belinkov et al. (2017) used linear classifiers to determine whether neural machine translation systems learned morphology and POS tags. Concurrent with our work, Khandelwal et al. (2018) studied the role of context in influencing language model predictions, Gaddy et al. (2018) analyzed neural constituency parsers, Blevins et al. (2018) explored whether RNNs trained with several different objectives can learn hierarchical syntax, and Conneau et al. (2018) examined to what extent sentence representations capture linguistic features. Our intrinsic analysis is most similar to Belinkov et al. (2017); however, we probe span representations in addition to word representations, evaluate the transferability of the biLM representations to semantic tasks in addition to syntax tasks, and consider a wider variety of neural architectures in addition to RNNs.

Other work has focused on attributing network predictions. Li et al. (2016) examined the impact of erasing portions of a network's representations on the output, Sundararajan et al. (2017) used a gradient based method to attribute predictions to inputs, and Murdoch et al. (2018) decomposed LSTMs to interpret classification predictions. In contrast to these approaches, we explore the types of contextual information encoded in the biLM internal states instead of focusing on attributing this information to words in the input sentence.

7 Conclusions and future work

We have shown that deep biLMs learn a rich hierarchy of contextual information, both at the word and span level, and that this is captured in three disparate types of network architectures. Across all architecture types, the lower biLM layers specialize in local syntactic relationships, allowing the higher layers to model longer range relationships such as coreference, and to specialize for the language modeling task at the top most layers. These results highlight the rich nature of the linguistic information captured in the biLM's representations and show that biLMs act as a general purpose feature extractor for natural language, opening the way for computer vision style feature re-use and transfer methods.

Our results also suggest avenues for future work. One open question is to what extent can the quality of biLM representations be improved by simply scaling up model size or data size? As our results have show that computationally efficient architectures also learn high quality representations, one natural direction would be exploring the very large model and data regime.

Despite their successes biLM representations are far from perfect; during training, they have access to only surface forms of words and their order, meaning deeper linguistic phenomena must be learned "tabula rasa". Infusing models with explicit syntactic structure or other linguistically motivated inductive biases may overcome some of the limitations of sequential biLMs. An alternate direction for future work combines the purely unsupervised biLM training objective with existing annotated resources in a multitask or semi-supervised manner.

Preposition Sense Disambiguation and Representation

Hongyu Gong, Jiaqi Mu, Suma Bhat, Pramod Viswanath
University of Illinois at Urbana-Champaign

Abstract

Prepositions are highly polysemous, and their variegated senses encode significant semantic information. In this paper we match each preposition's left- and right context, and their interplay to the geometry of the word vectors to the left and right of the preposition. Extracting these features from a large corpus and using them with machine learning models makes for an efficient preposition sense disambiguation (PSD) algorithm, which is comparable to and better than state-of-the-art on two benchmark datasets. Our reliance on no linguistic tool allows us to scale the PSD algorithm to a large corpus and learn sense-specific preposition representations. The crucial abstraction of preposition senses as word representations permits their use in downstream applications–phrasal verb paraphrasing and preposition selection–with new state-of-the-art results.

1 Introduction

English prepositions form a closed class showing no inflectional variation and are some of the most frequent words. A computational-linguistic understanding of prepositions remains challenging owing to their highly polysemous nature and frequent participation in idiomatic expressions (Saint-Dizier, 2006). In this paper, we study the problem of sense disambiguation for prepositions.

She blinked **with** *confusion*. (Manner & Mood)
He *combines* professionalism **with** humor. (Accompanier)
He *washed* a small red teacup **with** *water*. (Means)

Table 1: Examples showing polysemous behavior of *with* and the TPP senses.

The highly polysemous nature of prepositions drives several syntactic and semantic processes. For instance, the preposition *with* has 18 senses listed in The Preposition Project (TPP) (Litkowski and Hargraves, 2005), examples of which, are shown in Table 1. We notice that *with* indicates an emotional state in *with confusion* and refers to an accompanier in *combine with*, while it suggests the idea of a tool or means in *wash with water*. Thus, preposition sense disambiguation (PSD) is vital for natural language understanding and a closer look at the function of prepositions in specific contexts is an important computational step.

Previous approaches to PSD (for instance, (Ye and Baldwin, 2007; Hovy et al., 2011)) have relied on linguistic tools and resources (the minimum of which involves dependency parsers and POS taggers) to capture the crucial contextual information of prepositions. We depart from prior art by using *no linguistic resources or tools* other than a set of word representations (trained on a large corpus). We interpret preposition senses as groups of similar contexts, where each instance of the preposition 'sense' is represented as a vector of context-dependent features. We find a simple feature extraction process that creatively harnesses the *geometry* of word representations and contributes to a scalable PSD algorithm. Our algorithm can reach near and even beat state-of-the-art performance on two benchmark datasets (SemEval 2007 and OEC); this is true in both unsupervised and supervised PSD settings.

A PSD algorithm that *efficiently scales to a large corpus* naturally paves the way for distributed representations of the preposition senses: we enrich the corpus with sense-specific information of prepositions using our PSD algorithm. Next, we repurpose an off-the-shelf word representation algorithm (Word2vec (Mikolov et al., 2013)) to relearn word representations with the key aspect that the length of the context surrounding the prepositions is crucially reduced. Sense-specific preposition representations thus learnt are strongly validated by using them in two

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1510–1521
Brussels, Belgium, October 31 - November 4, 2018.

applications–phrasal verb paraphrasing and preposition selection–using available datasets. We released our PSD system and paraphrasing dataset [1] available.

We summarize our contributions below:

- **Novel Perspective of Preposition Behavior**: We provide a novel selectional aspect of the context that best represents the sense of a preposition, where we match classical ideas from linguistics with the appropriate geometry of word embeddings. The standard view focuses on the left context (attachment) and the right context (complement) of the preposition; in this paper, we include the *interplay* between these two elements via an appropriate geometric representation.

- **Resource-independent Disambiguation**: We rely only on a set of trained word representations and no other language processing tool, where almost all prior approaches have included at least POS tagging and dependency parsing. Our results are comparable to, or better than, state-of-the-art on standard benchmarks.

- **Preposition Sense Representation Learning**: To the best of our knowledge, this is the first work on preposition sense representation. The power of our sense representation is reflected in the experimental comparisons with strong baseline approaches to phrasal verb paraphrasing and preposition selection, where we demonstrate the superiority of our approach that uses sense representation of prepositions.

2 Related Works

We place our work in the context of related studies in preposition representation and **Preposition Sense Disambiguation**: Preposition disambiguation has been explored on the SemEval dataset via various methods and external resources (part of speech taggers, chunkers, dependency parsers, named entity extractors, WordNet based supersense taggers and semantic role labelers) since 2007 (Yuret, 2007; Ye and Baldwin, 2007; Tratz and Hovy, 2009; Hovy et al., 2011; Popescu et al., 2007; Tratz and Hovy, 2011; Srikumar and Roth, 2013). Recently, (Gonen and Goldberg, 2016) use a multilingual parallel corpus processed using sequence to sequence neural networks for preposition disambiguation and achieve an accuracy within 5% of the state-of-the-art, which includes (Litkowski, 2013; Hovy et al., 2010; Srikumar and Roth, 2013). We note that we achieve the comparable performance as (Gonen and Goldberg, 2016) using *only* word embeddings.

Preposition Representation: Representation learning is fundamental to machine learning models (Wu et al., 2018a,b; Xu et al., 2018). Word embeddings such as Word2vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014) have been widely recognized for their ability to capture linguistic regularities (including syntactic and semantic relations). On the other hand, no linguistic property of their prepositional embeddings is known; to the best of our knowledge, we propose the *first* sense-specific prepositional embeddings and demonstrate their linguistic regularities. A recent unsupervised approach by Gong et al. learns preposition representations to encode the syntactics and semantics by capturing their attachment and complement properties. Distantly related is (Hashimoto and Tsuruoka, 2015), which learns embeddings of prepositions acting as verb adjuncts by the factorization of a predicate tensor. Similarly, (Belinkov et al., 2014) explores the use of preposition representations optimized for the task of prepositional phrase attachment, but do not analyze their sense-specificity.

Sense-specific Representations: Several prior studies have sought polysemy-aware alternatives to word representations that take into account the context of the target word, including (Erk and Padó, 2008; Mitchell and Lapata, 2008; Reisinger and Mooney, 2010a; Thater et al., 2011; Dinu et al., 2012). More recently polysemy disambiguation for word embeddings have been proposed using external resources such as WordNet (Rothe and Schütze, 2015) or in an unsupervised way (Mu et al., 2017; Song et al., 2016; Arora et al., 2016; Neelakantan et al., 2014) with the latter two limiting the number of senses and validated for only nouns and verbs. The approach of (Neelakantan et al., 2014) is roughly similar to our baseline method using the average context vector. Our unsupervised approach is similar to that in (Reisinger and Mooney, 2010a), but limited to prepositions and uses novel features described next.

---

3 Preposition Sense Disambiguation

The key intuition behind our sense disambiguation approach is the modern descriptive linguistic view (Huddleston, 1984; DeCarrico, 2000): the sense of a preposition in any sentence is driven by both its *attachment* and its *complement*; classical prescriptive linguistics had focused only on the latter (Beal, 2004), pp. 110, (Cobbett, 1823), pp. 16, (Lowth, 1762), pp. 8, 91.

Referring again to the examples in Table 1 we point out that italicized words determine the sense of "with." In the first sentence, the word 'confusion,' appearing as the right context of the preposition, is the complement of 'with', from which we infer that 'with' encodes the sense of 'manner'. In the second sentence, the accompanier sense of 'with' is because of its governor (attachment), the verb 'combine' appearing in the left context. In the last sentence, the sense of 'with' is 'by means of' and is determined by *both* the verb in its left context and the argument in its right context. Consider a new sentence with changed right context: 'He washed a small cup with a handle.' Here 'with' functions as an attribute. Again, changing its left context we get the sentence 'He asked for a small cup with water', where 'with' serves as an attribute instead of encoding the sense of means.

That the *left* and *right* context and their *interplay* are critical to prepositional sense disambiguation is also well established in the literature (Hovy et al., 2011; Litkowski and Hargraves, 2007). We match these linguistic properties to appropriate *geometric* objects within the space of word embeddings; the word embeddings are borrowed off-the-shelf – this work uses word2vec. We describe this next, focusing first on the left context, next on the right context and then on their interplay.

Left context feature v_ℓ is the average of the vectors of the left k_ℓ words (here k_ℓ is a parameter roughly taking values 1 through 4). This simple geometric operation is motivated by recent works (Faruqui et al., 2015; Kenter et al., 2016; Yu et al., 2014) representing a sentence by the average of its constituent words robustly and successfully in a variety of downstream settings. Although prior work (Hovy et al., 2010) points out that fixed window sizes are insufficient, when compared to using specific syntactic features (e.g., POS tags and dependency as done in prior works), we will see that the semantic information embedded in word vectors largely compensates for this limitation.

Right context feature v_r is the average of the vectors of the right k_r words (here k_r is a parameter roughly taking values 1 through 4). This is identical to the method adopted for the left context.

We model the **Context-interplay feature** v_{inter} to geometrically relate to both the left and the right contexts as follows. We choose it to be the vector *closest* to both the subspace spanned by the left context word vectors and that spanned by the right context word vectors. This geometric representation appears crucial to capture the prepositional-sense when the interplay between the contexts matters decisively, as seen empirically in our extensive experiments.

Let v_i^ℓ and v_j^r be the left- and the right context word vectors respectively. A precise mathematical definition of v_{inter} is below:

$$v_{\text{inter}} = \operatorname*{argmin}_{v:\|v\|_2=1} \Big(\min_{a_1,\ldots,a_{k_\ell}} \|v - \sum_{i=1}^{k_\ell} a_i v_i^\ell\|_2^2 + \min_{b_1,\ldots,b_{k_r}} \|v - \sum_{j=1}^{k_r} b_j v_j^r\|_2^2 \Big) , \tag{1}$$

where $\{a_i\}_{i=1}^{k_\ell}$ and $\{b_j\}_{j=1}^{k_r}$ are scalars. It is easy to find optimal $\{a_i^*\}$ and $\{b_j^*\}$ to solve the inner minimization problem. We have $a_i^* = \frac{v^T v_i^\ell}{\|v_i^\ell\|^2}$, and $b_j^* = \frac{v^T v_j^r}{\|v_j^r\|^2}$.

The minimization problem (1) is a quadratic optimization problem, so we can find a closed form solution to the unit vector v_{inter}. Suppose that we stack context word vectors $\{v_i^\ell\}$ and $\{v_j^r\}$ as a matrix $V_{d\times(k_\ell+k_r)}$, where d is the dimension of word vectors. The optimal $d-$dimension vector v_{inter} is the first principal component of matrix V.

Unsupervised learning of the senses of a given preposition is conducted by *clustering* its instances represented as a concatenation of the three feature vectors, while harnessing the large number of instances of each preposition in the large WikiCorpus (here we fix $k_\ell = k_r = 2$ and use k-means clustering). If the features do capture the prepositional sense efficiently, then the same-sense instances belong to the same cluster. Based on this intuition, we label each cluster with the dominant label of the training instances within this cluster. Given a test instance, we assign it to the nearest cluster (based on its Euclidean distance), and tag it with the cluster label. We note that the preposition senses are not balanced in the training dataset leading to a situation where frequent senses dominate more than one cluster. We address this by setting the number of clusters k equal to twice the number of senses and find that it separates the infrequent senses from frequent ones, about as well as traditional approaches such as those based on information criteria (Sugar and James, 2003) and the elbow method (Ketchen Jr and Shook, 1996).

Supervised learning of the senses using the three feature vectors was conducted based on the training examples provided in the benchmark PSD datasets. We did this using the standard support vector machines (SVM) (Cortes and Vapnik, 1995), multilayer perceptron (MLP) (Glorot and Bengio, 2010) and weighted k-nearest neighbor (k-NN) (Andoni and Indyk, 2006) classifiers. Each of these allows potentially different weighting of the three features in a context dependent way. The parameters were tuned to maximize the disambiguation accuracy on the development set provided in the benchmark PSD datasets. These experiments are discussed in detail next.

4 Experiments on Sense Disambiguation

The PSD algorithms were validated on the general sense disambiguation task using two datasets provided by TPP. We begin by introducing two benchmarks: SemEval and OEC datasets.

The **SemEval Dataset** consists of 34 prepositions instantiated by $24,663$ sentences covering 332 senses. Among them, $16,557$ sentences are used as training instances (**semtrain**) and 8096 sentences are test instances (**semtest**) for the preposition disambiguation task.

The **OEC dataset** consists of $7,650$ sentences collected from the Oxford English Corpus. Since these sentences included more prepositions than those in the SemEval dataset, we chose $3,587$ sentences that included the same 34 prepositions as used in the SemEval task.

Word embeddings. The word embeddings we used in our experiments were trained on the most recent scrape of the English Wikipedia with the Word2Vec CBOW model (Mikolov et al., 2013), with dimension 300. The linear combination of three vectors v_ℓ, v_r and v_{inter} is the feature to k-NN classifier.

Unsupervised PSD was performed by clustering the training instances fom the SemEval dataset using k-means. In the evaluation phase, each test instance was assigned to the closest cluster, and its sense was the dominant training sense within this cluster. In Table 2 we report the disambiguation accuracy on **semtest**, a new state-of-the-art result.

Supervised PSD was conducted by first conducting a 80/20 split of **semtrain** into training and development sets. The disambiguation accuracy calculated on both **semtest** and OEC datasets is reported in Table 3, using standard off-the-shelf classifiers. The sense disambiguation can be regarded as a multi-class classification problem. We used the SVM classifier with a linear kernel and its penalty parameter C as a tunable parameter, the MLP classifier with one hidden layer, and the number of neurons as a tunable parameter, and the k-NN classifier (weighted k-NN), with the number of nearest neighbors and the feature weights as tunable parameters (a linear combination of the three vectors v_ℓ, v_r and v_{inter} was the feature input to the k-NN classifier); all tunable parameters were tuned using the development set. The output dimension of these classifiers was the number of senses of prepositions. Additionally, the context window sizes k_ℓ and k_r were parameters for all the three classifiers, each tuned on the development set.

Baseline. Recent works have shown that the average word embedding serves as a good representation of the compositional sentential semantics (Faruqui et al., 2015; Kenter et al., 2016; Yu et al., 2014), and this single feature – the average of all context word vectors (both to the left and the right) – serves as a natural baseline.

Results. In both the unsupervised and supervised disambiguation settings, the best performance is achieved by using *all three* features, v_ℓ, v_r and v_i.

As summarized in Table 2, our unsupervised method achieves a 2.4% improvement over state-of-art (Hovy et al., 2011). The results in the supervised setting, tabulated in Table 3, reveal that the weighted k-NN classifier performs best. Denoting left, right and interplay features by ℓ, r, i respectively, Table 2 and 3 report our experimental results using only subset combinations of these features on the two disambiguation tasks.

An ablation analysis of the features reveals that the context-interplay feature is most beneficial when testing on the OEC dataset, but on the SemEval dataset, the left context feature appears to be the most beneficial. A likely explanation to this behavior is that several instances in **semtrain** and **semtest** share the governors the prepo-

System	State-of-art (Hovy et al., 2011)	k-means clustering				
		average	(ℓ, r)	(ℓ, i)	(r, i)	(ℓ, r, i)
Accuracy	0.56	0.555	0.561	0.565	0.534	**0.584**

Table 2: Performance of the unsupervised PSD compared with the state-of-the-art. (ℓ, i), (ℓ, r) and (r, i) correspond to feature ablation results.

	SemEval Dataset					OEC Dataset				
Feature Type	average	(ℓ, r)	(ℓ, i)	(r, i)	(ℓ, r, i)	average	(ℓ, r)	(ℓ, i)	(r, i)	(ℓ, r, i)
SVM	0.712	0.765	0.775	0.700	0.782	0.305	0.330	0.333	0.325	0.351
MLP	0.712	0.758	0.780	0.704	0.777	0.322	0.353	0.353	0.347	0.375
Weighted k-NN	0.731	0.781	0.792	0.733	**0.804**	0.329	0.341	0.380	0.367	**0.400**

Table 3: Supervised disambiguation on SemEval and OEC datasets.

sitions attach to. Hence the left feature (encoding the governor information) helps disambiguation on **semtest**. The governors and complements in OEC instances differ from those in **semtrain**. Therefore, the context-interplay feature provides more general context information than provided by the left and right context features by themselves for sense disambiguation on the OEC dataset.

A side-by-side comparison of the performance of our supervised approach with prior approaches is shown in Table 4. We note that the accuracy of our system is significantly better than that of the best PSD system in SemEval 2007 (11% higher accuracy), and 8% higher on the OEC dataset. It is noteworthy that while (Litkowski, 2013) fared better than our system with the SemEval data, our system outperformed (Litkowski, 2013) on the OEC dataset. Also we achieve performance comparable to the recent work (Gonen and Goldberg, 2016) which had access to a multilingual translation corpus (and other linguistic tools).

4.1 Spatial Expression Disambiguation

Prepositions such as ‘in’ and ‘on’ are used to encode spatial relations between the point of attachment and the complement of the preposition, but their senses show diversity depending on the context. For example, ‘on’ refers to the support from above in the sentence *clothes on the rack*, while it refers to support from below in *clothes on the desk*. These are instances of a phenomenon in natural language in which the mere concatenation of lexical information is not sufficient to derive the meaning of the phrase but the interactions among the meanings of the words is to be considered (termed compositional distributional semantic models (Marelli et al., 2014; Ritter et al., 2015)). We hypothesize that the relative placement of the objects involved in these phrases is achieved by considering the spatial senses of the prepositions involved, which in turn, is done by considering the interaction of its contexts as done by our approach. For this study, we focus on the disambiguation of the spatial senses encoded using the prepositions ‘in’ and ‘on’.

Dataset. (Ritter et al., 2015) studied ways of combining the meanings of the words in context to arrive at the meaning of the phrase which included spatial expressions using the prepositions ‘in’ and ‘on’. Their dataset consists of 420 training examples and 80 test examples, covering 5 types of locative expressions and given a sentence, the task is to arrive at the kind of locative expression encoded by the preposition. As examples, the preposition *in* refers to full containment in the sentence “an apple in the refrigerator”, whereas it refers to partial containment in “finger in the ring”. Similarly, the spatial relations represented by the preposition *on* is classified into three categories: adhesion to vertical surface (e.g., “sign on the building”), support by horizontal surface (e.g., “leaf on the ground”) and support from above (e.g., “bat on the branch”). A key observation here is that the spatial sense of the preposition (equivalently, spatial category) is a function of the two objects connected by the preposition.

Task. Given a sentence, we need to classify each occurrence of the preposition to its spatial category; for our study this is a fine-grained intra-preposition sense disambiguation problem (intra-sense because the sense is one of the spatial senses, albeit different from the TPP senses).

Method. The very small size of the training set in this experiment calls for a reduction in the feature dimension. Accordingly, we use a weighted linear combination of the three features used in our PSD algorithm and the resulting feature is $v = v_\ell + \beta v_r + \gamma v_{\text{inter}}$.

Dataset	System	Resources	Accuracy
SemEval	Our system	English corpus	0.804
	(Litkowski, 2013)	lemmatizer, dependency parser, WordNet	**0.86**
	(Srikumar and Roth, 2013)	dependency parser, WordNet	0.85
	(Gonen and Goldberg, 2016)	multilingual corpus, aligner, dependency parser	0.81
	(Ye and Baldwin, 2007)	chunker, dependency parser, named entity extractor, WordNet	0.69
OEC	Our system	English corpus	**0.40**
	(Litkowski, 2013)	lemmatizer, dependency parser, WordNet	0.32

Table 4: Preposition disambiguation performance comparison on SemEval and OEC datasets.

sense	1	2	3	4
closest words	backwards, reverse, angles, diagonal, between, forward	wearing, dress, hats, dresses, trousers, sleeves, pants, jacket	back, inside, underneath, from, into, where, onto	where, near, from, at, southern, northern, during
example	in all directions, move in, differ in	dress in black, in leather, in size	in the mail	in the UK, in Argentina
TPP sense	Manner_or_Degree	VariableQuality	ThingEntered	ThingEnclosed

Table 5: Example senses of the preposition “in”.

Recall that the hyperparameters β and γ of the k-NN classifier on the PSD task were tuned on the (mismatched) SemEval development set. We then generated the weighted features $v = v_\ell + \beta v_r + \gamma v_{\text{inter}}$ using the tuned values of β, γ from the PSD task. Classification within the spatial sense disambiguation is now conducted using a Multi-Layer Perceptron (MLP) with the feature vector v.

Baseline. The state-of-the-art method (Ritter et al., 2015) used the inclusion of the left and the right noun vectors as features, which is equivalent to adding the left and the right context features with a context window size of 1 in our set-up; this serves as our baseline.

Our method achieves an accuracy of **77**%, a significant improvement over the baseline accuracy of 71% in (Ritter et al., 2015). We note that this improvement is achieved even though we tuned the hyperparameters β and γ on the mismatched (but relatively bigger) SemEval dataset. To complete the comparison, we found (via grid search) that the best β, γ values result in only a slightly higher accuracy of 79%. This performance adds credence to the conclusion that the geometric features ($v_\ell, v_r, v_{\text{inter}}$) do indeed represent the *preposition in its context* efficiently and accurately.

5 Preposition Sense Representation

Thus far, we have empirically validated our disambiguation algorithm on standardized, but still stylized, datasets. A more thorough analysis is enabled by conducting preposition sense disambiguation on a very large unlabeled corpus. Such is the goal of this section, where we scale our lightweight PSD algorithm on a large corpus and learn sense-specific prepositional representations. The quality of the representations serves as an “extrinsic” evaluation of our PSD algorithm; this validation is done by repurposing datasets meant for other tasks.

Standard embedding methods do not account for the inherent polysemy in words. This is exacerbated in the case of prepositions. Indeed, to the best of our knowledge, no linguistic properties of the standard embeddings (say, word2vec (Mikolov et al., 2013) or GloVe (Pennington et al., 2014)) are known for preposition vectors. Recent works that learn sense-specific embeddings use the distinct “topics” assumed by the senses of a given word (as in (Rothe and Schütze, 2015) that explicitly uses WordNet senses) and have only been validated with respect to nouns and verbs.

Below, we validate the quality of the resulting sense representations in two tasks, where prepositional senses play an important role: (a) phrasal verb paraphrasing, and (b) preposition selection.

5.1 Phrasal Verb Paraphrasing

Prepositions often act as a connection between verbs and complements, carrying nontrivial semantic information. We used the trained k-NN classifier on TPP senses to label the prepositions in the English Wikipedia corpus, and learned sense-specific embeddings. These sense-specific representations are readily interpretable in terms of the extensive-resources of TPP. Table 5 shows several senses of "in" together with their nearest neighbors in the vector space.

Embedding	Global	Simplex	Sense
Accuracy	0.44	0.44	**0.73**

Table 6: Accuracy on phrasal verbs paraphrasing.

To validate the sense-specific preposition representation, we infer the meaning of verb-particle construction (VPC), such as *climb down* with sense embeddings. This is a lexical paraphrasing task of finding one word that captures the meaning of VPC (e.g., *climb down* = *descend*).

Dataset. Because a dataset for paraphrasing of VPCs was not available, we created one (which is made available in the supplementary material). It consists of 91 phrasal verbs, extracted from the VPC datasets in (Baldwin, 2005), (McCarthy et al., 2003) and the online Oxford dictionary[2].

For each VPC instance, we first disambiguated the preposition sense in the given context using the supervised method described in Section 3. We consider a linear approximation of phrasal embeddings under three settings:

(1) *Sense-specific embedding*, approximating the representation of a VPC as the sum of the vectors of its verb and its preposition with a specific sense. Thus we have $v_{\text{vp}}^{\text{sense}} = v_{\text{verb}} + v_{\text{prep}}^{\text{sense}}$.

(2) *Global embedding baseline*: $v_{\text{vp}}^{\text{global}} = v_{\text{verb}} + v_{\text{prep}}^{\text{global}}$, where $v_{\text{prep}}^{\text{global}}$ is the global preposition embedding disregarding its sense.

(3) *Simplex embedding baseline* approximates the phrasal embedding to be just the verb embedding, i.e., $v_{\text{vp}}^{\text{simplex}} = v_{\text{verb}}$.

For each approximate phrasal embedding ($v_{\text{vp}}^{\text{sense}}$, $v_{\text{vp}}^{\text{global}}$, $v_{\text{vp}}^{\text{simplex}}$), we list the nearest three verbs (excluding the verb in the phrase) as its paraphrase, with the distance measured by the cosine similarity between the word vectors.

Two proficient English speakers set the gold standard for whether the paraphrase was valid or not (for polysemous verbs, we consider the verb to be a valid paraphrase if it conveys the meaning in any of its senses) and reconciled disagreements. We used accuracy as the evaluation metric, which is the percent of phrasal verbs with a valid paraphrase among candidates.

Results. We note that sense representations are able to capture the nuance of polysemous verb phrases. As is shown in Fig. 1, the phrase "fight for" has more than one meaning depending on the sense of its preposition. In the expression "fight for human rights", *for* carries the sense of purpose. Since the expression is semantically equivalent to "defend human rights", "defend" can paraphrase the phrase "fight for". In another context "fight for the prize" where *for* is related with benefits, "fight for" should be paraphrased as "win" and the expression "win the prize" is similar to "fight for the prize".

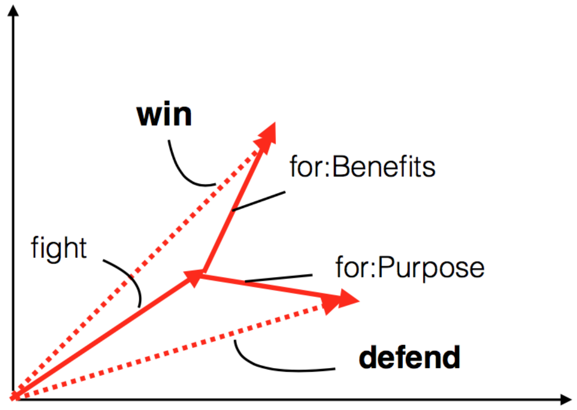

Figure 1: Paraphrasing polysemous verb phrases.

Some examples of phrasal verbs and paraphrases are shown in Table 7, with valid paraphrases highlighted. We report the performance of different embeddings in Table 6, where we notice that paraphrasing with the preposition sense embedding has a much higher accuracy than the two baselines. This validates the sense-specific preposition embedding suggesting its use in automatic paraphrasing of VPCs. Examples of paraphrases are shown in Table 7. A more detailed analysis of the results are in the appendix.

5.2 Preposition Selection

Given the polysemous and idiosyncratic nature of prepositions, choosing a preposition to fit a context can be a particularly challenging task for non-native English learners. Not surprisingly, preposition errors constitute the largest category of grammatical errors made by English learners (Chodorow et al., 2007). In this work, we show how the sense representations adequately capture the prepositional semantics, thus aiding preposition selection. Since TPP senses are fine-grained, we limit the senses available to be concrete or abstract by conflating the TPP senses to one of these

two types (Reisinger and Mooney, 2010b). For example, "in a room" stands for the concrete sense of the preposition 'in', while "in her heart" corresponds to the abstract sense. In this part, we consider two senses for each preposition.

Dataset. We used three datasets, which consist of sentences marked with grammatical corrections out of which we only chose those with preposition errors. The Cambridge First Certificate in English (FCE) dataset contains $60,279$ prepositions with 4.8% error, the CoNLL dataset has $3,241$ prepositions with 4.7% errors and the Stack Exchange (SE) dataset has $15,814$ prepositions with 38.2% error (Prokofyev et al., 2014). Owing to its size, the FCE dataset was used for training, and the other two were used for testing. For each sentence with a preposition the task is to replace it with the correct one if it is used incorrectly.

Method. We classify all occurrences of each preposition sense into the two senses (abstract and concrete) by using the unsupervised PSD approach described in Section 4 to cluster the available senses. Then the prepositions in Wikipedia are labeled with one of the two senses, again using the unsupervised PSD approach. We then train sense embeddings on the newly labeled corpus with word2vec.

For a given sentence in the preposition selection task, we first disambiguate the sense of the preposition by checking which cluster it is closest to. The selection task is divided into preposition error detection and error correction. At the detection stage, we decide whether a preposition is used appropriately in the sentence. For this, we use as features the cosine similarity between the preposition sense embedding and the average word embedding in the context (the context size is 3), the rank of the preposition among all preposition choices with respect to the cosine similarity just mentioned, and the probability that the current preposition is replaced estimated from the training corpus. A decision tree classifier is used with these features to identify preposition errors.

At the second stage, we replace the current preposition p with another one if an error was detected at the first stage. Suppose that we consider replacing preposition p with q. We first disambiguate preposition q's sense given the context. We then use preposition q's sense embedding, the left context vector v_ℓ, the right context vector v_r, the interplay vector v_{inter} and the probability that q takes the place of p in the training corpus as input features to a two-layer MLP with 500 and 10 units in each layer. The MLP outputs a scalar to estimate how well the preposition q fits in p's context. The preposition with highest score is selected as the replacement.

Baseline. The state-of-the-art on preposition selection is one of the baselines, which makes use of lexical statistics from a large corpus as well as part-of-speech tags (Prokofyev et al., 2014). Also to evaluate the advantage of preposition sense representation over word representation, we have another baseline which uses the same classifier but the input features are the word embeddings instead of sense embeddings. The word embeddings were trained on Wikipedia English corpus with word2vec CBOW model.

Result. We compare the sense embedding-based approach against baselines in Table 8. As we can see, the use of sense representation achieves comparable performance to the state-of-the-art without using external linguistic tools. It also outperforms the baseline with word representation by a large margin.

6 Discussion

Resource-independence: Previous approaches to PSD relied on a part-of-speech tagger or depen-

Dataset	Method	Precision	Recall	F1 score

	Word representation	0.156	0.158	0.157
	Sense representation	0.279	0.283	0.281
SE	State-of-the-art	0.270	0.296	0.282
	Word representation	0.245	0.259	0.252
	Sense representation	0.281	0.297	**0.289**

Table 8: Performance in preposition selection.

dency parser to extract words modified by and modifying a preposition. In general, these words occur in the preposition's local context. We have allowed the context window to be a tunable parameter so that the classifier can learn to cover informative words in the context, and thus effectively captures the dependency information in a resource-independent fashion.

Context feature: The context averaging approach, which disregards context word order, suffers in accuracy compared to models that use left and right context words. This indicates that information about the word order relative to the preposition is useful in preposition disambiguation. Additionally, our use of the context-interplay feature combines the information on *both* sides of the preposition to infer its underlying sense.

Suppose that three expressions *a cup of medicine*, *professor of humanity* and *professor of mathematics* are in the training corpus, and the senses of the preposition *of* are 'contents', 'possessor' and 'field'. Given a test instance *professor of medicine*, it would be hard for the method with only the left or the right feature to decide the preposition sense since the test instance has the same word as each of the training instance, and their features in these two baselines are similar. However, the interplay vector in *professor of medicine* is closer to that in "professor of mathematics" than to other two training instances. The interplay feature prompts that *of* refers to a field (or species) instead of contents or possessor.

Data-driven insights into context dependence: Knowing the weights on the context features in the k-NN supervised PSD classifier, we can infer the extent to which prepositions rely on the complement and the attachment. For example, we found that in the case of the prepositions *behind* (occurring in, "shut behind her", "dip behind clouds"), *to* (e.g., "testify to the depth", "mumbling to himself"), and *with* (e.g., "amalgamated with her old school", and "rub with bare hands"), the verbs they attach to strongly influence their sense. For other prepositions such as *during* (e.g., "during the incident") and *on* (e.g., "on his hands"), the complement noun has more influence on the senses than governors.

Sense helps paraphrasing: We observe that sense-specific preposition representation helps improve phrasal verb paraphrasing greatly. Working with the VPC dataset and the simplistic model of compositionality, we interpret the results as positive indicators of the viability of using sense-specific prepositional embeddings to paraphrase verb-particle constructions. In the case of *light verbs*, whose meaning is determined largely by the particles they combine with, (e.g., *come down* $\sim$ *fall*), a valid paraphrase is found in the top 3 candidates when the sense-specific representation is used, and not when the simplex or the global representation is used.

7 Conclusion

This paper studies the preposition sense disambiguation by encoding the attachment and complement properties into context features. The disambiguation method performs well on three standard PSD tasks and readily scales to a large corpus. The resulting sense-specific representations are shown to capture semantics of preposition senses in our quantitative analysis. They are also shown to aid two downstream tasks: phrasal verb paraphrasing and preposition selection.

Auto-Encoding Dictionary Definitions into Consistent Word Embeddings

Abstract

Monolingual dictionaries are widespread and semantically rich resources. This paper presents a simple model that learns to compute word embeddings by processing dictionary definitions and trying to reconstruct them. It exploits the inherent recursivity of dictionaries by encouraging consistency between the representations it uses as inputs and the representations it produces as outputs. The resulting embeddings are shown to capture semantic similarity better than regular distributional methods and other dictionary-based methods. In addition, the method shows strong performance when trained exclusively on dictionary data and generalizes in one shot.

1 Introduction

Dense, low-dimensional, real-valued vector representations of words known as *word embeddings* have proven very useful for NLP tasks (Turian et al., 2010). They can be learned as a by-product of solving a particular task (Collobert et al., 2011). Alternatively, one can pretrain generic embeddings based on co-occurrence counts or using an unsupervised criterion such as predicting nearby words (Bengio et al., 2003; Mikolov et al., 2013). These methods implicitly rely on the distributional hypothesis (Harris, 1954; Sahlgren, 2008), which states that words that occur in similar contexts tend to have similar meanings.

It is common to study the relationships captured by word representations in terms of either *similarity* or *relatedness* (Hill et al., 2016). "Coffee" is related to "cup" as coffee is a beverage often drunk in a cup, but "coffee" is not similar to "cup" in that coffee is a beverage and cup is a container. Methods relying on the distributional hypothesis often capture relatedness very well, reaching human performance, but fare worse in capturing similarity and especially in distinguishing it from relatedness (Hill et al., 2016).

It is useful to specialize word embeddings to focus on either relation in order to improve performance on specific downstream tasks. For instance, Kiela et al. (2015) report that improvements on relatedness benchmarks also yield improvements on document classification. In the other direction, embeddings learned by neural machine translation models capture similarity better than distributional unsupervised objectives (Hill et al., 2014).

There is a wealth of methods that postprocess embeddings to improve or specialize them, such as retrofitting (Faruqui et al., 2014). On similarity benchmarks, they are able to reach correlation coefficients close to inter-annotator agreements. But these methods rely on additional resources such as paraphrase databases (Wieting et al., 2016) or graphs of lexical relations such as synonymy, hypernymy, and their converse (Mrkšić et al., 2017).

Rather than relying on such curated lexical resources that are not readily available for the majority of languages, we propose a method capable of improving embeddings by leveraging the more common resource of monolingual dictionaries.[1] Lexical databases such as WordNet (Fellbaum, 1998) are often built from dictionary definitions, as was proposed earlier by Amsler (1980). We propose to bypass the process of explicitly building a lexical database – during which information is structured but information is also lost – and instead directly use its detailed source: dictionary definitions. The goal is to obtain better representations for more languages with less effort.

The ability to process new definitions is also desirable for future natural language understanding systems. In a dialogue, a human might want to explain a new term by explaining it in his own words,

---

[1] See Appendix A for a list of online monolingual dictionaries.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1522–1532
Brussels, Belgium, October 31 - November 4, 2018.

and the chatbot should understand it. Similarly, question-answering systems should also be able to grasp definitions of technical terms that often occur in scientific writing.

We expect the embedding of a word to represent its meaning compactly. For interpretability purposes, it would be desirable to be able to generate a definition from that embedding, as a way to verify what information it captured. Case in point: to analyse word embeddings, Noraset et al. (2017) used RNNs to produce definitions from pretrained embeddings, manually annotated the errors in the generated definitions, and found out that more than half of the wrong definitions fit either the antonyms of the defined words, their hypernyms, or related but different words. This points in the same direction as the results of intrinsic evaluations of word embeddings: lexical relationships such as lexical entailment, similarity and relatedness are conflated in these embeddings. It also suggests a new criterion for evaluating word representations, or even learning them: they should contain the necessary information to reproduce their definition (to some degree). In this work, we propose a simple model that exploits this criterion. The model consists of a definition autoencoder: an LSTM processes the definition of a word to yield its corresponding word embedding. Given this embedding, the decoder attempts to reconstruct the bag-of-words representation of the definition. Importantly, to address and leverage the recursive nature of dictionaries – the fact that words that are used inside a definition have their own associated definition – we train this model with a consistency penalty that ensures proximity of the embeddings produced by the LSTM and those that are used by the LSTM.

Our approach is self-contained: it yields good representations when trained on nothing but dictionary data. Alternatively, it can also leverage existing word embeddings and is then especially apt at specializing them for the similarity relation. Finally, it is also extremely data-efficient, as it permits to create representations of new words in one shot from a short definition.

2 Model

2.1 Setting and motivation

We suppose that we have access to a dictionary that maps words to one or several definitions. Definitions themselves are sequences of words. Our training criterion is built on the following principle: we want the model to be able to recover the definition from which the representation was built. This objective should produce similar embeddings for words which have similar definitions. Our hypothesis is that this will help capture semantic similarity, as opposed to relatedness. Reusing the previous example, “coffee” and “cup” should get different representations in virtue of having very different definitions, while “coffee” and “tea” should get similar representations as they are both defined as beverages and plants.

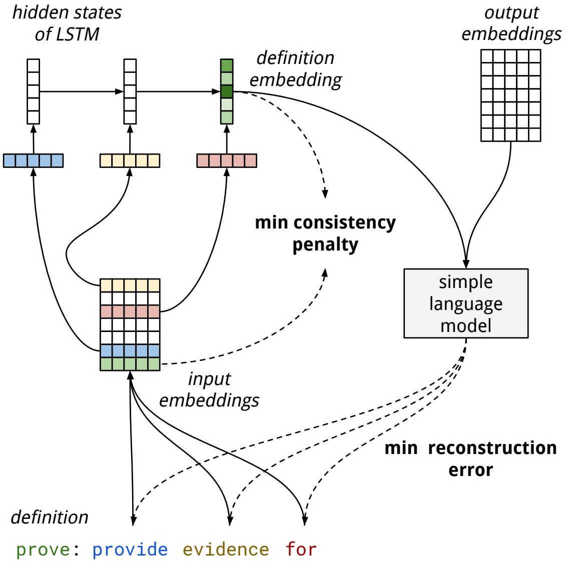

Figure 1: **Overview of the CPAE model.**

We chose to compute a single embedding per word in order to avoid having to disambiguate word senses. Indeed, word sense disambiguation remains a challenging open problem with mixed success on downstream task applications (Navigli, 2009). Also, recent papers have shown that a single word vector can capture polysemy and that having several vectors per word is not strictly necessary (Li and Jurafsky, 2015) (Yaghoobzadeh and Schütze, 2016). Thus, when a word has several definitions, we concatenate them to produce a single embedding.

2.2 Autoencoder model

Let $\mathcal{V}^{\mathcal{D}}$ be the set of all words that are *used* in definitions and $\mathcal{V}^{\mathcal{K}}$ the set of all words that are *defined*. We let $w \in \mathcal{V}^{\mathcal{K}}$ be a word and $D_w = (D_{w,1}, \dots, D_{w,T})$ be its definition, where $D_{w,t}$ is the index of a word in vocabulary $\mathcal{V}^{\mathcal{D}}$. We encode such a definition D_w by processing it with an

LSTM (Hochreiter and Schmidhuber, 1997).

The LSTM is parameterized by Ω and a matrix E of size $|\mathcal{V}^{\mathcal{D}}| \times m$, whose i^{th} row E_i contains an m-dimensional *input embedding* for the i^{th} word of $\mathcal{V}^{\mathcal{D}}$. These input embeddings can either be learned by the model or be fixed to a pretrained embedding. The last hidden state computed by this LSTM is then transformed linearly to yield an m-dimensional *definition embedding* h. Thus the encoder whose parameters are $\theta = \{E, \Omega, W, b\}$ computes this embedding h as

$$h = f_\theta(D_w) = W \, \mathrm{LSTM}_{E,\Omega}(D_w) + b.$$

The subsequent decoder can be seen as a conditional language model trained by maximum likelihood to regenerate definition D_w given definition embedding $h = f_\theta(D_w)$. We use a simple conditional unigram model with a linear parametrization $\theta' = \{E', b'\}$ where E' is a $|\mathcal{V}^{\mathcal{D}}| \times m$ matrix and b' is a bias vector. [2]

We maximize the log-probability of definition D_w under that model:

$$\begin{aligned} \log p_{\theta'}(D_w|h) &= \sum_t \log p_{\theta'}(D_{w,t}|h) \\ &= \sum_t \log \frac{e^{\left\langle E'_{D_{w,t}}, h\right\rangle + b'_{D_{w,t}}}}{\sum_k e^{\left\langle E'_k, h\right\rangle + b'_k}} \end{aligned} \quad (1)$$

where $\langle , \rangle$ denotes an ordinary dot product. We call E' the *output embedding* matrix. The basic autoencoder training objective to minimize over the dictionary can then be formulated as

$$J_r(\theta', \theta) = - \sum_{w \in \mathcal{V}^{\mathcal{K}}} \log p_{\theta'}(D_w | f_\theta(D_w)).$$

2.3 Consistency penalty

We introduced 3 different embeddings: a) *definition embeddings* h, produced by the definition encoder, are the embeddings we are ultimately interested in computing; b) *input embeddings* E are used by the encoder as inputs; c) *output embeddings* E' are compared to definition embeddings to yield a probability distribution over the words in the definition. We propose a soft weight-tying scheme that brings the input embeddings closer to the definition embeddings. We call this term a *consistency* penalty because its goal is to to ensure that the embeddings used by the encoder (input embeddings) and the embeddings produced by the encoder (definition embeddings) are consistent with each other. It is implemented as

$$J_p(\theta) = \sum_{w \in \mathcal{V}^{\mathcal{D}} \cap \mathcal{V}^{\mathcal{K}}} d(E_w, f_\theta(D_w))$$

where d is a distance. In our experiments, we choose d to be the Euclidian distance. The penalty is only applied to some words because $\mathcal{V}^{\mathcal{D}} \neq \mathcal{V}^{\mathcal{K}}$. Indeed, some words are defined but are not used in definitions and some words are used in definitions but not defined. In particular, inflected words are not defined. To balance the two terms, we introduce two hyperparameters $\lambda, \alpha \geq 0$ and the complete objective is

$$J(\theta', \theta) = \alpha J_r(\theta', \theta) + \lambda J_p(\theta).$$

We call the model *CPAE*, for *Consistency Penalized AutoEncoder* when $\alpha > 0$ and $\lambda > 0$ (see Figure 1).[3]

The consistency penalty is a cheap proxy for dealing with the circularity found in dictionary definitions. We want the embeddings of the words in definitions to be compositionally built from their definition as well. The recursive process of fetching definitions of words in definitions does not terminate, because all words are defined using other words. To counter that, our model uses input embeddings that are brought closer to definition embeddings and vice versa in an asynchronous manner.

Moreover, if λ is chosen large enough, then $E_w \approx f_\theta(D_w)$ after optimisation. This means that the definition embedding for w is close enough to the corresponding input embedding to be used by the encoder for producing other definition embeddings for other words. In that case, the model could enrich its vocabulary by computing embeddings for new words and consistently reusing them as inputs for defining other words.

Finally, the consistency penalty can be used to leverage pretrained embeddings and bootstrap the learning process. For that purpose, the encoder's input embeddings E can be fixed to pretrained embeddings. These provide targets to the encoder but

---

[2] We have tried using a LSTM decoder but it didn't yield good representations. It might overfit because the set of dictionary definitions is small. Also, using teacher forcing, we condition on ground-truth words, making it easier to predict the next words. More work is needed to address these issues.

[3] Our implementation is available at `https://github.com/tombosc/cpae`

also helps the encoder to produce better definition embeddings in virtue of using input embeddings that already contain meaningful information.

To summarize, the consistency penalty has several motivations. Firstly, it deals with the fact that the recursive process of building representation of words out of definitions does not terminate. Secondly, it is a way to enrich the vocabulary with new words dynamically. Finally, it is a way to integrate prior knowledge in the form of pretrained embeddings.

In order to study the two terms of the objective in isolation, we introduce two special cases. When $\lambda = 0$ and $\alpha > 0$, the model reduces to *AE* for *Autoencoder*. When $\alpha = 0$ and $\lambda > 0$, we retrieve *Hill's model*, as presented by Hill et al. (2015).[4] Hill's model is simply a recurrent encoder that uses pretrained embeddings as targets so it only makes sense in the case we use fixed pretrained embeddings.

3 Related work

3.1 Extracting lexical knowledge from dictionaries

There is a long history of attempts to extract and structure the knowledge contained in dictionaries. Amsler (1980) studies the possibility of automatically building taxonomies out of dictionaries, relying on the syntactic and lexical regularities that definitions display. One relation is particularly straightforward to identify: it is the *is a* relation that translates to hypernymy. Dictionary definitions often contain a *genus* which is the hypernym of the defined word, as well as a *differentia* which differentiates the hypernym from the defined word. For example, the word "hostage" is defined as "a prisoner who is held by one party to insure that another party will meet specified terms", where "prisoner" is the genus and the rest is the differentia.

To extract such relations, early works by Chodorow et al. (1985) and Calzolari (1984) use string matching heuristics. Binot and Jensen (1987) operate at the syntactic parse level to detect these relations. Whether based on the string representation or the parse tree of a definition, these rule-based systems have helped to create large lexical databases. We aim to reduce the manual labor involved in designing the rules and directly obtaining representations from raw definitions.

3.2 Improving word embeddings using lexical resources

Postprocessing methods for word embeddings use lexical resources to improve already trained word embeddings irrespective of how they were obtained. When it is used with fixed pretrained embeddings, our method can be seen as a postprocessing method.

Postprocessing methods typically have two terms for trading off conservation of distributional information that is brought by the original vectors with the new information from lexical resources. There are two main ways to preserve distributional information: Attract-Repel (Vulić and Mrkšić, 2017), retrofitting (Mrkšić et al., 2017) and our method control the distance between the original vector and the postprocessed vector so that the new vector does not drift too far away from the original vector. Counter-Fitting (Mrkšić et al., 2016) and dict2vec (Tissier et al., 2017) ensure that the neighbourhood of a vector in the original space is roughly the same as the neighbourhood in the new space.

Finally, methods differ by the nature of the lexical resources they use. To our knowledge, dict2vec is the only technique that uses dictionaries. Other postprocessing methods use various data from WordNet: sets of synonyms and sometimes antonyms, hypernyms, and hyponyms. For instance, Lexical Entailment Attract-Repel (LEAR) uses all of these (Vulić and Mrkšić, 2017). Other methods rely on paraphrase databases (Wieting et al., 2016).

3.3 Dictionaries and word embeddings

We now turn to the most relevant works that involve dictionaries and word embeddings.

Dict2vec (Tissier et al., 2017) combines the word2vec skip-gram objective (predicting all the words that appear in the context of a target word) with a cost for predicting related words. These related words either form *strong pairs* or *weak pairs* with the target word. Strong pairs have a greater influence in the cost. They are pairs of words that are in the neighbourhood of the target word in the

---

[4] It is not exactly their model as we use Euclidian distance instead of the cosine distance or the ranking loss. They also explore several variants where the input embeddings are learned, which we didn't find to produce any improvement. We haven't experimented with the ranking loss, but the cosine distance does not seem to improve over Euclidian. Finally, they also use a simple encoder that averages word vectors, which we found to be inferior.

original embedding, as well as pairs of words for which the definitions make reference to each other. Weak pairs are pairs of words where only one word appears in the definition of the other. Unlike dict2vec, our method can be used as either a standalone or a postprocessing method (when used with pretrained embeddings). It also focuses on handling and leveraging the recursivity found in dictionary definitions with the consistency penalty whereas dict2vec ignores this aspect of the structure of dictionaries.

Besides dict2vec, Hill et al. (2015) train neural language models to predict a pretrained word embedding given a definition. Their goal was to learn a general-purpose sentence encoder useful for downstream tasks. Noraset et al. (2017) propose the task of generating definitions based on word embeddings for interpretability purposes. Our model unifies these two approaches into an autoencoder. However, we have a different goal: that of creating or improving word representations. Their methods assume that pretrained embeddings are available to provide either targets or inputs, whereas our model is unsupervised, and the use of pretrained embeddings is optional.

Bahdanau et al. (2017) present a related model that produces embeddings from definitions such that it improves performance on a downstream task. By contrast our approach is used either stand-alone or as as a postprocessing step, to produce general-purpose embeddings at a lesser computational cost. The core novelty is the way we leverage the recursive structure of dictionaries.

Finally, Herbelot and Baroni (2017) also aim at learning representations for word embeddings in a few shots. The method consists of fine-tuning word2vec hyperparameters and can learn in one or several passes, but it is not specifically designed to handle dictionary definitions.

4 Experiments

4.1 Setup

We experiment on English to benefit from the many evaluation benchmarks available. The dictionary we use is that of WordNet (Fellbaum, 1998). WordNet contains graphs of linguistic relations such as synonymy, antonymy, hyponymy, etc. but also definitions. We emphasize that our method trains exclusively on the definitions and is thus applicable to any electronic dictionary.

However, in order to *evaluate* the quality of embeddings on unseen definitions, WordNet relations comes in handy: we use the sets of synonyms to split the dictionary into a train set and a test set, as explained in Section 7. Moreover, WordNet has a wide coverage and high quality, so we do not need to aggregate several dictionaries as done by Tissier et al. (2017). Finally, WordNet is explicitly made available for research purposes, therefore we avoid technical and legal difficulties associated with crawling proprietary online dictionaries.

We do not include part of speech tags that go with definitions. WordNet does not contain function words but contains homonyms of function words. We filter these out.

4.2 Similarity and relatedness benchmarks

Evaluating the learned representations is a complex issue (Faruqui et al., 2016). Indeed, different evaluation methods yield different rankings of embeddings: there is no single embedding that outperforms others on all tasks (Schnabel et al., 2015) and thus no single best evaluation method.

We focus on intrinsic evaluation methods. In particular, we study how different models trade off similarity and relatedness. We use benchmarks which consist of pairs of words scored according to some criteria. They vary in terms of annotation guidelines, number of annotators, selection of the words, etc. To evaluate our embeddings, we score each pair by computing the cosine similarity between the corresponding word vectors. Then the predicted scores and the ground truth are ranked and the correlation between the ranks is measured by Spearman's ρ. We leave aside analogy prediction benchmarks as they suffer from many problems (Linzen, 2016; Rogers et al., 2017).

We adopt one of the methods proposed by Faruqui et al. (2016) and use separate datasets for model selection. We choose the development set to be the development set of SimVerb3500 (Gerz et al., 2016) and MEN (Bruni et al., 2014), the only benchmarks with a standard train/test split.

We justified our emphasis on the similarity relation in Section 1: capturing this relation remains a challenge, and we hypothesize that dictionary data should improve representations in that respect. The model selection procedure reflects that we want embeddings specialized in similarity. To do that, we set the validation loss as a weighted mean which weights SimVerb twice as MEN.

4.3 Baselines

The objective function presented in section 2 gives us 3 different models: CPAE, AE, and Hill's model. The objective of CPAE comprises the sum of the objective of Hill's model and of AE. We compare the CPAE model to both of these to evaluate the individual contribution of the two terms to the performance. In addition, when we use external corpora to pretrain embeddings, we compare these models to dict2vec and retrofitting. The hyperparameter search is described in Appendix C.

The test benchmarks for the similarity relation includes SimLex999 (Hill et al., 2016) and more particularly SimLex333, a challenging subset of SimLex999 which contains only highly related pairs but in which similarity scores vary a lot. For relatedness, we use MEN (Bruni et al., 2014), RG (Rubenstein and Goodenough, 1965), WS353 (Finkelstein et al., 2001), SCWS (Huang et al., 2012), and MTurk (Radinsky et al., 2011; Halawi et al., 2012). The evaluation is carried out by a modified version of the Word Embeddings Benchmarks project.[5] Conveniently, all these benchmarks contain mostly lemmas, so we do not suffer too much from the problem of missing words.[6]

5 Results in the dictionary-only setting

In the first evaluation round, we train models only using a single monolingual dictionary. This allows us to check our hypothesis that dictionaries contain information for capturing the similarity relation between words.

Our baselines are regular distributional models: GloVe (Pennington et al., 2014) and word2vec (Mikolov et al., 2013). They are trained on the concatenation of defined words with their definitions.

Such a formatting introduces spurious co-occurrences that do not otherwise appear in free text. But these baselines are not designed for dictionaries and cannot deal with their particular structure.

We compare these models to the autoencoder model without (AE) and with (CPAE) the consistency penalty. In this setting, we cannot use Hill's model as it requires pretrained embeddings as targets. We also trained an additional CPAE model with pretrained word2vec embeddings trained on the concatenated definitions. The results are presented in Table 1.

GloVe is outperformed by word2vec by a large margin so we ignore this model in later experiments. Word2vec captures more relatedness than CPAE (+10.7 on MEN-t, +13.5 on MT, +13.2 on WS353) but less similarity than CPAE. The difference in the nature of the relations captured is exemplified by the scores on SimLex333. This subset of SimLex999 focuses on pairs of words that are very related but that can be either similar or dissimilar. On this subset, CPAE fares better than word2vec (+13.1).

The consistency penalty improves performance on every dataset. This penalty provides targets to the encoder, but these targets are themselves learned and change during the learning process. The exact dynamics of the system are unknown. It can be seen as a regularizer because it puts strong weight-sharing constraints on both types of embeddings. It also resembles *bootstrapping* in reinforcement learning, which consists of building estimates of values functions on top of over estimates (Sutton and Barto, 1998).

The last model is the CPAE model that uses the word2vec embeddings pretrained on the dictionary data. This combination not only equals other models on some benchmarks but outperforms them, sometimes by a large margin (+6.3 on SimLex999 and +7.5 on SimVerb3500 compared to CPAE, +6.1 on SCWS, +5.4 on MT compared to word2vec). Thus, the two kinds of algorithms are complementary through the different relationships that they capture best. The pretraining helps in two different ways, by providing quality input embeddings and targets to the encoder. The pretrained word2vec targets are already remarkably good. That is why the chosen consistency penalty coefficient selected is very high ($\lambda = 64$). The model can pay a small cost and deviate from the targets in order to encode information about the definitions.

To sum up, dictionary data contains a lot of data relevant to modeling the similarity relationship. Autoencoder based models learn different relationships than regular distributional methods. The consistency penalty is a very helpful prior and regularizer for dictionary data, as it always helps,

Table 1: **Positive effect of the consistency penalty and word2vec pretraining.** Spearman's correlation coefficient $\rho \times 100$ on benchmarks. Without pretraining, autoencoders (AE and CPAE) improve on similarity benchmarks while capturing less relatedness than distributional methods. The consistency penalty (CPAE) helps even without pretrained targets. Our method, combined with pretrained embeddings on the same dictionary data (CPAE-P), significantly improves on every benchmark.

regardless of what relationship we focus on. Finally, our model can drastically improve embeddings that were trained on the same data but with a different algorithm.

6 Improving pretrained embeddings

We have seen that CPAE with pretraining is very efficient. But does this result generalizes to other kind of pretraining data? To answer this question, we experiment using embeddings pretrained on the first 50 million tokens of a Wikipedia dump, as well as the entire Wikipedia dump. We compare our method to existing postprocessing methods such as dict2vec and retrofitting, which also aims at improving embeddings with external lexical resources.

Retrofitting, which operates on graphs, is not tailored for dictionary data, which consists in pairs of words along with their definitions. We build a graph where nodes are words and edges between nodes correspond to the presence of one of the words into the definition of another. Obviously, we lose word order in the process.

The results for the small corpus are presented in Table 2. By comparing Table 2 with Table 1, we see that word2vec does worse on similarity than when trained on dictionary data, but better on relatedness. Both dict2vec and retrofitting improve with regards to word2vec on similarity benchmarks and seem roughly on par. However, dict2vec fails to improve on relatedness benchmarks, whereas retrofitting sometimes improves (as in RG, MEN, and MT), sometimes equals (SCWS) and does worse (353).

We do an ablation study by comparing Hill's model and AE with CPAE. Recall that Hill's model lacks the reconstruction cost while AE lacks the consistency penalty. Firstly, CPAE always improves over AE. Thus, we confirm the results of the previous section on the importance of the consistency penalty. In that setting, it is more obvious why this penalty helps, as it now provides pretrained targets to the encoder. Secondly, CPAE improves over Hill on all similarity benchmarks by a large margin (+12.2 on SL999, +13.7 on SL333, +16.1 on SV3500). It is sometimes slightly worse on relatedness benchmarks (-3.3 on MEN-t, -5.6 on MT), other times better or equal. We conclude that both terms of the CPAE objective matter.

We see identical trends when using the full Wikipedia dump. As expected, CPAE can still improve over even higher quality embeddings by roughly the same margins. The results are presented in Appendix D.

Remarkably, the best model among all our experiments is CPAE in Table 1 and uses only the dictionary data. This supports our hypothesis that dictionaries contain similarity-specific information.

7 Generalisation on unseen definitions

A model that uses definitions to produce word representations is appealing because it could be extremely data-efficient. Unlike regular distributional methods which iteratively refine their representation as occurrences accumulate, such a model could output a representation in one shot. We now evaluate CPAE in a setting where some definitions are not seen during training.

The dictionary is split into train, validation (for early stopping) and test splits. The algorithm for splitting the dictionary puts words in batches. It ensures two things: firstly, that words which share at least one definition are in the same batch, and secondly, that each word in a batch is associated

	Development		Similarity			Relatedness				
	SV-d	MEN-d	SL999	SL333	SV-t	RG	SCWS	MEN-t	MT	353
word2vec	21.7	71.1	33.2	6.9	21.2	68.5	**65.8**	71.5	61.1	**65.3**
retrofitting	28.5	**71.6**	36.9	14.1	26.1	**78.9**	65.7	**74.4**	**62.8**	60.7

Hill	26.9	63.3	27.7	12.9	21.7	72.9	58.4	64.1	54.0	52.3
AE	33.5	47.0	33.1	20.4	32.5	66.0	52.0	46.4	40.2	43.7
CPAE ($\lambda = 4$)	**39.5**	60.8	**39.9**	**26.6**	**37.8**	69.7	59.2	60.8	48.4	55.6

Table 2: **Improving pretrained embeddings computed on a small corpus**. Spearman's correlation coefficient $\rho \times 100$ on benchmarks. All methods use pretrained embeddings. All methods (except maybe Hill) manage to improve the embeddings. Retrofitting outperforms dict2vec and efficiently specializes for relatedness. CPAE outperforms AE and allows to trade off relatedness for similarity.

	Similarity			Relatedness			
	999	333	SV-t	353	MEN	SCWS	MT
All	36.5	27.7	36.9	43.7	48.8	53.2	41.5
Train	40.0	28.5	36.7	46.9	53.4	57.1	42.9
Test	27.5	25.4	38.5	42.5	44.1	40.3	39.1

Table 3: **One pass generalisation.** Spearman's correlation coefficient $\rho \times 100$ on benchmarks. The model is CPAE (without pretrained embeddings). All: all pairs in the benchmarks. Train: pairs for which both words are in the training or validation set. Test: pairs which contain at least one word in the test set. Correlation is lower for test pairs but remains strong ($\rho > 0.3$): the model has good generalisation abilities.

with all its definitions. We can then group batches to build the training and the test sets such that the test set does not contain synonyms of words from the other sets. We sort the batches by the number of distinct definitions they contain. We use the largest batch returned by the algorithm as the training set: it contains mostly frequent and polysemous words. The validation and the test sets, on the contrary, contain many multiword expressions, proper nouns, and rarer words. More details are given in Appendix B.1.

We train CPAE only on the train split of the dictionary, with randomly initialized input embeddings. Table 3 presents the same correlation coefficients as in the previous tables but also distinguishes between two subsets of the pairs: the pairs for which all the definitions were seen during training (*train*) and the pairs for which at least one word was defined in the test set (*test*). Unfortunately, there are not enough pairs of words which both appear in the test set to be able to compute significant correlations. On small-sized benchmarks, correlation coefficients are sometimes not significant so we do not report them (when p-value > 0.01).

The scores of CPAE on the test pairs are quite correlated with the ground truth: except on SimLex999 and SCWS, there is no drop in correlation coefficients between the two sets. The scores of Hill's model follow similar trends, but are lower on every benchmark so we do not report them. This shows that recurrent encoders are able to generalize and produce coherent embeddings as a function of other embeddings in one pass.

8 Conclusion and future work

We have focused on capturing the similarity relation. It is a challenging task which we have proposed to solve using dictionaries, as definitions seem to encode the relevant kind of information.

We have presented an alternative for learning word embeddings that uses dictionary definitions. As a definition autoencoder, our approach is self-contained, but it can alternatively be used to improve pretrained embeddings, and includes Hill's model (Hill et al., 2015) as a special case.

In addition, our model leverages the inherent recursivity of dictionaries via a consistency penalty, which yields significant improvements over the vanilla autoencoder.

Our method outperforms dict2vec and retrofitting on similarity benchmarks by a quite large margin. Unlike dict2vec, our method can be used as a postprocessing method which does not require going through the original pretraining corpus, it has fewer hyperparameters, and it generalises to new words.

We see several directions for future work.

Firstly, more work is needed to evaluate the representations on other languages and tasks.

Secondly, solving downstream tasks requires representations for the inflected words as well. We have set aside this issue by focusing on benchmarks involving lemmas. To address it in future work, we might want to split word representations into a lexical and a morphological part. With such a split representation, we could postprocess only the lexical component, and all the words, whether inflected or not, would benefit from this. This seems desirable for postprocessing methods in general and would make them more suitable for synthetic languages.

Thirdly, dictionary defines every sense of words, so we could produce one embedding per sense (Chen et al., 2014) (Iacobacci et al., 2015). This requires potentially complicated modifications to our model as we would need to disambiguate senses inside each definition. However, some class of words might benefit a lot from such representations, for example words that can be used as different parts of speech.

Lastly, a more speculative direction could be to study iterative constructions of the set of embeddings. As our algorithm can generalize in one shot, we could start the training with a small set of words and their definitions and iteratively broaden the vocabulary and refine the representations without retraining the model. This could be useful in discovering a set of semantic primes from which one can define all the other words (Wierzbicka, 1996).

Abstract

We propose Odd-Man-Out, a novel task which aims to test different properties of word representations. An Odd-Man-Out puzzle is composed of 5 (or more) words, and requires the system to choose the one which does not belong with the others. We show that this simple setup is capable of teasing out various properties of different popular lexical resources (like WordNet and pre-trained word embeddings), while being intuitive enough to annotate on a large scale. In addition, we propose a novel technique for training multi-prototype word representations, based on unsupervised clustering of ELMo embeddings, and show that it surpasses all other representations on all Odd-Man-Out collections.

1 Introduction

Correctly disambiguating the sense of a polysemous word (e.g., "***spring** is a beautiful season*" versus "*John was ready to **spring** into action*") is a crucial part of various NLP tasks, such as translation, question answering, or textual entailment. The state-of-the-art, and the de-facto common practice for essentially all of these tasks, involves neural networks (see (Goldberg, 2015) for a recent survey), which are commonly initialized with pre-trained word vectors, such as Word2Vec (Mikolov et al., 2013a) or GloVe (Pennington et al., 2014).

These widely-used representations often significantly improve performance in downstream tasks, as they are able to leverage large amounts of unstructured data. However, most of the popular collections of word embeddings assign only one vector to each word, thus shifting the burden of word disambiguation to deeper, task-specific layers, which commonly rely on data of much smaller scales.

While there has been a significant body of work around *sense embeddings* (i.e., embedding senses, instead of lexical units), evaluating such representations remains the subject of debate (Faruqui et al., 2016; Gladkova and Drozd, 2016).

In this work, we propose a new evaluation task called Odd-Man-Out. The goal of an Odd-Man-Out puzzle is simple. Given a set of words[1] like **cherry, orange, apple, grass, grape**, the objective is to identify the word that does not belong (here, the answer is **grass**, because it is not a fruit). While there are often multiple relationships among the words, we will show that non-experts typically agree on the odd-man-out, and are able to generate hard puzzles on a large scale, using a novel crowdsourcing protocol.

Following the creation of this large test set, we conduct a thorough analysis of the ability of various lexical resources to correctly solve the task. In doing so, we embrace the suggestion of Gladkova and Drozd (2016), which argue for "a shift from absolute ratings of word embeddings towards more exploratory evaluations that would aim not for generic scores, but for identification of strengths and weaknesses of embeddings", and conduct rigorous analysis of each representation. Overall, we find that all lexical resources are prone to miss associations which are intuitive for humans, leaving ample room for future improvement. Moreover, we show empirical evidence that lexical resources that do not account for polysemy are handicapped by this weakness.

Finally, we propose a new sense embedding technique, which leverages the recent introduction of ELMo embeddings (Peters et al., 2018) by performing unsupervised clustering over a large unstructured corpus. We show that this new resource surpasses all other baselines on various Odd-Man-Out datasets.

---

[1] In this paper, we use the term "word" loosely to also include the multi-word expressions like "fire engine" and "magnifying glass."

Brussels, Belgium, October 31 - November 4, 2018.

We make all our code and models publicly available.[2]

2 Existing Evaluation Methods

In this section, we briefly survey some existing evaluation methods for lexical resources, and discuss their pros and cons.

2.1 Word Similarity

The *word similarity* task (Rubenstein and Goodenough, 1965) has been a dominant approach to assess word vector quality. In this task, systems are required to score the similarity of two words on a numeric scale, sometimes without context and sometimes in a sentential context (Huang et al., 2012). For instance, the pair (tiger, mammal) has a similarity score of 6.85 (out of 10) on the WordSim dataset (Finkelstein et al., 2001).

A common criticism (Faruqui et al., 2016; Gladkova and Drozd, 2016) of the word similarity task is that "similarity" is subjective, and conflates several different potential relationships between words. For instance, (Faruqui et al., 2016) questions why the pair (cup, coffee) should be considered more similar than (car, train), as it is according to the WordSim dataset.

Odd-man-out puzzles naturally disambiguate the nebulous concept of "similarity", because each puzzle implicitly defines a specific relationship. The words "car" and "train" may be similar, but this similarity is irrelevant is the context of a puzzle like **car, train, checkered flag, racetrack, pit stop**.

2.2 Analogies

Analogies like "king is to queen as man is to..." (Mikolov et al., 2013b; Jurgens et al., 2012) are related to the odd-man-out task. Analogies, however, are best suited to particular relationships, such as hypernym → hyponym (which are the subject of extensive research, e.g., (Shwartz et al., 2016)), while odd-man-out puzzles can capture a broader range of associations (see for instance, the auto-racing puzzle from the previous section). Analogies are also more subject to ambiguity, since the premise can involve only two words. For instance, the puzzle "cherry is to strawberry as grass is to..." could refer to the fact that cherry and strawberry are both fruits, both red, or both red fruits. Odd-man-out puzzles provide a simple way of reducing ambiguity: adding more choices to the puzzle.

2.3 Word Sense Disambiguation and Induction

Word sense disambiguation (Navigli, 2009) is a popular way to evaluate polysemous word representations. The common criticism is that systems are rewarded based on their ability to classify words according to a fixed inventory of senses, whose granularity is regarded by some as too coarse and others as too fine. An alternative is word sense induction (Manandhar et al., 2010), which allows systems to cluster word senses without an agreed-upon sense inventory. However, there is not an obvious evaluation metric. The two metrics used in SemEval 2010 Task 14 (Manandhar et al., 2010) yielded highly divergent system rankings.

2.4 Word Context Relevance

A recent evaluation method is Word Context Relevance (Arora et al., 2016; Sun et al., 2017a). The task is to identify whether a particular bag of words is "relevant" to a target word. For instance, "tie" is considered relevant to the bag "winner, score, tied, completion, identical, results, sports," but irrelevant to the bag "domestic, hog, pig, culinary, eaten, cooked, fat". This task has the attractiveness of being a simple binary evaluation, but demands only that a model can identify a broad sense of relatedness, not the ability to pinpoint specific relationships.

2.5 Lexical Substitution

Lexical substitution tasks (McCarthy and Navigli, 2007; Biemann, 2013; Kremer et al., 2014), in which the task is to determine whether one word can replace another word in a particular context, are effective, but are restricted in the kind of relationships they can test (mainly synonymy).

3 Odd Man Out Datasets

In this section, we describe the creation of several Odd-Man-Out datasets. We begin by describing a small-scale, curated annotation, then show how to scale the annotation using crowdsourcing techniques. In the subsequent sections, we use these datasets to explore the properties of a wide array of lexical resources.

---

[2] `https://github.com/gabrielStanovsky/odd-man-out`

3.1 Expert annotation

To create our first odd-man-out datasets, we used categories from the card game Anomia.[3] Anomia is a slapjack-style game in which players attempt to name instances of a particular category as quickly as possible. Categories include: "percussion instrument", "Mexican food", and "Michael Jackson song". A team of 4 people, trained in-house, created one odd-man-out puzzle for each category, yielding a total of 404 puzzles. For instance, the puzzle corresponding to "percussion instrument" is **clarinet, drum, xylophone, tambourine, cymbals**, where clarinet is the odd-man-out. The puzzle-writing team attempted to make the odd-man-out similar to the category, e.g. clarinet is a musical instrument but not a percussion instrument.

We divided the puzzles into 2 sets, one for puzzles comprised of common words (like the "percussion instruments" example above), and one for puzzles comprised of proper nouns (like the puzzle derived from the category "Michael Jackson songs"). Each set contained exactly 202 puzzles. We further divided each of these sets into a development set (used for error analysis) of size 100 and a test set of size 102. Henceforth, we will refer to these four datasets as ANOMIACOMMONDEV, ANOMIACOMMONTEST,ANOMIAPROPERDEV, andANOMIAPROPERTEST.

There are two potential pitfalls in creating these puzzles. First, the underlying category may not be detectable by humans. Second, we may inadvertently create an ambiguous puzzle with multiple odd-men-out. For instance, given the category "vegetables", we might create the puzzle **grass, celery, cucumber, carrot, lettuce**, for which the intended odd-man-out is **grass**, but the answer **carrot** is also a reasonable odd-man-out for the category "things that are green."

To ensure the answerability of our puzzles, we administered the ANOMIACOMMONDEV to five college-educated individuals, three of whom were native English speakers. Both groups did well. The native speakers averaged 95.3% accuracy, while the non-native speakers averaged 91.5%.

3.2 Crowdsourcing

Following the success of the curated annotation, as described above, we devised a crowdsourcing protocol to achieve annotation at a much larger scale. In this section, we describe this protocol and show that the Odd-Man-Out task is intuitive enough to be collected and annotated with high agreement by non-trained annotators, using a small expert seed annotation. This enables us to efficiently obtain a large set of 500K *hard* "training" samples on a small budget of $400. Finally, we also validate a set of 1000 puzzles, which we use in following sections for testing purposes.

Crowdsourcing protocol Our semi-automatic crowdsourcing protocol starts from a seed set of about 250 polysemous words,[4] and is composed of the following three consecutive stages:

1. **Seed categorization (expert)**: given a polysemous word w, we ask expert annotators to come up with at least two categories c_1, c_2, which describe w. For example, given w = "*bat*", the corresponding categories can be c_1 = "*nocturnal mammal*" and c_2 = "*baseball instrument*". This categorization was performed by the authors of this paper, and was done in about 3 person hours.

2. **Category expansion (crowdsourced)**: Given a seed word and a corresponding category (w, c) turkers are asked to provide five more examples of the category c , which are similar to, but different than, w. For example, given ("*bat*", "*nocturnal mammal*") turkers are expected to provide examples such as "*beaver*", "*badger*", or "*hedgehog*", while for ("*bat*", "*baseball instrument*"), proper answers include "*ball*" or "*cap*". We used the Amazon Mechanical Turk (AMT)[5] platform, paying 15¢ per elicitation.

3. **Puzzle creation (automatic)**: For each polysemous seed word w, belonging to categories c_1, c_2, we automatically create Odd-Man-Out puzzles by concatenating to w each possible combination of three words from c_1 (c_2), while the intended odd-man-out is any word from c_2 (c_1). For example, using the previous

---

[3] https://boardgamegeek.com/boardgame/142271/anomia-party-edition

[4] `https://en.wikipedia.org/wiki/List_of_true_homonyms`, following (Sun et al., 2017b).

[5] https://www.mturk.com

seed word and categories, we get the following puzzle: ("*cap*", "*bat*", "*beaver*", "*badger*", "*hedgehog*"). Creating puzzles by combining words from c_1 and c_2 in this manner ensures that task is challenging, as it requires to disambiguate the polysemous word (e.g., "*bat*").

Performing the process described above with the 249 polysemous seed words yielded a large corpus of $497,365$ puzzles, thanks to the combination process, with a vocabulary of $1,312$ different words. To create a gold high quality test corpus, and to assess the validity of this semi-automatic process, we sampled 1000 puzzles and administered each puzzle to three annotators on AMT, paying 6¢ per response. We found that for 84.3% of the instances there was a majority vote agreement on the intended odd-man-out word. We refer to this set of 843 puzzles as CROWDSOURCED843. Table 1 shows examples of the crowdsourced puzzles.

From an examination of turkers disagreement, we can attribute the vast majority to noise in one of the annotation stages, e.g., turkers which provide examples of the wrong sense of the seed word, resulting in invalid puzzles (where all of the words belong to the same category), or turkers marking the wrong odd-man-out, thus invalidating an otherwise correct puzzle.

Overall, the cost of the annotation and validation was below $500, for a large high-quality annotated resource and a smaller gold standard test corpus. Both corpora are made available.[6]

4 Taxonomy-Based Solvers

In this section, we show how to create odd-man-out solvers for taxonomies like WordNet (Miller, 1992).

Define a *taxonomy* as a triple (V, E, L), where (V, E) is a directed acyclic graph, and L maps each vertex V to a string. A simple example is shown in Figure 1, where the each vertex v is labeled with $L(v)$.

We create an odd-man-out solver from a taxonomy as follows:

- The *specificity* of a vertex v is defined as the reciprocal of the number of its descendants. For instance, the specificity of any leaf in Figure 1 is 1, while the specificity of the vertex labeled "element" is $\frac{1}{6}$.

Category	Puzzle
construction	**crane**, *pelican*, excavator, hoist, upraise
guitar part	**fret**, *crying*, inlays, truss rod, neck
alcoholic drinks	**gin**, *poker*, vodka, tequila, wine
card games	**gin**, *vodka*, bridge canasta, uno

Table 1: Selection of examples from the crowdsourced Odd-Man-Out dataset. The polysemous seed word appears in bold, while the correct answer is in italics. The last two examples demonstrate how a polysemous word (*gin*) can participate in two different puzzles.

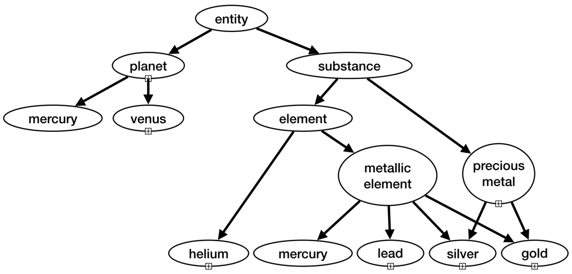

Figure 1: Example taxonomy.

- Given an odd-man-out puzzle $w_1, ..., w_n$, the *explanation* of word w_k is the vertex v of highest specificity such that: (i) for each word w_j such that $j \neq k$, there exists some descendent v' of v where $L(v') = w_j$, (ii) there does not exist a descendent v' of v such that $L(v') = w_k$. For instance, the explanation of **helium** with respect to the puzzle **helium, mercury, lead, silver, gold** is the node labeled "metallic element."
- If some word does not have an explanation, or if there is no word whose explanation is uniquely most specific, then the solver abstains from answering. Otherwise, the solver returns the word with the most specific explanation.

Using WordNet 3.0 (Miller, 1992; Fellbaum, 1998) as the taxonomy, the solver correctly solves

---

[6] `https://github.com/gabrielStanovsky/odd-man-out`

Puzzle	Explanation
chicken, screwdriver, margarita, mimosa, daiquiri	mixed drink
silver, steel, brass, bronze, pewter	alloy
canoe, school, flock, herd, pack	animal group
nightgown, afternoon, morning, evening, midnight	abstraction
king, *president*, queen, prince, princess	leader
dinghy, *crab*, boat, canoe, raft	travel (verb)

Table 2: Some of the WordNet solver's answers and explanations on AnomiaCommonDev. The solver's answer is in bold, while the correct answer is in italics.

40.6% of the AnomiaCommon puzzles, answering incorrectly for 13.4% and abstaining for 46.0% of the puzzles. Unsurprisingly (since WordNet focuses on common words), the WordNet solver gets only 1 out of 202 AnomiaProper puzzles, abstaining from all the rest. On Crowdsourced843, the solver correctly solves 22.0% of the puzzles, answering 15.1% incorrectly and abstaining from the rest.

4.1 Error Analysis

A nice property of the taxonomy-based solver is that it provides an explanation for its answer (i.e. the "explanation" vertex defined above). In Table 2, we show some of the WordNet solver's answers and explanations (specifically we show the name of the WordNet synset corresponding to the explanation vertex). For 85.4% of its correct answers, the solver also returns the correct explanation (like the "mixed drink," "alloy," and "animal group" explanations). In the handful of cases when it does not, it finds either an incorrect or an overly vague explanation (like the "abstraction" explanation) that still results in the correct answer.

Typically, the incorrect answers result from incompleteness in the WordNet taxonomy. For instance, the word "king" is not a hyponym of "leader," even though "president," "queen," "prince," and "princess" all are. In the bottommost puzzle of Table 2, the error results from "raft" not being considered a watercraft (or a conveyance of any kind) by WordNet. Because of this, the solver finds a more tenuous connection between "crab" and three of the other words, leveraging a rare sense of "crab" as a verb meaning "to move like a crab."

5 Embedding-Based Solvers

In this section, we create odd-man-out solvers from collections of word embeddings. Specifically, we experiment with two types of embeddings: (1) traditional word embeddings, which map words to a single vector representation (Subsection 5.2), and (2) sense embeddings, which map words to a *set* of vectors, each pertaining to a different sense of the word (Subsection 5.3).

5.1 Embedding Evaluation Framework

For the sake of comparison, we use a common framework to create odd-man-out solvers based on traditional word embeddings and sense embeddings. In this framework, given n puzzle options, we find the subset of $n-1$ words of maximal similarity (given some similarity score), and return the excluded word as the odd-man-out.

Specifically, define an *embedding* as a function that maps every word to a *set* (possibly empty) of real vectors. Note that this definition is general enough to allow for sense embeddings as well as traditional word embeddings, for which the returned sets are either singletons or the empty set (in case the word is not in the embedding's vocabulary).

Next, given a similarity score σ that maps any vector pair to a real number and an embedding E, define the *cohesion* $\kappa_{\sigma,E}$ of a set of words W as:

$$\kappa_{\sigma,E}(W) = \max_{v_1 \in E(w_1),\dots,v_n \in E(w_n)} \sum_{1 \le i < j \le n} \sigma(v_i, v_j) \tag{1}$$

Cohesion is undefined if any word $w \in W$ maps to the empty set. Throughout this paper we employ the widely used *cosine similarity* as our similiarity score.

Finally, given an embedding E and puzzle $W = \langle w_1, \dots, w_n \rangle$, we create an odd-man-out solver as follows:

1. If $E(w_i)$ is the empty set for any puzzle choice $w_i \in W$, then the solver abstains from answering.

2. Otherwise, the solver returns the word $\hat{w} \in W$ whose omission from the puzzle word set

Embedding Map	Training	AnomiaCommon			AnomiaProper			Crowdsourced

yields maximal cohesion:

$$\hat{w} = \operatorname*{argmax}_{w_i \in W} \kappa_\sigma(W \setminus \{w_i\}) \qquad (2)$$

5.2 Word Embeddings Solvers

Table 3 shows the results of embedding-based solvers on the Anomia and crowdsourced datasets, using several different pre-trained embedding maps. We find the best performance on AnomiaCommon and AnomiaProper using the word2vec vectors trained on 100 billion tokens from the Google News corpus.[7]

An analysis of the best embedding-based solver (w2v.googlenews) on AnomiaCommon-Dev shows that a high proportion of incorrect answers were polysemous (20 out of the 27 incorrect answers). A selection of these are shown in Table 4. We observe that for the "cocktails" puzzle, the word2vec solver zeroes in on "screwdriver" (whose dominant sense is the tool, not the cocktail), and for the "types of lettuce" puzzle, the solver selects "iceberg" (whose dominant sense is "large floating block of ice," not the lettuce).

To provide additional evidence of this bias, we came up with 5 cocktails whose dominant sense is the cocktail itself (mint julep, mai tai, mojito, martini, and bloody mary) and 5 polysemous cocktails (old fashioned, hurricane, cosmopolitan, zombie, and Manhattan). We then replaced "screwdriver" in the "cocktails" puzzle with each of these options and solved the resulting puzzle with the w2v.googlenews solver. In all 5 monosemous instances, the correct answer of "chicken" was selected. In 4 of the 5 polysemous instances (the exception being "Manhattan"), the polysemous replacement was selected. We repeated this experiment with the "groups of animals" puzzle, and again all 5 monosemous replacements yielded the correct answer, while 3 of 5 polysemous replacements were incorrectly chosen by the solver.

In a more rigorous experiment, we randomly generated 500 puzzles in the following way. Given a category (hyponym), we came up with 10 instances (hypernyms) of that category. For example, the category "type of transport" yielded: train, car, bus, airplane, helicopter, boat, ferry, taxi, tram, and monorail. We did this for 10 categories, yielding a total of 100 words. From these 10 lists, we randomly generated 500 puzzles by sampling 4 words from one list and 1 word from another. We call this puzzle set Hypernyms500.

The w2v.googlenews solver performs impressively on Hypernyms500, getting 90.8% correct, with only 46 incorrect answers (and no abstentions). Tellingly however, only 3 words are responsible for 67% of the incorrect answers: saw (as a kind of tool), lead (as a kind of metal), and rose (as a kind of flower). All three of these words have at least one dominant alternate sense. Given that there are 100 possible incorrect answers (which all appear with roughly equal frequency in the puzzles), the fact that only 3 of them comprise 67% of the incorrect answers suggests that the inability of vector directories to model multiple senses is an Achilles heel.

5.3 ELMo Sense Vectors

The previous analysis suggests that embeddings that explicitly model multiple senses may be important for the odd-man-out task. In this section,

we investigate this further.

Background: sense vectors There is a significant literature on how to learn a one-to-many mapping from words to vector representations. An early paradigm (Reisinger and Mooney, 2010; Huang et al., 2012; Liu et al., 2015; Wu and Giles, 2015) took a 2-pass approach. First, they clustered contexts of a target word like "bank." For instance, "the bank had an ATM" and "I got money from the bank" might fall into one cluster, while "I fished at the river bank" might fall into a second cluster. Second, they annotated each instance of the target word with its sense cluster and then learned a standard one-to-one vector mapping from the annotated corpus. For instance, they would learn vector representations using the sentences "the bank-1 had an ATM," "I got money from the bank-1," and "I fished at the river bank-2." Other researchers (Neelakantan et al., 2014; Tian et al., 2014; Chen et al., 2014; Li and Jurafsky, 2015; Bartunov et al., 2016) focused on modifying the vector learning model itself, typically the skip-gram model (Mikolov et al., 2013b), to directly learn multiple embeddings for each word. Additional work focused on using the technique of retrofitting (Faruqui et al., 2014) to adapt pretrained word vectors into sense vectors using auxiliary resources like WordNet (Jauhar et al., 2015) or parallel corpora (Ettinger et al., 2016). Other work (Guo et al., 2014; Suster et al., 2016; Upadhyay et al., 2017) used parallel corpora as the main signal for learning sense vectors.

Background: ELMo Recently, Peters et al. (2018) introduced the concept of Embeddings from Language Models (ELMo). ELMo dynamically represents each word based on the context with which it appears, achieved by representing a word in a sentence using its representation from a pretrained bidirectional Language Model (biLM), encoded using a bi-directional RNN (Schuster and Paliwal, 1997). Subsequently, the same word may get different representations in different contexts. For example, the representation of "*bank*" may differ between "*She fished by the river **bank***" and "*She deposited her check at the nearest **bank***". While ELMo embeddings were recently proven extremely beneficial in various sentence-level tasks (e.g., semantic role labeling, question answering, and textual entailment), many lexical tasks require the interpretation of words out of context, to which ELMo cannot be readily applied. We suggest to port ELMo's effectiveness back to the context-free setting, and propose a first approach for doing so.

Unsupervised ELMo clustering We compute pre-trained ELMo embedding (using the AllenNLP framework (Gardner et al., 2018)) *in context* of sentences in a large corpus C, while recording the observed representation $r_{w,s} \in \mathbb{R}^d$ of each word w, along with the corresponding context in which it appeared, i.e., the sentence $s \in C$. The result of this process is an embedding space *per word*, $r_w = \{r_{w,s} \mid s \in C, w \in s\}$. Ideally, similar senses of w would appear in similar contexts, and would therefore be closer in r_w, while different senses would be further apart. Following this intuition, we cluster each word to K clusters, using the k-means algorithm (Lloyd, 1982), whereby every vector in a cluster is interpreted as pertaining to the same sense of w. We collect the centroid

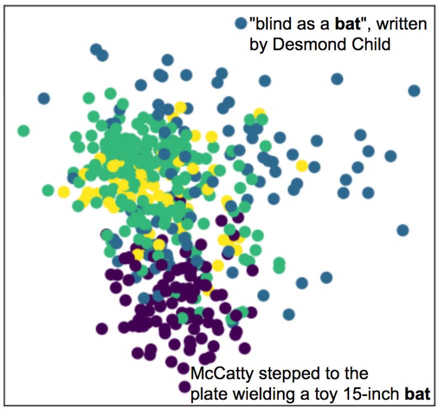

Figure 2: An example of a 2d projection of an ELMo embedding space for the word "bat" with 4 senses (denoted by different colors). Two example sentence excerpts appear next to their respective cluster.

vector w_i (where $1 \le i \le K$) of each cluster as a "sense vector" of w. Using $K = 1$, we get a single representation per word, averaging the different senses of w, comparable to "traditional" word embeddings. Conversely, we can get senses of arbitrarily fine granularity by increasing the number of clusters. These sense representations can then be readily plugged in to the embedding solver, as described in Subsection 5.1. We computed the sense vectors using a 2 billion token (97 Million sentences) Wikipedia dump from January 2018, which was extracted using WikiExtractor,[8] and tokenized with the SpaCy 2.0 toolkit (Honnibal and Montani, 2017).[9] These pre-computed vectors, which are readily applicable for other tasks, are made publicly available. Figure 2 depicts the resulting embedding space and clustering for the word "bat".

Evaluation We start by estimating an ideal value for K (the number of clusters). In Figure 3 we evaluate the performance of the ELMo clustering method on the expert development set, using different values for K, compared to the second best performing vectors on that dataset (Word2Vec). Several observations can be made based on this analysis. First, using $K = 1$, Word2Vec outperforms ELMo. This may be explained due to Word2Vec's larger training set (100B tokens versus only 1B). However, as K increases, ELMo clusters outperform the baseline,

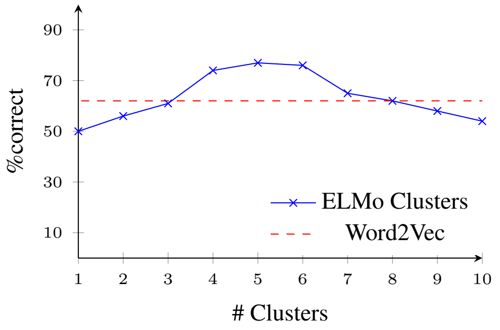

Figure 3: Performance of the ELMo cluster model (blue line) by the varying number of cluster (K), compared to the best performing baseline (word2vec), in the red horizontal line.

reaching its maximum performance at $K = 5$, indicating that a finer level of sense granularity is beneficial for focusing on the intended word sense. Inversely, having too many clusters hurts performance. This may be due to over-specification, harming the sense generalization obtained by a smaller number of clusters. Based on this tuning, we fixed the value of K to 5, and repeated the experiments from Section 5 (see the first row in Table 3). ELMo sense vectors clearly outperform all previous baselines on all Odd-Man-Out datasets. This improved performance can be attributed both to ELMo's better ability to capture context, as well as to the finer sense representation, as opposed to the single representation per word in most of the other baselines. We also evaluated another publicly available collection of sense embeddings (Neelakantan et al., 2014), but it did not perform on par with solvers based on conventional single-sense embeddings.

6 Discussion: Hypernyms vs. Other Associations

The attentive reader may have wondered why the w2v.googlenews solver performed so much better on the HYPERNYMS dataset (over 90% correct) than on the ANOMIACOMMON dataset (approximately 62% correct). Hypothesizing that embedding-based solvers can identify hypernym-hyponym relationships more easily than other associations, we created another odd-man-out dataset using the same methodology as HYPERNYMS.

This time, given a *color*, we came up with 8 to 13 objects that are typically associated with that color. For example, the category "yellow" yielded

---

[8] `https://github.com/attardi/wikiextractor`

[9] `https://spacy.io`

(among others): taxi, canary, corn kernel, daffodil, lemon, sun, and school bus. We did this for 10 colors. From these 10 lists, we again randomly generated 500 puzzles by sampling 4 words from one list and 1 word from another. We call this puzzle set COLORS500.

The w2v.googlenews solver performed considerably worse on COLORS500 than on HYPERNYMS500. Out of the puzzles it attempted, it guessed only 30% correctly (compared to the random chance baseline of 20%). There are several possible reasons why this dataset may be more difficult for an embedding-based solver. Possibly colors are not easily identifiable using embeddings built from language cues (maybe people do not often explicitly talk about how lemons are yellows). But perhaps it is also true that using the cosine similarity of the embeddings is not a good way to spot non-fundamental properties (like color) that link a group of words. We leave open how best to identify more oblique relationships.

7 Conclusion

We presented a new task for the evaluation of lexical resources, the Odd-Man-Out task. We showed that the task can be annotated reliably on a large scale. Following the creation of several Odd-Man-Out datasets, we conducted analyses showing that current word representations are suboptimal, especially in the presence of polysemous words. We concluded with a novel ELMo clustering sense-embedding technique which surpasses all baselines on the Odd-Man-Out task.

Abstract

Simile is a special type of metaphor, where comparators such as *like* and *as* are used to compare two objects. Simile recognition is to recognize simile sentences and extract simile components, i.e., the *tenor* and the *vehicle*. This paper presents a study of simile recognition in Chinese. We construct an annotated corpus for this research, which consists of 11.3k sentences that contain a comparator. We propose a neural network framework for jointly optimizing three tasks: simile sentence classification, simile component extraction and language modeling. The experimental results show that the neural network based approaches can outperform all rule-based and feature-based baselines. Both simile sentence classification and simile component extraction can benefit from multitask learning. The former can be solved very well, while the latter is more difficult.

1 Introduction

A metaphor is a figure of speech that describes an object or action in a way that isn't literally true. Metaphors are common in human language. Shutova and Teufel (2010) reported that 241 among 760 sentences in an annotated corpus contain a metaphor. The use of metaphors helps to explain an idea or realize rhetorical effects through an analogical procedure. Metaphor analysis has been drawn more attention for expanding current natural language processing (NLP) to high-level semantic tasks (Carbonell, 1980).

Metaphors reflect creative thought of humans. On the other hand, inferring the meaning of a metaphor has to integrate background knowledge, which makes it difficult to automatically recognize metaphors in language. Previous work on metaphor recognition mainly depends on linguistic cues (Goatly, 2011) and selectional preference violation on a pair of concepts (Fass, 1991) or their domains (Mason, 2004). The domains can be created by knowledge bases such as WordNet (Mason, 2004) or based on automatic clustering (Shutova et al., 2010).

In this paper, we focus on a special type of metaphor—simile. A simile is a figure of speech that directly compares two things using connecting words such as *like*, *as*, *than* in English and "像" or "犹如" in Chinese. Due to the use of such comparators, it is much easier to locate similes compared with locating other types of metaphors. As a result, it is possible to collect and annotate large scale of simile sentences and investigate data driven simile recognition. This task is to find simile sentences and extract simile components, i.e., the *tenor* and the *vehicle*. The mined simile structures can potentially be used to support general metaphor analysis, where large scale training data is lacking.

However, simile recognition is still challenging due to the diversity of syntactic roles of a word and the distinction between metaphorical and literal comparisons. As shown in Table 1, a sentence containing a comparator may not trigger a simile. It is necessary to analyze the relationship between meanings of concepts. And It is also difficult to define a complete set of rules to extract the objects to be compared with high accuracy and coverage.

This paper presents an end-to-end neural network framework for simile sentence recognition. Specifically, we make following contributions:

- We build a dataset consisting of 11.3k sentences containing a frequently used comparator "像" for simile recognition in Chinese, which can support data-driven approaches. In contrast to English, datasets on simile or

metaphor analysis are relatively less in Chinese. This dataset provides a new resource for related research. [1]

- We propose a neural multitask learning framework jointly optimizing three tasks: simile sentence classification, simile component extraction and language modeling. Simile classification is to determine whether a sentence with a comparator contains a simile, without knowing exactly what the tenor and the vehicle are. Simile component extraction aims to locate the tenor and the vehicle in a simile sentence. Intuitively, the two tasks should benefit each other. We design our model to enhance interactions between the two tasks. We also borrow the idea of Rei (2017) by incorporating a language modeling task, which attempts to predict neighbor words. All three tasks consider the whole sentence so that rich context information is involved.

- We conduct comprehensive experiments. The results demonstrate that the neural end-to-end framework is superior to feature-based and rule-based baselines and every single model can benefit from multitask learning. Simile sentence classification can be solved very well, while simile component extraction is more chellenging. With multitask learning enhanced classifier and extractor, a classification-then-extraction method achieves the best performance for simile component extraction.

2 Related Work

2.1 Metaphor/Simile Analysis

Metaphor analysis becomes active in recent years. The tasks include metaphor recognition, metaphor explanation and metaphor generation (Shutova et al., 2013; Veale, 1995; Jang et al., 2016).

Simile is a special type of metaphor with the comparator and it is relatively easier to locate metaphorical parts. Niculae and Danescu-Niculescu-Mizil (2014) aimed to distinguish a comparison from figurative or literal in product reviews using a series of linguistic cues as features. It is similar to simile sentence classification. So we take it as a baseline. In their work, they assumed that the components can be correctly recognized. In our work, we use an automated component extractor instead.

Syntactic patterns are often used for extracting potential simile components and semantic analysis is then used to distinguish similes from literal comparisons (Niculae and Yaneva, 2013; Niculae, 2013). The main limitation is that such pattern based method is difficult to deal with sentences with complex structures. As a result, the coverage is relatively small.

Qadir et al. (2016) used syntactic structures, dictionary definitions, statistical cooccurrence, and word embedding vectors to infer implicit properties in similes. Qadir et al. (2015) also built a classifier with lexical features, semantic features, and sentiment features to infer the affective polarity of simile in twitters. Veale and Hao (2007) and Veale (2012a) utilized knowledge generated by similes to deal with metaphor and irony, and Veale (2012b) built a lexical stereotype model from similes. These work demonstrates the wide applications of simile recognition.

In Chinese, Li et al. (2008) proposed a feature-based method for simile recognition. Their evaluation was done on a small dataset. The annotated data in this work is much larger.

2.2 Multitask Learning for NLP

Many researchers have proposed to jointly learn multiple tasks with shared representations (Collobert and Weston, 2008). Improvements are reported on joint models between closely related tasks, such as text classification (Liu et al., 2016), POS tagging and parsing (Zhang and Weiss, 2016), parsing and named entity recognition (NER) (Finkel and Manning, 2010), NER and linking (Luo et al., 2015), extraction of entities and relations (Miwa and Bansal, 2016). Bingel and Søgaard (2017) offered a systematic view of relations between different tasks.

3 Task and Data

3.1 Task Description

A metaphor is as a matter of cross-domain mappings in conceptual structure which are expressed in language. Lakoff and Johnson (2008) explains it as a mapping between the *target* and the *source*, corresponding to the terms *tenor* and *vehicle*. The tenor is the subject to which attributes are ascribed, while the vehicle is the object whose attributes are borrowed.

Simile can be seen as a special type of metaphor, which is signaled by explicit markers such as *like* or *as* in English and “像” or “犹如” in Chinese. We call such words **comparators** (Hanks, 2012). Notice that a sentence containing a comparator doesn’t guarantee that it is a simile sentence. Consider the examples in Table 1. All sentences contain the comparator “像”. The first two sentences form comparison structures, but the first one triggers a cross-domain concept mapping, while the second one is a literal comparison. The word “像” in the third sentence means *as if*, rather than forming a comparison, and the comparator in the fourth sentence is to give examples.

Simile Recognition task can be defined as: Given a sentence containing a comparator, determine whether it is a simile sentence, if so, extract the *tenor* and the *vehicle* from it.

Simile recognition involves two subtasks.

Simile Sentence Classification (SC). For a sentence containing a comparator, determine whether the comparator triggers a metaphorical comparison, in another word, whether the sentence is a simile sentence.

Simile Component Extraction (CE). For a simile sentence, extract text spans that are corresponding to the *tenor* and the *vehicle* objects respectively.

Both tasks have a realistic significance. Simile can be seen as a rhetorical device for making thoughts or expressions more vivid. Simile sentence classification could be used to provide a signal to evaluate rhetorical effects of writings. Simile component extraction is potentially useful for building cognitive knowledge base.

3.2 Data

We construct a dataset from Chinese student essays written in Mandarin Chinese. We focus on the comparator “像”, which is the most often used simile comparator in Chinese. The data annotation involves the following steps: (1) we sampled sentences that contain the word “像” from a sentence index built on more than 20,000 student essays; (2) we asked two annotators to label every sentence as a simile sentence or not; (3) the annotators further annotated boundaries of simile components, the tenor and the vehicle, in simile sentences.

Two points are important for annotation: (1) the definition of simile and (2) the boundary of simile components.

We desire that a simile sentence should satisfy at least two standards. First, there exists explicit tenor and vehicle, which are from different semantic domains. Second, the tenor and vehicle should have similar properties. We provided a manual and positive/negative examples to annotators. Even so, there are still fuzzy cases. The two annotators first labeled a sample of 200 sentences independently and then we measured their agreement and asked them to discuss the disagreements. After discussion, they labeled another set of sampled sentences to check whether they really reached a consensus. This process iterated several times. Their final inner-annotator agreement on simile sentence classification can reach to 91%. Finally, they labeled all sentences in the whole dataset.

Next, the annotators should further label simile components in simile sentences, which are usually noun phrases. Boundaries of simile components are required to be annotated as compact as possible until they can’t be simplified any more. In most cases, we asked the annotators to label the head noun phrase without a modifier. A modifier often plays a role as a *shared property*. For example, in the sentence 男孩的脸像一个红苹果(*The boy’s face is like a red apple*), 脸(*face*) and 苹果(*apple*) would be annotated as the tenor and vehicle respectively, while 男孩的(*boy’s*) and 红(*red*) are not included. In contrast, in the sentence 天气像孩子的脸说变就变(*The weather is like a child’s face, which changes unpredictably*), 孩子的脸*(child’s face)* is preferred to 脸(*face*) as a component, because 脸(*face*) alone can’t capture the property well. We used one annotator’s annotation of 200 sentences as the gold answer and the other’s annotation as the prediction to computer the F_1 score, which is 93.57% on all components and 90.7% on tenors and 96.47% on vehicles.

Table 2 shows the basic statistics of our dataset.

Avg. #token per vehicle	1.056
Avg. #token per sentence	29.47
Avg. #pair per simile sentence	1.024

Table 2: Statistics of the annotated simile dataset

4 Multitask Learning Approach

4.1 Motivation

Intuitively, the two subtasks in simile recognition can benefit each other and the interactions between them should not be ignored. If the component extractor knows that a sentence contains a simile, it would be more confident to extract the tenor and the vehicle. On the other hand, if the component extractor tells the classifier that the tenor and the vehicle likely exist, the classifier gets additional information for decision.

Therefore, we propose a multitask learning approach to combine them. Our approach jointly optimizes three tasks: simile sentence classification, simile component extraction and language modeling. Language modeling is used as auxiliary task, which can help capture local information. Figure 1 illustrates the main framework, which is based on neural networks. We will first explain the representation layers that are shared by multiple tasks, and then introduce separate prediction layers for individual tasks.

4.2 Shared Representation

Word embedding layer. We first map words to dense distributed word embeddings. Since our dataset is not so large, we make use of pre-trained word embeddings, which are trained on a much larger corpus with Word2Vec toolkit (Mikolov et al., 2013).

Sentence representation layer. Recurrent neural networks (RNNs) have become the natural choice for handling sequential data to capture long-range dependencies. Given a sentence $X = (x_1, x_2, ..., x_n)$ containing n words as an input, the RNNs produce $H = (h_1, h_2, ..., h_n)$ as the hidden states to represent the semantic of partial sequence so far. Recently, Long Short Term Memory (LSTM) model (Hochreiter and Schmidhuber, 1997) has been proved more effective in various NLP tasks. Therefore, we use LSTM as the basic memory cell. At time step t, LSTM takes the hidden state from the previous time step and the word embedding from the current step as input, and produces a new hidden state, as shown in Formula 1.

$$\overrightarrow{h_t} = LSTM(x_t, LSTM(\overrightarrow{h_{t-1}})) \quad (1)$$

The LSTM architecture is sensitive to word order, and the bidirectional LSTM (Schuster and Paliwal, 2002) allows model to look arbitrarily far at both the past and the future for the sake of grasping the whole sentence. Noted the forward LSTM as $\overrightarrow{h}$, and the backward as $\overleftarrow{h}$. Bidirectional LSTM concatenates the forward and backward states as the representation at the tth time step, i.e., $h_t = \left[\overrightarrow{h_t}; \overleftarrow{h_t}\right]$.

4.3 Task 1: Simile Component Extraction

We view simile component extraction as a sequence labeling problem. We convert the annotated dataset to IOBES scheme (indicating *Inside, Outside, Beginning, Ending, Single*) (Ratinov and Roth, 2009). We use different prefixes to distinguish the tenor and the vehicle components. For example, *tb* and *vb* indicate the beginning of a *tenor* and a *vehicle* respectively.

4.3.1 Neural Sequence Labeling Model

Conditional Random Field (CRF) (Lafferty et al., 2001) is a standard solution in such scenario to exploit the dependency among labels.To further make use of the dense representation of words, we build a CRF layer on the shared representation layers following (Lample et al., 2016).

Formally, $H = (h_1, h_2, ..., h_n)$ is a sequence of hidden states produced by the bidirectional LSTM for a sentence X and $y = (y_1, y_2, ..., y_n)$ is the tag sequence, $y_i \in L$ and $|L| = k$. Define $\psi(H, y)$ as the score of the sequence.

$$\psi(H, y) = \sum_{t=0}^{n} A_{y_t, y_{t+1}} + \sum_{t=1}^{n} P_{t, y_t} \tag{2}$$

where $A \in \mathbb{R}^{k \times k}$ is a transition matrix and $A_{y_t, y_{t+1}}$ records the score of a transition from current label y_t to next label y_{t+1}; $P = (p_1, ..., p_n) \in \mathbb{R}^{n \times k}$ is the emission matrix and P_{t, y_t} represents the score of assigning tag y_t to x_t.

Here, h_t is the tth hidden state that is as assigned by the bidirectional LSTM. It is first mapped to a hidden layer through a feedforward layer. After a non-linear activation transition $\tanh$, the output of the hidden layer is mapped to a k-dimension vector p_t, through another feedforward layer.

$$p_t = W_p \cdot \tanh(W_t h_t) \tag{3}$$

where W_t and W_p are parameter matrixes. p_t can be seen as a tag score vector given the current word without considering context words.

Taking the whole state sequence into account, the probability of tag sequence y given sentence X is:

$$p(y|H) = \frac{\psi(H, y)}{\sum_{\widetilde{y} \in Y} e^{\psi(H, \widetilde{y})}} \tag{4}$$

where Y indicates all possible sequences. Learning algorithm attempts to optimize the model by maximizing the log-likelihood of correct tag sequence. Thus, the loss function is

$$\begin{aligned} E_{ce} &= -log(p(y|H)) \\ &= -\psi(H, y) + \log \sum_{\widetilde{y} \in Y} e^{\psi(H, \widetilde{y})} \end{aligned} \tag{5}$$

4.4 Task 2: Simile Sentence Classification

The second task is simile sentence classification. To fully exploit contextual information, we consider all words in a sentence. For each word, instead of using hidden state h_t only, we combine h_t and its score vector p_t as a representation s_t:

$$s_t = [h_t; p_t]$$

Since p_t is directly related to the component extraction task, this labeling connection operation increases the interaction between the two tasks.

However, words in a sentence should not contribute the same for classification. Intuitively, the words corresponding to the tenor or the vehicle or near comparators should be more important. Therefore, we introduce the attention mechanism, which was firstly proposed for neural machine translation (Bahdanau et al., 2014).

Given the sequence of expanded word representations $S = (s_1, s_2, ..., s_n)$, the attention vector is computed via:

$$\alpha = softmax(\tanh(W_\alpha S)) \tag{6}$$

where W_α is a parameter matrix. The semantic representation of the sentence is:

$$r = \alpha^T \cdot S \tag{7}$$

This representation is fed into an activation and a softmax layer to generate the probability distribution. The loss function is the negative log-likelihood of the correct classification tag:

$$E_{sc} = -\log(p(y|s)). \tag{8}$$

4.5 Task 3: Language Modeling

Although LSTM can capture long dependencies, simile structure may be more related to local contexts. In many cases, the comparator and the vehicle are near, and similes often have some collocations involving the comparator such as "像...一样(the same as)" or "就像(just like)". As a result, we attempt to emphasize such local information.

Inspired by (Rei, 2017), we also incorporate language modeling as an auxiliary task. For each word, we let the model predict the next word. In our case, the representation of each word h_t is firstly mapped into a low dimension vector space through a nonlinear transform.

$$\overrightarrow{m_t} = \tanh\left(\overrightarrow{W_m} \cdot \overrightarrow{h_t}\right) \tag{9}$$

And the vehicle word is predicted by maximizing the probability of the specific next word, which is generated by a softmax layer.

$$P\left(w_{t+1}|\overrightarrow{m_t}\right) = softmax\left(\overrightarrow{W_q} \cdot \overrightarrow{m_t}\right) \tag{10}$$

where, $\overrightarrow{m_t}$ indicates the forward language modeling specific features. W_m, W_q are trainable parameters.

The loss function for a sequence is defined as the sum of the negative log-likelihood of the predicted words.

$$\overrightarrow{E_{lm}} = -\sum_{t=1}^{n-1} \log\left(P\left(w_{t+1}|\overrightarrow{m_t}\right)\right) \tag{11}$$

We can also predict the previous words in the same way and get another loss function noted as $\overleftarrow{E_{lm}}$. The losses in double direction are summed to be the loss function for language modeling task.

$$E_{lm} = \overrightarrow{E_{lm}} + \overleftarrow{E_{lm}} \tag{12}$$

4.6 The Final Loss Function

The final loss function for each sentence is a weighted sum of task-specific loss functions.

$$E = \gamma \cdot E_{lm} + \delta \cdot E_{ce} + \epsilon \cdot E_{sc} \tag{13}$$

where γ, δ, ϵ are non-negative weights, which are used to control the importance of three tasks. In experiments, they are hyper-parameters assigned beforehand, and we constrain the sum of γ, δ and ϵ to one.

5 Evaluation

5.1 Settings

The dataset is randomly divided into 5 folds, 4 of which are used as training set and validation set (80% for training, 20% for validation), and the rest one fold is used as test set. All models were trained on the training set. The best hyperparameters were gained based on the results on the validation set. The results reported were all evaluated on the test set.

We conduct word segmentation, part-of-speech (POS) tagging and dependency parsing with HIT-LTP[2].The word embeddings were pre-trained using Word2Vec (Mikolov et al., 2013), on a large essay corpus crawled from the web. We adopt the Theano framework (Theano Development Team, 2016) to implement neural network models.

The dimension of word embeddings is 50. The hidden size of LSTM is 128 for each direction. The dimension of activation layers for component extraction, simile sentence classification and language modeling are set to 64, 32 and 64 respectively. A dropout layer (Srivastava et al., 2014) is used between the word embedding layer and the bidirectional LSTM layer with the probability of 0.5. Moreover, early stopping (Prechelt, 1998) is adopted to finish the learning process. The AdaDelta (Zeiler, 2012) strategy is used for parameter optimization with a learning rate of 1.0.

5.2 Evaluating Simile Sentence Classification

5.2.1 Comparisons

We compare the following systems.

Feature based approaches. With manually designed features, we build two Random Forest classifiers to determine whether a sentence contains a simile. **Baseline1** follows (Niculae and Danescu-Niculescu-Mizil, 2014). It first extracts candidate simile components and then uses a classifier to determine whether they form a simile. We adopt our best neural component extractor (will be introduced in Section 5.3.1) to extract components. The classifier uses features including: (1) bag-of-words; (2) corresponding occurrence within constituents; (3) word embeddings of extracted components. Niculae and Danescu-Niculescu-Mizil (2014) also used domain specific information and lexicon knowledge, which our data lacks. **Baseline2** is based on (Li et al., 2008), which doesn't

---

Model	Simile Classification		
	P	R	F_1
Baseline1	0.6523	0.4752	0.5498
Baseline2	0.7661	0.7832	0.7745
Singletask (SC)	0.7751	0.8895	0.8284
Multitask (SC+CE)	0.8056	0.8886	0.8450
Multitask (SC+LM)	0.8021	0.9105	0.8525
Multitask (SC+CE+LM)	**0.8084**	**0.9220**	**0.8615**

Table 3: Experimental results on simile sentence classification. SC: simile sentence classification; CE: component extraction; LM: language modeling.

need to identify components beforehand. The features include: (1) the tokens and POS tags of the words around the comparator within a fixed window (set to 5 in experiments); (2) the tokens, POS tags and dependency relation tags of the words that have dependency relations with the comparator.

Singletask(SC). This system is a simplified version of our proposed model in Section 4 by considering the simile sentence classification task only.

Multitask learning approaches. The full architecture is described in Section 4. To see their contributions, we add simile component extraction, language modeling and their combination incrementally.

5.2.2 Results

Table 3 shows the performance of the systems. The results are reported with the precision (P), recall (R), and their harmonic mean F_1 score (F_1).

The two feature based methods perform differently. Baseline1 performs poorly. The reason may be that the classification depends on the performance of component extraction, while even our best component extractor performs far from perfect, which brings error propagation. In addition, classifying with component related features only ignores much context, which further decreases the performance. Baseline2 considers context windows and outperforms baseline1 largely. This confirms our intuition that context information implies the semantic of simile expression.

Furthermore, we have other observations: (1) neural network based approaches largely outperform feature-based classifiers;(2) multitask learning approaches outperform every single task approach and other baselines. Both the component extraction and the language modeling task contribute for simile sentence classification. Component extraction improves the precision and language modeling improves both the precision and the recall. Combining them together can achieve the best performance. The improvement of F_1 score can reach to 3.3% compared with the best single task model.

5.3 Evaluating Simile Component Extraction

5.3.1 Comparisons

We compare the following systems for simile component extraction.

Rule based approach. We follow (Niculae and Yaneva, 2013) to design syntactic patterns for extraction. We convert the original patterns to fit the outputs of the parser we used.

CRF model. Since we view component extraction as a sequence labeling problem, a CRF model with manually designed feature templates is used as a baseline. Feature template is designed for every word. The features include the tokens and their POS tags within a fixed context window (set to 5 in experiments). We also use dependency parsing based features to capture dependencies between words.

Singletask(CE). We remove the simile classification and language modeling modules from the multitask learning framework introduced in Section 4 to build an end-to-end single task component extractor.

Pipeline approaches. Pipeline approaches first classify a sentence as simile or not, and then extract components from simile sentences. We investigate two combinations: RandomForest→CRF, we use baseline2 for sentence classification and CRF for component extraction; SingleSC→SingleCE, we use neural network based single task sentence classifier and component extractor.

Multitask learning approaches. We exploit simile sentence classification and language modeling modules to enhance component extraction in our multitask learning framework.

5.3.2 Results and Discussion

A component (i.e., the tenor or the vehicle) is judged to be correct only if both the boundary and the tag exactly match the gold answer. For a simile sentence, we should extract both the tenor and the vehicle rather than only partial components. Therefore, we use *pair-wise* level precision (P), recall (R) and F_1 score (F_1) for evaluation. A tenor-vehicle pair is viewed as correct only if both components are correct.

Table 4 shows the results of various systems and settings on two test sets. The first dataset consists

Model	Gold simile sentences			Whole test set		
	P	R	F_1	P	R	F_1
Rule based	0.4094	0.1805	0.2505		—	
CRF	0.5619	0.5907	0.5760	0.3157	0.3698	0.3406
Singletask (CE)	0.7297	0.7854	0.7564	0.5580	0.6489	0.5998
RandomForest → CRF		—		0.4591	0.4980	0.4778
SingleSC → SingleCE		—		0.5720	0.7074	0.6325
Multitask (CE+SC)		—		0.5409	0.6400	0.5861
Multitask (CE+LM)	0.7530	0.7876	0.7699	0.5741	0.7015	0.6306
Multitask (CE+SC+LM)		—		0.5599	0.6989	0.6211
Optimized pipeline		—		0.6160	0.7361	0.6707

Table 4: Experimental results on component extraction. Experiments on dataset of simile sentences assume that the sentence classifier is perfect. CE: component extraction; SC: simile sentence classification; LM: language modeling.

of all manually labeled simile sentences in the test set and the second dataset is the whole test set. We want to compare how component extraction systems work when they know whether a sentence contains a simile or not. We report and discuss the results from the following aspects.

The effect of simile sentence classification. First, we can compare the results in the middle column and the rightmost column in Table 4. It is clear that the component extraction systems work much better when they know whether a sentence contains a simile or not. Second, we can see that both pipelines (the feature-based and the neural network based) achieve a better performance compared with extracting components directly using either the CRF model or the neural single task model. Third, Multitask(CE+SC) doesn't bring significant improvements compared with the single task neural model. These observations indicate that simile sentence classification is suitable to be a pre-processing for simile component classification. It is necessary to further study how to use high level predictions (sentence classification) to learn better representations for consistently improving local predictions (simile component extraction).

Rule based, feature-based and neural models. We can see that even on gold simile sentences, the rule based method doesn't work well. The poor performance of the rule based approach is due to the following reasons. First, the rule-based method is difficult to deal with complex sentence structures. It often fails when there are multiple subordinate clauses. Second, the comparator "像" in Chinese has multiple syntactic roles, sometimes is used as a verb, sometimes is used as a preposition. Third, the accuracy of Chinese dependency parser still has room to be improved.

The CRF method performs significantly better, because it considers more contextual signals. Our neural single task model achieves large improvements on both datasets. This verifies the effectiveness of the end-to-end approach. Neural models can see a long range of context and learn features automatically. The word embeddings learned on external resources implicitly have semantic domain information, which is not only useful for generalization but also important for figurative language processing.

The effect of language modeling. Surprisingly, using language modeling as an auxiliary task is very useful, especially when dealing with noisy sentences. It gains a 1.3% F_1 improvement on the gold simile sentences due to the improvement on the precision and a 3% F_1 improvement on the whole test set due to a large improvement on the recall. Generally, language modeling may help learn better task specific representations, especially when data size is limited (Rei, 2017). Another reason may be that language modeling aims to make local predictions, the same as simile component extraction. Additional information from the same level may be more useful.

Some observations help understand the effect of language modeling. Figure 2 illustrates the relative distance of tenors and vehicles to the comparator. Both tenors and vehicles tend to occur near the comparator and have a clear preference on which side of the comparator. Tenors are more dispersed compared with vehicles, which may increase the difficulty. As shown in Table 5, the performance on identifying tenors is obviously worse than identifying vehicles in both settings.

Figure 3 shows the distribution of extracted components by two settings on the whole test set. We can see that with language modeling, Mul-

Model	Tenor			Vehicle		
	P	R	F_1	P	R	F_1
Singletask(CE)	0.7156	0.6935	0.7044	0.7789	0.8313	0.8043
Multitask (CE+LM)	0.6792	0.7881	0.7296	0.7393	0.9026	0.8128

Table 5: Experimental results on identifying individual types of components.

titask(CE+LM) makes predictions more aggressively compared with Singletask(CE) and tends to recognize more nearby components. We also observe that Multitask(CE+LM) identifies more correct UNK components, which are out of vocabulary or low frequency concepts. This means that language modeling leads the model to consider more local contextual patterns.

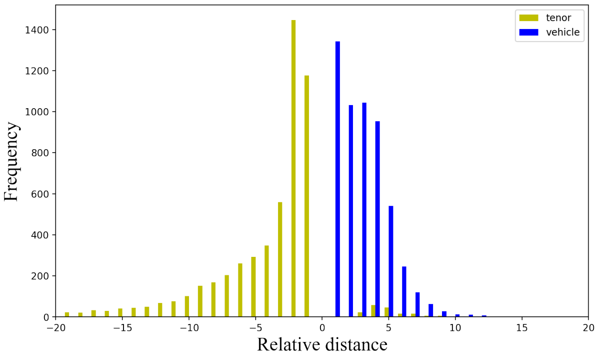

Figure 2: Relative distance of tenors and vehicles to the comparator in the dataset.

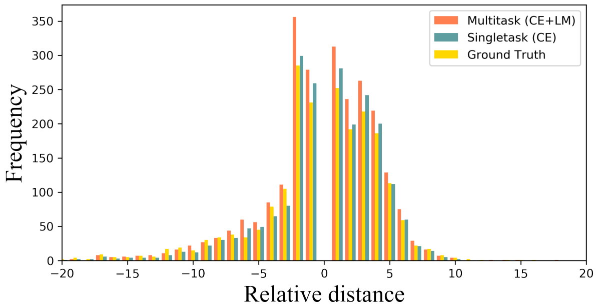

Figure 3: The distribution of extracted simile components on the whole test set.

Optimized Pipeline. According to the results and analysis, we can summarize that (1) simile sentence classification can achieve good performance by jointly optimizing three tasks; (2) simile components can be improved with language modeling as an auxiliary task; (3) simile sentence classification is suitable to be used as a pre-precessing for simile component classification. Therefore, we could build an optimized pipeline. We first use the enhanced simile sentence classifier to filter simile sentences and then use the enhanced component extractor to extract tenors and vehicles. As shown in Table 4, the optimized pipeline performs better than the strongest multitask learning setting.

However, in all settings, the precision scores are lower compared with the recall scores. This indicates that compared with identifying surface patterns, distinguishing metaphorical from literal meanings is much harder and more external knowledge should be incorporated.

6 Conclusion

This paper presented a study on simile recognition by exploiting neural networks. We construct a manually annotated dataset for advancing the research on simile analysis in Chinese. We propose a multitask learning framework, which jointly optimizes three tasks: simile sentence classification, simile component extraction and language modeling. The experimental results demonstrate the effectiveness of proposed approaches. It shows that simile sentence classification and simile component extraction both benefit from multitask learning. Simile sentence classification can achieve a high performance and simile component extraction still has a lot of room to improve.

In future, we plan to extend this work in several aspects: (1) enrich the simile component structure by adding shared properties or events so that the extracted structures would be more useful for metaphor processing; (2) improve representation learning for recognition by incorporating external knowledge; (3) apply simile recognition to study the use of figurative language in writings.

Structured Alignment Networks for Matching Sentences

Yang Liu*♠, Matt Gardner◇, and Mirella Lapata♠

yang.liu2@ed.ac.uk mattg@allenai.org mlap@inf.ed.ac.uk

Abstract

Many tasks in natural language processing involve comparing two sentences to compute some notion of relevance, entailment, or similarity. Typically, this comparison is done either at the word level or at the sentence level, with no attempt to leverage the inherent structure of the sentence. When sentence structure is used for comparison, it is obtained during a non-differentiable pre-processing step, leading to propagation of errors. We introduce a model of *structured alignments* between sentences, showing how to compare two sentences by matching their latent structures. Using a structured attention mechanism, our model matches candidate spans in the first sentence to candidate spans in the second sentence, simultaneously discovering the tree structure of each sentence. Our model is fully differentiable and trained only on the matching objective. We evaluate this model on two tasks, entailment detection and answer sentence selection, and find that modeling latent tree structures results in superior performance. Analysis of the learned sentence structures shows they can reflect some syntactic phenomena.

1 Introduction

There are many tasks in natural language processing that require matching two sentences: natural language inference (Bowman et al., 2015; Nangia et al., 2017) and paraphrase detection (Wang et al., 2017b) are classification tasks over sentence pairs, and question answering often requires an alignment between a question and a passage of text that may contain the answer (Tan et al., 2016a; Rajpurkar et al., 2016; Joshi et al., 2017).

Most neural models for these tasks perform comparisons between the two sentences either at the word level (Parikh et al., 2016), or at the sentence level (Bowman et al., 2015). Word-level comparisons ignore the inherent structure of the sentences being compared, at best relying on a recurrent neural network such as an LSTM (Hochreiter and Schmidhuber, 1997) to incorporate some amount of context from neighboring words into each word's representation. Sentence-level comparisons can incorporate the structure of each sentence individually (Bowman et al., 2016; Tai et al., 2015), but cannot easily compare substructures between the sentences, as these are all squashed into a single vector. Some models do incorporate sentence structure by comparing subtrees between the two sentences (Zhao et al., 2016; Chen et al., 2017), but require pipelined approaches where a parser is run in a non-differentiable preprocessing step, losing the benefits of end-to-end training.

In this paper we propose a method, which we call *structured alignment networks*, to perform comparisons between substructures in two sentences, in a more interpretable way, and without relying on an external, non-differentiable parser. We use a structured attention mechanism (Kim et al., 2017; Liu and Lapata, 2018) to compute a *structured alignment* between the two sentences, jointly learning a latent tree structure for each sentence and aligning spans between the two sentences.

Our method constructs a CKY chart for each sentence using the inside-outside algorithm (Manning et al., 1999), which is fully differentiable (Li and Eisner, 2009; Gormley et al., 2015). This chart has a node for each possible span in the sentence, and a score for the likelihood of that span being a constituent in a parse of the sentence, marginalized over all possible parses. We take these two charts and find alignments between them, representing each span in each sentence with structured attention over spans in the other sentence. These

---

Brussels, Belgium, October 31 - November 4, 2018.

span representations, weighted by the span's likelihood, are then used to compare the two sentences. In this way, we can perform comparisons between sentences by leveraging their internal structure in an end-to-end, fully differentiable model, trained only on one final objective. Our model helps obtain more precise representations of the sentence pair, with the learned tree structures and the alignment between them, and provides better interpretability, which most neural models lack in sentence matching tasks.

We evaluate this model on two sentence comparison datasets: SNLI (Bowman et al., 2015) and TREC-QA (Voorhees and Tice, 2000). We find that comparing sentences at the span level consistently outperforms comparing at the word level. Additionally, the learned sentence structures represent well-formed trees that reflect some syntactic phenomena.

2 Word-level Comparison Baseline

We first describe a common word-level comparison model, called *decomposable attention* (Parikh et al., 2016). This model was first proposed for the natural language inference task, but similar mechanisms have been used in many other tasks, such as for aligning question and passage words in the bi-directional attention model for question answering (Seo et al., 2017). This model serves as our main point of comparison, as our latent tree matching model simply replaces the word-level comparisons in decomposable attention model with span comparisons.

The decomposable attention model consists of three steps: *attend*, *compare*, and *aggregate*. As input, the model takes two sentences a and b represented by sequences of word embeddings $[\boldsymbol{a}_1, \cdots, \boldsymbol{a}_m]$ and $[\boldsymbol{b}_1, \cdots, \boldsymbol{b}_n]$. In the *attend* step, the model computes attention scores for each pair of words across the two input sentences and normalizes them as a soft alignment from a to b (and vice versa):

$$\boldsymbol{e}_{ij} = F_1(\boldsymbol{a}_i)^T F_1(\boldsymbol{b}_j) \tag{1}$$

$$\boldsymbol{B}_i = \sum_{j=1}^{n} \frac{exp(\boldsymbol{e}_{ij})}{\sum_{k=1}^{n} exp(\boldsymbol{e}_{ik})} \boldsymbol{b}_j \tag{2}$$

$$\boldsymbol{A}_j = \sum_{i=1}^{m} \frac{exp(\boldsymbol{e}_{ij})}{\sum_{k=1}^{m} exp(\boldsymbol{e}_{kj})} \boldsymbol{a}_i \tag{3}$$

where F_1 is a feed-forward neural network, $\boldsymbol{B}_i$ is the weighted summation of the words in b that are softly aligned to word $\boldsymbol{a}_i$ and vice versa for $\boldsymbol{A}_j$.

In the *compare* step, the input vectors $\boldsymbol{a}_i$ and $\boldsymbol{b}_j$ are concatenated with their corresponding attended vector $\boldsymbol{B}_i$ and $\boldsymbol{A}_j$, and fed into a feed-forward neural network, giving a comparison between each word and the words it aligns to in the other sentence:

$$\boldsymbol{v}_{ai} = F_2([\boldsymbol{a}_i, \boldsymbol{B}_i]) \quad \forall i \in [1, \cdots, m] \tag{4}$$

$$\boldsymbol{v}_{bj} = F_2([\boldsymbol{b}_j, \boldsymbol{A}_j]) \quad \forall j \in [1, \cdots, n] \tag{5}$$

The *aggregate* step is a simple summation of $\boldsymbol{v}_{ai}$ and $\boldsymbol{v}_{bj}$ for each word in sentence a and b, and the two resulting fixed-length vectors are concatenated and fed into a linear layer with $\boldsymbol{W}_y$ as the weight matrix, followed by a softmax layer for predicting the distribution $\boldsymbol{y}$:

$$\boldsymbol{v}_a = \sum_{i=1}^{m} \boldsymbol{v}_{ai} \quad \boldsymbol{v}_b = \sum_{j=1}^{n} \boldsymbol{v}_{bj} \tag{6}$$

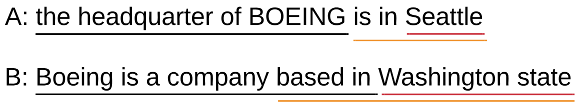
$$\boldsymbol{y} = softmax(\boldsymbol{W}_y[\boldsymbol{v}_a, \boldsymbol{v}_b])) \tag{7}$$

The decomposable attention model completely ignores the order and context of words in the sequence. There are some efforts to strengthen the decomposable attention model with a recurrent neural network (Liu and Lapata, 2018) or intra-sentence attention (Parikh et al., 2016). However, these models amount to simply changing the input vectors $\boldsymbol{a}$ and $\boldsymbol{b}$, and still only perform a word-level alignment between the two sentences.

3 Structured Alignment Networks

Language is inherently tree structured, and the meaning of sentences comes largely from composing the meanings of subtrees (Chomsky, 2002). It is natural, then, to compare the meaning of two sentences by comparing their substructures (MacCartney and Manning, 2009). For example, when determining the relationship between two sentences in Figure 1, the ideal units of comparison are spans determined by subtrees: "*is in Seattle*" compared to "*based in Washington state*".

The challenge with comparing spans drawn from subtrees is that the tree structure of the sentence is latent and must be inferred, either during pre-processing or in the model itself. In this section we present a model that operates on the *latent* tree structure of each sentence, comparing *all possible* spans in one sentence with *all possible* spans in the second sentence, weighted by *how*



A: the headquarter of BOEING is in Seattle

B: Boeing is a company based in Washington state

Figure 1: Example span alignments of a sentence pair, where different colors indicate matching spans. Note that some spans overlap, which cannot happen in a single tree; our model considers *all possible* span comparisons, weighted by the spans' marginal likelihood.

likely each span is to appear as a constituent in a parse of the sentence. We use the non-terminal nodes of a binary constituency parse to represent spans. Because of this choice of representation, we can use the nodes in a CKY parsing chart to efficiently marginalize span likelihood over all possible parses for each sentence, and compare nodes in each sentence's chart.

3.1 Learning Latent Constituency Trees

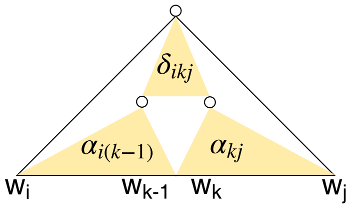
A constituency parser can be partially formalized as a graphical model with the following cliques (Klein and Manning, 2004): the latent variables $c_{ikj} \in 0, 1$ for all $i < j$, indicating whether the span from the i-th token to the j-th token ($span_{ij}$) is a constituency node built from the merging of sub-node $span_{ik}$ and $span_{(k+1)j}$. Given a sentence $x = [x_i, \cdots, x_n]$, the probability of a tree z is,

$$p(z|x) = \frac{\prod_{c_{ikj} \in z} p(c_{ikj} = 1)}{\sum_{z' \in Z} \prod_{c_{ikj} \in z'} p(c_{ikj} = 1)} \quad (8)$$

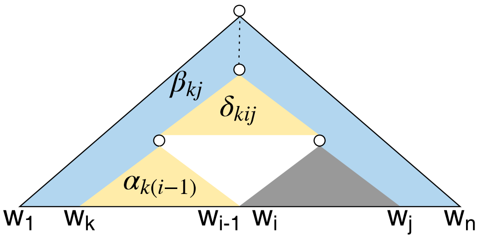
where Z represents all possible constituency trees for x.

The parameters for the graph-based CRF constituency parser are $\boldsymbol{\delta}_{ikj}$ reflecting the scores of $span_{ij}$ forming a binary constituency node with k as the splitting point. It is possible to calculate the marginal probability of each constituency node $p(c_{ijk} = 1|x)$ using the inside-outside algorithm (Klein and Manning, 2003). Although the inside-outside algorithm is constrained to generate a binary tree, this is not a severe limitation, as most structures can be easily binarized (Finkel et al., 2008).

In a typical constituency parser, the score $\boldsymbol{\delta}_{ikj}$ is parameterized according to the production rules of a grammar, e.g., with normalized categorical distributions for each non-terminal. Our unlabeled grammar effectively has only a single production rule, however, we parameterize these scores as bilinear functions operating on the representations of the two subtrees being merged. For the inside pass, as illustrated in Figure 2a, the inside score $\boldsymbol{\alpha}_{ij}$ for span from position i to j is marginalized over the splitting points k:



(a) Inside pass



(b) Outside pass

Figure 2: The inside-outside algorithm. (a) is the process for calculating the inside score $\boldsymbol{\alpha}_{ij}$. Three yellow spaces indicate $\boldsymbol{\alpha}_{i(k-1)}$, $\boldsymbol{\alpha}_{kj}$ and $\boldsymbol{\delta}_{ikj}$. (b) is a part of the process for calculating the outside score $\boldsymbol{\beta}_{ij}$, with target span $span_{ij}$ as the right child of a non-terminal. The blue space indicates $\boldsymbol{\beta}_{kj}$ and two yellow spaces indicate $\boldsymbol{\alpha}_{k(i-1)}$ and $\boldsymbol{\delta}_{kij}$.

$$\boldsymbol{\delta}_{ikj} = \boldsymbol{sp}_{ik}^T \boldsymbol{W} \boldsymbol{sp}_{(k+1)j} \quad (9)$$

$$\boldsymbol{\alpha}_{ij} = \sum_{i \,<\, k \,\le\, j} \boldsymbol{\delta}_{ikj} \boldsymbol{\alpha}_{i(k-1)} \boldsymbol{\alpha}_{kj} \quad (10)$$

where $\boldsymbol{sp}_{ij} \in \mathbb{R}^d$ is the representation for the span, and $\boldsymbol{W} \in \mathbb{R}^{d*d}$ is the weight matrix. This process is calculated recursively from bottom to root, generating the score for each possible constituent.

For the outside pass, the outside score $\boldsymbol{\beta}_{ij}$ is:

$$\begin{aligned} \boldsymbol{\beta}_{ij} = & \sum_{1 \le k < i} \boldsymbol{\delta}_{kij} \boldsymbol{\alpha}_{k(i-1)} \boldsymbol{\beta}_{kj} \\ & + \sum_{j < k \le n} \boldsymbol{\delta}_{ijk} \boldsymbol{\alpha}_{(j+1)k} \boldsymbol{\beta}_{ik} \end{aligned} \quad (11)$$

where the first term is the score for $span_{ij}$ being the right child on a non-terminal node and the second term is the score for $span_{ij}$ being the left child. In Figure 2b, we illustrate the outside process with the target span $span_{ij}$ being the right child of a non-terminal node. This process is calculated recursively from root to bottom.

The normalized marginal probability $\boldsymbol{\rho}_{ij}$ for each span $span_{ij}$, where $1 \leq i < n, i < j \leq n$ can be calculated by:

$$\boldsymbol{\rho}_{ij} = \boldsymbol{\alpha}_{ij}\boldsymbol{\beta}_{ij}/\boldsymbol{\alpha}_{0n} \tag{12}$$

To compute the representations of all possible spans, we use Long Short-Term Memory Neural Networks (LSTMs; Hochreiter and Schmidhuber 1997) with max-pooling and minus features (Cross and Huang, 2016; Liu and Lapata, 2017). We represent each sentence as a sequence of word embeddings $[\boldsymbol{w}_{sos}, \boldsymbol{w}_1, \cdots, \boldsymbol{w}_t, \cdots, \boldsymbol{w}_n, \boldsymbol{w}_{eos}]$ and run a bidirectional LSTM to obtain the output vectors. $\boldsymbol{h}_t = [\overrightarrow{\boldsymbol{h}}_t, \overleftarrow{\boldsymbol{h}}_t]$ is the output vector for the t^{th} word, and $\overrightarrow{\boldsymbol{h}}_t$ and $\overleftarrow{\boldsymbol{h}}_t$ are the output vectors from the forward and backward directions, respectively. We represent a constituent from position i to j with a span vector $\boldsymbol{sp}_{ij}$:

$$\boldsymbol{sp}_{ij}^{maxpool} = \max(\boldsymbol{h}_i, \cdots, \boldsymbol{h}_j) \tag{13}$$

$$\boldsymbol{sp}_{ij}^{minus} = [\overrightarrow{\boldsymbol{h}}_j - \overrightarrow{\boldsymbol{h}}_{i-1}, \overleftarrow{\boldsymbol{h}}_i - \overleftarrow{\boldsymbol{h}}_{j+1}] \tag{14}$$

$$\boldsymbol{sp}_{ij} = [\boldsymbol{sp}_{ij}^{maxpool}, \boldsymbol{sp}_{ij}^{minus}] \tag{15}$$

where $\max(\boldsymbol{x}_i, \cdots, \boldsymbol{x}_j)$ is the max-pooling operation over the sequence of output vectors within this constituent.

After applying the parsing process on two sentences, we obtain the marginal probabilities for all potential spans of the two constituency trees, which can then be used for aligning.

3.2 Learning Structured Alignments

After learning latent constituency trees for each sentence, we are able to perform span-level comparisons between the two sentences, instead of the word-level comparisons done by the decomposable attention model. The structure of these two comparison models is the same, but the basic elements of our structured alignment model are spans instead of words, and the marginal probabilities obtained from the inside-outside algorithm are used as a *re-normalization* value for incorporating structural information into the alignments.

For sentence a, we have the representation $\boldsymbol{sp}_{ij}^a$ for each $span_{ij}$ and its marginal probability $\boldsymbol{\rho}_{ij}^a$. And for sentence b, we also get $\boldsymbol{sp}_{ij}^b$ and $\boldsymbol{\rho}_{ij}^b$. The attention scores are computed between all pairs of spans across the two sentences, and the attended vectors can be calculated as:

$$\boldsymbol{e}_{ij,kl} = F_1(\boldsymbol{sp}_{ij}^a)^T F_1(\boldsymbol{sp}_{kl}^b) \tag{16}$$

$$\boldsymbol{B}_{ij} = \sum_{k=1}^{n}\sum_{l=k}^{n} \frac{exp(\boldsymbol{e}_{ij,kl} + ln(\boldsymbol{\rho}_{kl}^b))}{\sum_{s=1}^{n}\sum_{t=s}^{n} exp(\boldsymbol{e}_{ij,st} + ln(\boldsymbol{\rho}_{st}^b))} \boldsymbol{sp}_{kl}^b \tag{17}$$

$$\boldsymbol{A}_{kl} = \sum_{i=1}^{m}\sum_{j=i}^{m} \frac{exp(\boldsymbol{e}_{ij,kl} + ln(\boldsymbol{\rho}_{ij}^a))}{\sum_{s=1}^{m}\sum_{t=s}^{m} exp(\boldsymbol{e}_{st,kl} + ln(\boldsymbol{\rho}_{st}^a))} \boldsymbol{sp}_{ij}^a \tag{18}$$

Then, the span vectors are concatenated with the attended vectors and fed into a feed-forward neural network:

$$\boldsymbol{v}_{ij}^a = F_2([\boldsymbol{sp}_{ij}^a, \boldsymbol{B}_{ij}]) \tag{19}$$

$$\boldsymbol{v}_{kl}^b = F_2([\boldsymbol{sp}_{kl}^b, \boldsymbol{A}_{kl}]) \tag{20}$$

To aggregate these vectors, instead of using direct summation, we apply weighted summation with the marginal probabilities as weights:

$$\boldsymbol{v}_a = \sum_{i=1}^{m}\sum_{j=i}^{m} \boldsymbol{\rho}_{ij}^a \boldsymbol{v}_{ij}^a; \boldsymbol{v}_b = \sum_{k=1}^{n}\sum_{l=1}^{n} \boldsymbol{\rho}_{kl}^b \boldsymbol{v}_{kl}^b \tag{21}$$

where $\boldsymbol{\rho}^a$ and $\boldsymbol{\rho}^b$ work like the self-attention mechanism of (Lin et al., 2017) to replace the summation pooling step. We use a softmax function to compute the predicted distribution $\boldsymbol{y}$ of the input sentence pair:

$$\boldsymbol{y} = softmax(\boldsymbol{W}_y[\boldsymbol{v}_a, \boldsymbol{v}_b]) \tag{22}$$

4 Experiments

We evaluate our structured alignment model on two natural language matching tasks: question answering as sentence selection and natural language inference. We view our approach as a module for replacing the widely-used word-level alignment which can be plugged into other neural models. For that reason, our experiments are not intended to show performance improvements over state-of-the-art neural network architectures. Rather our evaluation studies aim to address three questions: (a) whether our methods can be trained effectively in an end-to-end fashion; (b) whether they yield improvements over standard word-level alignment models; and (c) whether they can learn plausible latent constituency tree structures.

Models	MAP	MRR
Word-level Attention	0.764	0.842

BiMPM (Wang et al., 2017b)	**0.802**	0.875

Table 1: Results of our models (top) and previously proposed systems (bottom) on the TREC-QA test set.

For both tasks, we initialize our model with 300D 840B GloVe word embeddings (Pennington et al., 2014). The hidden size for the BiLSTM is 150. The feed-forward networks F_1 and F_2 are two-layer perceptrons with ReLU as the hidden activation function and the size of the hidden and output layers is set to 300. All hyperparameters are selected based on the model's performance on the development set.

4.1 Answer Sentence Selection

We first study the effectiveness of our model for answer sentence selection tasks. Given a question, answer sentence selection aims to rank a list of candidate answer sentences based on their relatedness to the question. We experiment on the TREC-QA dataset (Wang et al., 2007), in which all questions with only positive or negative answers are removed. This leaves us with 1,162 training questions, 65 development questions and 68 test questions. Experimental results are listed in Table 1. We measure performance by the mean average precision (MAP) and mean reciprocal rank (MRR) using the standard TREC evaluation script.

In the first block of Table 1, we compare our model and variants thereof against several baselines. The first baseline is the *Word-level Decomposable Attention* model strengthened with a bidirectional LSTM for obtaining a contextualized representation for each word. The second baseline is a *Simple Span Alignment* model; we use an MLP layer over the LSTM outputs to calculate the unnormalized scores and replace the inside-outside algorithm with a simple softmax function to obtain the probability distribution over all candidate spans. We also introduce a pipelined baseline where we extract constituents from trees parsed by the CoreNLP (Manning et al., 2014) constituency parser, and use the *Simple Span Alignment* model to only align these constituents.

As shown in Table 1, we use two variants of the *Structured Alignment* model, since the structure of the question and the answer sentence may be different; the first model shares parameters across the question and the answer for computing the structures, while the second one uses separate parameters. We view the sentence selection task as a binary classification problem and the final ranking is based on the predicted probability of the sentence containing the correct answer (positive label). We apply dropout to the output of the BiLSTM with dropout ratio set to 0.2. All parameters (including word embeddings) are updated with AdaGrad (Duchi et al., 2011), and the learning rate is set to 0.05.

Table 1 (second block) also reports the performance of various comparison systems and state-of-the-art models. As can be seen, on both MAP and MRR metrics, structured alignment models perform better than the decomposable attention model, showing that structural bias is helpful for matching a question to the correct answer sentence. We also observe that using separate parameters achieves higher scores on both metrics. The simple span alignment model obtains results similar to the decomposable attention model, suggesting that the shallow softmax distribution is ineffective for capturing structural information and may even introduce redundant noise. The pipelined model with an external parser also slightly im-

Models	Accuracy	# Parameters

proves upon the baseline, but still cannot outperform the end-to-end trained structured alignment model which achieves results comparable with several strong baselines with fewer parameters. As mentioned earlier, our model could be used as a plug-in component for other more complex models, and may boost their performance by modeling the latent structures. At the same time, the structured alignment can provide better interpretability for sentence matching tasks, which is a defect of most neural models.

4.2 Natural Language Inference

The second task we consider is natural language inference, where the input is a pair of premise and hypothesis sentences, and the goal is to predict whether the premise entails the hypothesis, contradicts the hypothesis, or neither. For this task, we use the Stanford NLI dataset (Bowman et al., 2015). After removing sentences with unknown labels, we obtain 549,367 pairs for training, 9,842 for development and 9,824 for testing.

We compare our model against the same baselines used in the question answering task. All parameters (including word embeddings) are updated with AdaGrad (Duchi et al., 2011), and the learning rate is set to 0.05. Dropout is used with ratio 0.2. The structured alignment model in this experiment uses shared parameters for computing latent tree structures, since both the premise and hypothesis are declarative sentences.

The results of our experiments are shown in Table 2. Similar to the answer selection task, the tree matching model outperforms the decomposable model. Our structured alignment model gains 0.5% in accuracy over the baseline word-level comparison model without any additional annotation, simply from introducing a structural bias in the alignment between the sentences. Simple span alignment, however, is not helpfult and even slightly degrades the performance over the word-level model.

4.3 Analysis of Learned Tree Structures

In this section, we give a brief qualitative analysis of the learned tree structures. We present the CKY charts for two randomly-selected sentence pairs in the SNLI test set in Figure 3. Recall that the CKY chart shows the likelihood of each span appearing as a constituent in the parse of the sentence, marginalized over all possible parses. By visualizing these span probabilities, we can see that the model learns structures which correspond to known syntactic structures.

In subfigure (a), we can see that *band is playing* is a very-likely span, as is *at a large venue*. In subfigure (b), the phrases *performing at a local bar* and *at a local bar or club* also receive high probabilities. For the second sentence pair, we see that the model can even resolve some attachment ambiguities correctly. The prepositional phrase *with green feathers*, has a very low score for being attached to *women*. Instead, the model prefers to attach it to *lingerie*, forming the span *lingerie with green feathers*. We also present the top-5 spans and their alignments in subfigures (c) and (d), which can be used to interpret model decisions for sentence matching tasks.

The analysis above and our experimental results in the previous section suggest that our

(f) Alignment of top-5 spans

Figure 3: (a), (b), (d), and (e) are CKY charts showing marginalized span probabilities for sentence pairs in the SNLI test set. Each cell uses depth of the color to represent the probability of the span (from the i-th word to the j-th word) forming a proper constituent. (c) and (f) are the alignments of the top-5 spans from hypothesis sentence to the premise sentence, where the boldness of the lines indicates the probability of spans being aligned.

model is able to learn tree structures which are closely related to syntax, and in addition reflect the semantic-level characteristics of the task at hand. In both question answering and natural language inference tasks, we observe that structured alignment leads to performance improvements over word-level models. This is in contrast to prior work (Williams et al., 2017), where the discovery of tree structures based on a semantic objective is not helpful. Although we use the same supervision signal in our model, a difference between the two approaches is that they are trying to learn tree structures for each sentence *independently*, performing comparisons at the sentence level only. Comparing spans directly forces the model to induce trees with comparable constituents, giving the model a stronger inductive bias.

Although our main goal is not to induce a grammar, we perform some simple experiments to compare the learned latent trees with parser-generated ones. We parse the sentences in both test-sets with the CoreNLP (Manning et al., 2014) constituency parser to obtain silver trees. Based on the parsing part of the trained structured alignment model, we compute the marginal probabilities of test sentences and feed them into CKY algorithm (Younger, 1967) to find the most likely constituency trees. We then convert both silver and latent trees to sets of constituent brackets, and calculate the accuracy of the learned brackets against the silver parses. We use different combinations of training- and test-sets to examine the transferability of the learned tree structures. The results are shown in Table 3. We can see that although our model does not have any tree-structured input during training, it can still outperform the left-branching (LB) and right-branching baselines (RB) and achieve some consistency with the parser generated trees.

5 Related Work

Sentence comparison models The Stanford natural language inference dataset (Bowman et al., 2015), and the expanded multi-genre natural language inference dataset (Nangia et al., 2017), are

trained on tested on	SNLI	TREC	LB	RB

We show the transferability of the learned parser by applying it on a test-set different from the training-set. For example, we train the structured alignment model on the TREC-QA data, and apply it on SNLI to obtain the tree distributions. LB and RB are left- and right-branching baselines.

the most well-known recent sentence comparison tasks. The literature on this comparison task is far too extensive to include here, although the recent shared task on Multi-NLI gives a good survey of sentence-level comparison models (Nangia et al., 2017). Some of these models use sentence structures, which are obtained either in a latent fashion (Bowman et al., 2016) or during preprocessing (Zhao et al., 2016), but they squash all of the structure into a single vector, losing the ability to easily compare substructures between the two sentences.

For models doing a word-level comparison, the decomposable attention model (Parikh et al., 2016), which we have discussed already in this paper, is the most salient example, although many similar models exist in the literature (Chen et al., 2017; Wang et al., 2017b). The idea of word-level alignments between a question and a passage is also pervasive in the recent question answering literature (Seo et al., 2017; Wang et al., 2017a).

Finally, and most similar to our approach, several models have been proposed that directly compare subtrees between two sentences (Chen et al., 2017; Zhao et al., 2016). However, all of these models are pipelined; they obtain the sentence structure in a non-differentiable preprocessing step, losing the benefits of end-to-end training. Ours is the first model to allow comparison between *latent* tree structures, trained end-to-end on the comparison objective.

Structured attention While it has long been known that inference in graphical models is differentiable (Li and Eisner, 2009; Domke, 2011), and using inference in, e.g., a CRF (Lafferty et al., 2001) as the last layer in a neural network is common practice (Liu and Lapata, 2017; Lample et al., 2016), the use of inference algorithms as intermediate layers in end-to-end neural networks is a recent development. Kim et al. (2017) were the first to use inference to compute structured attentions over latent sentence variables, inducing tree structures trained on the end-to-end objective. Liu and Lapata (2018) showed how to do this more efficiently, although their work is still limited to structured attention over a single sentence. Our model is the first to include latent structured alignments between two sentences.

Grammar Induction Unsupervised grammar induction is a well-studied problem (Cohen and Smith, 2009). The most recent work in this direction was the Neural E-DMV model of Jiang et al. (2016). While our goal is not to induce a grammar, we do produce a probabilistic grammar as a byproduct of our model. Our results suggest that training on more complex objectives may be a good way to pursue grammar induction in the future; forcing the model to construct consistent, comparable subtrees between the two sentences is a strong signal for grammar induction. Very recently, a few models attempt to infer latent dependency tree structures with neural models in sentence modeling tasks (Yogatama et al., 2017; Choi et al., 2018).

6 Conclusions

In this paper we have considered the problem of comparing two sentences in natural language processing models. We have shown how to move beyond word- and sentence-level comparison to comparing spans between two sentences, without the need for an external parser. Through experiments on sentence comparison datasets, we have seen that span comparisons consistently outperform word-level comparisons, with no additional supervision. The proposed model can be trained effectively, in an end-to-end fashion and is able to induce plausible tree structures.

Our results have several implications for future work. First, the success of span comparisons over word-level comparisons suggests that it may be advantageous to include such comparisons in more complex models, either for comparing two sentences directly, or as intermediate parts of models for more complex tasks, such as reading comprehension. Second, our model's ability to infer trees from a semantic objective is intriguing, and suggestive of future opportunities in grammar induction research. The use of the inside-outside algorithm unavoidably renders the full model er (by 5–8 times) compared to the decomposable attention model. We hope to find a more efficient way to accelerate this dynamic programming method on a GPU.

Abstract

This paper presents a new deep learning architecture for Natural Language Inference (NLI). Firstly, we introduce a new architecture where alignment pairs are compared, compressed and then propagated to upper layers for enhanced representation learning. Secondly, we adopt factorization layers for efficient and expressive compression of alignment vectors into scalar features, which are then used to augment the base word representations. The design of our approach is aimed to be conceptually simple, compact and yet powerful. We conduct experiments on three popular benchmarks, SNLI, MultiNLI and SciTail, achieving competitive performance on all. A lightweight parameterization of our model also enjoys a ≈ 3 times reduction in parameter size compared to the existing state-of-the-art models, e.g., ESIM and DIIN, while maintaining competitive performance. Additionally, visual analysis shows that our propagated features are highly interpretable.

1 Introduction

Natural Language Inference (NLI) is a pivotal and fundamental task in language understanding and artificial intelligence. More concretely, given a premise and hypothesis, NLI aims to detect whether the latter *entails* or *contradicts* the former. As such, NLI is also commonly known as Recognizing Textual Entailment (RTE). NLI is known to be a significantly challenging task for machines whose success often depends on a wide repertoire of reasoning techniques.

In recent years, we observe a steep improvement in NLI systems, largely contributed by the release of the largest publicly available corpus for NLI - the Stanford Natural Language Inference (SNLI) corpus (Bowman et al., 2015) which comprises $570K$ hand labeled sentence pairs. This has improved the feasibility of training complex neural models, given the fact that neural models often require a relatively large amount of training data.

Highly competitive neural models for NLI are mostly based on soft-attention alignments, popularized by (Parikh et al., 2016; Rocktäschel et al., 2015). The key idea is to learn an alignment of sub-phrases in both sentences and learn to compare the relationship between them. Standard feed-forward neural networks are commonly used to model similarity between aligned (decomposed) sub-phrases and then aggregated into the final prediction layers.

Alignment between sentences has become a staple technique in NLI research and many recent state-of-the-art models such as the Enhanced Sequential Inference Model (ESIM) (Chen et al., 2017b) also incorporate the alignment strategy. The difference here is that ESIM considers a non-parameterized comparison scheme, i.e., *concatenating* the subtraction and element-wise product of aligned sub-phrases, along with two original sub-phrases, into the final comparison vector. A bidirectional LSTM is then used to aggregate the compared alignment vectors.

This paper presents a new neural model for NLI. There are several new novel components in our work. Firstly, we propose a *compare, compress and propagate* (ComProp) architecture where compressed alignment features are propagated to upper layers (such as a RNN-based encoder) for enhancing representation learning. Secondly, in order to achieve an efficient propagation of alignment features, we propose alignment factorization layers to reduce each alignment vector to a single scalar valued feature. Each scalar valued feature is used to augment the base word representation, allowing the subsequent RNN encoder layers to benefit from not only global but also cross sentence information.

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1565–1575
Brussels, Belgium, October 31 - November 4, 2018.

There are several major advantages to our proposed architecture. Firstly, our model is relatively compact, i.e., we compress alignment feature vectors and augment them to word representations instead. This is to avoid large alignment (or match) vectors being propagated across the network. As a result, our model is more parameter efficient compared to ESIM since the width of the middle layers of the network is now much smaller. To the best of our knowledge, this is the first work that explicitly employs such a paradigm.

Secondly, the explicit usage of compression enables improved interpretabilty since each alignment pair is compressed to a scalar and hence, can be easily visualised. Previous models such as ESIM use subtractive operations on alignment vectors, edging on the intuition that these vectors represent contradiction. Our model is capable of visually demonstrating this phenomena. As such, our design choice enables a new way of deriving insight from neural NLI models.

Thirdly, the alignment factorization layer is expressive and powerful, combining ideas from standard machine learning literature (Rendle, 2010) with modern neural NLI models. The factorization layer tries to decompose the alignment vector (constructed from the variations of $a - b$, $a \odot b$ and $[a; b]$), learning higher-order feature interactions between each compared alignment. In other words, it models the second-order (pairwise) interactions between *each* feature in *every* alignment vector using factorized parameters, allowing more expressive comparison to be made over traditional fully-connected layers (FC). Moreover, factorization-based models are also known to be able to model low-rank structure and reduce risks of overfitting. The effectiveness of the factorization alignment over alternative baselines such as feed-forward neural networks is confirmed by early experiments.

The major contributions of this work are summarized as follows:

- We introduce a *Compare, Compress and Propagate* (ComProp) architecture for NLI. The key idea is to use the myriad of generated comparison vectors for augmentation of the base word representation instead of simply aggregating them for prediction. Subsequently, a standard compositional encoder can then be used to learn representations from the augmented word representations. We show that we are able to derive meaningful insight from visualizing these augmented features.
- For the first time, we adopt expressive factorization layers to model the relationships between soft-aligned sub-phrases of sentence pairs. Empirical experiments confirm the effectiveness of this new layer over standard fully connected layers.
- Overall, we propose a new neural model - CAFE (**C**omProp **A**lignment-**F**actorized **E**ncoders) for NLI. Our model achieves state-of-the-art performance on SNLI, MultiNLI and the new SciTail dataset, outperforming existing state-of-the-art models such as ESIM. Ablation studies confirm the effectiveness of each proposed component in our model.

2 Related Work

Natural language inference (or textual entailment recognition) is a long standing problem in NLP research, typically carried out on smaller datasets using traditional methods (Maccartney, 2009; Dagan et al., 2006; MacCartney and Manning, 2008; Iftene and Balahur-Dobrescu, 2007).

The relatively recent creation of $570K$ human annotated sentence pairs (Bowman et al., 2015) have spurred on many recent works that use neural networks for NLI. Many advanced neural architectures have been proposed for the NLI task, with most exploiting some variants of neural attention which learn to pay attention to important segments in a sentence (Parikh et al., 2016; Chen et al., 2017b; Wang and Jiang, 2016b; Rocktäschel et al., 2015; Yu and Munkhdalai, 2017a).

Amongst the myriad of neural architectures proposed for NLI, the ESIM (Chen et al., 2017b) model is one of the best performing models. The ESIM, primarily motivated by soft subphrase alignment in (Parikh et al., 2016), learns alignments between BiLSTM encoded representations and aggregates them with another BiLSTM layer. The authors also propose the usage of subtractive composition, claiming that this helps model contradictions amongst alignments.

Compare-Aggregate models are also highly popular in NLI tasks. While this term was coined by (Wang and Jiang, 2016a), many prior NLI models follow this design (Wang et al., 2017; Parikh et al., 2016; Gong et al., 2017; Chen et al., 2017b). The key idea is to aggregate matching features and pass them through a dense layer for prediction. (Wang et al., 2017) proposed BiMPM, which adopts multi-perspective cosine matching across sequence pairs. (Wang and Jiang, 2016a) proposed a one-way attention and convolutional aggregation layer. (Gong et al., 2017) learns representations with highway layers and adopts ResNet for learning features over an interaction matrix.

There are several other notable models for NLI. For instance, models that leverage directional self-attention (Shen et al., 2017) or Gumbel-Softmax (Choi et al., 2017). DGEM is a graph based attention model which was proposed together with a new entailment challenge dataset, SciTail (Khot et al., 2018). Pretraining have been known to also be highly useful in the NLI task. For instance, contextualized vectors learned from machine translation (McCann et al., 2017) (CoVe) or language modeling (Peters et al., 2018) (ELMo) have showned to be able to improve performance when integrated with existing NLI models.

Our work compares and compresses alignment pairs using factorization layers which leverages the rich history of standard machine learning literature. Our factorization layers incorporate highly expressive factorization machines (FMs) (Rendle, 2010) into neural NLI models. In standard machine learning tasks, FMs remain a very competitive choice for learning feature interactions (Xiao et al., 2017) for both standard classification and regression problems. Intuitively, FMs are adept at handling data sparsity (typically interactions) by using factorized parameters to approximate a feature matching matrix. This makes it suitable in our model architecture since feature interaction between subphrase alignment pairs is typically very sparse as well.

A recent work (Beutel et al., 2018) reports an interesting empirical study pertaining to the ability of standard FC layers and their ability to model 'cross features' (or multiplicative features). Their overall finding suggests that while standard ReLU FC layers are able to approximate 2-way or 3-way features, they are extremely inefficient in doing so (requiring either very wide or deep layers). This further motivates the usage of FMs in this work and is well aligned with our empirical results, i.e., strong competitive performance with reasonably small parameterization.

3 Our Proposed Model

In this section, we provide a layer-by-layer description of our model architecture. Our model accepts two sentences as an input, i.e., P (premise) and H (hypothesis). Figure 1 illustrates a high-level overview of our proposed model architecture.

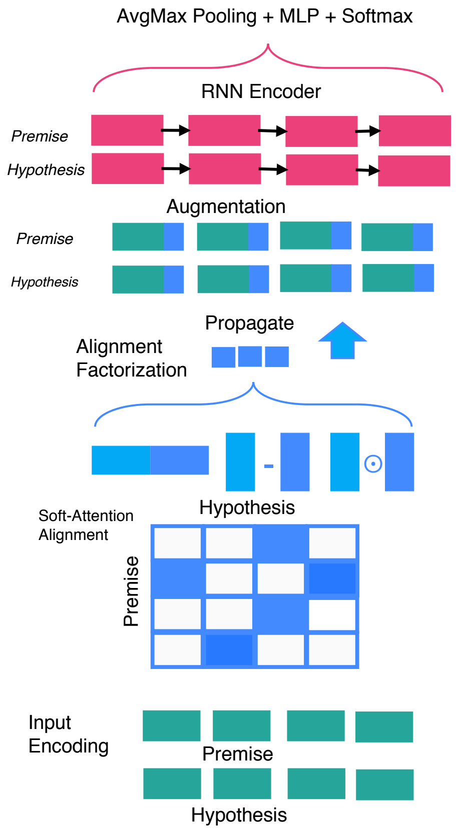

Figure 1: High level overview of our proposed architecture (*best viewed in color*). Alignment vectors are compressed and then propagated to upper representation learning layers (RNN encoders). Intra-attention is omitted in this diagram due to the lack of space.

3.1 Input Encoding Layer

This layer aims to learn a k-dimensional representation for each word. Following (Gong et al., 2017), we learn feature-rich word representations by concatenating word embeddings, character embeddings and syntactic (part-of-speech tag) embeddings (provided in the datasets). Character representations are learned using a convolutional encoder with max pooling function and is commonly used in many relevant literature (Wang et al., 2017; Chen et al., 2017c).

Highway Encoder Subsequently, we pass each concatenated word vector into a two layer highway network (Srivastava et al., 2015) in order to learn a k-dimensional representation. Highway networks are gated projection layers which learn adaptively control how much information is being carried to the next layer. Our strategy is similar to (Parikh et al., 2016) which trains the projection layer in place of tuning the embedding matrix. The usage of highway layers over standard projection layers is empirically motivated. However, an intuition would be that the gates in this layer adapt to learn the relative importance of each word to the NLI task. Let $H(.)$ and $T(.)$ be single layered affine transforms with ReLU and sigmoid activation functions respectively. A single highway network layer is defined as:

$$y = H(x, W_H) \cdot T(x, W_T) + C \cdot x \quad (1)$$

where $C = (1 - T(x, W_T))$ and $W_H, W_T \in \mathbb{R}^{r \times d}$ Notably, the dimensions of the affine transform might be different from the size of the input vector. In this case, an additional nonlinear transform is used to project x to the same dimensionality. The output of this layer is $\bar{P} \in \mathbb{R}^{k \times \ell_P}$ (premise) and $\bar{H} \in \mathbb{R}^{k \times \ell_H}$ (hypothesis), with each word converted to a r-dimensional vector.

3.2 Soft-Attention Alignment Layer

This layer describes two soft-attention alignment techniques that are used in our model.

Inter-Attention Alignment Layer This layer learns an alignment of sub-phrases between $\bar{P}$ and $\bar{H}$. Let $F(.)$ be a standard projection layer with ReLU activation function. The alignment matrix of two sequences is defined as follows:

$$e_{ij} = F(\bar{p}_i)^\top \cdot F(\bar{h}_j) \quad (2)$$

where $E \in \mathbb{R}^{\ell_p \times \ell_h}$ and $\bar{p}_i, \bar{h}_j$ are the i-th and j-th word in the premise and hypothesis respectively.

$$\beta_i = \sum_{j=1}^{\ell_p} \frac{exp(e_{ij})}{\sum_{k=1}^{\ell_p} exp(e_{ik})} \bar{p}_j \quad (3)$$

$$\alpha_j = \sum_{i=1}^{\ell_h} \frac{exp(e_{ij})}{\sum_{k=1}^{\ell_h} exp(e_{kj})} \bar{h}_i \quad (4)$$

where β_i is the sub-phrase in $\bar{P}$ that is softly aligned to h_i. Intuitively, β_i is a weighted sum across $\{p_j\}_{j=1}^{\ell_p}$, selecting the most relevant parts of $\bar{P}$ to represent h_i.

Intra-Attention Alignment Layer This layer learns a *self-alignment* of sentences and is applied to both $\bar{P}$ and $\bar{H}$ independently. For the sake of brevity, let $\bar{S}$ represent either $\bar{P}$ or $\bar{H}$, the intra-attention alignment is computed as:

$$s'_i = \sum_{j=1}^{\ell_p} \frac{exp(f_{ij})}{\sum_{k=1}^{\ell_p} exp(f_{ik})} \bar{s}_j \quad (5)$$

where $f_{ij} = G(\bar{s}_i)^\top \cdot G(\bar{s}_j)$ and $G(.)$ is a nonlinear projection layer with ReLU activation function. The intra-attention layer models similarity of each word with respect to the entire sentence, capturing long distance dependencies and 'global' context of the entire sentence.

3.3 Alignment Factorization Layer

This layer aims to learn a scalar valued feature for each comparison between aligned sub-phrases. Firstly, we introduce our factorization operation, which lives at the core of our neural model.

Factorization Operation Given an input vector x, the factorization operation (Rendle, 2010) is defined as:

$$Z(x) = w_0 + \sum_{i=1}^{n} w_i\, x_i + \sum_{i=1}^{n} \sum_{j=i+1}^{n} \langle v_i, v_j \rangle\, x_i\, x_j \quad (6)$$

where $Z(x)$ is a scalar valued output, $\langle .; . \rangle$ is the dot product between two vectors and w_0 is the global bias. Factorization machines model low-rank structure within the matching vector producing a scalar feature. The parameters of this layer are $w_0 \in \mathbb{R}, w \in \mathbb{R}^r$ and $v \in \mathbb{R}^{r \times k}$. The first term $\sum_{i=1}^{n} w_i\, x_i$ is simply a linear term. The second term $\sum_{i=1}^{n} \sum_{j=i+1}^{n} \langle v_i, v_j \rangle\, x_i\, x_j$ captures all pairwise interactions in x (the input vector) using the factorization of matrix v.

Inter-Alignment Factorization This operation compares the alignment between inter-attention aligned representations, i.e., (β_i, h_i) and (α_j, p_j). Let (a, b) represent an alignment pair, we apply the following operations:

$$y_c = Z([a; b]) \; ; \; y_s = Z(a - b) \; ; \; y_m = Z(a \odot b) \quad (7)$$

where $y_c, y_s, y_m \in \mathbb{R}$, $Z(.)$ is the factorization operation, $[.; .]$ is the concatenation operator and $\odot$ is the element-wise multiplication. The intuition of modeling subtraction is targeted at capturing contradiction. However, instead of simply concatenating the extra comparison vectors, we compress them using the factorization operation. Finally, for each alignment pair, we obtain three scalar-valued features which map precisely to a word in the sequence.

Intra-Alignment Factorization Next, for each sequence, we also apply alignment factorization on the intra-aligned sentences. Let (s, s') represent an *intra-aligned* pair from either the premise or hypothesis, we compute the following operations:

$$v_c = Z([s; s'])\ ;\ v_s = Z(s - s')\ ;\ v_m = Z(s \odot s') \tag{8}$$

where $v_c, v_s, v_m \in \mathbb{R}$ and $Z(.)$ is the factorization operation. Applying alignment factorization to intra-aligned representations produces another three scalar-valued features which are mapped to each word in the sequence. Note that each of the *six* factorization operations has its own parameters but shares them amongst all words in the sentences.

3.4 Propagation and Augmentation

Finally, the *six* factorized features are then aggregated[1] via concatenation to form a final feature vector that is propagated to upper representation learning layers via augmentation of the word representation $\bar{P}$ or $\bar{H}$.

$$u_i = [s_i; f^i_{intra}; f^i_{inter}] \tag{9}$$

where s_i is i-th word in $\bar{P}$ or $\bar{H}$, and f^i_{intra} and f^i_{inter} are the intra-aligned $[v_c; v_s; v_m]$ and inter-aligned $[y_c; y_s; y_m]$ features for the i-th word in the sequence respectively. Intuitively, f^i_{intra} augments each word with global knowledge of the sentence and f^i_{inter} augments each word with cross-sentence knowledge via inter-attention.

3.5 Sequential Encoder Layer

For each sentence, the augmented word representations $u_1, u_2, \ldots u_\ell$ are then passed into a sequential encoder layer. We adopt a standard vanilla LSTM encoder.

$$h_i = LSTM(u, i), \forall i \in [1, \ldots \ell] \tag{10}$$

where ℓ represents the maximum length of the sequence. Notably, the parameters of the LSTM are *siamese* in nature, sharing weights between both premise and hypothesis. We do not use a bidirectional LSTM encoder, as we found that it did not lead to any improvements on the held-out set. A logical explanation would be because our word representations are already augmented with global (intra-attention) information. As such, modeling in the reverse direction is unnecessary, resulting in some computational savings.

Pooling Layer Next, to learn an overall representation of each sentence, we apply a pooling function across all hidden outputs of the sequential encoder. The pooling function is a concatenation of temporal max and average (avg) pooling.

$$x = [\max([h_1, \cdots h_\ell]); avg([h_1, \cdots h_\ell])] \tag{11}$$

where x is a final $2k$-dimensional representation of the sentence (premise or hypothesis). We also experimented with *sum* and *avg* standalone poolings and found *sum* pooling to be relatively competitive.

3.6 Prediction Layer

Finally, given a fixed dimensional representation of the premise x_p and hypothesis x_h, we pass their concatenation into a two-layer h-dimensional highway network. Since the highway network has been already defined earlier, we omit the technical details here. The final prediction layer of our model is computed as follows:

$$y_{out} = H_2(H_1([x_p; x_h; x_p \odot x_h; x_p - x_h])) \tag{12}$$

where $H_1(.), H_2(.)$ are highway network layers with ReLU activation. The output is then passed into a final linear softmax layer.

$$y_{pred} = softmax(W_F \cdot y_{out} + b_F) \tag{13}$$

where $W_F \in \mathbb{R}^{h \times 3}$ and $b_F \in \mathbb{R}^3$. The network is then trained using standard multi-class cross entropy loss with L2 regularization.

4 Experiments

In this section, we describe our experimental setup and report our experimental results.

---

[1] Following (Parikh et al., 2016), we may also concatenate the intra-aligned vector to u_i which we found to have speed up convergence.

Model	Params	Train	Test
Single Model (w/o Cross Sentence Attention)			
300D Gumbel TreeLSTM (Choi et al., 2017)	2.9M	91.2	85.6
300D DISAN (Shen et al., 2017)	2.4M	91.1	85.6
300D Residual Stacked Encoders (Nie and Bansal, 2017)	9.7M	89.8	85.7
600D Gumbel TreeLSTM (Choi et al., 2017)	10M	93.1	**86.0**
300D CAFE (w/o CA)	3.7M	87.3	85.9
Single Models			
100D LSTM with attention (Rocktäschel et al., 2015)	250K	85.3	83.5
300D mLSTM (Wang and Jiang, 2016b)	1.9M	92.0	86.1
450D LSTMN + deep att. fusion (Cheng et al., 2016)	3.4M	88.5	86.3
200D DecompAtt + Intra-Att (Parikh et al., 2016)	580K	90.5	86.8
300D NTI-SLSTM-LSTM (Yu and Munkhdalai, 2017b)	3.2M	88.5	87.3
300D re-read LSTM (Sha et al., 2016)	2.0M	90.7	87.5
BiMPM (Wang et al., 2017)	1.6M	90.9	87.5
448D DIIN (Gong et al., 2017)	4.4M	91.2	88.0

Table 1: Performance comparison of all published models on the SNLI benchmark.

4.1 Experimental Setup

To ascertain the effectiveness of our models, we use the SNLI (Bowman et al., 2015) and MultiNLI (Williams et al., 2017) benchmarks which are standard and highly competitive benchmarks for the NLI task. We also include the newly released SciTail dataset (Khot et al., 2018) which is a binary entailment classification task constructed from science questions. Notably, SciTail is known to be a difficult dataset for NLI, made evident by the low accuracy scores even though it is binary in nature.

SNLI The state-of-the-art competitors on this dataset are the BiMPM (Wang et al., 2017), ESIM (Chen et al., 2017b) and DIIN (Gong et al., 2017). We compare against competitors across three settings. The first setting disallows cross sentence attention. In the second setting, cross sentence is allowed. The last (third) setting is a comparison between model ensembles while the first two settings only comprise single models. Note that we consider the 1st setting to be relatively less important (since our focus is not on the encoder itself) but still report the results for completeness.

MultiNLI We compare on two test sets (*matched* and *mismatched*) which represent in-domain and out-domain performance. The main competitor on this dataset is the ESIM model, a powerful state-of-the-art SNLI baseline. We also compare with ESIM + Read (Weissenborn, 2017).

SciTail This dataset only has one official setting. We compare against the reported results of ESIM (Chen et al., 2017b) and DecompAtt (Parikh et al.,

2016) in the original paper. We also compare with DGEM, the new model proposed in (Khot et al., 2018).

Across all experiments and in the spirit of fair comparison, we only compare with works that (1) do not use extra training data and (2) do not use external resources (such as external knowledge bases, etc.). However, for the sake of completeness, we still report their scores[2] (McCann et al., 2017; Chen et al., 2017a; Peters et al., 2018).

4.2 Implementation Details

We implement our model in TensorFlow (Abadi et al., 2015) and train them on Nvidia P100 GPUs. We use the Adam optimizer (Kingma and Ba, 2014) with an initial learning rate of 0.0003. L2 regularization is set to 10^{-6}. Dropout with a keep probability of 0.8 is applied after each fully-connected, recurrent or highway layer. The batch size is tuned amongst $\{128, 256, 512\}$. The number of latent factors k for the factorization layer is tuned amongst $\{5, 10, 50, 100, 150\}$. The size of the hidden layers of the highway network layers are set to 300. All parameters are initialized with xavier initialization. Word embeddings are preloaded with $300d$ GloVe embeddings (Pennington et al., 2014) and fixed during training. Sequence lengths are padded to batch-wise maximum. The batch order is (randomly) sorted within buckets following (Parikh et al., 2016).

4.3 Experimental Results

Table 1 reports our results on the SNLI benchmark. On the cross sentence (single model setting), the performance of our proposed CAFE model is extremely competitive. We report the test accuracy of CAFE at different extents of parameterization, i.e., varying the size of the LSTM encoder, width of the pre-softmax hidden layers and final pooling layer. CAFE obtains 88.5% accuracy on the SNLI test set, an extremely competitive score on the extremely popular benchmark. Notably, competitive results can be also achieved with a much smaller parameterization. For example, CAFE also achieves 88.3% and 88.1% test accuracy with only $3.5M$ and $1.5M$ parameters respectively. This outperforms the state-of-the-art ESIM and DIIN models with only a fraction of the parameter cost. At 88.1%, our model has about three times less parameters than ESIM/DIIN (i.e., 1.4M versus 4.3M/4.4M). Moreover, our lightweight adaptation achieves 87.7% with only $750K$ parameters, which makes it extremely performant amongst models having the same amount of parameters such as the decomposable attention model (86.8%).

Finally, an ensemble of 5 CAFE models achieves 89.3% test accuracy, the best test scores on the SNLI benchmark to date[3]. Overall, we believe that the good performance of our CAFE can be attributed to (1) the effectiveness of the ComProp architecture (i.e., providing word representations with global and local knowledge for better representation learning) and (2) the expressiveness of alignment factorization layers that are used to decompose and compare word alignments. More details are given at the ablation study. Finally, we emphasize that CAFE is also relatively lightweight, efficient and fast to train given its performance. A single run on SNLI takes approximately 5 minutes per epoch with a batch size of 256. Overall, a single run takes $\approx$ 3 hours to get to convergence.

	MultiNLI		SciTail
Model	Match	Mismatch	-
Majority	36.5	35.6	60.3
NGRAM$^{\#}$	-	-	70.6
CBOW$^{\flat}$	65.2	64.8	-
BiLSTM$^{\flat}$	69.8	69.4	-
ESIM$^{\#,\flat}$	72.4	72.1	70.6
DecompAtt$^{\#}$ -	-	-	72.3
DGEM$^{\#}$	-	-	70.8
DGEM + Edge$^{\#}$	-	-	77.3
ESIM†	76.3	75.8	-
ESIM + Read†	77.8	77.0	-
CAFE	78.7	77.9	**83.3**
CAFE Ensemble	**80.2**	**79.0**	-

Table 2: Performance comparison (accuracy) on MultiNLI and SciTail. Models with $\dagger$, $\#$ and $\flat$ are reported from (Weissenborn, 2017), (Khot et al., 2018) and (Williams et al., 2017) respectively.

Table 2 reports our results on the MultiNLI and SciTail datasets. On MultiNLI, CAFE significantly outperforms ESIM, a strong state-of-the-art model on both settings. We also outperform the ESIM + Read model (Weissenborn, 2017). An ensemble of CAFE models achieve competitive re-

---

[2] Additionally, we added ELMo (Peters et al., 2018) to our CAFE model at the embedding layer. We report CAFE + ELMo under external resource models. This was done post review after EMNLP. Due to resource constraints, we did not train CAFE + ELMo ensembles but a single run (and single model) of CAFE + ELMo already achieves 89.0 score on SNLI.

[3] As of 22nd May 2018, the deadline of the EMNLP submisssion.

sult on the MultiNLI dataset. On SciTail, our proposed CAFE model achieves state-of-the-art performance. The performance gain over strong baselines such as DecompAtt and ESIM are $\approx 10\% - 13\%$ in terms of accuracy. CAFE also outperforms DGEM, which uses a graph-based attention for improved performance, by a significant margin of 5%. As such, empirical results demonstrate the effectiveness of our proposed CAFE model on the challenging SciTail dataset.

4.4 Ablation Study

	Match	Mismatch
Original Model	79.0	78.9
(1a) Rm FM for 1L-FC	77.7	77.9
(1b) Rm FM for 1L-FC (ReLU)	77.3	77.5
(1c) Rm FM for 2L-FC (ReLU)	76.6	76.4
(2) Remove Char Embed	78.1	78.3
(3) Remove Syn Embed	78.3	78.4
(4) Remove Inter Att	75.2	75.6
(5) Replace HW Pred. with FC	77.7	77.9
(6) Replace HW Enc. with FC	78.7	78.7
(7) Remove Sub Feat	77.9	78.3
(8) Remove Mul Feat	78.7	78.6
(9) Remove Concat Feat	77.9	77.6
(10) Add Bi-directional	78.3	78.4

Table 3: Ablation study on MultiNLI development sets. HW stands for Highway.

Table 3 reports ablation studies on the MultiNLI development sets. In (1), we replaced all FM functions with regular full-connected (FC) layers in order to observe the effect of **FM versus FC**. More specifically, we experimented with several FC configurations as follows: (a) 1-layer linear, (b) 1-layer ReLU (c) 2-layer ReLU. The 1-layer linear setting performs the best and is therefore reported in Table 3. Using ReLU seems to be worse than nonlinear FC layers. Overall, the best combination (option a) still experienced a decline in performance in both development sets.

In (2-3), we explore the utility of using character and syntactic embeddings, which we found to have helped CAFE marginally. In (4), we remove the inter-attention alignment features, which naturally impact the model performance significantly. In (5-6), we explore the effectiveness of the highway layers (in prediction layers and encoding layers) by replacing them to FC layers. We observe that both highway layers have marginally helped the overall performance. Finally, in (7-9), we remove the alignment features based on their composition type. We observe that the *Sub* and *Concat* compositions were more important than the *Mul* composition. However, removing any of the three will result in some performance degradation. Finally, in (10), we replace the LSTM encoder with a BiLSTM, observing that adding bi-directionality did not improve performance for our model.

4.5 Linguistic Error Analysis

We perform a linguistic error analysis using the supplementary annotations provided by the MultiNLI dataset. We compare against the model outputs of the ESIM model across 13 categories of linguistic phenenoma (Williams et al., 2017). Table 4 reports the result of our error analysis. We observe that our CAFE model generally outperforms ESIM on *most categories*.

	Matched		Mismatched	
	ESIM	CAFE	ESIM	CAFE
Conditional	100	70	60	**85**
Word overlap	50	**82**	62	**87**
Negation	**76**	**76**	71	**80**
Antonym	67	**82**	58	**80**
Long Sentence	75	**79**	69	**77**
Tense Difference	73	**82**	79	**89**
Active/Passive	88	**100**	**91**	90
Paraphrase	**89**	88	84	**95**
Quantity/Time	33	**53**	54	**62**
Coreference	**83**	80	75	**83**
Quantifier	69	**75**	72	**80**
Modal	78	**81**	76	**81**
Belief	65	**77**	67	**83**

Table 4: Linguistic Error Analysis on MultiNLI dataset.

On the mismatched setting, CAFE outperforms ESIM in 12 out of 13 categories, losing only in one percentage point in *Active/Passive* category. On the matched setting, CAFE is outperformed by ESIM very marginally on coreference and paraphrase categories. Despite generally achieving much superior results, we noticed that CAFE performs poorly on *conditionals*[4] on the matched setting. Measuring the absolute ability of CAFE, we find that CAFE performs extremely well in handling linguistic patterns of *paraphrase detection* and *active/passive*. This is likely to be attributed by the alignment strategy that CAFE and ESIM both exploits.

4.6 Interpreting and Visualizing with CAFE

Finally, we also observed that the propagated features are highly interpretable, giving insights to the inner workings of the CAFE model. Figure 2 shows a visualization of the feature values from an example in the SNLI test set. The ground

---

[4] This only accounts for 5% of samples.

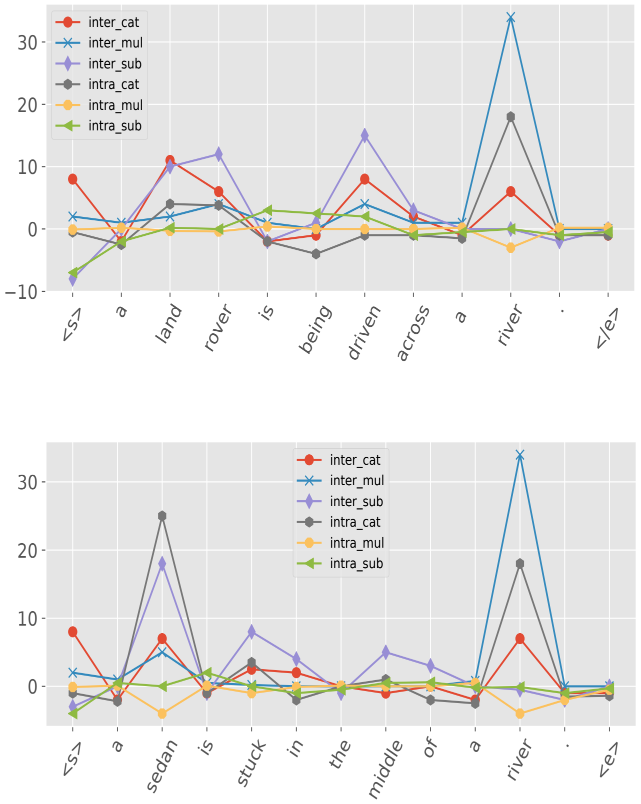

Figure 2: Visualization of *six* Propagated Features (*Best viewed in color*). Legend is denoted by {inter,intra} followed by the operations *mul*, *sub* or *cat* (concat).

truth is *contradiction*. Based on the above example we make several observations. Firstly, *inter_mul* features mostly capture identical words (or semantically similar words), i.e., *inter_mul* features for *'river'* spikes in both sentences. Secondly, *inter_sub* spikes on conflicting words that might cause contradiction, e.g., *'sedan'* and *'land rover'* are not the same vehicle. Another interesting observation is that we notice the *inter_sub* features for *driven* and *stuck* spiking. This also validates the observation of (Chen et al., 2017b), which shows what the *sub* vector in the ESIM model is looking out for contradictory information. However, our architecture allows the inspection of these vectors since they are compressed via factorization, leading to larger extents of explainability - a quality that neural models inherently lack. We also observed that intra-attention (e.g., intra_cat) features seem to capture the more important words in the sentence (*'river'*, *'sedan'*, *'land rover'*).

5 Conclusion

We proposed a new neural architecture, CAFE for NLI. CAFE achieves very competitive performance on three benchmark datasets. Extensive ablation studies confirm the effectiveness of FM layers over FC layers. Qualitatively, we show how different compositional operators (e.g., sub and mul) behave in NLI task and shed light on why subtractive composition helps in other models such as ESIM.

Abstract

Attention-based neural models have achieved great success in natural language inference (NLI). In this paper, we propose the Convolutional Interaction Network (CIN), a general model to capture the interaction between two sentences, which can be an alternative to the attention mechanism for NLI. Specifically, CIN encodes one sentence with the filters dynamically generated based on another sentence. Since the filters may be designed to have various numbers and sizes, CIN can capture more complicated interaction patterns. Experiments on three very large datasets demonstrate CIN's efficacy.

1 Introduction

Natural language inference (NLI) is a pivotal and challenging natural language processing (NLP) task. The goal of NLI is to identify the logical relationship (entailment, neutral, or contradiction) between a premise and a corresponding hypothesis. Generally, NLI is also related to many other NLP tasks under the paradigm of semantic matching of two texts, such as question answering Hu et al. (2014); Wan et al. (2016) and information retrieval Liu et al. (2015), and so on. An essential challenge is to capture the semantic relevance of two sentences. Due to the semantic gap (or lexical chasm) problem, natural language inference is still a challenging problem.

Recently, deep learning is raising a substantial interest in natural language inference and has achieved some great progresses Hu et al. (2014); Parikh et al. (2016); Chen et al. (2017a). To model the complicated semantic relationship between two sentences, previous models heavily utilize various attention mechanism Bahdanau et al. (2014); Vaswani et al. (2017) to build the interaction at different granularity (word, phrase and sentence level), such as ABCNN Yin et al. (2016), Attention LSTM Rocktäschel et al. (2015), bidirectional attention LSTM Chen et al. (2017a), and so on. While attention is very successful in natural language inference, its mechanism is quite simple and can be regarded as a weighted sum of the target vectors. This paradigm results in a lack of flexibility in more complicated interaction model.

In this paper, we propose a new interaction module, called Convolutional Interaction Network (CIN), which can serve as an alternative module of attention mechanism. Specifically, CIN utilizes convolutional neural network to extract the valued features (or representations) from sentences. In the case of NLI, whether a feature of one sentence being important depends on another sentence. Inspired by the idea of using one network to generate the parameters of another network Ha et al. (2016a); De Brabandere et al. (2016), we introduce a filter generation network to dynamically generate convolutional filters. Each sentence is convolved by a dynamically generated filter by another sentence. Thus, the convolved features of one sentence can be regarded as context-aware representations under the influence of another sentence.

The contributions of this paper can be summarized as follows.

1. CIN is a new interaction model, invented as an alternative module to the attention model. CIN can also capture both the intra- or inter-interactions of two sentences.

2. Compared to attention model, CIN is more general and flexible to capture the complicated interaction. As discussed in Section

3.3, the attention model is approximately equivalent to a special case of CIN.

3. We perform extensive empirical studies on three very large datasets. Experiment results demonstrate that our proposed architecture is effective for natural language inference.

2 Attentive Interaction for Natural Language Inference

Currently, the dominative method for natural language inference is to use attention mechanism to model the interaction between two sentence.

Given two input sentences $x = [x_1, x_2, \cdots, x_m]$ and $y = [y_1, y_2, \cdots, y_n]$ with length m and n respectively, we first encode them into two vectorial sequences

$$X = [\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_m] \in \mathbb{R}^{d\times m}, \quad (1)$$

$$Y = [\mathbf{y}_1, \mathbf{y}_2, \cdots, \mathbf{y}_n] \in \mathbb{R}^{d\times n}. \quad (2)$$

The encoder usually consists of one or several CNN/RNN layers to get the context-aware token representations.

To capture the interaction between two sentence, various neural attentions can be used, such as sentence2word attention Rocktäschel et al. (2015), word2word attention Parikh et al. (2016); Chen et al. (2017a).

Word2word Attentive Interaction The word2word attention captures the dependency between two words x_i and y_j from the concerned two sentences respectively. The word2word attention computes a similarity matrix M, in which each element $m_{i,j}$ is the alignment score between $\mathbf{x}_i$ and $\mathbf{y}_j$.

$$m_{i,j} = f(\mathbf{x}_i, \mathbf{y}_j),\ 1 \le i \le m, 1 \le j \le n, \quad (3)$$

where f is a score function.

There are two most prevalent attention functions: multiplicative attention and additive attention. Multiplicative attention is:

$$f(\mathbf{x}_i, \mathbf{y}_j) = \mathbf{x}_i^{\mathrm{T}} \mathbf{y}_j. \quad (4)$$

Additive attention computes a compatibility function by a feed-forward network with a single hidden layer.

$$f(\mathbf{x}_i, \mathbf{y}_j) = \mathbf{w}^{\top} \sigma(\mathbf{W}_1 \mathbf{x}_i + \mathbf{W}_2 \mathbf{y}_j + \mathbf{b}), \quad (5)$$

where $\mathbf{w}$, $\mathbf{W}_1$, $\mathbf{W}_2$ and $\mathbf{b}$ are learnable parameters.

While these two kinds of attentions have similar performance, the multiplicative attention is more popular in practice since it requires less computation power and have less memory demand with optimized matrix multiplication. With multiplicative attention, we can compute the *mimic* representations for both X and Y.

$$\bar{X} = Y \mathrm{softmax}(Y^{\mathrm{T}} X) \in \mathbb{R}^{d\times m}, \quad (6)$$

$$\bar{Y} = X \mathrm{softmax}(X^{\mathrm{T}} Y) \in \mathbb{R}^{d\times n}, \quad (7)$$

where $\mathrm{softmax}(\cdot)$ is column-wise normalization function. Each vector $\bar{\mathbf{x}}_i \in \bar{X}$ is called as *mimic vector*, which is a weighted summation of $\{\mathbf{y}_j\}_{j=1}^{n}$. Intuitively, the mimic vector $\bar{\mathbf{x}}_i$ provides the related information of token x_i extracted from sentence Y.

Prediction After interaction, a prediction module is used to aggregate the interaction information and extract the fix-length representation of two sentences. Finally, the final sentence representations are fed into a feed-forward network to predict the relationship between two sentences.

3 Convolutional Interaction Network

In this section, we propose a new interaction method by utilizing dynamic convolutional filters, called Convolutional Interaction Network (CIN). CIN can serve as an alternative module of attention mechanism.

We first briefly introduce how the convolution works over text sequence, then describe the proposed model and its connection to attention model.

3.1 Convolution over Sequence

Convolution is an effective operation in deep neural networks, which convolves the input with a set of filters to extract non-linear compositional features. Although originally designed for computer vision, convolutional models have subsequently shown to be effective for NLP and have achieved excellent performance in sentence modeling Kim (2014); Kalchbrenner et al. (2014), and other traditional NLP tasks Hu et al. (2014); Zeng et al. (2014); Gehring et al. (2017).

Given a sentence representation $X = [\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_m] \in \mathbb{R}^{d\times m}$, a convolutional filter $W^{(f)} \in \mathbb{R}^{d\times kd}$, the convolution process is defined as

$$\mathbf{x}'_i = f\left(W^{(f)}[\mathbf{x}_{i-[k/2]}, \cdots, \mathbf{x}_{i+[k/2]}] + \mathbf{b}^{(f)}\right), \quad (8)$$

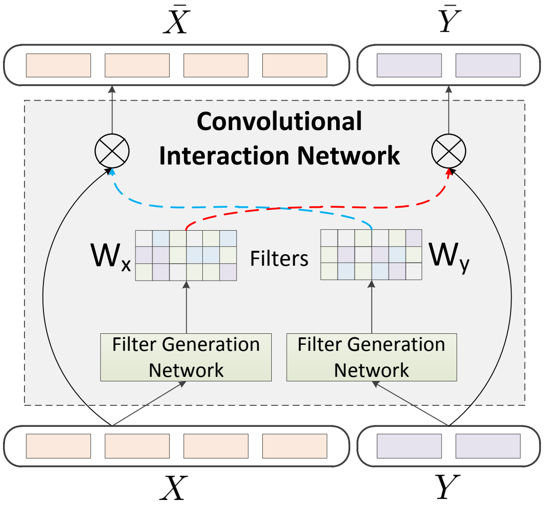

Figure 1: Convolutional Interaction Network. $\otimes$ denotes the convolution operation.

where $f(\cdot)$ is a non-linear activation function, such as ReLU, k indicates the size of convolution window, and $\mathbf{b}^{(f)} \in \mathbb{R}^d$ is a bias vector.

The convolution can be abbreviated as

$$X' = f(W^{(f)} \otimes X) \in \mathbb{R}^{d \times m}, \tag{9}$$

where $\otimes$ denotes the convolutional operation. To ensure the output of convolution has equal length as to the input, we pad $\lfloor \frac{k}{2} \rfloor$ zero vectors on both sides of the input.

3.2 Convolutional Interaction Network

Convolution is very effective when it comes to extracting useful features from a sentence. But for NLI, whether a word (or feature) being important in one sentence depends on another sentence. Therefore, a better convolution operation should have the ability to extract substantial features from one sentence according to another sentence. Thus, the convolutional filter should be dynamically changeable. Inspired by Jia et al. (2016); Ha et al. (2016b), we propose a *filter generation network* (FGN) to generate a dynamical filter, which is used to extract the context-aware information.

Given two sentences x, y, and their representations $X = [\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_m] \in \mathbb{R}^{d \times m}$ and $Y = [\mathbf{y}_1, \mathbf{y}_2, \cdots, \mathbf{y}_n] \in \mathbb{R}^{d \times n}$, the filter for each sentence is generated according to the other sentence by

$$W_x^{(f)} = \text{FGN}(X) \in \mathbb{R}^{d \times \tau d}, \tag{10}$$
$$W_y^{(f)} = \text{FGN}(Y) \in \mathbb{R}^{d \times \tau d}, \tag{11}$$

where τ is the width of filter, $\text{FGN}(\cdot)$ is the filter generation network. A detailed implementation of FGN is presented in Section 3.4.

Now we can convolve the two sentences with the generated filters.

$$\bar{X} = f(W_y^{(f)} \otimes X) \in \mathbb{R}^{d \times m}, \tag{12}$$
$$\bar{Y} = f(W_x^{(f)} \otimes Y) \in \mathbb{R}^{d \times n}, \tag{13}$$

where the attained matrix $\bar{X}$ and $\bar{Y}$ can be regarded as the context-aware representation of sentences x and y, depending on each other.

Figure 1 gives an illustration of CIN.

3.3 Connection to Attentive Interaction

CIN is more general than attention model. Assuming that we set $k = 1$ and FGN to be a function of $\text{FGN}(X) = XX^{\mathrm{T}}$, Eq. (12) and (13) of CIN can be written as

$$\bar{X} = (YY^{\mathrm{T}})X = Y(Y^{\mathrm{T}}X), \tag{14}$$
$$\bar{Y} = (XX^{\mathrm{T}})Y = X(X^{\mathrm{T}}Y). \tag{15}$$

Compared to Eq. (6) and (7), under the above assumption, CIN is equivalent to the word2word multiplicative attention model without softmax normalization.

3.4 An Implementation of Filter Generation Network (FGN)

To generate the dynamic filters, the key factor is how to choose the filter generation network $\text{FGN}(\cdot)$ in Eq. (10) and (11). Although many sophisticated networks can be employed, we give an simple implementation in this paper.

For ease of presentation, we only describe how we generate dynamical filter according to sentence x. The same procedure is utilized for sentence y.

Firstly, we summarize the information of sentence x with an over-time k-max pooling on X,

$$U_x = \text{ReLU}(W_u \otimes X) \in \mathbb{R}^{d \times m}, \tag{16}$$
$$\mathbf{z}_x^{1:k} = \text{k-max}(U_x) \in \mathbb{R}^{d \times k}, \tag{17}$$

where U_x is a non-linear transformation of X by convolution filter $W_u \in \mathbb{R}^{d \times d}$. The idea of k-max pooling is to capture the most important features (the k highest values) from sentence X.

Then we generate k filters W_x^j for $j = 1, \cdots, k$ by

$$W_x^j = \text{ReLU}\left(P\text{diag}(\mathbf{z}_x^j)Q + B\right), \tag{18}$$

where $P \in \mathbb{R}^{\frac{d}{k} \times d}$, $Q \in \mathbb{R}^{d \times \tau d}$ and $B \in \mathbb{R}^{\frac{d}{k} \times \tau d}$ are learnable parameters.

The final filter is obtained by concatenating the k generated filters,

$$W_x^{(f)} = [W_x^1; W_x^2; \cdots; W_x^k] \in \mathbb{R}^{d \times \tau d}. \tag{19}$$

Similar to x, we can also obtain the dynamic filters $W_y^{(f)}$ according to the sentence y.

4 Incorporating CIN into a Deep Network Architecture for NLI

Our overall network architecture for NLI is based on a successful model proposed by Chen et al. (2017a). The major difference is that we use CIN to capture the interaction, instead of bi-directional attention.

The network architecture consists of three components: (1) an encoding layer; (2) convolutional interaction layers; (3) a prediction layer. Figure 2 gives an illustration.

4.1 Encoding Layer

The input of natural language inference task is a pair of sentences x and y. Since each word in a sentence is a symbol that can not be directly processed by neural networks, we need first map each word to a d dimensional embedding vector.

Thus, the two sentences are mapped to two matrix $E_x \in \mathbb{R}^{d_e \times m}$ and $E_y \in \mathbb{R}^{d_e \times n}$ respectively. We also use syntactical and lexical information such as part of speech tagging information, exact match feature and character representation. In this paper, exact match value of each word is set to 1(default to be 0) if the word concerned share the same stem or lemma with any word in counterpart sentence. Character representation of the word is obtained using a convolution neural network followed by a max pooling along sequence length dimension as same as Kim (2014). The final representation of word is a concatenation of word embedding, character encoded vector, POS tagging embedding and exact match feature. Both character embedding and POS tagging embedding are randomly initialized. All embeddings are updated during training.

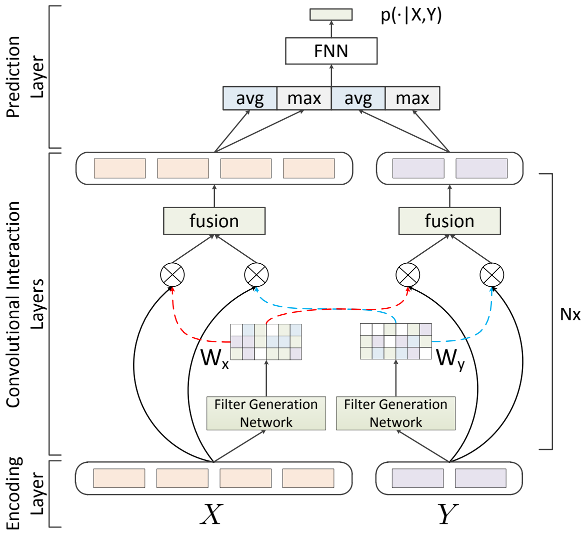

Figure 2: The overall network architecture for natural language inference. The N_x means the number of the stacking interaction layers.

We use bi-directional LSTM (BiLSTM) Hochreiter and Schmidhuber (1997) to incorporate the forward and backward context information of sequence. Thus, we can get the phrase-level encoding of two input sentences,

$$X = [\text{Bi-LSTM}(E_x); E_x], \tag{20}$$
$$Y = [\text{Bi-LSTM}(E_y); E_y], \tag{21}$$

where $X \in \mathbb{R}^{d \times m}$ and $Y \in \mathbb{R}^{d \times n}$ are the phrase-level encoding representation of sentence x and y respectively.

4.2 Convolutional Interaction Layers

In the interaction layers, we use our proposed CIN to model the interaction between two sentences.

We first dynamically generate context-aware filters $W_x^{(f)}$ and $W_y^{(f)}$ based on the sentence encodings X and Y respectively, which are further used for both intra-sentence and inter-sentence interaction.

Intra-Sentence Interaction The intra-sentence convolutional interaction is to convolve one sentence by the filter generated by itself.

$$X_{intra} = f(W_x^{(f)} \otimes X), \tag{22}$$
$$Y_{intra} = f(W_y^{(f)} \otimes Y), \tag{23}$$

The role of the intra-sentence convolutional interaction is the same as self-attention Shen et al. (2017), which is also very useful in NLI.

Inter-Sentence Interaction The inter-sentence interaction takes filters generated from the counterpart sentence to convolve the inputs.

$$X_{inter} = f(W_x^{(f)} \otimes Y), \tag{24}$$

$$Y_{inter} = f(W_y^{(f)} \otimes X), \tag{25}$$

The inter-sentence convolutional interaction plays a role similar to the cross-attention between two sentences.

Fusion Layer After CIN, we can fuse two kinds of context-aware representations of each sentence. For sentence x, the X_{intra} and X_{inter} represent the extracted features under consideration of information of itself and sentence y respectively.

To efficiently utilize X_{intra} and X_{inter}, a fusion layer is used. We use the comparing operation proposed in Chen et al. (2017a) to fuse the two kinds of representation. Let $\mathbf{u}_i$ and $\mathbf{v}_i$ be intra and inter attentive vector of the i-th word in sentence x, a heuristic and effective composition operator is used to combine two vectors.

$$\bar{\mathbf{x}}_i^{(c)} = [\mathbf{u}_i; \mathbf{v}_i; \mathbf{u}_i - \mathbf{v}_i; \mathbf{u}_i \odot \mathbf{v}_i; |\mathbf{u}_i - \mathbf{v}_i|], \tag{26}$$

$$\mathbf{x}_i^{(c)} = \mathrm{ReLU}(\mathbf{W}_c \bar{\mathbf{x}}_i^c + \mathbf{W}_x \mathbf{x}_i + \mathbf{b}_c), \tag{27}$$

Thus, we can obtain two fused representations $X^{(c)}$ and $Y^{(c)}$ for two sentences, which are further fed into the prediction layer or another stacked interaction layer. The interaction layers can be stacked for N_x times to capture the complicated matching information.

4.3 Prediction Layer

After interaction layers, an aggregation layer is employed to aggregate the two sequences of fustion vectors $X^{(c)}$ and $Y^{(c)}$ into a fixed-length matching vectors. The aggregation component usually consists of another BiLSTM layer and a following pooling layer. We then perform max pooling over time for both $X^{(c)}$ and $Y^{(c)}$ to get two fix representation vector for two sentences, $\mathbf{p}$ and $\mathbf{h}$:

$$\mathbf{p} = \max(X^{(c)}), \tag{28}$$

$$\mathbf{h} = \max(Y^{(c)}), \tag{29}$$

where the functions max is the max pooling operations over time steps.

Finally, the pooled vectors are composed as one relation vector and fed into a feed-forward network to predict the relationship between two sentences. Specially, the two-layer feed-forward network has one hidden layers with *tanh* activation and *softmax* output layer in our experiments.

	Train	Dev	Test	Len(P)	Len(H)	Vocab
SNLI	549K	9.8K	9.8K	14	8	36K
MultiNLI[1]	392K	9.8K	9.8K	22	11	85K
MultiNLI[2]	392K	9.8K	9.8K	22	11	85K
Quora	384K	10K	10K	12	12	107K

Table 1: Statistics of three datasets: SNLI, MultiNLI, Quora. Len(P) and Len(H) refer to the average length of two sentences. MultiNLI[1] and MultiNLI[2] indicate the in-domain and cross-domain datasets.

$$\mathbf{m} = [\mathbf{p}; \mathbf{h}; \mathbf{p} - \mathbf{h}; \mathbf{p} * \mathbf{h}; |\mathbf{p} - \mathbf{h}|], \tag{30}$$

$$p(\cdot|x, y) = \mathrm{FNN}(\mathbf{m}). \tag{31}$$

5 Training

Given a trainset $\{x^{(i)}, y^{(i)}, t^{(i)}\}_{i=1}^N$, the objective is to minimize a cross entropy loss $\mathcal{J}(\theta)$:

$$\mathcal{J}(\theta) = -\frac{1}{N}\sum_i \log p(t^{(i)}|x^{(i)}, y^{(i)}) + \lambda||\theta||_2^2, \tag{32}$$

where θ represents all the connection weights.

We use the Adam optimizer Kingma and Ba (2014) with an initial learning rate of 0.0004. Default L2 regularization λ is set to 10^{-6}. To avoid overfitting, dropout is applied after each fully connected, recurrent or convolutional layer.

Initialization We take advantage of pre-trained word embeddings such as Glove Pennington et al. (2014) to transfer more knowledge from vast unlabeled data. For the words that don't appear in Glove, we randomly initialize their embeddings from a normal distribution with mean 0.0 and standard deviation 0.1.

The network weights are initialized with Xavier normalization Glorot and Bengio (2010) to maintain the variance of activations throughout the forward and backward passes. Biases are uniformly set to zero when the network is constructed.

5.1 Datasets

To make quantitative evaluation, our model was evaluated on three well known datasets: Stanford Natural Language Inference dataset (SNLI), MultiNLI dataset and Quora Question pair dataset (Quora). Detailed statistical information of these datasets is shown in Table 1.

Models	**Train**	**Test**
Handcrafted features (Bowman et al., 2015)	99.7	78.2
LSTM with attention (Rocktäschel et al., 2015)	85.3	83.5
Match-LSTM (Wang and Jiang, 2016)	92.0	86.1
Decomposable attention model (Parikh et al., 2016)	90.5	86.8
BiMPM (Zhiguo Wang, 2017)	90.9	87.5
NTI-SLSTM-LSTM (Munkhdalai and Yu, 2017)	88.5	87.3
Re-read LSTM (Sha et al., 2016)	90.7	87.5
DIIN (Gong et al., 2017)	91.2	88.0
ESIM (Chen et al., 2017a)	92.6	88.0
CIN	**93.2**	**88.0**
ESIM (Chen et al., 2017a) (Ensemble)	93.5	88.6
BiMPM (Zhiguo Wang, 2017) (Ensemble)	93.2	88.8
DIIN (Gong et al., 2017) (Ensemble)	92.3	88.9
CIN (Ensemble)	**94.3**	**89.1**

Table 2: Performance on SNLI dataset.

SNLI The SNLI corpus Bowman et al. (2015) consists of 570,152 sentence pairs. Each sentence pair is labeled as one of entailment, contradiction and neutral relation.

MultiNLI Orgnized the same as SNLI, MultiNLI corpus Williams et al. (2017) is another dataset for NLI, it contains 433,000 sentence pairs. Like SNLI, each pair is labeled with one of entailment, contradiction and neutral label. Difference between MultiNLI and SNLI is that, MultiNLI have in-domain test set and development set as well as an out-of-domain test and development set.

Quora The Quora Question pair dataset have over 400k question pairs, each question pair is assigned with a binary label to indicate if the pair are paraphrase to each other. We evaluate our model on the data which was previously partitioned by Zhiguo Wang (2017)

5.2 Overall Results

We use the accuracy to evaluate the performance of our convolutional interaction network (CIN) and other models on SNLI, MultiNLI and Quora.

SNLI Table 2 shows the results of different models on the train set and test set of SNLI. The first row gives a baseline model with handcrafted features presented by Bowman et al. (2015). All the other models are attention-based neural networks. Wang and Jiang (2016) exploits the long short-term memory (LSTM) for NLI. Parikh et al. (2016) uses attention to decompose the problem into subproblems that can be solved separately. Chen et al. (2017a) incorporates the chain LSTM and tree LSTM jointly. Zhiguo Wang (2017) proposes a bilateral multi-perspective matching for NLI.

In Table 2, the second block gives the single models. As we can see, our proposed model CIN achieves 88.0% in accuracy on SNLI test set. Compared to the previous work, CIN obtains competitive performance.

To further improve the performance of NLI systems, researchers have built ensemble models. Ensemble systems obtained the best performance on SNLI. Our ensemble model obtains 89.1% in accuracy and outperforms the current state-of-the-art model.

Overall, single model of CIN performs competitively well and outperforms the previous models on ensemble scenarios for the natural language inference task.

MultiNLI Table 3 shows the performance of different models on MultiNLI. The original aim of this dataset is to evaluate the quality of sentence representations. Recently this dataset is also used to evaluate the interaction model involving attention mechanism.

The first line of Table 3 gives a baseline model without interaction. The second block of Table 3 gives the attention-based models. The proposed

Models	Match	Mismatch
BiLSTM (Williams et al., 2017)	67.0	67.6
InnerAtt (Balazs et al., 2017)	72.1	72.1
ESIM (Chen et al., 2017a)	72.3	72.1
Gated-Att BiLSTM (Chen et al., 2017b)	73.2	73.6
ESIM (Chen et al., 2017a)	76.3	75.8
CIN	**77.0**	**77.6**

Table 3: Performance on MultiNLI test set.

Models	Test
Siamese-CNN	79.60
Multi-Perspective CNN	81.38
Siamese-LSTM	82.58
Multi-Perspective-LSTM	83.21
L.D.C	85.55
BiMPM (Zhiguo Wang, 2017)	88.17
CIN	**88.62**

Table 4: Performance on Quora question pair dataset.

model, CIN, achieves the accuracies of 77.0% and 77.6% on the *match* and *mismatch* test sets respectively. The results show that our model outperforms the other models.

Quora Table 4 shows the performance of different models on the Quora test set. The baselines on Table 4 are all implemented in Zhiguo Wang (2017). The Siamese-CNN model and Siamese-LSTM model encode sentences with CNN and LSTM respectively, and then predict the relationship between them based on the cosine similarity. Multi-Perspective-CNN and Multi-Perspective-LSTM are transformed from Siamese-CNN and Siamese-LSTM respectively by replacing the cosine similarity calculation layer with their multi-perspective cosine matching function. The L.D.C is a general compare-aggregate framework that performs word-level matching followed by a aggregation of convolution neural networks. As we can see, our model outperforms the baselines and achieve 88.62% in the test sets of Quora corpus.

Models	Dev	Test
CIN	**88.6**	**88.0**
Remove whole interaction	85.6	85.1
Remove intra-attention	88.1	87.7

Table 5: Ablation experiment on SNLI dataset.

Premise
(1) A girl playing a violin along with a group of people
(2) A girl playing a violin along with a group of people

Hypothesis
(1) A girl is playing an instrument .
(2) A girl is playing an instrument .

Table 6: Gradient visualization of premise and hypothesis. (1) Gradient scale of X, Y on encoding layer. (2) Gradient scale of $X^{(c)}$, $Y^{(c)}$ on first CIN layer. Darker color corresponds to a higher scale of gradient, and implies a higher contribution to the final prediction.

5.3 Model Ablation

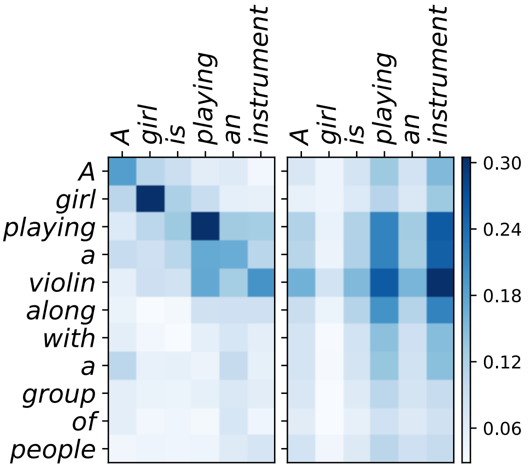
To better understand the performance of our model, we analyze the effect of each key component of the proposed model. As illustrated in Table 5, the first row is the full CIN model. By dropping convolutional interaction layers, the performance decreases to 85.1% on the test set, which indicate the interaction information is crucial for NLI. By just dropping intra-attention layer, the performance decreases to 87.7% on the test set. According to the results, all of the components positively contribute to the final performance.

5.4 Case Study

To give an intuitive understanding of how our model works, we give an analysis on the following case from the test set.

Premise: A girl playing a violin along with a group of people.
Hypothesis: A girl is playing an instrument.
Label: Entailment.

The visualization results are produced from model with two stacked CINs. X, Y is the hidden states at encoding layer, and $X^{(c)}$, $Y^{(c)}$ is the hidden states at first CIN layer. For a hidden state



(a) (b)

Figure 3: A visualization of word to word correlation. Darker color correspond to a higher correlation. (a) Correlation of $X^{\mathrm{T}}Y$ at encoder layer. (b) Correlation of ${X^{(c)}}^{\mathrm{T}}Y^{(c)}$ at first CIN layer.

$\mathbf{x}_i$ of word x_i, we can calculate its gradient scale $||\frac{\partial \mathcal{J}}{\partial \mathbf{x}_i}||^2$ to show its contribution to final prediction.

Table 6 shows the gradient scales of hidden states of each word in the encoding layer and the first CIN layer. As we can see, some phrases (like *playing a violin* and *playing an instrument*) instead of isolated words (like *violin* and *instrument*) become more focused after a CIN layer. It implies CIN could capture some higher level patterns.

Figure 3 gives a visualization of correlations of hidden states of two sentences. (a) shows the correlations after the encoding layer, the same words are most correlated. This is because embedding layer and encoding layer are shared between premise and hypothesis. (b) shows the correlations after the first CIN layer, the correlation exists between phrases $\{$*playing a violin* vs. *playing an instrument*$\}$, instead of the same words. The interaction layer connects *playing* in Premise to Hypothesis *instrument*, and connects *playing* in Hypothesis to Premise *violin*. Thus, the correlation between *instrument* in Hypothesis and *violin* in Premise are boosted, as we know these are important to reasoning.

6 Related Work

There are mainly two threads of work related to ours.

One thread of work is using attention-based model for natural language inference (NLI). NLI has been widely investigated for many years. Benefiting from the development of deep learning and the availability of large-scale annotated datasets, deep neural models have achieved great success. Rocktäschel et al. (2015) firstly use LSTM with attention for text matching task. Wang and Jiang (2016) use word-by-word attention to exploit the word-level match. Parikh et al. (2016) propose a new framework to model the relationship between two sentences using interact-compare-aggregate architecture. Chen et al. (2017a) incorporates the chain LSTM and tree LSTM jointly. Zhiguo Wang (2017) use self-attention mechanism to capture contextual information from the whole sentence.

Unlike the above models, we use an alternative model to capture the complicate interaction information of two sentences.

Another thread of work is the idea of using one network to generate the parameters of another network. De Brabandere et al. (2016) proposed the dynamic filter network to implicitly learn a variety of filtering operations. Ha et al. (2016a) proposed the model hypernetwork, which uses a small network to generate the weights for a larger network.

Unlike these models, our dynamical filter is employed for interaction. Therefore, a filter generation function is proposed to capture the related intra and inter dependent information of a sentence pair.

7 Conclusion

In this paper, we propose an alternative interaction model, Convolutional Interaction Network (CIN), for natural language inference. CIN utilizes the dynamic convolutional filters to model the interaction between two sentences. Specifically, each sentence is convolved by dynamical filters generated based on another sentence. CIN is more general and flexible since the filters may have various numbers and sizes, thereby capturing more complicated interaction patterns. Experiments on three very large datasets demonstrate the efficacy of our proposed model.

In future work, we hope to improve the extensibility of CIN and apply it to other NLP tasks, such as machine comprehension.

Abstract

State of the art models using deep neural networks have become very good in learning an accurate mapping from inputs to outputs. However, they still lack generalization capabilities in conditions that differ from the ones encountered during training. This is even more challenging in specialized, and knowledge intensive domains, where training data is limited. To address this gap, we introduce MedNLI[1] – a dataset annotated by doctors, performing a natural language inference task (NLI), grounded in the medical history of patients. We present strategies to: 1) leverage transfer learning using datasets from the open domain, (e.g. SNLI) and 2) incorporate domain knowledge from external data and lexical sources (e.g. medical terminologies). Our results demonstrate performance gains using both strategies.

1 Introduction

Natural language inference (NLI) is the task of determining whether a given *hypothesis* can be inferred from a given *premise*. This task, formerly known as recognizing textual entailment (RTE) (Dagan et al., 2006) has long been a popular task among researchers. Moreover, contribution of datasets from past shared tasks (Dagan et al., 2009), and recent research (Bowman et al., 2015; Williams et al., 2018) have pushed the boundaries for this seemingly simple, but challenging problem.

The Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015) is a large, high quality dataset and serves as a benchmark to evaluate NLI systems. However, it is restricted to a single text genre (Flickr image captions) and mostly consists of short and simple sentences. The MultiNLI corpus (Williams et al., 2018) which introduced NLI corpora from multiple genres (e.g. fiction, travel) was a welcome step towards addressing these limitations. MultiNLI offers diversity in linguistic phenomena, which makes it more challenging.

Following these efforts, we explore the problem of NLI in the clinical domain. Language inference in specialized domains such as medicine is extremely complex and remains unexplored by the machine learning community. Moreover, since this domain has a distinct sublanguage (Friedman et al., 2002), clinical text also presents unique challenges (abbreviations, inconsistent punctuation, misspellings, etc.) that differentiate it from open-domain data (Meystre et al., 2008).

In this paper, we address these gaps and make the following contributions:

- Introduce MedNLI - a new, publicly available, expert annotated dataset for NLI in the clinical domain.
- A systematic comparison of several state-of-the-art open domain models on MedNLI.
- A study of transfer learning techniques from the open domain to the clinical domain.
- Techniques for incorporating domain-specific knowledge from knowledge bases (KB) and domain specific data into neural networks.

2 The MedNLI dataset

Let us recall the procedure followed for creating the SNLI dataset: annotators were presented with captions for a Flickr photo (the *premise*) without the photos themselves. They were asked to write three sentences (*hypotheses*): 1) A clearly true description of the photo, 2) A clearly false description, and 3) A description that might be true or false. This procedure produces three training pairs

Brussels, Belgium, October 31 - November 4, 2018.

#	Premise	Hypothesis	Label
1	ALT , AST , and lactate were elevated as noted above	patient has abnormal lfts	entailment
2	Chest x-ray showed mild congestive heart failure	The patient complains of cough	neutral
3	During hospitalization , patient became progressively more dyspnic requiring BiPAP and then a NRB	The patient is on room air	contradiction
4	She was not able to speak , but appeared to comprehend well	Patient had aphasia	entailment
5	T1DM : x 7yrs , h/o DKA x 6 attributed to poor medication compliance , last A1c [** 3-23 **] : 13.3 % 2	The patient maintains strict glucose control	contradiction
6	Had an ultimately negative esophagogastroduodenoscopy and colonoscopy	Patient has no pain	neutral
7	Aorta is mildly tortuous and calcified .	the aorta is normal	contradiction

Table 1: Examples from the development set of MedNLI

of sentences for each premise with three different labels: entailment, contradiction, and neutral, respectively. In order to produce a comparable dataset, we used the same approach adjusted for the clinical domain.

2.1 Premise sampling and hypothesis generation

As the source of *premise* sentences, we used the MIMIC-III v1.3 (Johnson et al., 2016) database. With de-identified records of 38,597 patients, it is the largest repository of publicly available clinical data. Along with medications, lab values, vital signs, etc. MIMIC-III contains 2,078,705 clinical notes written by healthcare professionals in English. The *hypothesis* sentences were generated by clinicians.

Clinical notes are typically organized into sections such as `Chief Complaint`, `Past Medical History`, `Physical Exam`, `Impression`, etc. These sections can be easily identified since the formatting for associated section headers often resembles capital letters, followed by a colon. The clinicians in our team suggested `Past Medical History` to be the most informative section of a clinical note, from which critical inferences can be drawn about the patient.

Therefore, we segmented these notes into sections using a simple rule based program capturing the formatting of these section headers. We extracted the `Past Medical History` section and used a sentence splitter trained on biomedical articles (Lingpipe, 2008) to get a pool of candidate *premises*. We then randomly sampled a subset from these candidates and presented them to the clinicians for annotation. Figure 1 shows the exact prompt shown to the clinicians for the annotation task. SNLI annotations are grounded since they are associated with captions of the same image. We seek to achieve the same goal by grounding the annotations against the medical history of the same patient.

> You will be shown a sentence from the `Past Medical History` section of a de-identified clinical note. Using only this sentence, your knowledge about the field of medicine, and common sense:
>
> - Write one alternate sentence that is **definitely** a **true** description of the patient. Example, for the sentence “Patient has type II diabetes” you could write “Patient suffers from a chronic condition“
> - Write one alternate sentence that **might be** a **true** description of the patient. Example, for the sentence “Patient has type II diabetes” you could write “Patient has hypertension”
> - Write one sentence that is **definitely** a **false** description of the patient. Example, for the sentence “Patient has type II diabetes” you could write “The patient’s insulin levels are normal without any medications.”

Figure 1: Annotation prompt shown to clinicians

As discussed earlier, examples shown in Table 1 depict unique challenges that involve reasoning over domain-specific knowledge. For instance, the first three examples require the knowledge about clinical terminology. The fourth example requires awareness of medications and the last example elicits knowledge about radiology images. We make the MedNLI dataset available[2] through the

---

[2] https://jgc128.github.io/mednli/

MIMIC-III derived data repository. Thus, any individual certified to access MIMIC-III can also access MedNLI.

2.2 Annotation collection

Conclusions in the clinical domain are known to be context dependent and a source of multiple uncertainties (Han et al., 2011). We had to ensure that such subjective interpretations do not result in annotation conflicts affecting the quality of the dataset. To ensure agreement, we worked with clinicians and generated annotation guidelines for a pilot study. Two board certified radiologists worked on the annotation task, and were presented with the 100 unique premises each.

Some premises, often marred by de-identification artifacts, did not contain any information from which useful inferences could be drawn, e.g. `This was at the end of [**Month (only) 1702**] of this year.` Such sentences were deemed as invalid for the task and discarded based on clinician judgment. The MIMIC-III dataset contains many de-identification artifacts associated with dates and names (persons and places) which also makes MedNLI more challenging.

After discarding 16 premises, the result of hypothesis generation was a set of 552 pairs. To calculate agreement, we presented pairs generated by one clinician, and sought annotations from the other clinician, determining if the inference was "Definitely true", "Maybe true", or "Definitely false" (Bowman et al., 2015). Comparison of these annotations resulted in a Cohen's kappa of $\kappa = 0.78$. While this is substantial if not perfect agreement by itself (McHugh, 2012), it is particularly good given the challenging nature of NLI and the complexity of the domain.[3]

On reviewing the annotations, we found that labeling differences between "Definitely true" and "Maybe true" were the major source of disagreement. This was primarily because one clinician would think of a scenario that is generally true, while the other would think of assumptions (e.g. patient might be lying, or patient might be pregnant) when it would not.

A discussion with clinicians concluded that the annotation guideline was clear and any person with a formal background of medicine should be able to complete the task successfully. To generate the final dataset, we recruited two additional clinicians, both board certified medical students pursuing their residency programs. Unlike SNLI, we did not collect multiple annotations per sentence pair because of the time and funding constraints.

2.3 Dataset statistics

Together, the four clinicians worked on a total of 4,683 premises over a period of six weeks. The resulting dataset consists of 14,049 unique sentence pairs. Following Bowman et al. (2015), we split the dataset into training, development, and testing subsets and ensured that no premise was overlapping between the three subsets. Table 2 presents key statistics of MedNLI.

Dataset size	
Training pairs	11232
Development pairs	1395
Test pairs	1422
Average sentence length in tokens	
Premise	20.0
Hypothesis	5.8
Maximum sentence length in tokens	
Premise	202
Hypothesis	20

Table 2: Key statistics of the dataset

3 Models

To establish a baseline performance on MedNLI, we experimented with a feature-based system. To further explore the performance of modern neural networks-based systems, we experimented several models of various degrees of complexity: Bag of Words (BOW), InferSent (Conneau et al., 2017) and ESIM (Chen et al., 2017). Note that our goal here is not to outperform existing models, but to explore the relative gain of the proposed methods, and compare them to a baseline. We used the same set of hyperparameters in all models to ensure that any difference in performance is exclusively due to the algorithms.

Feature-based system We used a gradient boosting classifier incorporating a variety of hand crafted features. Apart from standard NLP features, we also infused clinical knowledge from the Unified Medical Language System (UMLS) (Bodenreider, 2004). Each terminology in the UMLS can be viewed as a graph where nodes represent medical concepts, and edges represent relations

---

[3] Rajpurkar et al. (2017) report F1 < 0.45 for four radiologists when compared among themselves

between them. These are canonical relationships found in ontologies such as *IS A* and *SYNONYMY*. For instance, *diabetes IS A disorder of the endocrine system*. The domain specific features we added to the model represent similarity between UMLS concepts from the premise and the hypothesis, based how close they appear in the UMLS graph (Pedersen et al., 2007). Following (Shivade et al., 2015; Pedersen et al., 2007) we used the SNOMED-CT terminology in our experiments.

The groups below summarize the feature sets used in our model (35 features in total):

1. BLEU score
2. Number of tokens (e.g. min, max, difference)
3. Negations (e.g. keywords such as *no, do not*)
4. TF-IDF similarity (e.g. cosine, euclidean)
5. Edit distances (e.g. Levenshtein)
6. Embedding similarity (e.g. cosine, euclidean)
7. UMLS similarity features (e.g. shortest path distance between UMLS concepts)

Bag of words We use a bag-of-words (BOW) model as a simple baseline for the NLI task: the *Sum of words* model by Bowman et al. (2015) with a small modification. While Bowman et al. (2015) use $tanh$ as the activation function in the model, we use ReLU, since it trained faster and achieved better results (Glorot et al., 2011). In order to represent an input sentence as a single vector, this architecture simply sums up the vectors of individual tokens. The premise and hypothesis vectors are then concatenated and passed through a multi-layer neural network. Recent work shows that even this straightforward approach encodes a non-trivial amount of information about the sentence (Adi et al., 2017).

InferSent InferSent (Conneau et al., 2017) is a model for sentence representation that demonstrated close to state-of-the-art performance across a number of tasks in NLP (including NLI) and computer vision. The main differences from the BOW model are as follows:

- A bidirectional LSTM encoder of input sentences and a max-pooling operation over timesteps are used to get a vector for the premise (p) and for the hypothesis (h);
- A more complex scheme of interaction between the vectors p and h to get a single vector z that contains all the information needed to produce a decision about the relationship between the input sentences: $z = [p, h, |p - h|, p * h]$.

ESIM The ESIM model, developed by Chen et al. (2017), is shown in Figure 2. It is a fairly complex model that makes use of two bidirectional LSTM networks. The basic idea of ESIM is as follows:

- The first LSTM produces a sequence of hidden states.
- Pairwise attention matrix e is computed between all tokens in the premise and the hypothesis to produce new sequences of "attended" hidden states, which are then fed into the second LSTM.
- Max and average pooling are performed over the output of the LSTMs.
- The output of the pooling operations is combined in a way similar to the InferSent model.

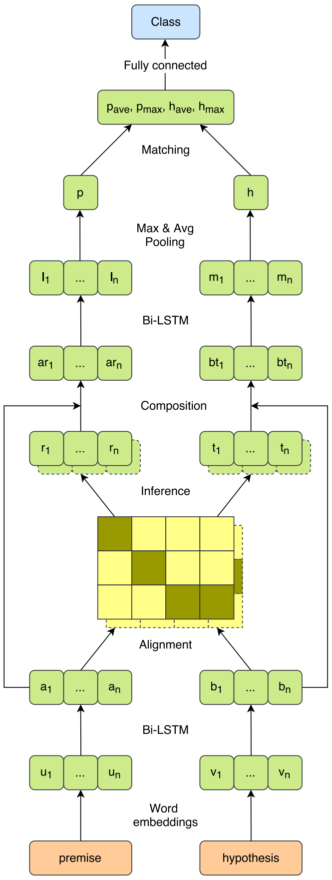

Figure 2: ESIM model. Dashed blocks illustrate the knowledge-directed attention matrix and the corresponding vectors (see Section 4.2.2 for details).

The three aforementioned models exemplify the architectures that are, perhaps, the most widely used for NLI task, spanning from simple bag-of-words approaches to complicated models with Bi-LSTM and inter-sentence attention. We additionally experimented with a plain Bi-LSTM model as well as GRU (Cho et al., 2014), but since their performance was not remarkable (in the same range as BOW) we do not report it here.

4 Transfer learning

Given the existence of larger general-domain NLI datasets such as SNLI and MultiNLI, it stands to reason to try to leverage them to improve the performance in the clinical domain. Transfer learning has been shown to improve performance on variety of tasks such as: machine translation on low-resource languages (Zoph et al., 2016) and also some tasks from the bio-medical domain in particular (Sahu and Anand, 2017; Lee et al., 2018). To see if a corresponding boost would be possible for the NLI task, we investigated three common transfer learning techniques on the MedNLI dataset using SNLI and five different genres from MultiNLI.

Direct transfer is the simplest method of transfer learning. After training a model on a large *source domain* dataset, the model is directly tested on the *target domain* dataset. If the source and the target domains are similar to some extent, one can achieve a reasonable accuracy by simply applying a model pre-trained on the source domain to the target domain. In our case the source domain is general domain in SNLI and the various genres in MultiNLI, and the target domain is clinical.

Sequential transfer is the most widely used technique. After pre-training the model on a large source domain, the model is further fine-tuned using the smaller training data of the target domain. The assumption is that while the model would learn domain-specific features, it would also learn some domain-independent features that will be useful for the target domain. Furthermore, the fine-tuning process would affect the learned features from the source domain and make them more suitable for the target domain.

Multi-target transfer is a more complex method involving separation of the model into three components (or layers):

- *The shared component* is trained on both the source and target domains;
- *The source domain component* is trained only during the pre-training phase and does not participate in the prediction of the target domain;
- *The target domain component* is trained during the fine-tuning stage and it produces the predictions together with the shared component.

The motivation for multi-target transfer is that performance should be improved by splitting deeper layers of the model into domain-specific parts and having a shared block early in the network, where it presumably learns domain-independent features.

4.1 Word embeddings

Another way to improve the accuracy on the target domain is to use domain-specific word embeddings instead of, or, in addition to, open-domain ones. For example, Stanovsky et al. (2017) achieved state of the art results on the task of recognizing Adverse Drug Reaction using graph-based embeddings trained on the “Drugs” and “Diseases” categories from DBpedia (Lehmann et al., 2015), as well as embeddings trained on web-pages categorized as “medical domain”.

We experimented with the following publicly available general-domain word embeddings:

- **GloVe$_{\text{[CC]}}$**: GloVe embeddings (Pennington et al., 2014), trained on Common Crawl[4].
- **fastText$_{\text{[Wiki]}}$**: fastText embeddings (Bojanowski et al., 2017), trained on Wikipedia.
- **fastText$_{\text{[CC]}}$**: fastText embeddings, trained on Common Crawl.

Furthermore, we trained fastText embeddings on the following domain-specific corpora:

- **fastText$_{\text{[BioASQ]}}$**:A collection of PubMed abstracts from the BioASQ challenge data (Tsatsaronis et al., 2015). This data includes abstracts from 12,834,585 scientific articles from the biomedical domain.
- **fastText$_{\text{[MIMIC-III]}}$**: Clinical notes for patients from the MIMIC-III database (Johnson et al., 2016): 2,078,705 notes with 320 tokens in each on average.

Finally, we experimented with initializing word embeddings with pre-trained vectors from general

---

[4] `http://commoncrawl.org/`

domain and further training on a domain-specific corpus:

- $\text{GloVe}_{[\text{CC}]} \rightarrow \text{fastText}_{[\text{BioASQ}]}$: GloVe embeddings for initialization, and the BioASQ data for fine-tuning.
- $\text{GloVe}_{[\text{CC}]} \rightarrow \text{fastText}_{[\text{BioASQ}]} \rightarrow \text{fastText}_{[\text{MIMIC-III}]}$: GloVe embeddings for initialization, and two consequent fine-tuning using the BioASQ and MIMIC-III data.
- $\text{fastText}_{[\text{Wiki}]} \rightarrow \text{fastText}_{[\text{MIMIC-III}]}$: fastText Wikipedia embeddings for initialization, and the MIMIC-III data for fine-tuning.

Experiments using other approaches to word embeddings, such as `word2vec` (Mikolov et al., 2013) and CoVe (McCann et al., 2017) did not show any gains. All the above trained embeddings are available for download.

4.2 Knowledge integration

Since understanding medical texts requires domain-specific knowledge, we experimented with different ways of incorporating such knowledge into the systems. First, we can modify the input to the system so it carries a portion of clinical information. Second, we can modify the model itself, integrating domain knowledge directly into it.

The UMLS is the largest, publicly available, and regularly updated database of medical terminologies, concepts, and relationships between them. It can be viewed as a graph where clinical concepts are nodes, connected by edges representing relations, such as synonymy, parent-child, etc. Following past work, we restricted to the SNOMED-CT terminology in UMLS and experimented with two techniques for incorporating knowledge: retrofitting and attention.

4.2.1 Retrofitting

Retrofitting (Faruqui et al., 2015) modifies pre-trained word embeddings based on an ontology. The basic idea is to try to bring the representations of the concepts that are connected in the ontology closer to one another in vector space. The authors showed that retrofitting using WordNet (Fellbaum, 1998) synsets improves accuracy on several word-level tasks, as well as sentiment analysis.

4.2.2 Knowledge-directed attention

Attention proved to be a useful technique for many NLP tasks, starting from machine translation (Bahdanau et al., 2015) to parsing (Vinyals et al., 2015) and NLI itself (Parikh et al., 2016; Rocktäschel et al., 2016). In most models (including the ESIM model that we use in our experiments) attention is learned in an end-to-end fashion. However, if we have knowledge about relationships between concepts, we could leverage it to explicitly tell the model to attend to specific concepts during the processing of the input sentence.

For example, there is an edge in SNOMED-CT from the concept *Lung consolidation* to *Pneumonia*. Using this information, during the processing of a sentence pair

- **Premise** The patient has *pneumonia*.
- **Hypothesis** The patient has a *lung* disease.

the model could attend to the token *lung* while processing *pneumonia*.

We propose to integrate this knowledge in a way similar to how attention is used in the ESIM model. Specifically, we calculate the attention matrix $e \in \mathbb{R}^{n \times m}$ between all pairs of tokens a_i and b_j in the inputs sentences, where n is the length of the hypothesis and m is the length of the premise. The value in each cell reflects the length of the shortest path l_{ij} between the corresponding concepts of the premise and the hypothesis in SNOMED-CT (the shorter is the path, the higher is the value).

This process could be informally described as follows: each token $\tilde{a_i}$ of the premise is a weighted sum of relevant tokens b_j of the hypothesis, according to the medical ontology, and vice versa. This enables the medical domain knowledge to be integrated directly into the system.

We used the original tokens a_i as well as the attended $\tilde{a_i}$ inside the model for both InferSent and ESIM. For InferSent, we simply concatenate them across the time dimension:

$$\hat{a} = [a_1, a_2, \ldots, a_n, \tilde{a_1}, \tilde{a_2}, \ldots, \tilde{a_n}]$$

where n is the length of the inputs sequence. For the ESIM model, we concatenate a_i and $\tilde{a_i}$ before passing them to the composition layer (see Figure 2 and Section 3.3 in the original paper (Chen et al., 2017)). This enables the model to learn the relative importance of both the token and the knowledge directed attention.

Set	Features	BOW	InferSent	ESIM
Dev	51.9	71.9	**76.0**	74.4
Test	51.9	70.2	**73.5**	73.1

Table 3: Baseline accuracy on the development and the test set of MedNLI for different models.

5 Results and discussion

We implemented all models using PyTorch[5] and trained them with the Adam optimizer (Kingma and Ba, 2015) until the validation loss showed no improvement for 5 epochs. The epoch with the lowest loss on the validation set was selected for testing. We used the GloVe word embeddings (Pennington et al., 2014) in all experiments, except for subsection 5.3. In all experiments we report the average result of 6 different runs, with the same hyperparameters and different random seeds. Medical concepts in SNOMED-CT were identified in the premise and hypothesis sentences using Metamap (Aronson and Lang, 2010). The code for all experiments is publicly available.[6]

5.1 Baselines

Table 3 shows the baseline results: the performance of a model when trained and tested on the MedNLI dataset. The feature-based system performed the worst. As for neural networks-based systems, the BOW model showed the lowest performance on the both development and test sets. The InferSent model, in contrast, achieved the highest accuracy, despite ESIM outperforming it on SNLI. This could be attributed to the fact that ESIM has twice as many parameters as InferSent, and so InferSent overfits less to the smaller MedNLI dataset.

5.2 Transfer learning

As expected, Table 4 shows that direct transfer is worse than the baseline but is still better than a random baseline of 33.3%. Sequential and multi-target transfer learning, in contrast, yields a considerable gain for all the models. The maximum gain is 2.4%, 0.9%, and 0.3% for the BOW, InferSent, and ESIM models correspondingly.

Second, note that the biggest SNLI domain gave the most boost in only two out of six cases, implying that the size of the domain should not be the most important factor in choosing the source domain for transfer learning. The best accuracy for all the models was obtained with the "slate" domain from MultiNLI corpus with sequential transfer (note, however, that the accuracy of ESIM is actually lower than the baseline accuracy). This is consistent with observations of Williams et al. (2018). Finally, although some domains are better for particular transfer learning methods with particular models, there is no single combination that works for all cases.

5.3 Word embeddings

Table 5 shows that simply using of the embeddings trained on the MIMIC-III notes significantly increases the accuracy for all the models. Furthermore, the InferSent models achieves a 3.1% boost with the fastText Wikipedia embeddings, fine-tuned on the MIMIC-III data. Note that the results $\text{fastText}_{[\text{Wiki}]}$ are worse than the baseline $\text{GloVe}_{[\text{CC}]}$ for all models, which could be due to the source corpus size. However, the results on BioASQ are worse than on MIMIC-III, despite the significantly larger corpus of the BioASQ embeddings. Overall, our experiments show the benefit of domain-specific rather than general-domain word embeddings.

5.4 Knowledge integration

5.4.1 Retrofitting

Table 6 shows that retrofitting only hurts the performance. This is in contrast with the results of the original study, where retrofitting was beneficial not only for word-level tasks but also for tasks such as sentiment analysis (Faruqui et al., 2015). We hypothesize that although WordNet and UMLS are structurally similar, significant differences in the content (Burgun and Bodenreider, 2001) might be the reason for these results. Retrofitting should be more useful when it is used on a WordNet-like database where the main relation is synonymy, and tested on tasks such as word similarity tests or sentiment analysis. The UMLS semantic network is more complex and contains relations that may not be suitable for retrofitting.

Moreover, retrofitting works only on directly related concepts in a knowledge graph (although it might affect, to some extent, indirectly related concepts by transitivity). However, as Figure 3 shows, UMLS contains few training pairs that have such concepts (namely, pairs with a path of

length 1). In contrast, the lengths of the shortest path in SNLI using WordNet fall close to 1. This suggests that the medical inferences represented in MedNLI requires more complex reasoning, typically involving multiple steps.

As a sanity check, we applied retrofitting to the GloVe embeddings and tested the InferSent model on the "fiction" domain from the MultiNLI corpus. We used the code and lexicons provided by Faruqui et al. (2015) and confirmed that retrofitting hurts the performance in that case as well.

BOW	InferSent	ESIM
-1.7	-2.0	-2.7

Table 6: Absolute gain in accuracy using retrofitting for MedNLI.

5.4.2 Knowledge-directed attention

To evaluate the potential of knowledge-directed attention, let us consider its effect on a baseline embedding (GloVe$_{[\text{CC}]}$) and a fastText embedding trained on MIMIC-III (fastText$_{[\text{MIMIC-III}]}$) that showed good performance in section 5.3.

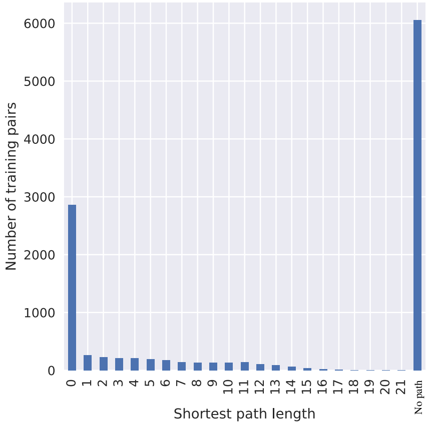

Figure 3: Lengths of the shortest paths between concepts in the premise and the hypothesis. 0 indicates that they contain the same concept.

Knowledge-directed attention showed positive effect with the InferSent model on GloVe$_{[\text{CC}]}$ (0.3 gain), and was not detrimental to ESIM. However, in case of the fastText$_{[\text{MIMIC-III}]}$ embeddings knowledge-directed attention was beneficial to both models, as shown in Table 7. Note that while retrofitting can use only direct relations during the training process, our method incorporates information about relationships of any length, which is a necessity (as evident from Figure 3).

Embedding	InferSent	ESIM
GloVe$_{[\text{CC}]}$	0.3	0.0
fastText$_{[\text{MIMIC-III}]}$	0.2	0.3

Table 7: Absolute gain in accuracy using knowledge-directed attention.

6 Error analysis

The neutral class is the hardest to recognize for all models. Majority errors stem from confusion between entailment and the neutral class. Use of domain-specific embeddings trained on MIMIC-

Category	**Premise**	**Hypothesis**	**Predicted**	**Expected**
Numerical Reasoning	WBC 12 , Hct 41 .	WBC slightly elevated	contradiction	entailment
World Knowlegde	No known sick contacts	No recent travel	entailment	neutral
Abbreviations	No CP or fevers.	Patient has no angina	neutral	entailment
Medical Knowledge	EKG showed T-wave depression in V3-5, with no prior EKG for comparison.	Patient has a normal EKG	neutral	contradiction
Negations	Head CT was negative for bleed.	The patient has intracranial hemorrhage	neutral	contradiction

Table 8: Representative errors made by different models

III result in gains which are equally distributed across all three classes. Interestingly, gains from knowledge-directed attention stem mostly (60%) from the neutral class. Moreover, 87% of these neutral predictions were predicted as entailment before adding the knowledge directed attention.

We categorized the errors made by all the models in four broad categories. Table 8 outlines representative errors made by most models in these categories. Numerical reasoning such as *abnormal lab value* $\rightarrow$ *disease* or *abnormal vital sign* $\rightarrow$ *finding* are very hard for a model to learn unless it has seen multiple instances of the same numerical value.[7] The first step is to learn what values are *abnormal* and the next is to actually perform the inference. Many inferences require world knowledge that could be deemed close to open domain NLI. While these are very subtle, some are quite domain specific (e.g. *emergency admission* $\nrightarrow$ *planned visit*). Abbreviations are ubiquitously found in clinical text. While some are standard and therefore frequent, clinicians tend to use non standard abbreviations making inference harder. Finally, many inferences are at the core of reasoning with clinical knowledge. While training on large datasets maybe a natural but impractical solution, this is an open research problem for researchers in the community.

7 Limitations

Unlike SNLI and MultiNLI, each example in the MedNLI dataset was single annotated. However, this was the best we could do in the limited time and resources available. Very recently Gururangan et al. (2018) discovered annotation artifacts in NLI datasets. Since we followed the exact same process, we found them to be present in MedNLI as well. The premise-oblivious text-classifier that achieves 67.0 F1 on SNLI, and 53.9 on Multi-NLI achieves 61.9 on MedNLI.

8 Conclusion

We have presented MedNLI, an expert annotated, public dataset for natural language inference in the clinical domain. To the best of our knowledge, MedNLI is the first dataset of its kind. Our experiments with several state-of-the-art models provide a strong baseline for this dataset. Our work compliments the current efforts in NLI by presenting thorough experiments for the specialized and knowledge intensive field of medicine. We also demonstrated that a simple use of domain-specific word embeddings provides a performance boost. Finally, we also presented a method for integrating domain ontologies into the training regime of models. We hope the released code and dataset with clear benchmarks help advance research in clinical NLP and the NLI task.

Acknowledgments

This work would not have been possible without Adam Coy, Andrew Colucci, Chanida Thammachart, and Hassan Ahmad – the clinicians in our team who helped us in creating the dataset. We are grateful to Vandana Mukherjee and Tanveer Syeda-Mahmood for supporting the project. We would also like to thank Anna Rumshisky and Anna Rogers for their help in this work. Most importantly, we would like to thank Leo Anthony Celi and Alistair Johnson from the MIMIC team for helping us in making MedNLI publicly available.

Abstract

We study how to learn a semantic parser of state-of-the-art accuracy with less supervised training data. We conduct our study on WikiSQL, the largest hand-annotated semantic parsing dataset to date. First, we demonstrate that question generation is an effective method that empowers us to learn a state-of-the-art neural network based semantic parser with thirty percent of the supervised training data. Second, we show that applying question generation to the full supervised training data further improves the state-of-the-art model. In addition, we observe that there is a logarithmic relationship between the accuracy of a semantic parser and the amount of training data.

1 Introduction

Semantic parsing aims to map a natural language utterance to an executable program (logical form) (Zelle and Mooney, 1996; Wong and Mooney, 2007; Zettlemoyer and Collins, 2007). Recently, neural network based approaches (Dong and Lapata, 2016; Jia and Liang, 2016; Xiao et al., 2016; Guu et al., 2017; Dong et al., 2018) have achieved promising performance in semantic parsing. However, neural network approaches are data hungry, which performances closely correlate with the volume of training data. In this work, we study the influence of training data on the accuracy of neural semantic parsing, and how to train a state-of-the-art model with less training data.

We conduct the study on WikiSQL (Zhong et al., 2017), the largest hand-annotated semantic parsing dataset which is larger than other datasets in terms of both the number of logical forms and the number of schemata. The task is to map a natural language question to a SQL query. We use a state-of-the-art end-to-end semantic parser based on neural networks (detailed in Section 3), and vary the number of supervised training instances. Results show that there is a logarithmic relationship between accuracy and the amount of training data, which is consistent with the observations in computer vision tasks (Sun et al., 2017).

We further study how to achieve state-of-the-art parsing accuracy with less supervised data, since annotating a large scale semantic parsing dataset requires funds and domain expertise. We achieve this through question generation, which generates natural language questions from SQL queries. Our question generation model is based on sequence-to-sequence learning. Latent variables (Cao and Clark, 2017) are introduced to increase the diversity of generated questions. The artificially generated question-SQL pairs can be viewed as pseudo-labeled data, which can be combined with a small amount of human-labeled data to train the semantic parser.

Results on WikiSQL show that the state-of-the-art logical form accuracy drops from 60.7% to 53.7% with only thirty percent of training data, while increasing to 61.0% when we combine the pseudo-labeled data generated from the question generation model. Applying the question generation model to full training data brings further improvements with 3.0% absolute gain. We further conduct a transfer learning experiment that applies our approach trained on WikiSQL to WikiTableQuestions (Pasupat and Liang, 2015). Results show that incorporating generated instances improves the state-of-the-art neural semantic parser (Krishnamurthy et al., 2017).

2 Overview of the Approach

Our task aims to map a question to a SQL query, which is executable over a table to yield the an-

Brussels, Belgium, October 31 - November 4, 2018.

swer. Formally, the task takes a question q and a table t consisting of n column names and $n \times m$ cells as the input, and outputs a SQL query y. In this section, we describe an overview of our approach, which is composed of several components.

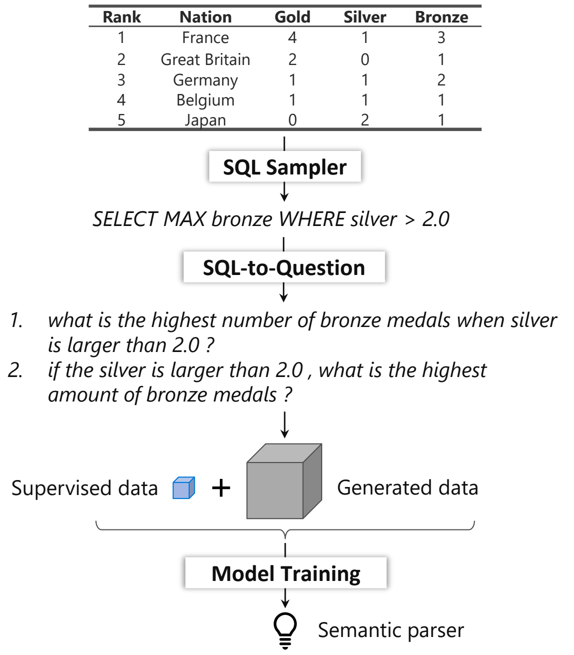

Figure 1: An overview of our approach that improves semantic parsing with question generation.

Figure 1 gives an overview of our approach. First, given a table, a SQL query sampler is used to sample valid, realistic, and representative SQL queries. Second, a question generation component takes SQL queries as inputs to obtain natural language questions. Here, the question generation model is learnt from a small-scale supervised training data that consists of SQL-question pairs. Lastly, the generated question-SQL pairs are viewed as the pseudo-labeled data, which are combined with the supervised training data to train the semantic parser.

Since we conduct the experiment on WikiSQL dataset, we follow Zhong et al. (2017) and use the same template-based SQL sampler, as summarized in Table 1. The details about the semantic parser and the question generation model will be introduced in Sections 3 and Section 4, respectively.

3 Semantic Parsing Model

We use a state-of-the-art end-to-end semantic parser (Sun et al., 2018) that takes a natural language question as the input and outputs a SQL query, which is executed on a table to obtain the answer. To make the paper self-contained, we briefly describe the approach in this section.

Format of a Sampled SQL Query	
SELECT *agg_op* *agg_col* From *table* WHERE *cond1_col* *cond1_op* *cond1* AND *cond2_col* ...	
Sampling Rules	
Variable	Sampling range
agg_col or *cond_col*	The aggregation column *agg_col* and the condition column *cond_col* can be one of columns in the table.
agg_op	The aggregation operator *agg_op* can be empty or *COUNT*. If the type of *agg_col* is numeric, *agg_op* can additionally be one of *MAX* and *MIN*.
cond_op	The condition operator *cond_op* is =. If the type of *cond_col* is numeric, *cond_op* can additionally be one of > and <.
cond	The condition value *cond* can be any cell value under the *cond_col*. If the type of *cond_col* is numeric, *cond* can be numerical value sampled from minimum value to maximum value in the *cond_col*.
Filter Rules	
1.The condition will be removed if doing the action does not change the execution result. 2.We only save the sampled SQL queries that produce non-empty result set.	

Table 1: The SQL sampler of (Zhong et al., 2017).

The semantic parser is abbreviated as **STAMP**, which is short for Syntax- and Table- Aware seMantic Parser. Based on the encoder-decoder framework, STAMP takes a question as the input and generates a SQL query. It extends pointer networks (Zhong et al., 2017; Vinyals et al., 2015) by incorporating three "channels" in the decoder, in which the column channel predicts column names, the value channel predicts table cells and the SQL channel predicts SQL keywords. An additional switching gate selects which channel to be used for generation. In STAMP, the probability of a token to be generated is calculated as Equation 1, where $p_z(\cdot)$ is the probability of the channel z_t to be chosen, and $p_w(\cdot)$ is the probability distribution of generating a word y_t from the selected channel.

$$p(y_t|y_{<t},x) = \sum_{z_t} p_w(y_t|z_t,y_{<t},x)p_z(z_t|y_{<t},x) \tag{1}$$

Specifically, the encoder takes a question as the input, uses bidirectional RNN with GRU cells to compute the hidden states, and feeds the concatenation of both ends as the initial state of the decoder. The decoder has another GRU to calculate the hidden states.

Each channel is implemented with an attentional neural network. In the SQL channel, the input of the attention module includes the decoder hidden state and the embedding of the SQL keyword to be calculated (i.e. e_i^{sql}).

$$p_w^{sql}(i) \propto exp(W_{sql}[h_t^{dec}; e_i^{sql}]) \tag{2}$$

In the column channel, the vector of a column name includes two parts, as given in Equation 3. The first vector (h_i^{col}) is calculated with a bidirectional GRU because a column name might contain multiple words. The second vector is a question-aware cell vector, which is weighted averaged over the cell vectors belonging to the column. Cell vectors (h_i^{cell}) are also obtained by a bidirectional GRU. The importance of a cell is measured by the number of co-occurred question words, which is further normalized through a $softmax$ function to yield the final weight $\alpha_j^{cell} \in [0, 1]$.

$$p_w^{col}(i) \propto exp(W_{col}[h_t^{dec}; h_i^{col}; \sum_{j \in col_i} \alpha_j^{cell} h_j^{cell}]) \tag{3}$$

In the value channel, the model has two distributions and weighted average them as Equation 4. Similar to $p^{sql}(\cdot)$, a standard cell distribution $\hat{p}_w^{cell}(\cdot)$ is calculated over the cells belonging to the last predicted column name. They incorporate an additional probability distribution $\alpha^{cell}(\cdot)$ based on the aforementioned word co-occurrence. The hyper parameter λ is tuned on the dev set.

$$p_w^{cell}(j) = \lambda \hat{p}_w^{cell}(j) + (1 - \lambda)\alpha_j^{cell} \tag{4}$$

Please see more details on model training and inference in Sun et al. (2018).

4 Question Generation Model

In this section, we present our SQL-to-question generation approach, which takes a SQL query as the input and outputs a natural language question. Our approach is based on sequence-to-sequence learning (Sutskever et al., 2014; Bahdanau et al., 2015). In order to replicate rare words from SQL queries, we adopt the copying mechanism. In addition, we incorporate latent variables to increase the diversity of generated questions.

4.1 Encoder-Decoder

Encoder: A bidirectional RNN with gated recurrent unit (GRU) (Cho et al., 2014) is used as the encoder to read a SQL query $x = (x_1, ..., x_T)$. The forward RNN reads a SQL query in a left-to-right direction, obtaining hidden states $(\overrightarrow{h_1}, ..., \overrightarrow{h_T})$. The backward RNN reads reversely and outputs $(\overleftarrow{h_1}, ..., \overleftarrow{h_T})$. We then get the final representation $(h_1, ..., h_T)$ for each word in the query, where $h_j = [\overrightarrow{h_j}; \overleftarrow{h_j}]$. The representation of the source sentence $h_x = ([\overrightarrow{h_T}; \overleftarrow{h_1}])$ is used as initial hidden state of the decoder.

Decoder: We use a GRU with an attention mechanism as the decoder. At each time-step t, the attention mechanism obtains the context vector c_t that is computed same as the multiplicative attention (Luong et al., 2015). Afterwards, the concatenation of the context vector, the embedding of the previously predicted word y_{t-1}, and the last hidden state s_{t-1} is fed to the next step.

$$s_t = GRU(s_{t-1}, y_{t-1}, c_t) \tag{5}$$

After obtaining hidden states s_t, we adopt the copying mechanism that predicts a word from the target vocabulary or from the source sentence (detailed in Subsection 4.2).

4.2 Incorporating Copying Mechanism

In our task, the generated question utterances typically include informative yet low-frequency words such as named entities or numbers. Usually, these words are not included in the target vocabulary but come from SQL queries. To address this, we follow CopyNet (Gu et al., 2016) and incorporate a copying mechanism to select whether to generate from the vocabulary or copy from SQL queries.

The probability distribution of generating the t-th word is calculated as Equation 6, where $\psi_g(\cdot)$ and $\psi_c(\cdot)$ are scoring functions for generating from the vocabulary $\boldsymbol{\nu}$ and copying from the source sentence x, respectively.

$$p(y_t|y_{<t}, x) = \frac{e^{\psi_g(y_t)} + e^{\psi_c(y_t)}}{\sum_{v \in \boldsymbol{\nu}} e^{\psi_g(v)} + \sum_{w \in \mathbf{x}} e^{\psi_c(w)}} \tag{6}$$

The two scoring functions are calculated as follows, where W_g and W_c are model parameters, v_i is the one-hot indicator vector for y_i and h_i is the hidden state of word y_i in the source sentence.

$$\begin{aligned} \psi_g(y_i) &= v_i^T W_g s_t \\ \psi_c(y_i) &= tanh({h_i}^T W_c) s_t \end{aligned} \tag{7}$$

4.3 Incorporating Latent Variable

Increasing the diversity of generated questions is very important to improve accuracy, generalization, and stability of the semantic parser, since this increases the mount of training data and produces more diverse questions for the same intent. In this work, we incorporate stochastic latent variables (Cao and Clark, 2017; Serban et al., 2017) to the sequence-to-sequence model in order to increase question diversity.

Specifically, we introduce a latent variable $z \sim p(z)$, which is a standard Gaussian distribution $\mathcal{N}(0, I_n)$ in our case, and calculate the likelihood of a target sentence y as follows:

$$p(y|x) = \int_z p(y|z,x)p(z)\,dz \tag{8}$$

We maximize the evidence lower bound (ELBO), which decomposes the loss into two parts, including (1) the KL divergence between the posterior distribution and the prior distribution, and (2) a cross-entropy loss between the generated question and the ground truth.

$$\begin{aligned} logp(y|x) \geq -D_{KL}(Q(z|x,y)||p(z)) \\ +E_{z \sim Q} logp(y|z,x) \end{aligned} \tag{9}$$

The KL divergence in Equation 9 is calculated as follow, where n is the dimensionality of z.

$$\begin{aligned} &D_{KL}(Q(z|x,y)||p(z)) = \\ &-\frac{1}{2}\sum_{j=1}^{n}(1 + log(\sigma_j^2) - \mu_j^2 - \sigma_j^2) \end{aligned} \tag{10}$$

$Q(z|x,y)$ is a posterior distribution with Gaussian distribution. The mean μ and standard deviation σ are calculated as follows, where h_x and h_y are representations of source and target sentences in the encoder, respectively. Similar to h_x, h_y is obtained by encoding the target sentence.

$$\begin{aligned} \mu &= W_\mu[h_x; h_y] + b_\mu \\ log(\sigma^2) &= W_\sigma[h_x; h_y] + b_\sigma \end{aligned} \tag{11}$$

4.4 Training and Inference

At the training phase, we sample z from $Q(z|x,y)$ using the re-parametrization trick (Kingma and Welling, 2014), and concatenate the source last hidden state h_x and z as the initial state of the decoder. Since the model tends to ignore the latent variables by forcing the KL divergence to 0 (Bowman et al., 2016), we add a variable weight to the KL term during training. At the inference phase, the model will generate different questions by first sampling z from $p(z)$, concatenating h_x and z as the initial state of the decoder, and then decoding deterministically for each sample.

Here, we list our training details. We set the dimension of the encoder hidden state as 300, and the dimension of the latent variable z as 64. We use dropout with a rate of 0.5, which is applied to the inputs of RNN. Model parameters are initialized with uniform distribution, and updated with stochastic gradient decent. Word embedding values are initialized with Glove vectors (Pennington et al., 2014). We set the learning rate as 0.1 and the batch size as 32. We tune hyper parameters on the development, and use beam search in the inference process.

5 Experiment

We conduct experiments on the WikiSQL dataset[1] (Zhong et al., 2017). WikiSQL is the largest hand-annotated semantic parsing dataset which is an order of magnitude larger than other datasets in terms of both the number of logical forms and the number of schemata (tables). WikiSQL is built by crowd-sourcing on Amazon Mechanical Turk, including 61,297 examples for training, and 9,145/17,284 examples for development/testing. Each instance consists of a natural language question, a SQL query, a table and a result. Here, we follow Zhong et al. (2017) to use two evaluation metrics. One is logical form accuracy (Acc$_{lf}$), which measures the percentage of exact string match between the generated SQL queries and the ground truth SQL queries. Since different logical forms might obtain the same result, another metric is execution accuracy (Acc$_{ex}$), which is the percentage of the generated SQL queries that result in the correct answer.

5.1 Impact of Data Size

We study how the number of training instances affects the accuracy of semantic parsing.

In this experiment, we randomly sample 20 subsets of examples from the WikiSQL training data, incrementally increased by 3K examples (about 1/20 of the full WikiSQL training data). We use the same training protocol and report the accuracy of the STAMP model on the dev set. Results are given in Figure 2. It is not surprising that more training examples bring higher accuracy. Interestingly, we observe that both accuracies of the neural network based semantic parser grow logarith-

Methods	Training Data	Dev		Test	
		Acc_{lf}	Acc_{ex}	Acc_{lf}	Acc_{ex}
Attentional Seq2Seq	100%	23.3%	37.0%	23.4%	35.9%
Aug.PntNet (Zhong et al., 2017)	100%	44.1%	53.8%	43.3%	53.3%
Aug.PntNet (re-implemented by us)	100%	51.5%	58.9%	52.1%	59.2%
Seq2SQL (Zhong et al., 2017)	100%	49.5%	60.8%	48.3%	59.4%
SQLNet (Xu et al., 2017)	100%	–	69.8%	–	68.0%
STAMP	30%	54.6%	69.7%	53.7%	68.9%
STAMP + QG	30%	61.6%	74.4%	61.2%	73.9%
STAMP	100%	61.5%	74.8%	60.7%	74.4%
STAMP + QG	100%	64.3%	76.5%	63.7%	75.5%

Table 2: Performance of different approaches on the WikiSQL dataset. The two evaluation metrics are logical form accuracy (Acc_{lf}) and execution accuracy (Acc_{ex}). The settings of the training data represent the proportion of supervised data we use.

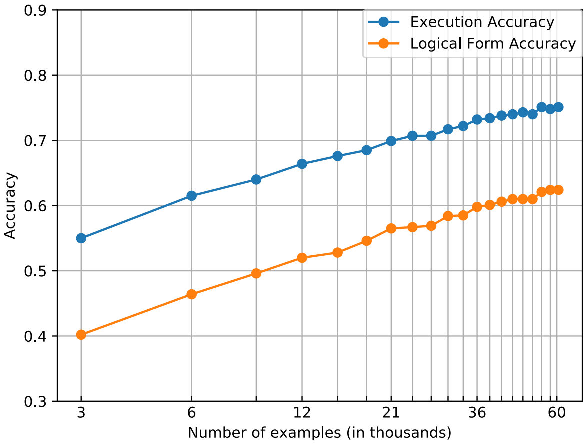

Figure 2: Semantic parsing accuracies of the STAMP model on WikiSQL. The x-axis is the training data size in log-scale, and the y-axis includes two evaluation metrics Acc_{lf} and Acc_{ex}.

mically as training data expands, which is consistent with the observations in computer vision tasks (Sun et al., 2017).

5.2 Model Comparisons

We report the results of existing methods on WikiSQL, and demonstrate that question generation is an effective way to improve the accuracy of semantic parsing. Zhong et al. (2017) implement several methods, including **Attentional Seq2Seq**, which is a basic attentional sequence-to-sequence learning baseline; **Aug.PntNet**, which is an augmented pointer network in which words of the target sequence come from the source sequence; and **Seq2SQL** which extends Aug.PntNet by further learning two separate classifiers for SELECT aggregator and SELECT column. Xu et al. (2017) develop **SQLNet**, which uses two separate models to predict SELECT and WHERE clauses, respectively, and introduce a sequence-to-set neural network to predict the WHERE clause. **STAMP** stands for the semantic parser which has been described in Section 3.

From Table 2, we can see that STAMP performs better than existing systems when trained on the full WikiSQL training dataset, achieving state-of-the-art execution accuracy and logical form accuracy on WikiSQL. We further conduct experiments to demonstrate the effectiveness of our question generation driven approach. We run the entire pipeline (STAMP+QG) with different percentages of training data. The second column "Training Data" in Table 2 and the x-axis in Figure 3 represent the proportion of WikiSQL training data we use for training the QG model and semantic parser. That is to say, STAMP +QG with 30% means that we sample 30% WikiSQL training data to train the QG model, and then combine QG generated data and exactly the same 30% WikiSQL training data we sampled before to train the semantic parser. In this experiment, we sample five SQL queries for each table in the training data, resulting in 43.5K SQL queries. Applying the QG model on these SQL queries, we get 92.8K SQL-question pairs. From Figure 3, we see that accuracy increases as the amount of supervised training data expands. Results show that QG empowers the STAMP model to achieve the same accuracy on WikiSQL dataset with 30% of the training data. Applying QG to the STAMP model under the full setting brings further improvements, resulting in new state-of-the-art accuracies.

Methods	Dev			Test		
	Acc_{sel}	Acc_{agg}	Acc_{where}	Acc_{sel}	Acc_{agg}	Acc_{where}
Aug.PntNet (re-implemented by us)	80.9%	89.3%	62.1%	81.3%	89.7%	62.1%
Seq2SQL (Zhong et al., 2017)	89.6%	90.0%	62.1%	88.9%	90.1%	60.2%
SQLNet (Xu et al., 2017)	91.5%	90.1%	74.1%	90.9%	90.3%	71.9%
STAMP	89.4%	89.5%	77.1%	88.9%	89.7%	76.0%
STAMP+QG	89.7%	90.1%	79.8%	89.1%	90.2%	79.0%

Table 3: Fine-grained accuracies on the WikiSQL dev and test sets. Logical form accuracy (Acc_{lf}) is evaluated on SELECT column (Acc_{sel}) , SELECT aggregator (Acc_{agg}), and WHERE clause (Acc_{where}), respectively. All these models are trained on the full WikiSQL training data.

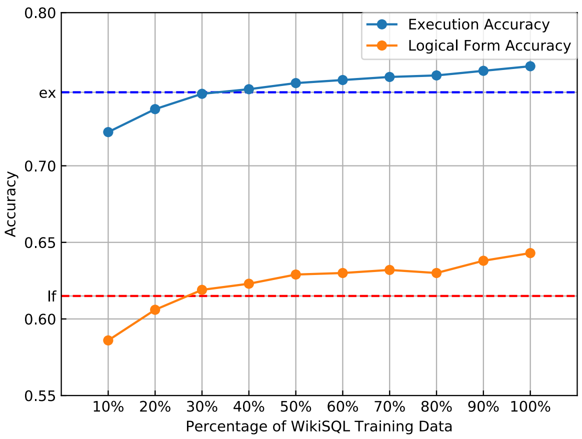

Figure 3: Accuracies of STAMP+QG with different portions of supervised data. Dashed lines are Acc_{lf} and Acc_{ex} of STAMP on the full training data.

5.3 Fine-grained Accuracies

Since SQL queries in WikiSQL consist of SELECT column, SELECT aggregator, and WHERE clause, we report fine-grained accuracies with regard to these aspects, respectively.

From Table 3, we observe that the main advantage of STAMP+QG over STAMP comes from the prediction of the WHERE clause, which is also the main challenge of the WikiSQL dataset. We further analyze STAMP and STAMP+QG on the WHERE clause by splitting the dev and test sets into three groups according to the number of conditions in the WHERE clause. From Table 4, we see that combining QG is helpful when the number of WHERE conditions is more than one. The main reason is that dominant instances in the WikiSQL training set have only one WHERE condition, as shown in Table 5, thus the model might not have memorized enough patterns for the other two limited-data groups. Therefore, the pseudo-labeled instances generated by our SQL sampler and QG approach are more precious to the limited-data groups (i.e #where =2 and #where≥3).

#where	STAMP		STAMP+QG	
	dev	test	dev	test
$= 1$	80.9%	80.2%	81.5%	80.9%
$= 2$	65.1%	65.4%	68.3%	66.9%
≥ 3	44.1%	48.2%	53.4%	51.9%

Table 4: Execution accuracy (Acc_{ex}) on different groups of WikiSQL dev and test sets.

#where	supervised data	generated data
$= 1$	69.1%	55.4%
$= 2$	24.1%	33.0%
≥ 3	6.1%	11.4%

Table 5: Distribution of the number of WHERE conditions in supervised and generated data.

5.4 Influences of Different QG Variations

To better understand how various components in our QG model impact the overall performance, we study different QG model variations. We use three evaluation metrics, including two accuracies and BLEU score (Papineni et al., 2002). The BLEU score evaluates the question generation.

Methods	Scale	BLEU	Acc_{lf}	Acc_{ex}
s2s	30%	20.6	59.0%	72.1%
s2s+lv	30%	22.1	60.0%	72.3%
s2s+cp	30%	29.6	60.8%	73.5%
s2s+cp+lv	30%	29.5	61.2%	73.9%
s2s	100%	26.0	62.6%	74.9%
s2s+lv	100%	26.3	63.0%	75.3%
s2s+cp	100%	31.5	63.2%	75.6%
s2s+cp+lv	100%	31.6	63.7%	75.5%

Table 6: Performances of different question generation variations.

SQL	SELECT COUNT 2nd leg WHERE aggregate = 7-2
Question (ground truth)	what is the total number of 2nd leg where aggregate is 7-2
Question (s2s + cp)	how many 2nd leg with aggregate being 7-2
Question (s2s + cp + lv)	(1) what is the total number of 2nd leg when the aggregate is 7-2 ? (2) how many 2nd leg with aggregate being 7-2 (3) name the number of 2nd leg for 7-2

Table 7: Generated examples from different question generation model variations.

Results are shown in Table 6, in which **s2s** represents the basic attentional sequence-to-sequence learning model (Luong et al., 2015), **cp** means the copying mechanism, and **lv** stands for the latent variable. We can see that incorporating a latent variable improves QG model performance, especially in limit-supervision scenarios. This is consistent with our intuition that the performance of the QG model is improved by incorporating the copying mechanism, since rare words of great importance mainly come from the input sequence.

To better understand the impact of incorporating a latent variable, we show examples generated by different QG variations in Table 7. We can see that incorporating a latent variable empowers the model to generate diverse questions for the same intent.

5.5 Transfer Learning on WikiTableQuestions

In this part, we conduct an extensional experiment on WikiTableQuestions[2] (Pasupat and Liang, 2015) in a transfer learning scenario to verify the effectiveness of our approach. WikiTableQuestions contains 22,033 complex questions on 2,108 Wikipedia tables. Each instance consists of a natural language question, a table and an answer. Following Pasupat and Liang (2015), we report development accuracy which is averaged over the first three 80-20 training data splits. Test accuracy is reported on the train-test data.

In this experiment, we apply the QG model learnt from WikiSQL to improve the state-of-the-art semantic parser (Krishnamurthy et al., 2017) on this dataset. Different from WikiSQL, this dataset requires question-answer pairs for training. Thus, we generate question-answer pairs by follow steps. We first sample SQL queries on the tables from WikiTableQuestions, and then use our QG model to generate question-SQL pairs. Afterwards, we obtain question-answer pairs by executing SQL queries. The generated question-answer pairs will be combined with the original WikiTableQuestions training data to train the model.

	Dev	Test
Pasupat and Liang (2015)	37.0%	37.1%
Neelakantan et al. (2016)	37.5%	37.7%
Haug et al. (2017)	-	38.7%
Zhang et al. (2017)	40.4%	43.7%
STAMP (WikiSQL)	-	14.5%
STAMP (WikiSQL) + QG	-	15.2%
NSP	41.9%	43.8%
NSP + QG	42.2%	44.2%

Table 8: Accuracy (Acc_{ex}) of different approaches on WikiTableQuestion dev and test sets.

Results are shown in Table 8, in which **NSP** is short for the state-of-the-art neural semantic parser (Krishnamurthy et al., 2017). Since the train-test data used in NSP is different from others, we retrain the NSP under the same protocol. **STAMP (WikiSQL)** means that the STAMP model trained on WikiSQL is directly tested on WikiTableQuestions. Despite applying QG slightly improves STAMP in this setting, the low accuracy reflects the different question distribution between these two datasets. In the supervised learning setting, we can see that incorporating QG further improves the accuracy of NSP from 43.8% to 44.2%.

5.6 Discussion

To better understand the limitations of our QG model, we analyze a randomly selected set of 100 questions. We observe that 27% examples do not correctly express the meanings of SQL queries, among which the majority of them miss information from the WHERE clause. This problem might be mitigated by incorporating a dedicated encoder/decoder that takes into account the SQL structure. Among the other 73% of examples that correctly express SQL queries, there are two po-

---

[2] `https://nlp.stanford.edu/software/sempre/wikitable/`

tential directions to make further improvements. The first direction is to leverage table information such as the type of a column name or column-cell correlations. For instance, without knowing that cells under the column name "*built*" are all building years, the model hardly predicts a question "*what is the average building year for superb?*" for "*SELECT AVG built WHERE name = superb*". The second direction is to incorporate common knowledge, which would help the model to predict *the earliest week* rather than *the lowest week*.

6 Related Work

Semantic Parsing. Semantic parsing is a fundamental problem in NLP that maps natural language utterances to logical forms, which could be executed to obtain the answer (denotation) (Zettlemoyer and Collins, 2005; Liang et al., 2011; Berant et al., 2013; Krishnamurthy and Kollar, 2013; Pasupat and Liang, 2016; Iyer et al., 2017). Existing works can be classified into three areas, including (1) the language of the logical form, e.g. first-order logic, lambda calculus, lambda dependency-based compositional semantics (lambda DCS) and structured query language (SQL); (2) the form of the knowledge base, e.g. facts from large collaborative knowledge bases, semi-structured tables and images; and (3) the supervision used for learning the semantic parser, e.g. question-denotation pairs and question-logical form pairs. In this work, we regard the table as the knowledge base, which is critical for accessing relational databases with natural language, and also for serving information retrieval for structured data. We use SQL as the logical form, which has a broad acceptance to the public. In terms of supervision, this work uses a small portion of question-logical form pairs to initialize the QA model and train the QG model, and incorporate more generated question-logical form pairs to further improve the QA model.

Question Generation Our work also relates to the area of question generation, which has drawn plenty of attention recently partly influenced by the remarkable success of neural networks in text generation. Studies in this area are classified based on the definition of the answer, including a sentence (Heilman, 2011), a topic word (Chali and Hasan, 2015), a fact (including a subject, a relation phrase and an object) from knowledge bases (Serban et al., 2016), an image (Mostafazadeh et al., 2016), etc. Recent studies in machine reading comprehension generate questions from an answer span and its context from the document (Du et al., 2017; Golub et al., 2017). Wang et al. (2015) first generate logical forms, and then use AMTurkers to paraphrase them to get natural language questions. Iyer et al. (2017) use a template-based approach based on the Paraphrase Database (Ganitkevitch et al., 2013) to generate questions from SQL. In this work, we generate questions from logical forms, in which the amount of information from two directions are almost identical. This differs from the majority of existing studies because a question typically conveys less semantic information than the answer.

Improving QA with QG This work also relates to recent studies that uses a QG model to improve the performance of a discriminative QA model (Wang et al., 2017; Yang et al., 2017; Duan et al., 2017; Konstas et al., 2017). The majority of these works generate a question from an answer, while there also exists a recent work (Dong et al., 2017) that generates a question from a question through paraphrasing. In addition, Tang et al. (2017) consider QA and QG as dual tasks, and further improve the QG model in a dual learning framework. These works fall into three categories: (1) regarding the artificially generated results as additional training instances (Yang et al., 2017; Golub et al., 2017); (2) using generated questions to calculate additional features (Duan et al., 2017; Dong et al., 2017); and (3) using the QG results as additional constraints in the training objectives (Tang et al., 2017). This work belongs to the first direction. Our QG approach takes a logical form as the input, and considers the diversity of generated questions by incorporating latent variables.

7 Conclusion

In this paper, we observe the logarithmic relationship between the accuracy of a semantic parser and the amount of training data, and present an approach that improves neural semantic parsing with question generation. We show that question generation helps us obtain a state-of-the-art neural semantic parser with less supervised data, and further improves the state-of-the-art model with full annotated data on WikiSQL and WikiTableQuesions datasets. In future work, we would like to make use of table information and external knowledge to improve our QG model. We also plan to apply the approach to other tasks.

Abstract

Recent research proposes syntax-based approaches to address the problem of generating programs from natural language specifications. These approaches typically train a sequence-to-sequence learning model using a syntax-based objective: maximum likelihood estimation (MLE). Such syntax-based approaches do not effectively address the goal of generating semantically correct programs, because these approaches fail to handle *Program Aliasing*, i.e., semantically equivalent programs may have many syntactically different forms. To address this issue, in this paper, we propose a semantics-based approach named SemRegex. SemRegex provides solutions for a subtask of the program-synthesis problem: generating regular expressions from natural language. Different from the existing syntax-based approaches, SemRegex trains the model by maximizing the expected semantic correctness of the generated regular expressions. The semantic correctness is measured using the DFA-equivalence oracle, random test cases, and distinguishing test cases. The experiments on three public datasets demonstrate the superiority of SemRegex over the existing state-of-the-art approaches.

1 Introduction

Translating natural language (NL) descriptions into executable programs is a fundamental problem for computational linguistics. An end user may have difficulty to write programs for a certain task, even when the task is already specified in NL. For some tasks, even for developers, who have experience in writing programs, it can be time consuming and error prone to write programs based on the NL description of the task. Naturally, automatically synthesizing programs from NL can help alleviate the preceding issues for both end users and developers.

Recent research proposes syntax-based approaches to address some tasks of this problem in different domains, such as regular expressions (regex) (Locascio et al., 2016), Bash scripts (Lin et al., 2017), and Python programs (Yin and Neubig, 2017). These approaches typically train a sequence-to-sequence learning model using maximum likelihood estimation (MLE). Using MLE encourages the model to output programs that are syntactically similar with the ground-truth programs in the training set. However, such syntax-based training objective deviates from the goal of synthesizing semantically equivalent programs. Specifically, these syntax-based approaches fail to handle the problem of *Program Aliasing* (Bunel et al., 2018), i.e., a semantically equivalent program may have many syntactically different forms. Table 1 shows some examples of the *Program Aliasing* problem. Both Program 1 and Program 2 are desirable outputs for the given NL specification but one of them is penalized by syntax-based approaches if the other one is used as the ground truth, compromising the overall effectiveness of these approaches.

In this paper, we focus on generating regular expressions from NL, an important task of the program-synthesis problem, and propose SemRegex, a semantics-based approach to generate regular expressions from NL specifications. Regular expressions are widely used in various applications, and "regex" is one of the most common tags in Stack Overflow[1] with more than $190,000$ related questions. The huge number of regex-related questions indicates the importance of this task.

Different from the existing syntax-based approaches, SemRegex alters the syntax-based training objective of the model to a semantics-based objective. To encourage the translation model to generate semantically correct regular expressions, instead of MLE, SemRegex trains the model by maximizing the expected semantic correctness of

Brussels, Belgium, October 31 - November 4, 2018.

Table 1: Examples of *Program Aliasing*: for each NL specification, Program 2 is semantically equivalent to Program 1; however, if Program 1 is the ground truth in the training set, Program 2 is penalized by syntax-based approaches although it is a desirable program.

Domain	**NL Specification**	**Program 1**	**Program 2**
Regex	Match lines that start with an uppercase vowel and end with ‘X’	`([AEIOUaeiou]&[A-Z]).*X`	`([AEIOU].*)&(.*X)`
Bash	Rename file ‘f1’ to ‘f1.txt’	`mv ’f1’ ’f1.txt’`	`cp ’f1’ ’f1.txt’; rm ’f1’`
Python	Assign the greater value of ‘a’ and ‘b’ to variable ‘c’	`c = a if a > b else b`	`c = [b, a][a > b]`

generated regular expressions. We follow the technique of policy gradient (Williams, 1992) to estimate the gradients of the semantics-based objective and perform optimization.

The measurement of semantic correctness serves as a key part in the semantics-based objective, which should represent the semantics of programs. In this paper, we convert a regular expression to a minimal Deterministic Finite Automaton (DFA). Such conversion is based on the insight that semantically equivalent regular expressions have the same minimal DFAs. We define the semantic correctness of a generated regular expression as whether its corresponding minimal DFA is the same as the ground truth's minimal DFA.

When our approach is applied on domains other than regular expressions such as Python programs and Bash scripts, a perfect equivalence oracle such as minimal DFAs may not be feasibly available. To handle a more general case, we propose correctness assessment based on test cases for regular expression; such correctness assessment can be easily generalized for other tasks of program synthesis. Concretely, we generate test cases to represent semantics of the ground truth. For a generated regular expression, we assess its semantic correctness by checking whether it can pass all the test cases. However, a regular expression may have infinite positive (i.e., matched) or negative (i.e., unmatched) string examples; thus, we cannot perfectly represent the semantics. To use limited string examples to differentiate whether a generated regular expression is semantically correct or not, we propose an intelligent strategy for test generation to generate distinguishing test cases instead of just using random test cases.

We evaluate SemRegex on three public datasets: NL-RX-Synth, NL-RX-Turk (Locascio et al., 2016), and KB13 (Kushman and Barzilay, 2013). We compare SemRegex with the existing state-of-the-art approaches on the task of generating regular expressions from NL specifications. Our evaluation results show that SemRegex outperforms the start-of-the-art approaches on all of three datasets. The evaluation results confirm that by maximizing semantic correctness, the model can output more correct regular expressions even when the regular expressions are syntactically different from the ground truth.

In summary, this paper makes the following three main contributions. (1) We propose a semantics-based approach to optimize the semantics-based objective for the task of generating regular expressions from NL specifications. (2) We introduce the measurement of semantic correctness based on test cases, and propose a strategy to generate distinguishing test cases, in order to better measure the semantic correctness than using random test cases. (3) We evaluate our approach on three public datasets. The evaluation results show that our approach outperforms the existing state-of-the-art on all of the three datasets.

2 Problem Formulation

Consider the problem of automatically generating a regular expression R given an NL specification S as an input. Let $S = s_1, s_2, \ldots, s_m$ denote the NL specification, where s_i represents a word in the vocabulary; let $R = r_1, r_2, \ldots, r_n$ denote the regular expression, where r_i is a valid character in the regular expression.

We assume that we have a training set consisting of K NL and regular expression pairs:

$$\mathcal{D} = \left\{ (S^{(i)}, R^{(i)}) \right\}_{i=1..K}$$

Given an NL specification, it is possible to have multiple regular expressions fitting the specification. In the training set, only one regular expression is provided for each NL specification.

3 SemRegex Approach

In this section, we illustrate our SemRegex approach in detail. First, we introduce our model, which is a sequence-to-sequence learning model.

Next, we alter the standard Maximum Likelihood Estimation (MLE) objective to maximize semantic correctness. We leverage policy gradient to train the model with the semantics-based objective. Finally, we discuss how to measure semantic correctness.

3.1 Model

It is natural to apply a machine-translation model on the program-synthesis problem. We follow a previous attempt (Locascio et al., 2016) to use a sequence-to-sequence learning model (Sutskever et al., 2014) augmented with the attention mechanism (Bahdanau et al., 2014). The model consists of an encoder network and a decoder network. In both the encoder network and decoder network, we use LSTM (Hochreiter and Schmidhuber, 1997) units that can be summarized as follow:

$$\begin{aligned} i_t &= \sigma(W_i x_t + U_i h_{t-1} + b_i) \\ f_t &= \sigma(W_f x_t + U_f h_{t-1} + b_f) \\ o_t &= \sigma(W_o x_t + U_o h_{t-1} + b_o) \\ \tilde{c}_t &= \phi(W_c x_t + U_c h_{t-1} + b_c) \\ c_t &= f_t \circ c_{t-1} + i_t \circ \tilde{c}_t \\ h_t &= o_t \circ \phi(c_t) \end{aligned}$$

where σ is the sigmoid function, ϕ is the hyperbolic tangent function, and $\circ$ is the element-wise multiplication; weight matrices W and U along with biases b are learnable parameters of the model. In the encoder network, the input x_t is an embedding vector of the word s_t in the NL input sequence. In the decoder network, the input x_t is an embedding vector of the previous character r_{t-1} in the output regular expression. The hidden vectors h_t of the encoder network are fed into an attention layer (Bahdanau et al., 2014) to output an overall representation of the input sentence considering the output position. The hidden vectors h_t of the decoder network are fed into a dense layer $z_t = W_z h_t$, where z_t holds the dimension of the vocabulary size of the regular expression. z_t is the output of the decoder network to predict the output character $r_t = \arg\max_j z_{t,j}$.

A softmax function is applied on z_t to obtain a probability distribution on output character candidates. The probability of character j at output position t is as follow:

$$p(r_t = j | r_{<t}, S) = \frac{e^{z_{t,j}}}{\sum_{j'} e^{z_{t,j'}}}$$

3.2 Training

Let θ represent all learnable parameters in the model. We discuss two objective functions of θ to train the model.

Maximum Likelihood Estimation (MLE). A sequence-to-sequence learning model learns the distribution of regular expressions R given an input NL sentence S:

$$p_\theta(R|S) = \prod_{t=1}^{T} p_\theta(r_t | r_{<t}, S)$$

By default, the sequence-to-sequence learning model uses maximum likelihood estimation (MLE) for training, i.e., maximizing the likelihood of mapping the input sequence to the output sequence for each pair in the training set. Specifically, the optimal parameters θ^* are obtained as follow:

$$\begin{aligned} \theta^* &= \arg\max_\theta \prod_{(S^{(i)},R^{(i)})\in\mathcal{D}} p_\theta(R^{(i)}|S^{(i)}) \\ &= \arg\max_\theta \sum_{(S^{(i)},R^{(i)})\in\mathcal{D}} \log p_\theta(R^{(i)}|S^{(i)}) \end{aligned}$$

Gradient descent is used to search out optimal parameters θ^*.

However, MLE fails to consider the fact that semantically equivalent regular expressions might be syntactically different. The MLE objective function forces the model to generate syntactically similar regular expressions, but penalizes semantically equivalent and syntactically different regular expressions. Such a syntax-based training objective does not fit our task's objective (i.e., generating any semantically correct regular expression).

Maximizing Semantic Correctness. To encourage the model to generate any semantically correct regular expression, we alter the MLE training objective function to maximize semantic correctness.

For an NL specification, we define a reward of a predicted regular expression $\boldsymbol{r}(R)$ as its semantic correctness (we discuss how to measure the correctness later in this section). We encourage the model to generate regular expressions to maximize expected rewards instead of MLE. Concretely, we train the model parameters θ to maximize the following objective function:

$$\begin{aligned} J(\theta) &= \sum_{(S^{(i)},R^{(i)})\in\mathcal{D}} \mathbb{E}_{R\sim p_\theta(\cdot|S^{(i)})} \boldsymbol{r}(R) \\ &= \sum_{(S^{(i)},R^{(i)})\in\mathcal{D}} \sum_R p_\theta(R|S^{(i)}) \boldsymbol{r}(R) \end{aligned}$$

However, to compute the expected reward, we need to go over all possible regular expressions, and the number of all possible regular expressions is infinite. To address this problem, we use the Monte Carlo estimate as the approximation of the expected value. Specifically, M regular expressions $R_1, \dots, R_M$ are sampled following the output probability of the model. We average the reward of each sample to estimate the expected reward:

$$J(\theta) \approx \sum_{(S^{(i)},R^{(i)})\in\mathcal{D}} \sum_{j=1}^{M} \frac{1}{M}\boldsymbol{r}(R_j), \quad \text{where } R_j \sim p_\theta(\cdot|S^{(i)})$$

In order to compute the gradient of the expected reward and to maximize the objective using gradient descent, we employ the REINFORCE technique of policy gradient (Williams, 1992), which is based on the following estimation:

$$\nabla_\theta J(\theta) \approx \sum_{(S^{(i)},R^{(i)})\in\mathcal{D}} \sum_{j=1}^{M} \frac{1}{M}\boldsymbol{r}(R_j)\nabla_\theta \log p_\theta(R_j|S^{(i)}), \quad \text{where } R_j \sim p_\theta(\cdot|S^{(i)})$$

In practice, we subtract the mean reward of all samples to reduce the variance of estimated gradient (Williams, 1992). The final gradient estimate is as follow:

$$\nabla_\theta J(\theta) \approx \sum_{(S^{(i)},R^{(i)})\in\mathcal{D}} \sum_{j=1}^{M} \frac{1}{M}\tilde{\boldsymbol{r}}(R_j)\nabla_\theta \log p_\theta(R_j|S^{(i)}),$$

$$\text{where } \tilde{\boldsymbol{r}}(R_j) = \boldsymbol{r}(R_j) - \sum_{j'=1}^{M} \frac{1}{M}\boldsymbol{r}(R_{j'})$$

The overall training algorithm is summarized in Algorithm 1. We initialize θ by pre-training the model using MLE on the training set. For each pair in training set, we sample M regular expressions to estimate the gradient.

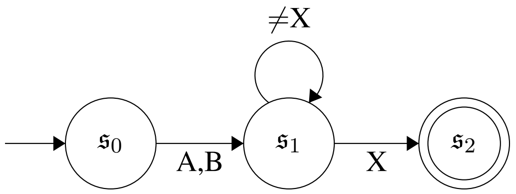
3.3 Measurement of Semantic Correctness

In this paper, we propose two types of measuring semantic correctness based on minimal DFAs and test cases, respectively.

Minimal DFAs. We convert a regular expression to a minimal DFA and utilize the fact that equivalent regular expressions have the same minimal DFAs even when they are syntactically different (Hopcroft et al., 1979). For example, the minimal DFA of regular expression “`([ABab]&[A-Z]).*X`” is shown in Figure 1(a). A syntactically different regular expression “`((A|B).*)&(.*X)`” can be converted to the same minimal DFA as shown in Figure 1(a), indicating that these two regular expressions are semantically equivalent.

Algorithm 1: Policy-gradient method to maximize semantic correctness

```
Input: Training set: $\mathcal{D} = \{(S^{(i)}, R^{(i)})\}$
Initilize $\theta$ from pretrained model using MLE on $\mathcal{D}$ ;
for each epoch do
    for $(S^{(i)}, R^{(i)}) \in \mathcal{D}$ do
        Sample $R_1, \dots, R_M$ using current model ;
        Get rewards $\boldsymbol{r}(R_1), \dots, \boldsymbol{r}(R_M)$ ;
        Estimate $\nabla_\theta J(\theta)$ using (3.2) ;
        Update $\theta$ using $\nabla_\theta J(\theta)$ by gradient descent ;
    end
end
```



(a)

Path	String example
$\mathfrak{s}_0 \xrightarrow{A} \mathfrak{s}_1 \xrightarrow{X} \mathfrak{s}_2$	`AX`
$\mathfrak{s}_0 \xrightarrow{B} \mathfrak{s}_1 \xrightarrow{K} \mathfrak{s}_1 \xrightarrow{X} \mathfrak{s}_2$	`BKX`
$\mathfrak{s}_0 \xrightarrow{B} \mathfrak{s}_1 \xrightarrow{X} \mathfrak{s}_2$	`BX`

(b)

Figure 1: Minimal DFA converted from “`([ABab]&[A-Z]).*X`” and generated string examples, where $\mathfrak{s}_0$ represents the start state and $\mathfrak{s}_2$ is the only accept state.

We check whether two regular expressions are equivalent by checking whether their corresponding minimal DFAs are the same. When the policy-gradient method is performed, if a sampled regular expression R is equivalent to the ground truth, then $\boldsymbol{r}(R) = 1$; otherwise $\boldsymbol{r}(R) = 0$.

Test Cases. A perfect equivalence oracle such as using the minimal DFA may not be feasibly available for some tasks, e.g., when our approach is applied on other domains such as generating Bash scripts and Python programs. To handle a more general case, we propose correctness measurement based on test cases. We generate test cases (i.e., inputs and expected outputs) and check whether a program can pass the test cases that are generated from the ground truth to approximately check whether the program and the ground truth are equivalent.

Given a regular expression R, we generate test cases that contain positive (acceptable/matched) and negative (unacceptable/unmatched) string examples. Here we consider only positive examples because negative examples can be obtained by generating positive examples of its complement regular expression $\sim R$. To generate positive string examples from regular expression R, we convert R to its corresponding minimal DFA. Each positive string example corresponds to a path from the start state of the minimal DFA to any accept state[2], and vice versa. Thus, we generate paths randomly from the start state to any accept state, and convert the paths to their corresponding strings as shown in Figure 1(b). To generate distinct string examples, we aim to generate paths to cover as many transitions as possible. In particular, we mask all transitions that have been covered by previously generated paths. When we generate a new path, the not-covered transitions have higher priority to be explored than covered ones.

Because complex regular expressions may accept/match or reject/unmatch infinite string examples, we augment random generation with a new strategy to generate distinguishing test cases to better represent the semantics. Considering that the generated test cases are used to check whether a Monte-Carlo sampled regular expression is equivalent to the ground truth in the policy-gradient method, only test cases that can differentiate an incorrect sample and the ground truth are useful. Based on such insight, we give preference to test cases that differentiate Monte-Carlo samples and the ground truth. A challenge here is that we do not know the samples before performing the policy-gradient method. However, we find that there is a high chance to get the same samples repeatedly when the model is pre-trained using MLE on the training set, because sampling is following the distribution learned by the pre-trained model. Based on the observation, we use the Beam Search algorithm on the pre-trained model to obtain B most likely samples $\hat{R}_1, \ldots, \hat{R}_B$. We generate string examples that can differentiate these samples and the ground truth, named as distinguishing string examples. For each $\hat{R}$ and ground truth R, we construct a new regular expression $R\&(\sim\hat{R})$, and generate its string examples that can differentiate R and $\hat{R}$.

The overall idea of our strategy for generating string examples is shown in Algorithm 2. Once we have a set of positive and negative string examples, we define the reward of a regular expression as $\boldsymbol{r}(R) = 1$ if it can pass all the test cases, and $\boldsymbol{r}(R) = 0$ otherwise.

When extending SemRegex on other languages where a perfect equivalence oracle is not available, it is desirable to use a technique to generate test cases for a program. There exist techniques (discussed in Section 5) to generate test cases for a general executable program.

Algorithm 2: Generating distinguishing test cases for regular expressions

```
Input: Training set: $\mathcal{D} = \{(S^{(i)}, R^{(i)})\}$,
       the number of examples to generate:
       $T$, and a pre-trained model
Output: Positive and negative example
        sets $\mathcal{P}^{(i)}$ and $\mathcal{N}^{(i)}$
for $(S^{(i)}, R^{(i)}) \in \mathcal{D}$ do
    $\mathcal{P}^{(i)} \leftarrow \emptyset$ ;
    $\mathcal{N}^{(i)} \leftarrow \emptyset$ ;
    Beam search on pre-trained model to
      obtain $\hat{R}_1, \ldots, \hat{R}_B$ ;
    repeat
        Randomly pick a $j$ in $[1, B]$ ;
        $R_p \leftarrow R^{(i)}\&(\sim\hat{R}_j)$ ;
        $R_n \leftarrow (\sim R^{(i)})\&\hat{R}_j$ ;
        Generate an example $p$ from $R_p$ ;
        Generate an example $n$ from $R_n$ ;
        $\mathcal{P}^{(i)} \leftarrow \mathcal{P}^{(i)} \cup \{p\}$ ;
        $\mathcal{N}^{(i)} \leftarrow \mathcal{N}^{(i)} \cup \{n\}$ ;
    until $|\mathcal{P}^{(i)}| \geq T$ && $|\mathcal{N}^{(i)}| \geq T$;
end
```

4 Experiments

We evaluate the effectiveness of SemRegex by comparing it to the state-of-the-art approaches. We also study how using different measurements of correctness impacts the effectiveness of SemRegex.

---

[2] A DFA has one start state and a set of accept states.

4.1 Experiment Setup

Datasets. We conduct our experiments on three public datasets for the task of generating regular expressions from NL specifications.

- **KB13.** KB13 (Kushman and Barzilay, 2013) includes 824 pairs of NL and regular expression. When conducting data labeling, labeling workers are asked to generate the NL specifications to capture a subset of the lines in a file. Then programmers are asked to generate regular expressions for these NL specifications written by the labeling workers. We split the data into 75% training and 25% testing sets, following what the authors of KB13 do.

- **NL-RX-Synth.** NL-RX-Synth (Locascio et al., 2016) is a synthetic dataset much larger than KB13. Its authors define a small grammar for parsing regular expressions to NL. The grammar is used to stochastically generate 10,000 regular expressions and their corresponding synthetic NL specifications. We split the pairs into 65% training, 10% development, and 25% testing sets, following what the authors of NL-RX-Synth do.

- **NL-RX-Turk.** NL-RX-Turk (Locascio et al., 2016) comes from the NL-RX-Synth dataset. Instead of directly using synthetic NL descriptions in the dataset, the authors of NL-RX-Turk ask labeling workers to paraphrase the synthetic specifications. The dataset also consists of 10,000 pairs of NL and regular expression. We split the pairs into 65% training, 10% development, and 25% testing sets, following what the authors of NL-RX-Turk do.

Training Setting. We use a two-layer stacked LSTM architecture in both the encoder and decoder networks. The dimensions of encoder and decoder hidden states are set to 256. We use random embedding layers with the dimension of 128 for both input and output words. We also tune our hyper-parameters on the development set. The best results are obtained when the learning rate $= 0.001$ and the batch size = 25. We use the Monte-Carlo method to sample $M = 10$ regular expressions to estimate the gradient. To generate distinguishing string examples, we perform Beam Search to obtain $B = 10$ most likely samples. Before performing the policy-gradient method, we pre-train the model using MLE for 100 epochs. Then we train the model for 40 epochs using the policy-gradient method, and choose the model with the best effectiveness on the development set. Our model is implemented in TensorFlow (Abadi et al., 2016).

4.2 Results and Analysis

Comparison Results. We demonstrate the effectiveness of our approach by comparing it to the existing approaches including Semantic-Unify (Kushman and Barzilay, 2013) and Deep-Regex(MLE) (Locascio et al., 2016). We also compare the results of our approach with different measurements of semantic correctness. Table 2 shows the comparison results of different approaches, with detailed discussion as follows.

- **Semantic-Unify.** Semantic-Unify (Kushman and Barzilay, 2013) learns to parse NL to regular expressions. Similarly, DFA equivalence is applied as a semantic unification when training the parser.

- **Deep-Regex(MLE).** Deep-Regex(MLE) (Locascio et al., 2016) regards the problem as a black-box task of machine translation without utilizing any domain knowledge of regular expressions. A syntax-based objective (MLE) is used to train the model. To the best of our knowledge, Deep-Regex(MLE) is the state-of-the-art approach on these three datasets.

- **SemRegex(DFA Oracle).** In SemRegex (DFA Oracle), we use the oracle of DFA equivalence to measure semantic correctness. SemRegex(DFA Oracle) outperforms Deep-Regex(MLE), the existing state-of-the-art approach, by an accuracy increase of 12.6% on KB13, 2.9% on NL-RX-Synth, and 4.1% on NL-RX-Turk, respectively. Compared to Deep-Regex(MLE), the results demonstrate the effectiveness of maximizing semantic correctness during the training phase. SemRegex(DFA Oracle) shows more improvement on the KB13 dataset over Deep-Regex(MLE) than on other datasets. Such result indicates that supervised learning based on MLE is less effective to learn from a small training set. When the policy-gradient method is used, Monte-Carlo samples can provide more information beyond only training samples especially on a small training set;

Table 2: Effectiveness comparison of different approaches (using DFA-equivalence accuracy as metrics)

Approach	**KB13**	**NL-RX-Synth**	**NL-RX-Turk**
Semantic-Unify	65.5%	46.3%	38.6%
Deep-Regex(MLE)	65.6%	88.7%	58.2%
SemRegex(DFA Oracle)	**78.2%**	**91.6%**	**62.3%**
SemRegex(Distinguishing Test Cases)	77.5%	90.2%	61.3%
SemRegex(Random Test Cases)	66.5%	90.2%	59.5%

such more information significantly improves the effectiveness.

- **SemRegex(Distinguishing Test Cases).** When we do not have access to an oracle such as DFA equivalence, we can generate test cases to define semantic correctness. SemRegex(Distinguishing Test Cases) uses Algorithm 2 to generate distinguishing test cases (10 positive examples and 10 negative examples) that differentiate the results returned by Beam Search and the ground truth. The results show that by using distinguishing test cases, SemRegex(Distinguishing Test Cases) outperforms Deep-Regex(MLE), an existing syntax-based approach, on all of three datasets. Meanwhile, the effectiveness of SemRegex(Distinguishing Test Cases) drops no more than 1.4% on accuracy compared to SemRegex(DFA Oracle). Such result indicates that limited distinguishing test cases generated by the proposed strategy can well represent the semantics.

- **SemRegex(Random Test Cases).** SemRegex(Random Test Cases) generates random test cases instead of distinguishing test cases. It outperforms the existing approaches (Semantic-Unify and Deep-Regex(MLE)) because random test cases can still represent the semantics and differentiate some inequivalent regular expressions. Compared to SemRegex(Distinguishing Test Cases), its effectiveness shows a big drop on KB13 and a slight drop on NL-RX-Turk. Such results indicate the benefit of distinguishing test cases over random test cases.

Effectiveness of Semantics-Based Objective. To understand the effect of using a semantics-based learning objective, we record the semantic accuracy (DFA equivalence) and syntactic accuracy (exact-match) on the NL-RL-Turk testing set after each epoch as shown in Figure 2. During pre-training (epochs 1 to 100), we use MLE to train the model to increase both semantic accuracy and syntactic accuracy iteratively. Then, we alter the training objective to maximize the expected semantic correctness. We notice that while semantic accuracy continues increasing for about 10%, the syntactic accuracy does not show a significant growth after pre-training. Such result indicates that the model is no longer encouraged to generate regular expressions that are syntactically equivalent to the ground truths. Instead, the model learns to generate semantically correct regular expressions.

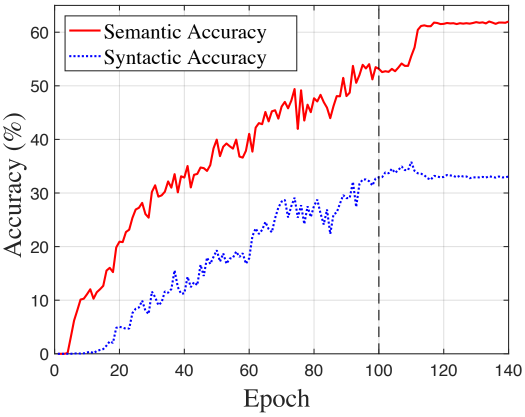


Figure 2: Semantic accuracy (DFA equivalence) and syntactic accuracy (exact-match) on the NL-RL-Turk testing set after each epoch. The training objective is replaced to maximize expected correctness after 100 epochs. The correctness is measured by the DFA-equivalence oracle in this figure.

Analysis of Semantic Correctness Based on Test Cases. The correctness measurements based on test cases serve as an approximate oracle. Figure 3 shows an example of how the approximate oracle helps make improvement. Furthermore, we evaluate how the correctness based on test cases is close to the DFA-equivalence oracle. In Monte-Carlo estimate, we count the samples with the approximate oracle that equals to the minimal DFA oracle. When using random test cases, there are 89.8% samples with the approximate oracle that equals to the minimal DFA oracle. When using distinguish-

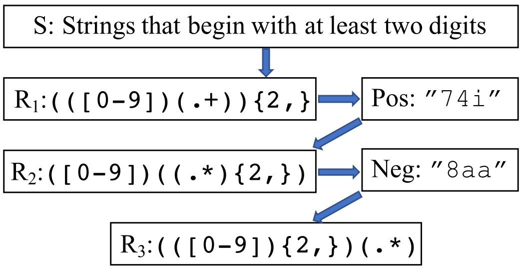

Figure 3: An example of how test cases help with training. At the beginning of the policy-gradient method, the model outputs an incorrect answer R_1, which cannot pass a positive test case. R_1 gets penalized because it receives a reward 0. Then the model changes to output an incorrect answer R_2, which cannot pass a negative test case. Similarly, R_2 gets penalized as training continues. R_3 receives a reward 1 because it passes all test cases, resulting in an increase of its likelihood from the model in iterations. Finally, the model outputs the correct answer R_3.

ing test cases, such percentage increases to 96.3%. Such result illustrates that test cases are able to approximately check the semantic equivalence even when the test cases are generated randomly. The result also suggests that distinguishing test cases represent the semantics more effectively than random test cases.

Impact of the Number of Test Cases. We study how the number of test cases impacts the effectiveness. We enumerate the number of distinguishing or random positive/negative string examples from $T = 1$ to $T = 10$ to show the impact on the effectiveness ($T = 0$ refers to using MLE to train the model). As shown in Figure 4, when more distinguishing test cases are used, higher accuracy is reached. However, more random test cases make limited improvement.

5 Related Work

Program Synthesis. Our work falls into the general topic of program synthesis. Program synthesis is the problem of automatically generating programs from high-level specifications (Gulwani et al., 2017). There has been a lot of progress made in this area, classified based on (1) the form of specifications, e.g., NL descriptions (Yin and Neubig, 2017; Guu et al., 2017; Lin et al., 2017; Krishnamurthy and Mitchell, 2012; Liu et al., 2018), input-output examples (Balog et al., 2017; Chen et al., 2018; Kalyan et al., 2018), and hybrid of the two preceding types of specifications (Manshadi et al., 2013; Raza et al., 2015); (2) the programming languages, e.g., LISP (Biermann, 1978), Python (Yin and Neubig, 2017; Rabinovich et al., 2017), SQL (Zhong et al., 2017; Sun et al., 2018), and Domain-Specific Languages (DSL) such as FlashFill (Gulwani, 2011). In this paper, we focus on an important subtask of the program-synthesis problem: generating regular expressions from NL.

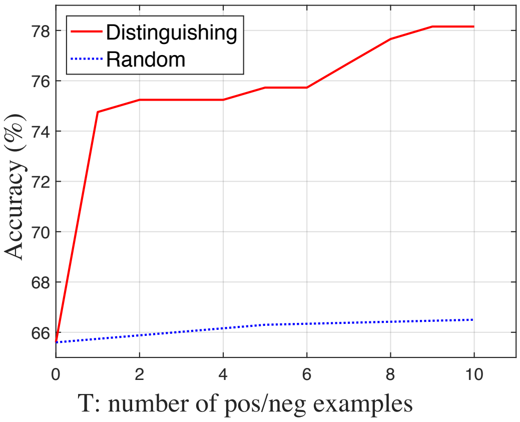

Figure 4: Impact of the number of distinguishing or random test cases on accuracy on the KB13 dataset.

Generating Regular Expressions. Recent research has attempted to automatically generate regular expressions from NL specifications. Ranta (1998) propose a rule-based approach to build an NL interface for regular expressions. Kushman and Barzilay (2013) develop an approach for learning a probabilistic grammar model to parse an NL description into a regular expression. Locascio et al. (2016) regard the problem as a black-box task of machine translation, and train a sequence-to-sequence learning model to address the problem. There exists also a lot of work focusing on generating regular expressions from string examples. Recent work typically uses an evolutionary algorithm to address the problem (Svingen, 1998; Cetinkaya, 2007; Bartoli et al., 2012, 2016).

Inspired by our previous study (Zhong et al., 2018), in this paper, we leverage the help of string examples generated from ground truths to improve the state of the art for the problem of generating regular expressions from NL. Compared with previous state-of-the-art approaches (Locascio et al., 2016) that maximize the likelihood of ground truths in the training set, SemRegex leverages the policy-gradient method to encourage the model to generate semantically correct regular expressions.

Generating Test Cases. When SemRegex is applied on domains other than synthesizing regular expressions, a perfect equivalence oracle such as using the minimal DFA may not be feasibly available. In order to handle a more general case, we propose to generate test cases from the ground truths to measure the semantic correctness of a program candidate. State-of-the-art test-generation techniques are typically based on Dynamic Symbolic Execution (DSE) (Godefroid et al., 2005). Given a program that we want to generate test cases for, DSE executes the program for some seed test cases, and at the same time collects symbolic constraints from branch statements along the execution path. Then DSE generates new test cases to cover different branches in iterations by flipping a branching node in previous execution path. In this way, DSE is able to generate test cases that can be used to approximately check the semantic equivalence. Furthermore, DSE can effectively generate distinguishing test cases for two executable programs by relating these two programs in a single execution (Taneja and Xie, 2008). Various DSE tools have been implemented for different programming languages, such as PyExZ3 (Python) (Ball and Daniel, 2015), JPF-SE (Java) (Anand et al., 2007), Pex (C#) (Tillmann and De Halleux, 2008; Tillmann et al., 2014; Li et al., 2009), and CUTE (C) (Sen et al., 2005).

6 Conclusion

We have proposed SemRegex, a semantics-based approach to generate regular expressions from NL specifications. SemRegex trains a sequence-to-sequence model by maximizing the expected semantic correctness. We measure the semantic correctness using the DFA-equivalence oracle, random test cases, and distinguishing test cases. Our evaluation results show that SemRegex outperforms the existing start-of-the-art approaches on three public datasets.

Decoupling Structure and Lexicon for Zero-Shot Semantic Parsing

Jonathan Herzig[1] and **Jonathan Berant**[1,2]

Abstract

Building a semantic parser quickly in a new domain is a fundamental challenge for conversational interfaces, as current semantic parsers require expensive supervision and lack the ability to generalize to new domains. In this paper, we introduce a zero-shot approach to semantic parsing that can parse utterances in unseen domains while only being trained on examples in other source domains. First, we map an utterance to an abstract, domain-independent, logical form that represents the structure of the logical form, but contains slots instead of KB constants. Then, we replace slots with KB constants via lexical alignment scores and global inference. Our model reaches an average accuracy of 53.4% on 7 domains in the OVERNIGHT dataset, substantially better than other zero-shot baselines, and performs as good as a parser trained on over 30% of the target domain examples.

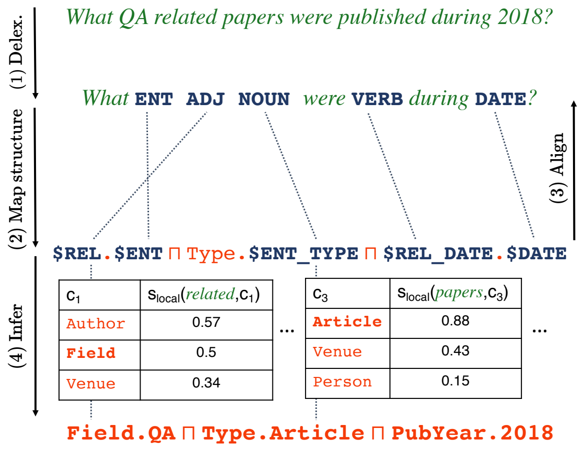

Figure 1: A test utterance is delexicalized (1) and mapped to its abstract logical form (2). Slots ("\$" variables) are then aligned to the abstract utterance (3), and are filled with the top assignment in terms of local and global scores (4). Logical forms throughout this paper are in λ-DCS (Liang, 2013).

1 Introduction

Semantic parsing, the task of mapping natural language utterances into executable logical forms, is a key paradigm in developing conversational interfaces (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Kwiatkowski et al., 2011; Berant and Liang, 2015). The recent success of conversational interfaces such as Amazon Alexa, Google Assistant, Apple Siri, and Microsoft Cortana has led to soaring interest in developing methodologies for training semantic parsers quickly in any new domain and from little data.

Prior work focused on alleviating data collection by training from weak supervision (Clarke et al., 2010; Liang et al., 2011; Kwiatkowski et al., 2013; Artzi and Zettlemoyer, 2013), or developing protocols for fast data collection through paraphrasing (Berant and Liang, 2014; Wang et al., 2015) or a human-in-the-loop (Iyer et al., 2017). However, all these approaches rely on supervised training data in the target domain and ignore data collected previously for other domains.

In this paper, we propose an alternative, zero-shot approach to semantic parsing, where no labeled or unlabeled examples are provided in the target domain, but annotated examples from other domains are available. This is a challenging setup as in semantic parsing each dataset is associated with its own knowledge-base (KB) and thus all target domain KB constants (relations and entities) are unobserved at training time. Moreover, this is a natural use-case as more and more conversational interfaces are developed in multiple domains.

Our approach is motivated by recent work (Herzig and Berant, 2017; Su and Yan, 2017; Fan et al., 2017; Richardson et al., 2018) that showed that while the lexicon and KB constants in dif-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1619–1629
Brussels, Belgium, October 31 - November 4, 2018.

ferent domains vary, the structure of language composition repeats across domains. Therefore, we propose that by abstracting away the domain-specific lexical items of an utterance, we can learn to map the structure of an abstract utterance to an abstract logical form that does not include any domain-specific KB constants, using data from other domains only.

Figure 1 illustrates this approach. A test utterance in the target domain is delexicalized and mapped to an abstract, domain-independent representation, where some content words are replaced by abstract tokens (step 1). Then, a structure-mapping model maps this representation into an abstract logical form that contains slots instead of KB constants (step 2). A major technical challenge at this point is to replace slots in the abstract logical form with KB constants from the target domain. We show that it is possible to learn a domain-independent lexical alignment model that aligns each slot to a word in the original utterance (step 3). This alignment, combined with a global inference procedure (step 4) allows one to find the best assignment of KB constants and produce a final logical form. Importantly, both of our models are trained from data in *other* domains only.

We show that our zero-shot framework parses 7 different unseen domains from the OVERNIGHT dataset with an average denotation accuracy of 53.4%. This result dramatically outperforms several natural baselines, and achieves the same result as training a parser on over 30% of the fully supervised target domain examples. To our knowledge, this work is the first to train a zero-shot semantic parser that can handle unseen domains. All our code is available at `https://github.com/jonathanherzig/zero-shot-semantic-parsing`.

2 Background

Neural Semantic Parsing Sequence-to-sequence models (Sutskever et al., 2014) were recently proposed for semantic parsing (Jia and Liang, 2016; Dong and Lapata, 2016). In this setting, a sequence of input language tokens $x_1, \ldots, x_m$ is mapped to a sequence of output logical tokens $z_1, \ldots, z_n$. We briefly review the model by Jia and Liang (2016), which we use as part of our framework, and also as a baseline.

The **encoder** is a BiLSTM (Hochreiter and Schmidhuber, 1997) that converts $x_1, \ldots, x_m$ into a sequence of context sensitive states. The attention-based **decoder** (Bahdanau et al., 2015; Luong et al., 2015) is an LSTM language model additionally conditioned on the encoder states. Formally, the decoder is defined by:

$$p(z_j = w \mid x, z_{1:j-1}) \propto \exp(U[s_j, c_j]),$$
$$s_{j+1} = LSTM([\phi^{(out)}(z_j), c_j], s_j),$$

where s_j are decoder states, U and the embedding function $\phi^{(out)}$ are the decoder parameters, and the context vector, c_j, is the result of global attention (Luong et al., 2015). We also employ attention-based copying (Jia and Liang, 2016), but omit details for brevity.

Semantic Parsing over Multiple KBs Recently, Herzig and Berant (2017), Su and Yan (2017) and Fan et al. (2017) proposed to exploit structural regularities in language across different domains. These works pooled together examples from multiple datasets in different domains, each corresponding to a separate KB, and trained a single sequence-to-sequence model over all examples, sharing parameters across domains. They showed that this substantially improves parsing accuracy. While these works implicitly capture linguistic regularities across domains, they rely on annotated data in the target domain. We, conversely, explicitly decouple structure mapping from the assignment of KB constants, and thus can tackle the zero-shot setting where no target domain examples are available. This is the focus of the next section.

3 Zero-Shot Semantic Parsing

3.1 Overview

Following the empirical success of sharing structural information between different semantic parsing domains, we propose in this paper to take a more radical approach and to explicitly decouple semantic parsing into a structure mapping model and a lexicon mapping model. We now provide an overview of our approach and explain how this decoupling facilitates zero-shot semantic parsing.

We assume access to D different source domains, where for every domain d we receive a KB $\mathcal{K}_d$, and a training set of pairs of utterances and logical forms $\{(x_i, z_i)\}_{i=1}^{N_d}$. We further assume a lexicon L that maps each KB constant in $\mathcal{K}_d$ to a short phrase that describes it (e.g., $L($`PubYear`$)\rightarrow$*"publication year"*), as in Wang

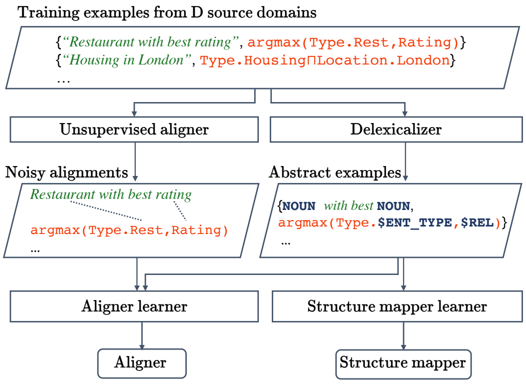

Figure 2: Training flow. Examples in source domains are delexicalized. Abstract examples are used to train both the structure mapper learner and aligner learner, where the aligner learner uses noisy alignments as labels.

Lexical representation
"What meetings have no more than 3 attendees?"
$\texttt{Type.Meeting} \sqcap \mathbf{R}[\lambda x.\text{count}(\texttt{Attendee}.x)].\leq.\texttt{3}$
"Which recipe needs no more than two ingredients?"
$\texttt{Type.Recipe} \sqcap \mathbf{R}[\lambda x.\text{count}(\texttt{IngredientOf}.x)].\leq.\texttt{2}$

Abstract representation
"What NOUN have no more than NUM NOUN?"
$\texttt{Type.\$ENT\_TYPE} \sqcap \mathbf{R}[\lambda x.\text{count}(\texttt{\$REL}.x)].\leq.\texttt{\$NUM}$
"Which NOUN VERB no more than NUM NOUN."
$\texttt{Type.\$ENT\_TYPE} \sqcap \mathbf{R}[\lambda x.\text{count}(\texttt{\$REL}.x)].\leq.\texttt{\$NUM}$

Figure 3: Examples in different domains (CALENDAR and RECIPES) in their original and abstract representations. A similar structural regularity (a comparative structure) maps to an identical abstract logical form.

et al. (2015). Finally, we assume a pre-trained, static, embedding function $\phi(w) \in \mathbb{R}^f$ for every word w, used to measure cross-domain lexical semantic similarity. Our goal is to train a semantic parser that maps a new utterance x to the correct logical form z from a new domain d_{new} given $\mathcal{K}_{d_{\text{new}}}$.

Figure 2 describes the flow of our training procedure: we first employ a simple rule-based method to transform training examples to an abstract representation, where content words (in utterances) and KB constants (in logical forms) are delexicalized. We then train the following two models that decouple structure from lexicon (a) The structure mapper that maps abstract utterances to abstract logical forms. (b) The aligner that provides an alignment from abstract logical form tokens to abstract utterance tokens. Training the aligner is challenging because no gold alignments between the abstract utterance and abstract logical form are available. To overcome this challenge we propose a distillation strategy: we obtain noisy supervision by training a state-of-the-art unsupervised alignment model on the D source domains. Then, we train a second supervised alignment model that receives abstract utterances, abstract logical forms, and target noisy alignments as input and learns to predict the noisy alignments.

Once the two models are trained, we can tackle a new domain without training examples (Figure 1). Given an utterance from the target domain, we first abstract it using the delexicalizer, and then predict its abstract structure using the structure mapper. We treat delexicalized logical form tokens as slots to be filled with KB constants. Candidate assignments are then scored locally according to the semantic similarity of a KB constant (represented by its entry value in the lexicon L) to words the slot aligns to according to the aligner. For this we use the pre-trained embedding function $\phi(\cdot)$ as the only cross-domain information. Finally, we choose a final assignment of KB constants by exactly maximizing a global scoring function, which takes into account both local alignment scores as well as global constraints.

We next describe in detail the four components of our framework: the delexicalizer, structure mapper, aligner, and inference procedure.

3.2 Delexicalizer

The goal of the delexicalizer is to strip utterances and logical forms from their domain-specific components and preserve domain-independent parts. We note that it is possible that some words contain both domain-specific and domain-general aspects (*"cheapest"*). However, we conjecture that it is possible to decompose examples in a manner that enables zero-shot semantic parsing.

The output of the delexicalizer is an abstract representation that should manifest structural linguistic regularities across domains (Figure 3). For example, a comparative structure will correspond to the same abstract logical form in different domains. In this representation, used as input to our models, content words and KB constants are transformed to an abstract type. This rule-based preprocessing step is applied to all D source domain training examples (utterances and logical forms), and to target domain utterances at test time. We now describe the process of delexicalization.

Source	Category	Abstract Type	Examples
Utterance	Noun	`NOUN`	*“cuisines”*, *“housing”*, *“time”*
	Verb	`VERB`	*“published”*, *“born”*, *“posted”*
	Adjective	`ADJ`	*“high”*, *“cooking”*, *“monthly”*
	Number	`NUM`	*“4”*, *“three”*
	Date	`DATE`	*“2018”*, *“january 2nd”*
	Entity	`ENT`	*“midtown”*, *“alice”*, *“dinner”*
Logical Form	Number	`$NUM`	`1,2,3`
	Date	`$DATE`	`1_6_2018`
	Entity	`$ENT`	`MidtownWest, CentralOffice`
	Entity type	`$ENT_TYPE`	`Person, Location, Recipe`
	Numerical entity	`$ENT_NUM`	`Rent, Size, CookingTime`
	Binary relation	`$REL`	`Author, Attendee`
	Unary relation	`$REL_UNARY`	`AllowsCats, WonAward`
	Numerical relation	`$REL_NUM`	`Height, Length, StarRating`
	Date relation	`$REL_DATE`	`PostingDate, PubYear`

Table 1: Categories of content words and KB constants, and their corresponding abstract type notation.

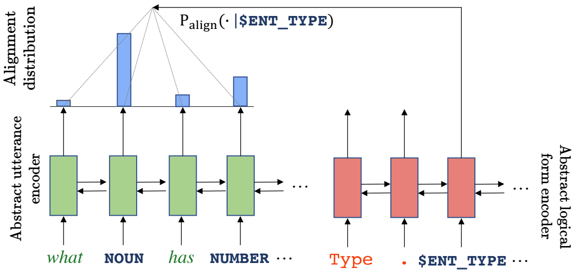

Figure 4: The aligner model. Alignments are derived by comparing the slot hidden state against all utterance hidden states.

Utterances Table 1 describes the full list of abstraction rules. We delexicalize several categories of content words and keep function words, which describe the utterance structure, in their lexicalized form. Specifically, any verb[1] whose lemma is not *“be”* or *“do”* is delexicalized. All nouns are delexicalized, except for a small vocabulary of three words (*“average”*, *“total”*, and *“number”*), which denote a domain-general operation. Adjectives tend to distribute more evenly between domain-specific words and domain-general words, thus discriminating them is harder (e.g., *“outdoor”*, *“wide”* and *“cooking”* are domain-specific words while *“minimum”*, *“same”* and *“many”* are domain-general words). Thus, we take a statistical approach and only delexicalize adjectives that are unique to the domain (i.e., did not appear in the training set of any other source domain). We also delexicalize dates and numbers, and identify entities in the utterance by string matching against the entities in the KB. These are then delexicalized to their corresponding abstract type (Table 1).

Logical Forms We delexicalize all KB constants to their abstract type, which is given as part of the KB schema (Table 1).

3.3 Structure Mapper

As a first step towards predicting the lexical logical form, we map an abstract utterance, to an abstract logical form. The model is the neural semantic parser described in Section 2, only here the input and output are the abstract examples in all D domains, which the delexicalizer outputs. The model utilizes a single encoder-decoder pair shared across all domains. As Figure 3 suggests, the model should learn, e.g., that a noun modified by a wh-question often maps to `$ENT_TYPE`, and that *“no more than”* maps to the $\leq$ operator.

3.4 Aligner

The output of the structure mapper is an abstract logical form that contains slots instead of KB constants. To predict a complete logical form, we must assign a KB constant to each slot.

We observe that the description of a KB constant that appears in the logical form (`Article`) is often semantically similar to some word in the utterance (*“paper”*). Thus, we can obtain signal for the identity of a KB constant by solving an alignment problem: each slot can be aligned to words in the utterance that have similar meaning to that of the gold KB constant. Naturally, in some cases a KB constant is not semantically similar to any utterance word (e.g., the relation `Field` in Figure 1), which we will mediate by using a global inference procedure (Section 3.5).

Thus, our goal is to learn a model that given an abstract utterance-logical form pair $(x^{\text{abs}}, z^{\text{abs}})$ produces an alignment matrix A, where A_{ij} corresponds to the alignment probability $p(x_j^{\text{abs}} \mid z_i^{\text{abs}})$. A central challenge is that no gold alignments are provided in any domain. Therefore, we adopt a “distillation approach”, where we train a supervised model over abstract examples to mimic the predictions of an unsupervised model that has access to the full lexicalized examples.

Specifically, we use a standard unsupervised word aligner (Dyer et al., 2013), which takes all lexicalized examples $\{(x_i, z_i)\}_{i=1}^{N_d}$ in all D domains and produces an Alignment matrix A^* for every example, where $A^*_{ij} = 1$ iff token i in the logical form is aligned to token j in the utterance. Then, we treat A^* as gold alignments and gener-

---

[1] Numbers, dates and part-of-speech tags are extracted using Stanford CoreNLP (Manning et al., 2014).

ate examples $(x^{\text{abs}}, z^{\text{abs}}, A^*)$ to train the aligner. Learning alignments over abstract representations is possible, as a slot in a specific context tends to align to specific types of abstract words (e.g., Figure 3 suggests that a relation that is aggregated, often aligns to the `NOUN` that appears after the `NUM` in the abstract utterance).

We now present our alignment model, depicted in Figure 4. The model uses two different BiLSTMs to encode x^{abs} and z^{abs} to their context sensitive states $b_1, \ldots, b_m$ and $s_1, \ldots, s_n$ respectively. We model the alignment probability $p_{\text{align}}(x_j^{\text{abs}} \mid z_i^{\text{abs}})$ with a bi-linear form similar to attention (Luong et al., 2015):

$$e_{ij} = s_i^T W b_j,$$

$$p_{\text{align}}(x_j^{\text{abs}} \mid z_i^{\text{abs}}) = \frac{\exp(e_{ij})}{\sum_{j'=1}^{m} \exp(e_{ij'})},$$

where the parameters W are learned during training. We train the model to minimize the negative log-likelihood of gold alignments while considering only alignments of slots (since we only align slots at test time). The cross-entropy loss for a training example $(x^{\text{abs}}, z^{\text{abs}}, A^*)$ is then given by:

$$-\sum_{i:i \in S_z}^{n} \sum_{j=1}^{m} A_{ij}^* \log p_{\text{align}}(x_j^{\text{abs}} \mid z_i^{\text{abs}}),$$

where S_z are the slot indices in z^{abs}.

Our model can be viewed as an attention model, dedicated to aligning logical form tokens to utterance tokens. Using a separate alignment model rather than the attention weights of the structure mapper has two advantages: First, alignments are generated given the entire generated sequence z^{abs} rather than just a prefix. Second, our model focuses its capacity on the alignment task without worrying about generation of z^{abs}. In Section 4, we will demonstrate that training a dedicated aligner substantially improves performance.

3.5 Inference

The aligner provides a distribution over utterance tokens for every slot in the abstract logical form. To compute the final logical form, we must replace each slot with a KB constant. Formally, let $(z_{j_1}^{\text{abs}}, \ldots, z_{j_l}^{\text{abs}})$ be the sequence of slots in z^{abs} and denote them for simplicity as $y = (y_1, \ldots, y_l)$. Our goal is to predict a sequence of KB constants $c = (c_1, \ldots, c_l)$, where each c_i is chosen from a candidate set $\mathcal{C}(y_i)$ that is determined by the abstract token y_i according to Table 1 (e.g., if y_i is `$REL`, then $\mathcal{C}(y_i)$ is the set of binary relations).

Our scoring function depends on alignments computed by the aligner. However, because slots are independent in the aligner, we introduce a few global constraints that capture the dependence between different slots. Formally, we wish to find c^* that maximizes the following scoring function, which depends on the utterance x, the slot sequence y, the abstract logical form z^{abs}, the alignment matrix A and the embedding function ϕ:

$$\arg\max_{c} \sum_{i=1}^{l} \left(s_{\text{local}}(c_i, y_i, x, A, \phi)\right) + s_{\text{global}}(c, z^{\text{abs}}).$$

We now describe our scoring functions in detail.

Local Score Because inference is applied only at test time, we have access to the lexicalized utterance and not only the abstract one. Thus, the aligner outputs a distribution over words for a slot y (e.g., in Figure 1, `$REL_DATE` aligns with high probability to `VERB`, which corresponds to the word *"published"*). Each word, in turn, has different semantic similarity to each KB constant in $\mathcal{C}(y)$. Intuitively, we would like to assign a KB constant that has high similarity with words the slot is aligned to. Thus, we define s_{local} of a KB constant c_i for every slot y_i to be its expected semantic similarity under the alignment distribution:

$$s_{\text{local}}(c_i, y_i, x, A, \phi) = E_{x \sim p_{\text{align}}(x^{\text{abs}} \mid y_i)}[\mathit{sim}_\phi(x, c_i)]$$

$$= \sum_{j=1}^{m} p_{\text{align}}(x_j^{\text{abs}} \mid y_i) \cdot \mathit{sim}_\phi(x_j, c_i).$$

We define $\mathit{sim}_\phi(x_j, c_i)$ to be the cosine similarity between the embedding $\phi(x_j)$ and the embedding $\phi(c_i)$ (scaled to the range [0,1]), where $\phi(c_i)$ is defined to be the average embedding of all words in $L(c_i)$, that is, $\mathit{sim}(x_j, c_i) = \frac{1+\cos(\phi(x_j), \phi(c_i))}{2}$.

Global Score Utilizing only a local scoring function raises several concerns. First, slots are treated independently and dependencies between slots are ignored, which might result in a final logical form that is globally inconsistent. For example, we could generate the logical form `Birthplace.ComputerScience`, which is semantically dubious. Second, some KB constants do not align to any word in the utterance and appear in the logical form only implicitly. For example, the logical form in Figure 1 contains the `Field` relation, however *"field"* is implicit in the utterance. Therefore, we define $exe_{\mathcal{K}}(z)$ to be true iff z executes against $\mathcal{K}$ without errors, and define a global score that prevents assignments c that result in a logical form z such that $exe_{\mathcal{K}}(z)$ is false.

Moreover, we can use similar constraints to prevent logical forms that are highly unlikely according to our prior knowledge. Specifically, we define $once(z)$ to be true iff each date, named entity, and number in the logical form z appear exactly once. We then define a global score that prevents logical forms in which $once(z)$ is false. Empirically, we find such assignments to be mostly wrong (e.g., `Type.Article ⊓ (Field.QA ⊔ Field.QA)`).

Formally, our scoring function is defined as:

$$s_{\text{global}}(c, z^{abs}) = \begin{cases} 0 & exe_{\mathcal{K}}(z^{abs}|_c), once(z^{\text{abs}}|_c) \\ -\infty & \text{otherwise,} \end{cases}$$

where $z^{abs}|_c$ is the result of assigning the KB constants c to the slots in z^{abs}.

Inference Algorithm. While each local scoring function can be efficiently maximized independently, the global constraints that depend on the entire assignment c make inference more complicated. However, because the global scoring function introduces hard constraints, an exact and efficient inference algorithm is still possible. Our inference algorithm generates solutions one-by-one sorted by the local scoring function only. Then, it checks for each one whether it satisfies the global constraints defined by s_{global}, and stops once a satisfying solution is found, which is guaranteed to maximize our scoring function. While in the worst case, this procedure is exponential in the size of c, in practice solutions are found after only a few steps. We also always halt after T steps if a solution has not been found.

Algorithm 1 describes the details of our inference procedure. We define *cands* to be a data structure that contains l lists of candidate KB constants (a list for each slot), sorted according to the local scoring function s_{local} in descending order. Additionally, *getAssign*$(cands, a)$ is a function that accesses *cands*, and retrieves the assignment with indices a. For example, *getAssign*$(cands, \{0\}^l)$ retrieves the top scoring local assignment. Last, we define $a_{\text{inc}(i)}$ to be the indices a, where a_i is incremented by 1.

Algorithm 1 Exact inference algorithm

```
Input: $cands, T$
Output: $c^*$ - the top scoring assignment
$horizon \leftarrow \emptyset$                    ▷ Max heap
$a_{\text{init}} \leftarrow \{0\}^l$
$push(horizon, a_{\text{init}})$
for $t \leftarrow 1$ to $T$ do
    $a \leftarrow pop(horizon)$
    $c \leftarrow getAssign(cands, a)$
    if $s_{\text{global}}(c, z^{\text{abs}}) = 0$ then
        return $c$
    for $i \leftarrow 1$ to $l$ do
        $push(horizon, a_{\text{inc}(i)})$
return $NULL$
```

The algorithm proceeds as follows. First we initialize a maximum heap *horizon* into which we will dynamically push candidate assignments. Then, we iteratively pop the best current assignment from the heap, and check if it satisfies the global constraints. If it does, we return this assignment and stop. Otherwise, we generate the next possible candidates, one from each list (there is no need to add more than one because candidates are sorted). If no satisfying assignment is found after T steps, we return $NULL$. It is easy to show that when the algorithm returns an assignment it is guaranteed to be the one that maximizes our global scoring function.

4 Experiments

4.1 Experimental Setup

Data We evaluated our method on the OVERNIGHT semantic parsing dataset, which contains $13,682$ examples of language utterances paired with logical forms across eight domains, which were chosen to explore diverse types of language phenomena. As described, our approach depends on having linguistic regularities repeat across domains. However two domains contain logical forms that are based on neo-davidsonian semantics for treating events with multiple arguments. Since such logical forms are completely absent in six domains, it is not possible for our method to generalize to those in our zero-shot approach. Therefore, we do not evaluate on the BASKETBALL domain, in which 98% of the examples contain such logical forms, and omit all examples (68%) that contain such logical forms in the SOCIAL domain. We evaluated on the same train/test split as Wang et al. (2015), using the same accuracy metric, i.e., the proportion of questions for which the denotations of the

Model	Blocks	Calendar	Housing	Publications	Recipes	Restaurants	Social	Avg.
InLex	59.9	73.8	72.0	79.5	79.2	76.2	83.4	74.8
InAbstract	39.6	57.7	51.9	59.6	66.2	68.4	66.1	58.5
CrossLex	0.0	0.0	0.5	0.0	1.4	1.2	1.0	0.6

Table 2: Test accuracy for all models on all domains.

	In-domain	**Cross-domain**
Lexical	InLex	CrossLex
Abstract	InAbstract	ZeroShot

Table 3: Evaluated models.

predicted and gold logical forms are equal. We additionally used the lexicon L they provided with descriptions for KB constants.

Evaluated Models We evaluated different models (Table 3) according to the following two attributes. Firstly, whether the model is trained on target domain data (*in-domain*) or on source domains data only (*cross-domain*). Secondly, we trained the neural semantic parser described in Section 2 over the lexical data representation (*lexical*), or in comparison trained our model over the abstract representation (*abstract*).

As CrossLex can not generate KB constants unseen during training, we additionally implemented CrossLexRep. In this model, we added an additional step that modifies the output of CrossLex: we replaced a generated KB constant with its most similar KB constant from the target KB that also shares its abstract type.

Implementation Details In all experiments, for our embedding function $\phi(\cdot)$, we used pre-trained GloVe (Pennington et al., 2014) vectors with dimension 300. In a single experiment we considered one domain as the target domain, while other domains were the source domains (and repeated for all domains). For InLex, CrossLex and CrossLexRep we used exactly the same experimental setup as Jia and Liang (2016). For our zero-shot model, we used 20% of the training data as a development set for tuning hyper-parameters. We first tuned parameters for the structure mapper, and used the best setting for tuning the aligner.

We provide the list of hyper-parameters and their values for our zero-shot framework. **Structure mapper:** number of epochs (22, using early stopping), hidden unit dimension (300), word vector dimension (100), learning rate (0.1 with SGD optimizer), $L2$ regularization (0.001). At test time, we used beam search with beam size 5, and then picked the highest-scoring logical form that we could infer an assignment for. **Aligner:** number of epochs (30, using early stopping), hidden unit dimension (250), word vector dimension (100), learning rate (0.0002 with Adam optimizer), dropout rate over hidden states (0.4). For both models, word vectors are updated during training. **Inference:** we used $T = 500$ steps, after which we halted.

4.2 Results

We trained all models above and evaluated on the test set for all seven domains. Results show (Table 2) that ZeroShot substantially outperforms other zero-shot baselines. CrossLex performs poorly, as it can only generate KB constants seen during training. CrossLexRep performs better, as it can generate KB constants from the target domain, however, generating the correct constant usually fails. This highlights the challenge in the zero-shot semantic parsing setting.

For baselines trained on target domain data, InLex (re-implementation of (Jia and Liang, 2016)) achieved average accuracy of 74.8, which is comparable to the 74.4 average accuracy they report on our seven domains. Training on the target domain with our method InAbstract achieved 58.5% average accuracy, which shows that while the abstract representation in our framework loses some valuable information, it is still successful. Importantly, the performance of ZeroShot (53.4%) is only slightly lower than InAbstract, showing that our model degrades gracefully and generalizes well across domains compared to CrossLex.

Model Ablations We now measure the effect of different components of our framework on denotation accuracy. We examined the effect of removing components completely, or replacing them with simpler ones. Thus, the following ablated models can be viewed as additional baselines.

Model	Blocks	Calendar	Housing	Publications	Recipes	Restaurants	Social	Avg.
ZEROSHOT	29.2	60.4	57.3	47.7	59.5	63.0	64.0	54.5
-GLOBALHEUR	29.2	60.4	56.7	46.9	60.1	46.0	62.2	51.6
-ALIGNER	22.6	57.5	52.7	46.9	58.4	43.0	60.4	48.8
-INFERENCE	28.2	51.5	44.7	43.0	42.2	44.5	45.8	42.8
-ALIGNER,INFERENCE	20.4	38.8	32.7	37.5	37.0	15.5	36.9	31.2

Table 4: Development accuracy for all ablations.

1. -ALIGNER: Replacing the alignment distribution from the aligner with alignment distribution from the decoder of the structure mapper.
2. -INFERENCE: Discarding the global scoring function and maximizing each slot independently.
3. -ALIGNER,INFERENCE: Discarding both of our main technical contributions.
4. -GLOBALHEUR: Discarding the global inference heuristics (denoted as $once(z)$).

Table 4 shows that ablating each of the components hurts performance. Discarding our two main technical contributions results in 31.2% accuracy compared to 54.5% in the full model. Performing inference with global constraints dramatically improve performance, showing that using the alignment model alone results often in incoherent logical forms. Our dedicated aligner also improves performance compared to alignments learned by the decoder of the structure mapper. This is pronounced without global constraints (a drop from 42.8% to 31.2%), but is less severe when global inference is used (a drop from 54.5% to 48.8%).

Intrinsic Analysis While we evaluated performance above via denotation accuracy, we now evaluate our framework's modules with different metrics (on the development set). We evaluated the structure mapper by measuring the exact match of the top candidate in the beam to the gold abstract logical form (49.1%). We further evaluated the aligner by measuring alignment accuracy for top candidate alignments, in comparison to the unsupervised aligner output (72.9%).

Finally, we measured inference performance in the following ways. The fraction of cases where inference succeeded within T steps is 70% (as some predicted abstract logical forms are not valid in terms of their syntax), and the average number of steps in case of success (3.67 steps). In addition, the fraction of correct global assignments given an abstract logical form that exactly matches the gold one is 77.0%. To conclude, results show that the structure mapping problem is harder than slot filling, for which we learned good alignments and performed fast and mostly accurate inference.

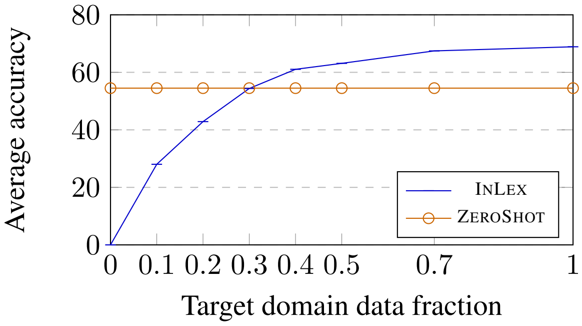

Figure 5: Learning curve for INLEX, compared to ZEROSHOT average performance.

Valuation To estimate the value of our zero-shot framework in terms of target domain examples, we plot a learning curve (Figure 5) that shows development set average accuracy for INLEX (trained on target domain data). In comparison, ZEROSHOT utilizes no target domain data, thus it is fixed. As Figure 5 shows, our framework's value is equal to 30% of the target domain training data. In our setting this equals to 400 examples manually-annotated with full logical forms. Note that this value is gained every time a semantic parser for a new domain is needed. Moreover, our parser can be used as an initial system, deployed to begin training from user interaction directly.

Limitations We now outline some of the limitations of our approach for zero-shot semantic parsing. We hypothesized that language regularities repeat across domains, however as mentioned above, neo-davidsonian semantics occurs mostly in one domain in the OVERNIGHT dataset and thus we were not able to generalize to it. Our parser also obtained low accuracy in BLOCKS. This domain contains mostly spatial language, different from other domains in OVERNIGHT. Specifically, prepositions, which we did not lexicalize map to relations in the KB (e.g., *"below"* and *"above"* map to the relations `Below` and `Above`). This shows the challenge involved in decomposing the structure from the lexicon with rules. In addition, since some spatial relations in this domain are semantically similar (`Length`, `Width` and `Height`), we found it hard to rank them correctly during inference. This stresses that in our framework, we assume KB constants to be sufficiently distinguishable in the pre-trained embedding space, which is not always the case.

5 Related Work

While zero-shot executable semantic parsing is still under-explored, some works focused on the open-vocabulary setting which handles unseen relations by replacing a formal KB with a probabilistic database learned from a text corpus (Choi et al., 2015; Gardner and Krishnamurthy, 2017).

Our abstract utterance representation is related to other attempts to generate intermediate representations that improve generalization such as dependency trees (Reddy et al., 2016), syntactic CCG parses (Krishnamurthy and Mitchell, 2015), abstract templates (Abujabal et al., 2017; Goldman et al., 2018) or masked enitites (Dong and Lapata, 2016). Our abstract logical form representation is similar to that Dong and Lapata (2018) used in to guide the decoding of the full logical form. The main difference with our work is that we focus on a comprehensive abstract representation tailored for zero-shot semantic parsing.

It is worth mentioning other work that inspected various aspects of zero-shot parsing. Bapna et al. (2017) focused on frame semantic parsing, and assumed that relations appear across different domains to learn a better mapping in the target domain. Also in frame semantic parsing, Ferreira et al. (2015) utilized word embeddings to map words to unseen KB relations. Finally, Lake and Baroni (2017) inspected whether neural semantic parsers can handle types of compositionality that were unseen during training. The main difference between their work and ours is that we focus on a scenario where a compositional logical form is generated, but the target KB constants do not appear in any of the source domains.

6 Conclusion

In this paper we address the challenge of zero-shot semantic parsing. We introduce a model that can parse utterances in unseen domains by decoupling structure mapping from lexicon mapping, and demonstrate its success on 7 domains from the OVERNIGHT dataset.

In future work, we would like to automatically learn a delexicalizer from data, tackle zero-shot parsing when the structure distribution in the target domain is very different from the source domains, and apply our framework to datasets where only denotations are provided.

Abstract

We present a simple and accurate span-based model for semantic role labeling (SRL). Our model directly takes into account all possible argument spans and scores them for each label. At decoding time, we greedily select higher scoring labeled spans. One advantage of our model is to allow us to design and use span-level features, that are difficult to use in token-based BIO tagging approaches. Experimental results demonstrate that our ensemble model achieves the state-of-the-art results, 87.4 F1 and 87.0 F1 on the CoNLL-2005 and 2012 datasets, respectively.

1 Introduction

Semantic Role Labeling (SRL) is a shallow semantic parsing task whose goal is to recognize the predicate-argument structure of each predicate. Given a sentence and a target predicate, SRL systems have to predict semantic arguments of the predicate. Each argument is a *span*, a unit that consists of one or more words. A key to the argument span prediction is how to represent and model spans.

One popular approach to it is based on BIO tagging schemes. State-of-the-art neural SRL models adopt this approach (Zhou and Xu, 2015; He et al., 2017; Tan et al., 2018). Using features induced by neural networks, they predict a BIO tag for each word. Words at the beginning and inside of argument spans have the “B” and “I” tags, and words outside argument spans have the tag “O.” While yielding high accuracies, this approach reconstructs argument spans from the predicted BIO tags instead of directly predicting the spans.

Another approach is based on labeled span prediction (Täckström et al., 2015; FitzGerald et al., 2015). This approach scores each span with its label. One advantage of this approach is to allow us to design and use span-level features, that are difficult to use in BIO tagging approaches. However, the performance has lagged behind that of the state-of-the-art BIO-based neural models.

To fill this gap, this paper presents a simple and accurate span-based model. Inspired by recent span-based models in syntactic parsing and coreference resolution (Stern et al., 2017; Lee et al., 2017), our model directly scores all possible labeled spans based on span representations induced from neural networks. At decoding time, we greedily select higher scoring labeled spans. The model parameters are learned by optimizing log-likelihood of correct labeled spans.

We evaluate the performance of our span-based model on the CoNLL-2005 and 2012 datasets (Carreras and Màrquez, 2005; Pradhan et al., 2012). Experimental results show that the span-based model outperforms the BiLSTM-CRF model. In addition, by using contextualized word representations, ELMo (Peters et al., 2018), our ensemble model achieves the state-of-the-art results, 87.4 F1 and 87.0 F1 on the CoNLL-2005 and 2012 datasets, respectively. Empirical analysis on these results shows that the label prediction ability of our span-based model is better than that of the CRF-based model. Another finding is that ELMo improves the model performance for span boundary identification.

In summary, our main contributions include:

- A simple span-based model that achieves the state-of-the-art results.
- Quantitative and qualitative analysis on strengths and weaknesses of the span-based model.
- Empirical analysis on the performance gains by ELMo.

Our code and scripts are publicly available.[1]

2 Model

We treat SRL as *span selection*, in which we select appropriate spans from a set of possible spans for each label. This section formalizes the problem and provides our span selection model.

2.1 Span Selection Problem

Problem Setting

Given a sentence that consists of T words $w_{1:T} = w_1, \cdots, w_T$ and the target predicate position index p, the goal is to predict a set of labeled spans $Y = \{\langle i, j, r\rangle_k\}_{k=1}^{|Y|}$.

$$\textbf{Input}: X = \{w_{1:T}, p\},$$
$$\textbf{Output}: Y = \{\langle i, j, r\rangle_k\}_{k=1}^{|Y|} \ .$$

Each labeled span $\langle i, j, r\rangle$ consists of word indices i and j in the sentence ($1 \leq i \leq j \leq T$) and a semantic role label $r \in \mathcal{R}$.

One simple method to predict Y is to select the highest scoring span (i, j) from all possible spans $\mathcal{S}$ for each label r,

$$\underset{(i,j)\in\mathcal{S}}{\text{argmax}} \ \textsc{Score}_r(i, j), \ r \in \mathcal{R} \ . \tag{1}$$

Function $\textsc{Score}_r(i, j)$ returns a real value for each span $(i, j) \in \mathcal{S}$ (described in Section 2.2 in more detail). The number of possible spans $\mathcal{S}$ in the input sentence $w_{1:T}$ is $\frac{T(T+1)}{2}$, and $\mathcal{S}$ is defined as follows,

$$\mathcal{S} = \{(i, j) \mid i, j \in \{1, \cdots, T\}, i \leq j\} \ .$$

Note that some semantic roles may not appear in the sentence. To deal with the absence of some labels, we define the predicate position span (p, p) as a Null span and train a model to select the Null span when there is no span for the label.[2]

Example

Consider the following sentence with the set of correct labeled spans Y.

$$\begin{array}{cccc} \text{She}_1 & \underline{\text{kept}_2} & \text{a}_3 & \text{cat}_4 \\ [\ \texttt{A0}\ ] & & [& \texttt{A1} \quad] \end{array}$$

$$Y = \{\ \langle 1, 1, \texttt{A0}\rangle, \ \langle 3, 4, \texttt{A1}\rangle,$$
$$\langle 2, 2, \texttt{A2}\rangle, \cdots, \langle 2, 2, \texttt{TMP}\rangle\ \}$$

The input sentence is $w_{1:4}$ = "She kept a cat", and the target predicate position is $p = 2$. The correct labeled span $\langle 1, 1, \texttt{A0}\rangle$ indicates that the A0 argument is "She", and $\langle 3, 4, \texttt{A1}\rangle$ indicates that the A1 argument is "a cat". The other labeled spans $\langle 2, 2, *\rangle$ indicate there are no arguments.

All the possible spans in this sentence are as follows,

$$\mathcal{S}_{w_{1:4}} = \{(1, 1), (1, 2), (1, 3), (1, 4), (2, 2),$$
$$(2, 3), (2, 4), (3, 3), (3, 4), (4, 4)\} \ ,$$

where the predicate span $(2, 2)$ is treated as the Null span. Among these candidates, we select the highest scoring span for each label. As a result, we can obtain correct labeled spans Y.

2.2 Scoring Function

As the scoring function for each span in Eq. 1, we model normalized distribution over all possible spans $\mathcal{S}$ for each label r,

$$\begin{aligned} \textsc{Score}_r(i, j) &= \mathrm{P}_\theta(i, j \mid r) \\ &= \frac{\exp(\mathrm{F}_\theta(i, j, r))}{\sum\limits_{(i', j')\in\mathcal{S}} \exp(\mathrm{F}_\theta(i', j', r))} \ , \end{aligned} \tag{2}$$

where function F_θ returns a real value.

We train the parameters θ of F_θ on a training set,

$$\begin{aligned} \mathcal{D} &= \{(X^{(n)}, Y^{(n)})\}_{n=1}^{|\mathcal{D}|} \ , \\ X &= \{w_{1:T}, p\} \ , \\ Y &= \{\langle i, j, r\rangle_k\}_{k=1}^{|Y|} \ . \end{aligned}$$

To train the parameters θ of F_θ, we minimize the cross-entropy loss function,

$$\mathcal{L}(\theta) = \sum_{(X,Y)\in\mathcal{D}} \ell_\theta(X, Y) \ , \tag{3}$$
$$\ell_\theta(X, Y) = \sum_{\langle i,j,r\rangle\in Y} \log \mathrm{P}_\theta(i, j|r) \ ,$$

where function $\ell_\theta(X, Y)$ is a loss for each sample.

2.3 Function F_θ

Function F_θ in Eq. 2 consists of three types of functions; the base feature function f_{base}, the span feature function f_{span} and the labeling function f_{label} as follows,

$$\mathbf{h}_{1:T} = f_{base}(w_{1:T}, p) \ , \tag{4}$$
$$\mathbf{h}_s = f_{span}(\mathbf{h}_{1:T}, s) \ , \tag{5}$$
$$\mathrm{F}_\theta(i, j, r) = f_{label}(\mathbf{h}_s, r) \ . \tag{6}$$

---

[2] Since the predicate itself can never be an argument of its own, we define the position as the Null span.

Firstly, f_{base} calculates a base feature vector $\mathbf{h}_t$ for each word $w_t \in w_{1:T}$. Then, from a sequence of the base feature vectors $\mathbf{h}_{1:T}$, f_{span} calculates a span feature vector $\mathbf{h}_s$ for a span $s = (i, j)$. Finally, using $\mathbf{h}_s$, f_{label} calculates the score for the span $s = (i, j)$ with a label r.

Each function in Eqs. 4, 5 and 6 can arbitrarily be defined. In Section 3, we describe our functions used in this paper.

2.4 Inference

The simple argmax inference (Eq. 1) selects one span for each label. While this argmax inference is computationally efficient, it faces the following two problematic issues.

(a) The argmax inference sometimes selects spans that overlap with each other.

(b) The argmax inference cannot select multiple spans for one label.

In terms of (a), for example, when $\langle 1, 3, \texttt{A0} \rangle$ and $\langle 2, 4, \texttt{A1} \rangle$ are selected, a part of these two spans overlaps. In terms of (b), consider the following sentence.

He <u>came</u> to the U.S. yesterday at 5 p.m.
`[A0]      [  A4  ][ TMP  ][ TMP ]`

In this example, the label `TMP` is assigned to the two spans ("yesterday" and "at 5 p.m."). Semantic role labels are mainly categorized into (i) *core labels* or (ii) *adjunct labels*. In the above example, the labels `A0` and `A4` are regarded as core labels, which indicate obligatory arguments for the predicate. In contrast, the labels like `TMP` are regarded as adjunct labels, which indicate optional arguments for the predicate. As the example shows, adjunct labels can be assigned to multiple spans.

To deal with these issues, we use a greedy search that keeps the consistency among spans and can return multiple spans for adjunct labels. Specifically, we greedily select higher scoring labeled spans subject to two constraints.

Overlap Constraint: Any spans that overlap with the selected spans cannot be selected.

Number Constraint: While multiple spans can be selected for each adjunct label, at most one span can be selected for each core label.

As a precise description of this algorithm, we describe the pseudo code and its explanation in Appendix A.

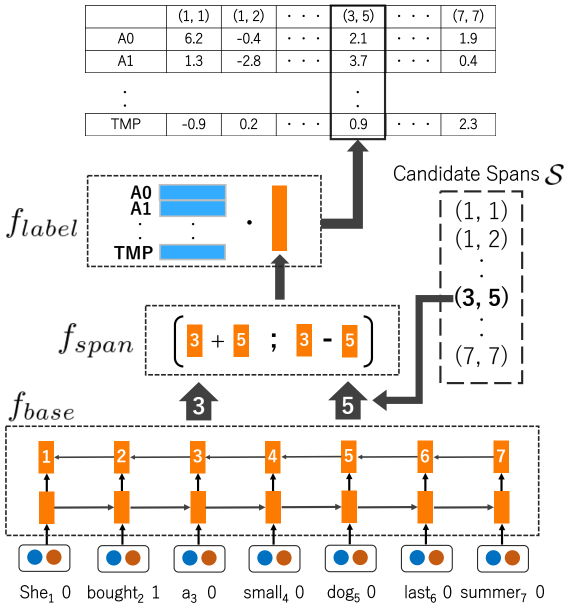

Figure 1: Overall architecture of our BiLSTM-span model.

3 Network Architecture

To compute the score for each span, we have introduced three functions ($f_{base}, f_{span}, f_{label}$) in Section 2.3. As an instantiation of each function, we use neural networks. This section describes our neural networks for each function and the overall network architecture.

3.1 BiLSTM-Span Model

Figure 1 illustrates the overall architecture of our model. The first component f_{base} uses bidirectional LSTMs (BiLSTMs) (Schuster and Paliwal, 1997; Graves et al., 2005, 2013) to calculate the base features. From the base features, the second component f_{span} extracts span features. Based on them, the final component f_{label} calculates the score for each labeled span. In the following, we describe these three components in detail.

Base Feature Function

As the base feature function f_{base}, we use BiLSTMs,

$$f_{base}(w_{1:T}, p) = \textsc{BiLSTM}(w_{1:T}, p) \ .$$

There are some variants of BiLSTMs. Following the deep SRL models proposed by Zhou and Xu (2015) and He et al. (2017), we stack BiLSTMs in an interleaving fashion. The stacked BiLSTMs process an input sequence in a left-to-right manner at odd-numbered layers and in a right-to-left manner at even-numbered layers.

The first layer of the stacked BiLSTMs receives word embeddings $\mathbf{x}^{word} \in \mathbb{R}^{d^{word}}$ and predicate mark embeddings $\mathbf{x}^{mark} \in \mathbb{R}^{d^{mark}}$. As the word embeddings, we can use existing word embeddings. The mark embeddings are created from the mark feature which has a binary value. The value is 1 if the word is the target predicate and 0 otherwise. For example, at the bottom part of Figure 1, the word "bought" is the target predicate and assigned 1 as its mark feature.

Receiving these inputs, the stacked BiLSTMs calculates the hidden states until the top layer. We use these hidden states as the input feature vectors $\mathbf{h}_{1:T}$ for the span feature function f_{span} (Eq. 5). Each vector $\mathbf{h}_t \in \mathbf{h}_{1:T}$ has d^{hidden} dimensions. We provide a detailed description of the stacked BiLSTMs in Appendix B.

Span Feature Function

From the base features induced by the BiLSTMs, we create the span feature representations,

$$f_{span}(\mathbf{h}_{1:T}, s) = [\mathbf{h}_i + \mathbf{h}_j; \mathbf{h}_i - \mathbf{h}_j] \ , \quad (7)$$

where the addition and subtraction features of the i-th and j-th hidden states are concatenated and used as the feature for a span $s = (i, j)$. The resulting vector $\mathbf{h}_s$ is a $2d^{hidden}$ dimensional vector.

The middle part of Figure 1 shows an example of this process. For the span $(3, 5)$, the span feature function f_{span} receives the 3rd and 5th features ($\mathbf{h}_3$ and $\mathbf{h}_5$). Then, these two vectors are added, and the 5th vector is subtracted from the 3rd vector. The resulting vectors are concatenated and given to the labeling function f_{label}.

Our design of the span features is inspired by the span (or segment) features used in syntactic parsing (Wang and Chang, 2016; Stern et al., 2017; Teranishi et al., 2017). While these neural span features cannot be used in BIO-based SRL models, they can easily be incorporated into span-based models.

Labeling Function

Taking a span representation $\mathbf{h}_s$ as input, the labeling function f_{label} returns the score for the span $s = (i, j)$ with a label r. Specifically, we use the following labeling function,

$$f_{label}(\mathbf{h}_s, r) = \mathbf{W}[r] \cdot \mathbf{h}_s \ , \quad (8)$$

where $\mathbf{W} \in \mathbb{R}^{|\mathcal{R}| \times 2d^{hidden}}$ has a row vector associated with each label r, and $\mathbf{W}[r]$ denotes the r-th row vector. As the result of the inner product of $\mathbf{W}[r]$ and $\mathbf{h}_s$, we obtain the score for a span (i, j) with a label r.

The upper part of Figure 1 shows an example of this process. The span representation $\mathbf{h}_s$ for the span $s = (3, 5)$ is created from addition and subtraction of $\mathbf{h}_3$ and $\mathbf{h}_5$. Then, we calculate the inner product of $\mathbf{h}_s$ and $\mathbf{W}[r]$. The score for the label `A0` is 2.1, and the score for the label `A1` is 3.7. In the same manner, by calculating the scores for all the spans $\mathcal{S}$ and labels $\mathcal{R}$, we can obtain the score matrix (at the top part of Figure 1).

3.2 Ensembling

We propose an ensemble model that uses span representations from multiple models. Each base model trained with different random initializations has variance in span representations. To take advantage of it, we introduce a variant of a mixture of experts (MoE) (Shazeer et al., 2017), [3]

$$\mathbf{h}_s^{\text{moe}} = \mathbf{W}_s^{\text{moe}} \cdot \sum_{m=1}^{M} \alpha_m \, \mathbf{h}_s^{(m)} \ , \quad (9)$$

$$f_{label}^{\text{moe}}(\mathbf{h}_s^{\text{moe}}, r) = \mathbf{W}^{\text{moe}}[r] \cdot \mathbf{h}_s^{\text{moe}} \ . \quad (10)$$

Firstly, we combine span representations $\mathbf{h}_s^{(m)}$ from each model $m \in \{1, \cdots, M\}$. $\mathbf{W}_s^{\text{moe}}$ is a parameter matrix and $\{\alpha_m\}_{m=1}^{M}$ are trainable, softmax-normalized parameters. Then, using the combined span representation $\mathbf{h}_s^{\text{moe}}$, we calculate the score in the same way as Eq. 8. We use the same greedy search algorithm used for our base model (Section 2.4).

During training, we update only the parameters of the ensemble model, i.e., $\{\mathbf{W}_s^{\text{moe}}, \mathbf{W}^{\text{moe}}, \{\alpha_m\}_{m=1}^{M}\}$. That is, we fix the parameters of each trained model m. As the loss function, we use the cross-entropy (Eq. 3).

4 Experiments

4.1 Datasets

We use the CoNLL-2005 and 2012 datasets[4]. We follow the standard train-development-test split and use the official evaluation script[5] from the CoNLL-2005 shared task on both datasets.

---

[3] One popular ensemble model for SRL is the product of experts (PoE) model (FitzGerald et al., 2015; He et al., 2017; Tan et al., 2018). In our preliminary experiments, we tried the PoE model but it did not improve the performance.

[4] We use the version of OntoNotes downloaded at: http://cemantix.org/data/ontonotes.html.

[5] The script can be downloaded at: http://www.lsi.upc.edu/ srlconll/soft.html

4.2 Baseline Model

For comparison, as a model based on BIO tagging approaches, we use the BiLSTM-CRF model proposed by Zhou and Xu (2015). The BiLSTMs for the base feature function f_{base} are the same as those used in our BiLSTM-span model.

4.3 Model Setup

As the base function f_{base}, we use 4 BiLSTM layers with 300 dimensional hidden units. To optimize the model parameters, we use Adam (Kingma and Ba, 2014). Other hyperparameters are described in Appendix C in detail.

Word Embeddings

Word embeddings have a great influence on SRL models. To validate the model performance, we use two types of word embeddings.

- Typical word embeddings, SENNA[6] (Collobert et al., 2011)
- Contextualized word embeddings, ELMo[7] (Peters et al., 2018)

SENNA and ELMo can be regarded as different types of embeddings in terms of the context sensitivity. SENNA and other typical word embeddings always assign an identical vector to each word regardless of the input context. In contrast, ELMo assigns different vectors to each word depending on the input context. In this work, we use these word embeddings that have different properties.[8] These embeddings are fixed during training.

Training

As the objective function, we use the cross-entropy $\mathcal{L}_\theta$ in Eq. 3 with L2 weight decay,

$$\mathcal{L}_\theta = \sum_{(X,Y)\in\mathcal{D}} \ell_\theta(X,Y) + \frac{\lambda}{2}||\theta||^2 \ , \qquad (11)$$

where the hyperparameter λ is the coefficient governing the L2 weight decay.

---

[6] http://ronan.collobert.com/senna/

[7] http://allennlp.org/elmo

[8] In our preliminary experiments, we also used the GloVe embeddings (Pennington et al., 2014), but the performance was worse than SENNA.

4.4 Results

We report averaged scores across five different runs of the model training.

Tables 1 and 2 show the experimental results on the CoNLL-2005 and 2012 datasets. Overall, our span-based ensemble model using ELMo achieved the best F1 scores, 87.4 F1 and 87.0 F1 on the CoNLL-2005 and CoNLL-2012 datasets, respectively. In comparison with the CRF-based single model, our span-based single model consistently yielded better F1 scores regardless of the word embeddings, SENNA and ELMO. Although the performance difference was small between these models using ELMO, it seems natural because both models got much better results and approached to the performance upper bound.

Table 3 shows the comparison with existing models in F1 scores. Our single and ensemble models using ELMO achieved the best F1 scores on all the test sets except the Brown test set.

5 Analysis

To better understand our span-based model, we addressed the following questions and obtained the following findings.

Questions

- **(a)** What are strengths and weaknesses of our span-based model compared with the CRF-based model?
- **(b)** What aspect of SRL does ELMo improve?

Findings

- **(a)** While the CRF-based model is better at span boundary identification (Section 5.1), the span-based model is better at label prediction, especially for A2 (Section 5.2).
- **(b)** ELMo improves the model performance for span boundary identification (Section 5.1).

In addition, we have conducted qualitative analysis on span and label representations learned in the span-based model (Section 5.3).

5.1 Performance for Span Boundary Identification

We analyze the results predicted by the single models. We evaluate F1 scores only for the span boundary match, shown by Table 4. We regard a predicted boundary $\langle i, j, * \rangle$ as correct if it matches the gold annotation regardless of its label.

		CoNLL-05		CoNLL-12	
EMB	MODEL	F1	diff	F1	diff
SENNA	SPAN	86.6	-0.4	87.3	-0.6
	CRF	87.0		87.9	
ELMO	SPAN	90.5	-0.7	90.3	-0.6
	CRF	91.2		90.9	

Table 4: F1 scores only for span boundary match.

		CoNLL-05		CoNLL-12	
EMB	MODEL	Acc.	diff	Acc.	diff
SENNA	SPAN	95.3	+1.5	95.1	+1.5
	CRF	93.8		93.6	
ELMO	SPAN	96.1	+0.9	95.7	+1.3
	CRF	95.2		94.4	

Table 5: Accuracies only for semantic role labels.

On both datasets, the CRF-based models achieved better F1 than that of the span-based models. Also, compared with SENNA, ELMO yielded much better F1 by over 3.0. This suggests that a factor of the overall SRL performance gain by ELMO is the improvement of the model ability to identify span boundaries.

5.2 Performance for Label Prediction

We analyze labels of the predicted results. For labeled spans whose boundaries match the gold annotation, we evaluate the label accuracies. As Table 5 shows, the span-based models outperformed the CRF-based models. Also, interestingly, the performance gap between SENNA and ELMO was not so big as that for span boundary identification.

Label-wise Performance

Table 6 shows F1 scores for frequent labels on the CoNLL-2005 and 2012 datasets. For A0 and A1, the performances of the CRF-based and span-based models were almost the same. For A2, the span-based models outperformed the CRF-based model by about 1.0 F1 on the both datasets. [9]

Label Confusion Matrix

Figure 2 shows a confusion matrix for labeling errors of the span-based model using ELMo.[10] Following He et al. (2017), we only count predicted arguments that match the gold span boundaries.

---

[9] The PNC label got low scores on the CoNLL-2012 dataset in Table 6. Almost all the gold PNC (purpose) labels are assigned to only the news article domain texts of the CoNLL-2012 dataset. The other 6 domain texts have no or very few PNC labels. This can lead to the low performance.

[10] We have observed the same tendency of labeling confusions between the models using ELMo and SENNA.

Figure 2: Confusion matrix for labeling errors of our span-based model using ELMo. Each cell shows the percentage of predicted labels for each gold label.

The span-based model confused A0 and A1 arguments the most. In particular, the model confused them for ergative verbs. Consider the following two sentences:

People start their own business ...
`[ A0 ]`

.. Congress has started to jump on ...
`[  A1  ]`

where the constituents located at the syntactic subjective position fulfill a different role A0 or A1 according to their semantic properties, such as animacy. Such arguments are difficult for SRL models to correctly identify.

Another point is the confusions of A2 with DIR and LOC. As He et al. (2017) pointed out, A2 in a lot of verb frames represents semantic relations such as direction or location, which can cause the confusions of A2 with such location-related adjuncts. To remedy these two problematic issues, it can be a promising approach to incorporate frame knowledge into SRL models by using verb frame dictionaries.

“· · · toy makers to move [across the border] .” GOLD:A2 PRED:DIR		
Nearest neighbors of “across the border”		
1	DIR	across the Hudson
2	DIR	outside their traditional tony circle
3	DIR	across the floor

6	DIR	off its foundation
7	DIR	off the center field wall
8	A3	out of bed
9	A2	through cottage rooftops
10	DIR	through San Francisco

Table 7: Example of the CoNLL-2005 development set, in which our model misclassified the label for the span “across the border”. We collect 10 nearest neighbors of this span from the training set.

5.3 Qualitative Analysis on Our Model

On Span Representations

Our span-based model computes and uses span representations (Eq. 7) for label prediction. To investigate a relation between the span representations and predicted labels, we qualitatively analyze nearest neighbors of each span representation with its predicted label. Specifically, for each predicted span in the development set, we collect 10 nearest neighbor spans with their gold labels from the training set.

Table 7 shows 10 nearest neighbors of a span “across the border” for the predicate “move”. The label of this span was misclassified, i.e., the predicted label is DIR but the gold is A2. Looking at its nearest neighbor spans, they have different gold labels, such as DIR, A2 and A3. Like this case, we have observed that spans with a misclassified label often have their nearest neighbors with inconsistent labels.

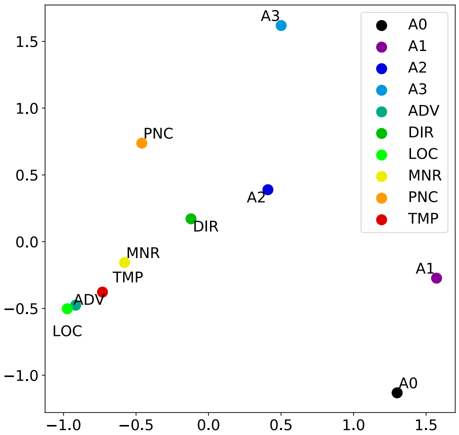

Figure 3: Label embedding distribution of our span-based model.

On Label Embeddings

We analyze the label embeddings in the labeling function (Eq. 8). Figure 3 shows the distribution of the learned label embeddings. The adjunct labels are close to each other, which are likely to be less discriminative. Also, the core label A2 is close to the adjunct label DIR, which are often confused by the model. To enhance the discriminative power, it is promising to apply techniques that keep label representations far away from each other (Wen et al., 2016; Luo et al., 2017).

6 Related Work

6.1 Semantic Role Labeling Tasks

Automatic SRL has been widely studied (Gildea and Jurafsky, 2002). There have been two main styles of SRL.

- FrameNet-style SRL (Baker et al., 1998)
- PropBank-style SRL (Palmer et al., 2005)

In this paper, we have tackled PropBank-style SRL.[11]

In PropBank-style SRL, there have been two main task settings.

- Span-based SRL: CoNLL-2004 and 2005 shared tasks (Carreras and Marquez, 2004; Carreras and Màrquez, 2005)
- Dependency-based SRL: CoNLL-2008 and 2009 shared tasks (Surdeanu et al., 2008; Hajič et al., 2009)

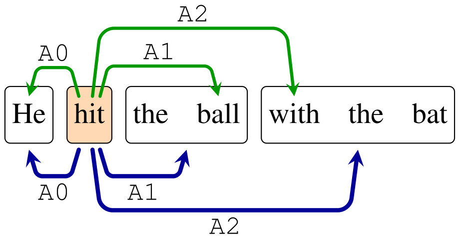

Figure 4: Example of dependency-based SRL (the upper part) and span-based SRL (the lower part).

Figure 4 illustrates an example of span-based and dependency-based SRL. In dependency-based SRL (at the upper part of Figure 4), the correct A2 argument for the predicate “hit” is the word “with”. On one hand, in span-based SRL (at the lower part of Figure 4), the correct A2 argument is the span “with the bat”.

For span-based SRL, the CoNLL-2004 and 2005 shared tasks (Carreras and Marquez, 2004; Carreras and Màrquez, 2005) provided the task settings and datasets. In the task settings, various SRL models, from traditional pipeline models to recent neural ones, have been proposed and competed with each other (Pradhan et al., 2005; He et al., 2017; Tan et al., 2018). For dependency-based SRL, the CoNLL-2008 and 2009 shared tasks (Surdeanu et al., 2008; Hajič et al., 2009) provided the task settings and datasets. As in span-based SRL, recent neural models achieved high-performance in dependency-based SRL (Marcheggiani et al., 2017; Marcheggiani and Titov, 2017; He et al., 2018b; Cai et al., 2018). This paper focuses on span-based SRL.

6.2 BIO-based SRL Models

Span-based SRL can be solved as BIO sequential tagging (Hacioglu et al., 2004; Pradhan et al., 2005; Màrquez et al., 2005).

Neural models State-of-the-art SRL models use neural networks based on the BIO tagging approach. The pioneering neural SRL model was proposed by Collobert et al. (2011). They use convolutional neural networks (CNNs) and CRFs. Instead of CNNs, Zhou and Xu (2015) and He et al. (2017) used stacked BiLSTMs and achieved strong performance without syntactic inputs. Tan et al. (2018) replaced stacked BiLSTMs with self-attention architectures. Strubell et al. (2018) improved the self-attention SRL model by incorporating syntactic information.

---

[11] Detailed descriptions on FrameNet-style and PropBank-style SRL can be found in Baker et al. (1998); Das et al. (2014); Kingsbury and Palmer (2002); Palmer et al. (2005).

Word representations Typical word representations, such as SENNA (Collobert et al., 2011) and GloVe (Pennington et al., 2014), have been used and contributed to the performance improvement (Collobert et al., 2011; Zhou and Xu, 2015; He et al., 2017). Recently, Peters et al. (2018) integrated contextualized word representation, ELMo, into the model of He et al. (2017) and improved the performance by 3.2 F1 score. Strubell and McCallum (2018) also integrated ELMo into the model of Strubell et al. (2018) and reported the performance improvement.

6.3 Span-based SRL Models

Another line of approaches to SRL is labeled span modeling (Xue and Palmer, 2004; Koomen et al., 2005; Toutanova et al., 2005).

Typical models Typically, in this approach, models firstly identify candidate argument spans (argument identification) and then classify each span into one of the semantic role labels (argument classification). For inference, several effective methods have been proposed, such as structural constraint inference by using integer linear programming (Punyakanok et al., 2008) or dynamic programming (Täckström et al., 2015; FitzGerald et al., 2015).

Recent span-based model A very recent work, He et al. (2018a), proposed a span-based SRL model similar to our model. They also used BiLSTMs to induce span representations in an end-to-end fashion. A main difference is that while they model $\mathrm{P}(r|i,j)$, we model $\mathrm{P}(i,j|r)$. In other words, while their model seeks to select an appropriate label for each span (*label selection*), our model seeks to select appropriate spans for each label (*span selection*). This point distinguishes between their model and ours.

FrameNet span-based model For FrameNet-style SRL, Swayamdipta et al. (2017) used a segmental RNN (Kong et al., 2016), combining bidirectional RNNs with semi-Markov CRFs (Sarawagi and Cohen, 2004). Their model computes span representations using BiLSTMs and learns a conditional distribution over all possible labeled spans of an input sequence. Although we cannot compare our results with theirs, we can regard that our model is simpler and effective for PropBank-style SRL.

6.4 Span-based Models in Other NLP Tasks

In syntactic parsing, Wang and Chang (2016) proposed an LSTM-based sentence segment embedding method named LSTM-Minus. Stern et al. (2017); Kitaev and Klein (2018) incorporated the LSTM Minus into their parsing model and achieved the best results in constituency parsing. In coreference resolution, Lee et al. (2017, 2018) presented an end-to-end coreference resolution model, which considers all spans in a document as potential mentions and learn distributions over possible antecedents for each. Our model can be regarded as an extension of their model.

7 Conclusion and Future Work

We have presented a simple and accurate span-based model. We treat SRL as *span selection* and our model seeks to select appropriate spans for each label. Experimental results have demonstrated that despite the simplicity, the model outperforms a strong BiLSTM-CRF model. Also, our span-based ensemble model using ELMo achieves the state-of-the-art results on the CoNLL-2005 and 2012 datasets. Through empirical analysis, we have obtained some interesting findings. One of them is that the span-based model is better at label prediction compared with the CRF-based model. Another one is that ELMo improves the model performance for span boundary identification.

An interesting direction for future work concerns evaluating span representations from our span-based model. Since the investigation on the characteristics of the representations can lead to interesting findings, it is worthwhile evaluating them intrinsically and extrinsically. Another promising direction is to explore methods of incorporating frame knowledge into SRL models. We have observed that a lot of label confusions arise due to the lack of such knowledge. The use of frame knowledge to reduce these confusions is a straightforward approach.

A Span-Consistent Greedy Search

Algorithm 1 Span-Consistent Greedy Search

```
 1: Input: Score Matrix $\mathbf{M} \in \mathbb{R}^{|\mathcal{R}|\times|\mathcal{S}|}$,
 2:        Predicate Position Index $p$
 3:        Core Label Set $\mathcal{R}^{(\text{core})}$
 4: spans $\leftarrow \phi$
 5: used_cores $\leftarrow \phi$
 6: $\mathcal{U} \leftarrow \{(i, j, r, \text{score}) \in flatten(\mathbf{M})\}$
 7: $\mathcal{U} \leftarrow filter(\mathcal{U}, p)$
 8: for $(i, j, r, \text{score}) \in sort(\mathcal{U})$ do
 9:   if $r \notin$ used_cores and
10:     is_overlap($(i, j)$, spans) is False then
11:       spans $\leftarrow$ spans $\cup \{\langle i, j, r\rangle\}$
12:       if $r \in \mathcal{R}^{(\text{core})}$ then
13:         used_cores $\leftarrow$ used_cores $\cup \{r\}$
14: return spans
```

Algorithm 1 describes the pseudo code of the greedy search algorithm introduced in Section 2.4. This algorithm receives the three inputs (line 1-3). $\mathbf{M}$ is the score matrix illustrated at the top part of Figure 1 in Section 3. Each cell of the matrix represents the score of each span. p is a target predicate position index. $\mathcal{R}^{(\text{core})}$ is the set of core labels. At line 4, the variable "spans" is initialized. This variable stores the selected spans to be returned as the output. At line 5, the variable "used_cores" is initialized. This variable keeps track of the already selected core labels.

At line 6, the score matrix $\mathbf{M}$ is converted to tuples, (i, j, r, score), by the function $flatten(\cdot)$. These tuples are stored in the variable $\mathcal{U}$. At line 7, from $\mathcal{U}$, we remove the tuples that fall into any one of the followings, (i) the tuples whose boundary (i, j) overlaps with the predicate position p or (ii) the tuples whose score is lower than that of the predicate span tuples. In terms of (i), since spans whose boundary (i, j) overlaps with the predicate position, $i \leq p \leq j$, can never be a correct argument, we remove such tuples. In terms of (ii), we remove the tuples $(*, *, r, \text{score})$ whose score is lower than that of the predicate span tuple (p, p, r, score). In Section 2, we define the predicate span (p, p) as the NULL span, implying that we can regard the spans whose score is lower than that of the NULL span as an inappropriate argument. Thus, we remove such tuples from the set of the candidates $\mathcal{U}$.

The main processing starts from line 8. Based on the scores, the function $sort(\cdot)$ sorts the tuples (i, j, r, score) in a descending order. At line 9-10, there are constraints for output spans. At line 9, "$r \notin$ used_cores" represents the constraint that at most one span can be selected for each core label. At line 10, the function is_overlap$(\cdot)$ takes as input a span (i, j) and the set of the selected spans, and returns the boolean value ("True" or "False") that represents whether the span overlaps with any one of the selected spans or not.

At line 11, the span is added to the set of the selected spans. At line 12-13, if the label r is included in the core labels $\mathcal{R}^{(\text{core})}$, the label is added to "used_cores". At line 14, as the final output, the set of the selected spans "spans" is returned.

B BiLSTMs

As the base feature function f_{base} (Eq. 4 in Section 2.3), we use BiLSTMs,

$$f_{base}(w_{1:T}, p) = \text{BiLSTM}(w_{1:T}, p) \ .$$

In particular, we use the stacked BiLSTMs in an interleaving fashion (Zhou and Xu, 2015; He et al., 2017). The stacked BiLSTMs process an input sequence in a left-to-right manner for odd-numbered layers and in a right-to-left manner for even-numbered layers.

The stacked BiLSTMs consist of L layers. The hidden state in each layer $\ell \in \{1, \cdots, L\}$ is calculated as follows,

$$\mathbf{h}_t^{(\ell)} = \begin{cases} \text{LSTM}^{(\ell)}(\mathbf{x}_t^{(\ell)},\ \mathbf{h}_{t-1}^{(\ell)}) & (\ell = \text{odd}) \\ \text{LSTM}^{(\ell)}(\mathbf{x}_t^{(\ell)},\ \mathbf{h}_{t+1}^{(\ell)}) & (\ell = \text{even}) \ . \end{cases}$$

Both of the odd- and even-numbered layers receive $\mathbf{x}_t^{(\ell)}$ as the first input of the LSTM. For the second input, odd-numbered layers receive $\mathbf{h}_{t-1}^{(\ell)}$, whereas even-numbered layers receive $\mathbf{h}_{t+1}^{(\ell)}$.

Between the LSTM layers, we use the following connection (Zhou and Xu, 2015),

$$\mathbf{x}_t^{(\ell+1)} = \text{ReLU}(\mathbf{W}^{(\ell)} \cdot [\mathbf{x}_t^{(\ell)}; \mathbf{h}_t^{(\ell)}]) \ .$$

Here, we firstly concatenate $\mathbf{x}_t^{(\ell)}$ and $\mathbf{h}_t^{(\ell)}$, and then calculate the inner product of the concatenated vector and the parameter matrix $\mathbf{W}^{(\ell)}$ with the rectified linear units (ReLU). As a result, we obtain the input representation $\mathbf{x}_t^{(\ell+1)}$ for the next ($\ell + 1$-th) LSTM layer.

In the first layer, LSTM$^{(1)}$ receives an input feature vector $\mathbf{x}_t^{(1)}$. Following He et al. (2017), we create this vector by concatenating a word embedding and predicate mark embedding,

$$\mathbf{x}_t^{(1)} = [\mathbf{x}_t^{word}; \mathbf{x}_t^{mark}] \ ,$$

where $\mathbf{x}^{word} \in \mathbb{R}^{d^{word}}$ and $\mathbf{x}^{mark} \in \mathbb{R}^{d^{mark}}$. The mark embedding is created from the binary mark feature. The value is 1 if the word is the target predicate and 0 otherwise.

After the L-th LSTM layer runs, we obtain $\mathbf{x}_{1:T}^{(L+1)} = \mathbf{x}_1^{(L+1)}, \cdots, \mathbf{x}_T^{(L+1)}$. We use them as the input of the span feature function f_{span} (Eq. 5 in Section 2.3), i.e., $\mathbf{h}_{1:T} = \mathbf{x}_{1:T}^{(L+1)}$. Each vector $\mathbf{h}_t \in \mathbf{h}_{1:T}$ has d^{hidden} dimensions.

C Hyperparameters

Name	Value
Word Embedding d^{word}	50-dimensional SENNA 1024-dimensional ELMo
Mark Embedding d^{mark}	50-dimensional vector
LSTM Layers L	4
LSTM Hidden Units d^{hidden}	300 dimensions
Mini-batch Size	32
Optimization	Adam
Learning Rate	0.001
L2 Regularization λ	0.0001
Dropout Ratio for BiLSTMs	0.1
Dropout Ratio for ELMo	0.5

Table 8: Hyperparameters for our span-based model.

C.1 Span-based Model

Table 8 lists the hyperparameters used for our span-based model.

Word representation setup As word embeddings $\mathbf{x}^{word}$, we use two types of embeddings, (i) SENNA (Collobert et al., 2011), 50-dimensional word vectors ($d^{word} = 50$), and (ii) ELMo (Peters et al., 2018), 1024-dimensional vectors ($d^{word} = 1024$). During training, we fix these word embeddings (not update them). As predicate mark embeddings $\mathbf{x}^{mark}$, we use randomly initialized 50-dimensional vectors ($d^{mark} = 50$). During training, we update them.

Network setup As the base feature function f_{base}, we use 4 stacked BiLSTMs (2 forward and 2 backward LSTMs) with 300-dimensional hidden units ($d^{hidden} = 300$). Following He et al. (2017), we initialize all the parameter matrices in BiLSTMs with random orthonormal matrices (Saxe et al., 2013). Other parameters are initialized following Glorot and Bengio (2010), and bias parameters are initialized with zero vectors.

Regularization We set the coefficient λ for the L2 weight decay (Eq. 11 in Section 4.3) to 0.0001. We apply dropout (Srivastava et al., 2014) to the input vectors of each LSTM with dropout ratio of 0.1 and the ELMo embeddings with dropout ratio of 0.5.

Training To optimize the parameters, we use Adam (Kingma and Ba, 2014) with $\beta_1 = 0.9$ and $\beta_2 = 0.999$. The learning rate is initialized to 0.001. After training 50 epochs, we halve the learning rate every 25 epochs. Parameter updates are performed in mini-batches of 32. The number of training epochs is set to 100. We save the parameters that achieve the best F1 score on the development set and evaluate them on the test set. Training our model on the CoNLL-2005 training set takes about one day and on the CoNLL-2012 training set takes about two days on a single GPU, respectively.

C.2 Ensemble Model

Our ensemble model uses span representations $\mathbf{h}_s^{(m)}$ from base models $m \in \{1, \cdots, M\}$ (Section 3.2). We use 5 base models ($M = 5$) learned over different runs. Note that, during training, we fix the parameters of the five base models and update only the parameters of the ensemble model.

Network setup The parameter matrix $\mathbf{W}_s^{\text{moe}}$ (Eq. 9 in Section 3.2) is initialized with the identity matrix. The scalar parameters $\{\alpha_m\}_{m=1}^{M}$ (Eq. 9) are initialized with 0. Each row vector $\mathbf{W}^{\text{moe}}[r]$ of the parameter matrix $\mathbf{W}^{\text{moe}}$ (Eq. 10) is initialized with the averaged vector over the row vectors $\mathbf{W}^{(m)}[r]$ of each model m, i.e., $\frac{1}{M}\sum_{m=1}^{M} \mathbf{W}^{(m)}[r]$.

Training To optimize the parameters, we use Adam with $\beta_1 = 0.9$ and $\beta_2 = 0.999$. The learning rate is set to 0.0001. Parameter updates are performed in mini-batches of 8. The number of training epochs is set to 20. We save the parameters that achieve the best F1 score on the development set and evaluate them on the test set. Training one ensemble model on the CoNLL-2005 and 2012 training sets takes about one day on a single GPU.

Mapping Language to Code in Programmatic Context

Abstract

Source code is rarely written in isolation. It depends significantly on the programmatic context, such as the class that the code would reside in. To study this phenomenon, we introduce the task of generating class member functions given English documentation and the programmatic context provided by the rest of the class. This task is challenging because the desired code can vary greatly depending on the functionality the class provides (e.g., a sort function may or may not be available when we are asked to "return the smallest element" in a particular member variable list). We introduce CONCODE, a new large dataset with over 100,000 examples consisting of Java classes from online code repositories, and develop a new encoder-decoder architecture that models the interaction between the method documentation and the class environment. We also present a detailed error analysis suggesting that there is significant room for future work on this task.

1 Introduction

Natural language can be used to define complex computations that reuse the functionality of rich, existing code bases. However, existing approaches for automatically mapping natural language (NL) to executable code have considered limited language or code environments. They either assume fixed code templates (i.e., generate only parts of a method with a predefined structure; Quirk et al., 2015), a fixed context (i.e., generate the body of the same method within a single fixed class; Ling et al., 2016), or no context at all (i.e., generate code tokens from the text alone; Oda et al., 2015). In this paper, we introduce new data and methods for learning to map language to source code within the context of a real-world programming environment, with application to generating member functions from documentation for automatically collected Java class environments.

```
public class SimpleVector implements Serializable {
  double[] vecElements;
  double[] weights;

  NL Query: Adds a scalar to this vector in place.
  Code to be generated automatically:
  public void add(final double arg0) {
    for (int i = 0; i < vecElements.length; i++){
      vecElements[i] += arg0;
    }
  }

  NL Query: Increment this vector
  Code to be generated automatically:
  public void inc() {
    this.add(1);
  }
}
```

Figure 1: Code generation based on the class environment and method documentation. The figure shows a class where the programmer wants to automatically generate the `add` method from documentation, assuming the rest of the class is already written. The system needs to understand that `vecElements` is the vector to be augmented, and that the method must take in a scalar parameter as the element to be added. The model also needs to disambiguate between the member variables `vecElements` and `weights`.

The presence of rich context provided by an existing code environment better approximates the way programmers capitalize on code re-use, and also introduces new language understanding challenges. Models must (a) map the NL to environment variables, library API calls and user-defined methods found elsewhere in the class based on their names, types and signatures, and (b) decide on the structure of the resulting code. For example, in Figure 1, to generate the method `inc()` from the corresponding NL, *Increment this vector*, it is crucial to know of the existence of class method `add()`. This helps us decide if it should directly call `add()` or generate the method from scratch by iterating through the `vecElements` array and incrementing each element. Similarly, for generating the `add()` method, the code needs to use the class variable

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1643–1652
Brussels, Belgium, October 31 - November 4, 2018.

`vecElements` correctly. Overall, the code environment provides rich information relating to the intent of the developer, and can be used to considerably reduce ambiguity in the NL documentation.

To learn such a code generator, we use a specialized neural encoder-decoder model that (a) encodes the NL together with representations based on subword units for environment identifiers (member variables, methods) and data types, and (b) decodes the resulting code using an attention mechanism with multiple steps, by first attending to the NL, and then to the variables and methods, thus also learning to copy variables and methods. This two-step attention helps the model to match words in the NL with representations of the identifiers in the environment. Rather than directly generating the output source code tokens (Dong and Lapata, 2016; Iyer et al., 2017), the decoder generates production rules from the grammar of the target programming language similar to Rabinovich et al. (2017), Yin and Neubig (2017), and Krishnamurthy et al. (2017) and therefore, guarantees the syntactic well-formedness of the output.

To train our model, we collect and release CONCODE, a new dataset comprising over 100,000 (class environment, NL, code) tuples by gathering Java files containing method documentation from public Github repositories. This is an order of magnitude larger than existing datasets that map NL to source code for a general purpose language (MTG from Ling et al. (2016) has 13k examples), contains a larger variety of output code templates than existing datasets built for a specific domain, and is the first to condition on the environment of the output code. Also, by design, it contains examples from several domains, thus introducing open-domain challenges of new identifiers during test time (some e.g. class environments are LookupCommand, ColumnFileReader and ImageSequenceWriter). Our model achieves an exact match accuracy of 8.6% and a BLEU score (a metric for partial credit; Papineni et al., 2002) of 22.11, outperforming retrieval and recent neural methods. We also provide an extensive ablative analysis, quantifying the contributions that come from the context and the model, and suggesting that our work opens up various areas for future investigation.

Figure 2: Our task involves generating the derivation of the source code of a method based on the NL documentation, class member variables (names and data types), and other class member methods (method names and return types), which form the code environment.

2 Task Definition

We introduce the task of generating source code from NL documentation, conditioned on the class environment the code resides in. The environment comprises two lists of entities: (1) class member variable names with their data types (for example, `double[] vecElements` as seen in Figure 2), and (2) member function names together with their return types (for example, `void inc()`).[1] Formally, let $q^{(i)}$, $a^{(i)}$ denote the NL and source code respectively for the i^{th} training example, where $a^{(i)}$ is a sequence of production rules that forms the derivation of its underlying source code. The environment comprises a list of variables names ${v^{(i)}}_{1..|v^{(i)}|}$ and their corresponding types ${t^{(i)}}_{1..|t^{(i)}|}$, as well as method names ${m^{(i)}}_{1..|m^{(i)}|}$ and their return types

---

[1] The method parameters and body can be used as well but we leave this to future work.

$r^{(i)}{}_{1..|r^{(i)}|}$. Our goal is to generate the derivation of $a^{(i)}$ given $q^{(i)}$ and the environment (see Figure 2).

3 Models

We evaluate a number of encoder-decoder models that generate source code derivations from NL and the class environment. Our best model encodes all environment components broken down into subword units (Sennrich et al., 2016) separately, using Bi-LSTMs and decodes these contextual representations to produce a sequence of valid production rules that derive syntactically valid source code. The decoder also uses a two-step attention mechanism to match words in the NL with environment components, and then uses a supervised copy mechanism (Gu et al., 2016a) to incorporate environment elements in the resulting code. We describe this architecture below.

3.1 Encoder

The encoder computes contextual representations of the NL and each component in the environment. Each word of the NL, q_i, is embedded into a high dimensional space using Identifier matrix I (denoted as $\mathbf{q_i}$) followed by the application of a n-layer bidirectional LSTM (Hochreiter and Schmidhuber, 1997). The hidden states of the last layer $(h_1, \cdots, h_z)$ are passed on to the attention layer, while the hidden states at the last token are used to initialize the decoder.

$$h_1, \cdots, h_z = \text{BiLSTM}(\mathbf{q_1}, \ldots, \mathbf{q_z})$$

To encode variables and methods, the variable types (t_i) and method return types (r_i) are embedded using a type matrix T (denoted as $\mathbf{t_i}$ and $\mathbf{r_i}$). To encode the variable and method names (v_i, m_i), they are first split based on camel-casing, and each component is embedded using I, represented as $\mathbf{v_{i1}}, \ldots, \mathbf{v_{ij}}$ and $\mathbf{m_{i1}}, \ldots, \mathbf{m_{ik}}$. The encoded representation of the variable and method names is the final hidden state of the last layer of a Bi-LSTM over these embeddings ($\mathbf{v_i}$ and $\mathbf{m_i}$). Finally, a 2-step Bi-LSTM is executed on the concatenation of the variable type embedding and the variable name encoding. The corresponding hidden states form the final representations of the variable type and the variable name $(\hat{t_i}, \hat{v_i})$ and are passed on to the attention mechanism. Method return types and names are processed identically using the same Bi-LSTMs and embedding matrices $(\hat{r_i}, \hat{m_i})$.

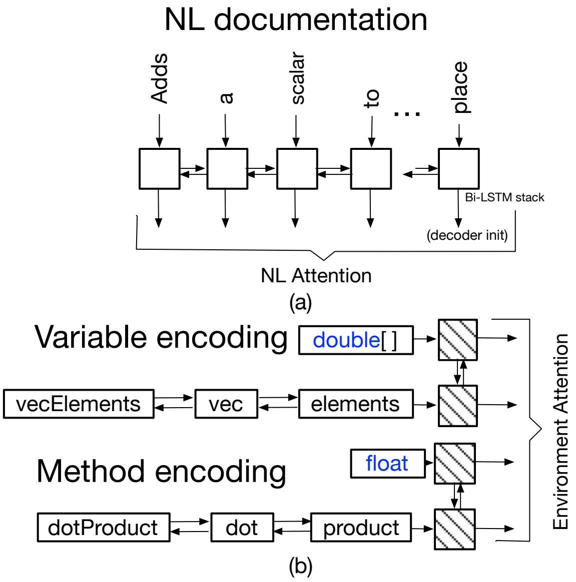

Figure 3: The encoder creates contextual representations of the NL (a), the variables and the methods (b). Variable (method) names are split based on camel-casing and encoded using a BiLSTM. The variable (method) type and name are further contextualized using another BiLSTM.

$$\begin{aligned}
\mathbf{t_i} &= t_i T;\ \mathbf{v_{ij}} = v_{ij} I \\
\mathbf{r_i} &= r_i T;\ \mathbf{m_{ik}} = m_{ik} I \\
\mathbf{v_i} &= \text{BiLSTM}(\mathbf{v_{i1}}, \ldots, \mathbf{v_{ij}}) \\
\mathbf{m_i} &= \text{BiLSTM}(\mathbf{m_{i1}}, \ldots, \mathbf{m_{ik}}) \\
\hat{t_i}, \hat{v_i} &= \text{BiLSTM}(\mathbf{t_i}, \mathbf{v_i}) \\
\hat{r_i}, \hat{m_i} &= \text{BiLSTM}(\mathbf{r_i}, \mathbf{m_i})
\end{aligned}$$

Figure 3 shows an example of the encoder.

3.2 Decoder

We represent the source code to be produced as a sequence of production rules (a_t at step t), with a non-terminal n_t on the left hand side and a combination of terminal and non-terminal symbols on the right hand side (see Figure 2). The first non-terminal is *MemberDeclaration*. Subsequently, every non-terminal is expanded in a depth first left to right fashion, similar to Yin and Neubig (2017). The probability of a source code snippet is decomposed as a product of the conditional probability of generating each step in the sequence of rules conditioned on the previously generated rules. Our decoder is an LSTM-based RNN that produces a context vector c_t at each time step, which is used to compute a distribution over next actions.

$$p(a_t|a_{<t}) \propto exp(W^{n_t} c_t) \qquad (1)$$

Here, W^{n_t} is a $|n_t| \times H$ matrix, where $|n_t|$ is the total number of unique production rules that n_t can be expanded to. The context vector c_t is computed using the hidden state s_t of an n-layer decoder LSTM cell and attention vectors over the NL and the context (z_t and e_t), as described below.

Decoder LSTM The decoder uses an n-layer LSTM whose hidden state s_t is computed based on the current non-terminal n_t to be expanded, the previous production rule a_{t-1}, the parent production rule $\text{par}(n_t)$ that produced n_t, the previous decoder LSTM state s_{t-1}, and the decoder state of the LSTM cell that produced n_t, denoted as s_{n_t}.

$$s_t = \text{LSTM}(n_t, a_{t-1}, \text{par}(n_t), s_{t-1}, s_{n_t}) \qquad (2)$$

We use an embedding matrix N to embed n_t and matrix A to embed a_{t-1} and $\text{par}(n_t)$. If a_{t-1} is a rule that generates a terminal node that represents an identifier or literal, it is represented using a special rule *IdentifierOrLiteral* to collapse all these rules into a single previous rule.

Two-step Attention At time step t, the decoder first attends to every token in the NL representation, h_i, using the current decoder state, s_t, to compute a set of attention weights α_t, which are used to combine h_i into an NL context vector z_t. We use a general attention mechanism (Luong et al., 2015), extended to perform multiple steps.

$$\alpha_{t,i} = \frac{\exp(s_t^{\mathrm{T}} \mathbf{F} h_i)}{\sum_i \exp(s_t^{\mathrm{T}} \mathbf{F} h_i)}$$
$$z_t = \sum_i \alpha_{t,i} h_i$$

The context vector z_t is used to attend over every type (return type) and variable (method) name in the environment, to produce attention weights β_t that are used to combine the entire context $x = [t : v : r : m]$ into an environment context vector e_t.[2]

$$\beta_{t,j} = \frac{\exp(z_t^{\mathrm{T}} \mathbf{G} x_j)}{\sum_j \exp(z_t^{\mathrm{T}} \mathbf{G} x_j)}$$
$$e_t = \sum_j \beta_{t,j} x_j$$

Finally, c_t is computed using the decoder state and both context vectors z_t and e_t:

$$c_t = tanh(\hat{W}[s_t : z_t : e_t])$$

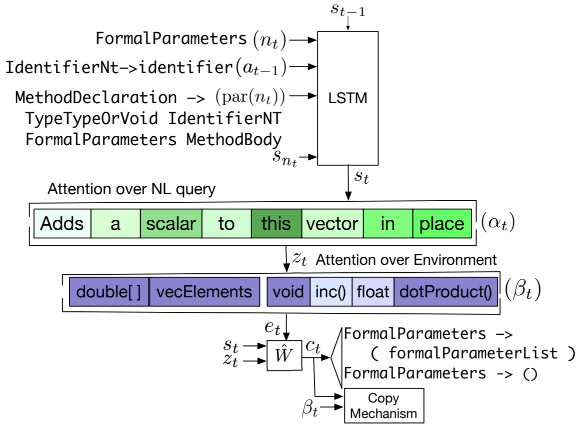

Figure 4: The hidden state s_t of our decoder is a function of the previous hidden state, current non-terminal, previous production rule, parent rule, and the parent hidden state. s_t is used to attend on the NL and compress it into z_t, which is then used to attend over the environment variables and methods to generate e_t. The decoder uses all these context vectors to produce a distribution over valid right hand side values of the current non-terminal, and also learns to copy from the environment.

Supervised Copy Mechanism Since the class environment at test time can belong to previously unseen new domains, our model needs to learn to copy variables and methods into the output. We use the copying technique of Gu et al. (2016a) to compute a copy probability at every time step t using vector b of dimensionality H.

$$\text{copy}(t) = \sigma(b^T c_t)$$

Since we only require named identifiers or user defined types to be copied, both of which are produced by production rules with n_t as *IdentifierNT*, we make use of this copy mechanism only in this case. Identifiers can be generated by directly generating derivation rules (see equation 1), or by copying from the environment. The probability of copying an environment token x_j, is set to be the attention weights $\beta_{t,j}$ computed earlier, which attend exactly on the environment types and names which we wish to be able to copy. The copying process is supervised by preprocessing the production rules to recognize identifiers that can be copied from the environment, and both the generation and the copy probabilities are weighted by $1 - \text{copy}(t)$ and $\text{copy}(t)$ respectively. The LSTM decoder with attention mechanism is illustrated in Figure 4.

3.3 Baseline Models

Retrieval We evaluate a retrieval baseline, where the output source code for a test example is the training example source code whose NL is closest

---

[2] ":" denotes concatenation.

in terms of cosine similarity to the test NL using a tf-idf representation. We then replace all occurrences of environment variables and methods in the chosen training source code with similarly typed variables and methods from the environment of the test example, and we break ties randomly.

Seq2seq We evaluate a Seq2Seq baseline by representing the NL and context as a sequence formed by the concatenation of the NL, the variables and the methods with separators between them. The variables (methods) are represented with the type (return type) followed by the name, with a different separator between them. The encoder is an n-layer LSTM which initializes an LSTM-based decoder using its final hidden states. The decoder uses an attention mechanism (Luong et al., 2015) over the encoder states to produce a conditional distribution over the next source code token (not production rule) given all the previous tokens. We replace UNK tokens in the output with source tokens having the most attention weight. We also attempted to evaluate the Seq2Tree model of Dong and Lapata (2016) but the redundancy in the model resulted in extremely long output sequences which did not scale. Experiments on a smaller dataset gave comparable results to Seq2seq.

Seq2prod This baseline corresponds to the action sequence model by Yin and Neubig (2017), with a BiLSTM over a sequence representation of the NL and context (same as Seq2seq), and a decoder that learns to generate a derivation of the AST of the underlying source code, similar to our model. The decoder uses the same attention mechanism as the Seq2seq, however, it uses supervised copying from the entire input sequence to handle unknown words encountered during testing.

4 CONCODE

We built a new dataset (CONCODE) from public Java projects on Github that contains environment information together with NL (Javadoc-style method comments) and code tuples. We gather Java files from $\sim$33,000 repositories, which are then split into train, development, and test sets based on repository, rather than purely randomly. Dividing based on the repository keeps the domains in the test set separate from the training set, therefore providing near zero-shot conditions that should truly test the ability of models to generalize to associate unseen NL tokens with previously unseen environment variables and methods. We also remove all examples from the development and test sets where the NL is exactly present in the training set. We further eliminate all Java classes that inherit from parent classes, since the resulting code may use variables and methods inherited from parent classes that reside in separate source files. While this is an important and interesting feature, we leave it for future work.

% Unknown Types	7.65%

Table 1: Statistics of our dataset of (NL, context and code) tuples collected from Github. *Does not include rules that generate identifiers.

Every method that contains a Javadoc comment is treated as a training example. The Javadoc comment forms the NL, the method body is the target code to be generated, and all member variables, as well as other member method signatures are extracted and stored as part of the context. The Javadoc is preprocessed by stripping special symbols such as `@link`, `@code`, `@inheritDoc` and special fields such as `@params`. Methods that do not parse are eliminated and the rest are pre-processed by renaming locally defined variables canonically, beginning at *loc0* and similarly for arguments, starting with *arg0*. We also replace all method names with the word *function* since it doesn't affect the semantics of the resulting program. Generating informative method names has been studied by Allamanis et al. (2015a). We replace all string literals in the code with constants as they are often debug messages. Finally, we use an ANTLR java grammar[3] that is post-processed by adding additional non-terminals and rules to eliminate wildcard symbols in the grammar, in order to convert the source code into a sequence of production rules. The resulting dataset contains 100,000 examples for training, and 2000 examples each for development and testing, respectively. Table 1 summarizes the various statistics. We observe that on average, an environment contains $\sim$5 variables and $\sim$11 methods. Around 68% of the target code uses class member variables, and 16% of them use member methods, from the environment. Based on a frequency cutoff of 2 on the training set, we find that 7% of the types in the development set code are unknown, hence they need to be copied from the environment. Since CONCODE is extracted from a diverse set of online repositories, there is a high variety of code templates in the dataset compared to existing datasets. For example, a random baseline on the Hearthstone card game dataset (Ling et al., 2016) gives a BLEU score of 40.3, but only a score of 10.2 on CONCODE. We plan to release all code and data from this work.[4]

5 Experimental Setup

We restrict all models to examples where the length of the combination of the NL and the context is at most 200 tokens and the length of the output source code is at most 150 tokens. Source NL tokens are lower-cased, camel-cased identifiers are split and lower-cased, and are used together with the original version. The vocabulary for identifiers uses a frequency threshold of 7, resulting in a vocabulary of $32,600$ tokens. The types vocabulary uses a threshold of 2 resulting in $22,324$ types. We include all 153 non-terminals and 342 previous rules. We use a threshold of 2 for output production rules to filter out the long tail of rules creating identifiers and literals, resulting in $18,135$ output rules. Remaining values are replaced with the UNK symbol.

Hyperparameters We use an embedding size H of 1024 for identifiers and types. All LSTM cells use 2-layers and a hidden dimensionality of 1024 (512 on each direction for BiLSTMs). We use an embedding size of 512 for encoding non-terminals and rules in the decoder. We use dropout with $p = 0.5$ in between LSTM layers and at the output of the decoder over c_t. We train our model for 30 epochs using mini-batch gradient descent with a batch size of 20, and we use Adam (Kingma and Ba, 2015) with an initial learning rate of 0.001 for optimization. We decay our learning rate by 80% based on performance on the development set after every epoch.

Model	Exact	BLEU
Retrieval	2.25 (1.65)	20.27 (18.15)
Seq2Seq	3.2 (2.9)	23.51 (21.0)
Seq2Prod	6.65 (5.55)	21.29 (20.55)
Ours	8.6 (7.05)	22.11 (21.28)

-Methods	6.2	21.74
-Two step attention	5.75	17.2
-Camel-case encoding	5.7	21.83

Table 3: Ablation of model features on the development set.

Inference and Metrics Inference is done by first encoding the NL and context of the test example. We maintain a stack of symbols starting with the non-terminal, *MemberDeclaration*, and at each step, a non-terminal (terminals are added to the output) is popped off the stack to run a decoding step to generate the next set of symbols to push onto the stack. The set of terminals generated along the way forms the output source code. We use beam search and maintain a ranked list of partial derivations (or code tokens for Seq2seq) at every step to explore alternate high-probability derivations. We use a beam size of 3 for all neural models. We copy over source tokens whenever preferred by the model output. We restrict the output to 150 tokens or 500 production rules.

To evaluate the quality of the output, we use Exact match accuracy between the reference and generated code. As a measure of partial credit, we also compute the BLEU score (Papineni et al., 2002), following recent work on code generation (Ling et al., 2016; Yin and Neubig, 2017). BLEU is an n-gram precision-based metric that will be higher when more subparts of the predicted code match the provided reference.

Figure 5: Analysis of our model output on development set examples. Some environment variables and methods are omitted for space. (a)-(d) represent cases where the model exactly produced the reference output. (e)-(g) are cases where the model output is very reasonable for a practical setting. In (f), the model produces a better solution than the reference. In (h), the context lacks information to produce the reference code. The model chooses the wrong element in (i) and could be improved by better encoder representations.

6 Results

We present results for the context based code generation task on the test and dev sets in Table 2. Our model outperforms all baselines and achieves a gain of 1.95% exact match accuracy and 0.82 BLEU points, with respect to the next best models. The combination of independently encoding subword units and applying a two-step attention mechanism helps the model learn to better associate the correct variables/methods from the context and the language in the NL. Figure 5 (a) shows an example output of our model, which produces code structure intermixed with member variables (tags). In (b) our model learns to call method `addUnderscores` (an UNK in the vocabulary) with its correct return type (`String`). Similarly, in (d) our model also successfully learns to use a previously unseen type (`ExecutionDataStore`) when making use of the corresponding variable. (c) is an example of where the NL does not directly refer to the variable to be used. The mismatch between dev and test results is because we ensure that the dev and test examples come from non-overlapping Github repositories, resulting in different distributions.

Using a constrained decoder that generates syntax tree rules instead of tokens leads to significant gains in terms of exact match score (6.65 for Seq2prod vs 3.2 for Seq2seq), and shows that this is an important component of code generation systems. Seq2prod, however, fails on examples (b)-(d), since it is harder to learn to match the NL tokens with environment elements. Finally, all neural models outperform the retrieval baseline with member substitution.

To understand which components of the data and the model contribute most to the output, we perform an ablation study on the development set (Table 3). Removing the variables leads to a significant hit in exact match accuracy since 68% of examples (Table 1) refers to class variables; a similar but smaller reduction is incurred by removing methods. The presence of these components makes this task more challenging and also more aligned with programming scenarios in practice. Removing the two-step attention mechanism leads to a 1.3% drop in accuracy since the attention on the NL is unable to interact with the attention on the environment variables/methods. Removing camel-case encoding leads to a small drop mainly because many variable (method) names are single words.

Category	Fraction
Totally Wrong	62%
Marginally Correct	9%
Mostly Correct	16%
Exact Match	11%
Semantically Equivalent	2%

Table 4: Qualitative distribution of errors on the development set.

7 Error Analysis

Subfigures 5(e)-(i) show cases where our model output did not exactly match the reference. In (e)-(g), the model output is semantically equivalent to the reference and is a very reasonable prediction in a practical setting. For example, in (e) the only difference between the prediction and the reference is the string concatenations to the url. Interestingly, in example (f) the prediction is a cleaner way to achieve the same effect as the reference, and this is a great example of the application of these models for suggesting standard and efficient code. Unfortunately, our model is penalized by the exact match metric here. Similarly, in (g), the model uses a generic list (`List<?>`) in place of the specific type (`Transformer[]`). Example (h) demonstrates a case where the model is unaware of methods that can be called on class members (specifically that `evictAll` is a member of the `TimestampsRegion` class), and requires augmenting the environment with additional member type documentation, which we believe will be an important area for future work. Example (i) calls for richer encoder representations, since our model incorrectly uses the `_values` variable instead of `_register`, as it is unable to associate the word "registry" with the right elements.

We further perform a qualitative analysis of 100 predictions on our development set (Table 4) and find that there is significant room for improvement with 71% of the predictions differing significantly from their references. 16% of the predictions are very close to their references with the difference being 1-2 tokens, while 11% are exactly correct. 2% of the predictions were semantically equivalent but not exactly equal to their references.

8 Related Work

There is significant existing research on mapping NL directly to executable programs in the form of logical forms (Zettlemoyer and Collins, 2005), λ-DCS (Liang et al., 2013), regular expressions (Kushman and Barzilay, 2013; Locascio et al., 2016), database queries (Iyer et al., 2017; Zhong et al., 2017) and general purpose programs (Balog et al., 2016; Allamanis et al., 2015b). Ling et al. (2016) generate Java and Python source code from NL for card games, conditioned on categorical card attributes. Manshadi et al. (2013) generate code based on input/output examples for applications such as database querying. Gu et al. (2016b) use neural models to map NL queries to a sequence of API calls, and Neelakantan et al. (2015) augment neural models with a small set of basic arithmetic and logic operations to generate more meaningful programs. In this work, we introduce a new task of generating programs from NL based on the environment in which the generated code resides, following the frequently occurring pattern in large repositories where the code depends on the types and availability of variables and methods in the environment.

Neural encoder-decoder models have proved effective in mapping NL to logical forms and also for directly producing general purpose programs. Ling et al. (2016) use a sequence-to-sequence model with attention and a copy mechanism to generate source code. Instead of directly generating a sequence of code tokens, recent methods focus on constrained decoding mechanisms to generate syntactically correct output using a decoder that is either grammar-aware or has a dynamically-determined modular structure paralleling the structure of the abstract syntax tree (AST) of the code (Dong and Lapata, 2016; Rabinovich et al., 2017; Krishnamurthy et al., 2017; Yin and Neubig, 2017). Our model also uses a grammar-aware decoder similar to Yin and Neubig (2017) to generate syntactically valid parse trees, augmented with a two-step attention mechanism (Chen et al., 2016), followed by a supervised copying mechanism (Gu et al., 2016a) over the class environment.

Recent models for mapping NL to code have been evaluated on datasets containing highly templated code for card games (Hearthstone & MTG; Ling et al., 2016), or manually labeled per-line comments (DJANGO; Oda et al., 2015). These datasets contain $\sim$20,000 programs with short textual descriptions possibly paired with categorical data, whose values need to be copied onto the resulting code from a single domain. In this work, we collect a new dataset of over 100,000 NL and code pairs, together with the corresponding class environment. Each environment and NL describe a specific domain and the dataset comprises thousands of different domains, that poses additional challenges. Having an order of magnitude more data than existing datasets makes training deep neural models very effective, as we saw in the experimental evaluation. While massive amounts of Github code have been used before for creating datasets on source code only (Allamanis and Sutton, 2013, 2014; Allamanis et al., 2016), we instead extract from Github a dataset of NL and code with an emphasis on context, in order to learn to map NL to code within a class.

9 Conclusion

In this paper, we introduce new data and methods for learning to generate source code from language within the context of a real-world code base. To train models for this task, we collect and release CONCODE, a large new dataset of NL, code, and context tuples from online repositories, featuring code from a variety of domains. We also introduced a new encoder decoder model with a specialized context encoder which outperforms strong neural baselines by 1.95% exact match accuracy. Finally, analysis suggests that even richer models of programmatic context could further improve these results.

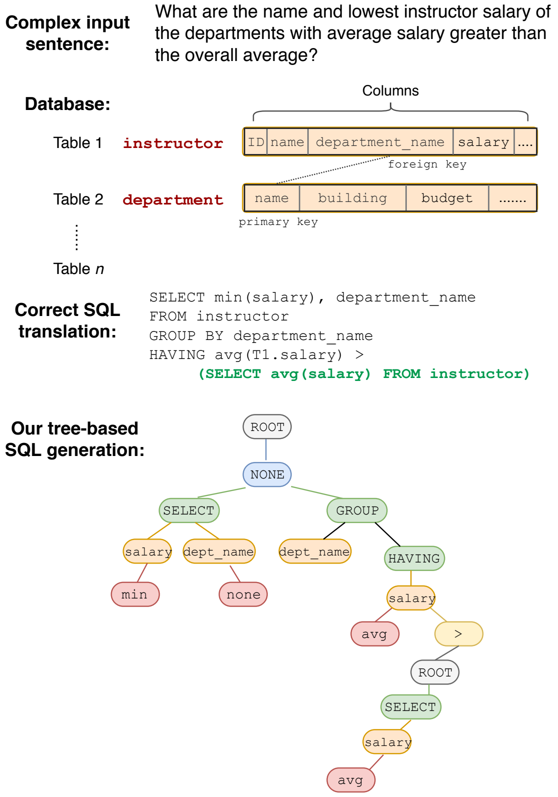
Abstract

Most existing studies in text-to-SQL tasks do not require generating complex SQL queries with multiple clauses or sub-queries, and generalizing to new, unseen databases. In this paper we propose SyntaxSQLNet, a syntax tree network to address the *complex* and *cross-domain* text-to-SQL generation task. SyntaxSQLNet employs a SQL specific syntax tree-based decoder with SQL generation path history and table-aware column attention encoders. We evaluate SyntaxSQLNet on a new large-scale text-to-SQL corpus containing databases with multiple tables and complex SQL queries containing multiple SQL clauses and nested queries. We use a database split setting where databases in the test set are unseen during training. Experimental results show that SyntaxSQLNet can handle a significantly greater number of complex SQL examples than prior work, outperforming the previous state-of-the-art model by 9.5% in exact matching accuracy. To our knowledge, we are the first to study this complex text-to-SQL task. Our task and models with the latest updates are available at https://yale-lily.github.io/seq2sql/spider.

1 Introduction

Text-to-SQL task is one of the most important subtask of semantic parsing in natural language processing (NLP). It maps natural language sentences to corresponding SQL queries.

In recent years, some state-of-the-art methods with Seq2Seq encoder-decoder architectures are able to obtain more than 80% exact matching accuracy on some complex text-to-SQL benchmarks such as ATIS and GeoQuery. These models seem to have already solved most problems in this area.



What are the name and lowest instructor salary of the departments with average salary greater than the overall average?

```
SELECT min(salary), department_name
FROM instructor
GROUP BY department_name
HAVING avg(T1.salary) >
     (SELECT avg(salary) FROM instructor)
```

Figure 1: To address the complex text-to-SQL generation task, SyntaxSQLNet employs a tree-based SQL generator. For example, our model can systematically generate a nested query as illustrated above.

However, as (Finegan-Dollak et al., 2018) show, because of the problematic task definition in the traditional datasets, most of these models just learn to match semantic parsing results, rather than truly learn to understand the meanings of inputs and generalize to new programs and databases. More specifically, most existing complex text-to-SQL datasets have less than 500 SQL labels. They are expanded by paraphrasing 4-10 questions for each SQL query. Under the standard train and test split (Zettlemoyer and Collins, 2005), most queries in the test set also appear in the train set. The WikiSQL dataset recently developed by (Zhong et al., 2017) is much larger and does use different databases for training and testing, but it only contains very simple SQL queries and

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1653–1663
Brussels, Belgium, October 31 - November 4, 2018.

database schemas.

To address those issues in the current semantic parsing datasets, Yu et al. (2018b) have developed a large-scale human labeled text-to-SQL dataset consisting of about 6,000 complex SQL queries and 200 databases with multiple tables. This dataset defines a new *complex* and *cross-domain* text-to-SQL task that requires models to generalize well to both new SQL queries and databases. The task cannot be solved easily without truly understanding the semantic meanings of the input questions.

In this paper, we propose SyntaxSQLNet, a SQL specific syntax tree network to address the aforementioned task. Specifically, to generate complex SQL queries with multiple clauses, selections and sub-queries, we develop a syntax tree-based decoder with SQL generation path history. To make our model learn to generalize to new databases with new tables and columns, we also develop a table-aware column encoder. Our contributions are as follows:

- We propose SQL specific syntax tree networks for the complex and cross-domain text-to-SQL task, which is even able to solve nested queries on new, unseen databases. We are the first to develop a methodology for this challenging semantic parsing task.
- We introduce a SQL specific syntax tree-based decoder with SQL path history and table-aware column attention encoders. Even with no hyper-parameter tuning, our model can significantly outperform the previous best models, with 4.8% boost in exact matching accuracy. Error analysis shows that our model is able to generalize, and solve much more complex (e.g., nested) queries in unseen databases than prior work.
- We also develop a cross-domain data augmentation method to generate more diverse training examples across databases, which further improves the exact matching accuracy by 7.5%. As a result, our model achieves 22.0% accuracy, a 12.3% total improvement compared with the previous best models.

2 Related Work

Semantic parsing maps natural language to formal meaning representations. There are a range of representations, such as logic forms and executable programs (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Wong and Mooney, 2007; Das et al., 2010; Liang et al., 2011; Banarescu et al., 2013; Artzi and Zettlemoyer, 2013; Reddy et al., 2014; Berant and Liang, 2014; Pasupat and Liang, 2015).

As a sub-task of semantic parsing, the text-to-SQL problem has been studied for decades (Warren and Pereira, 1982; Popescu et al., 2003a, 2004; Li et al., 2006; Giordani and Moschitti, 2012; Wang et al., 2017b). The methods proposed in the database community (Li and Jagadish, 2014; Yaghmazadeh et al., 2017) tend to involve hand feature engineering and user interactions with the systems. In this work, we focus on recent neural network-based approaches (Yin et al., 2016; Zhong et al., 2017; Xu et al., 2017; Wang et al., 2017a; Iyer et al., 2017). Dong and Lapata (2016) introduce a sequence-to-sequence (seq2seq) approach to converting texts to logical forms. Most previous work focuses on a specific table schema. Zhong et al. (2017) publish the WikiSQL dataset and propose a seq2seq model with reinforcement learning to generate SQL queries. Xu et al. (2017) further improve the results on the WikiSQL task by using a SQL-sketch based approach employing a sequence-to-set model. Dong and Lapata (2018) propose a coarse-to-fine model which achieves the new state-of-the-art performances on several datasets including WikiSQL. Their model first generate a sketch of the target program. Then the model fills in missing details in the sketch.

Our syntax tree-based decoder is related to recent work that exploits syntax information for code generation tasks (Yin and Neubig, 2017; Rabinovich et al., 2017). Yin and Neubig (2017) introduce a neural model that transduces a natural language statement into an abstract syntax tree (AST). While they format the generation process as a seq2seq decoding of rules and tokens, our model uses a module for each grammar component, and calls them recursively to generate a SQL syntax tree. Similarly, Rabinovich et al. (2017) propose abstract syntax networks that use a collection of recursive modules for decoding. Our model differs from theirs in the following points. First, we exploit a SQL specific grammar instead of AST. AST-based models have to predict many non-terminal rules before predicting the terminal tokens, involving more steps. Whereas, our SQL-specific grammar enables direct prediction of SQL tokens. Second, our model uses different sequence-to-set modules to avoid the "ordering issue" (Xu et al., 2017) in many code generation tasks. Third, different from (Rabinovich et al., 2017), we pass a pre-order traverse of SQL decoding history to each module. This provides each module with important dependence information: e.g., if a SQL query has `GROUP BY`, it is very likely that the grouped column have appeared in `SELECT` too.

In addition to the distinction in model design, our work differs from theirs in the data and task definition. They aim to develop general syntax model for code generation via abstract syntax trees. Instead, we are interested in solving the complex and cross-domain SQL query generation problem; this motivates us to take advantage of SQL specific syntax for decoding, which guides systematic generation of complex SQL queries.

3 Problem Formulation

This work aims to tackle the complex text-to-SQL task that involves multiple tables, SQL clauses and nested queries. Further, we use separate databases for training and testing, aiming to develop models that generalize to new databases.

Dataset. We use *Spider* (Yu et al., 2018b) as the main dataset, which contains 10,181 questions, 5,693 unique complex SQL queries, and 200 databases with multiple tables.

Task and Challenges.

- The dataset contains a large number of complex SQL labels, which involve more tables, SQL clauses, and nested queries than prior datasets such as WikiSQL. Existing models developed for the WikiSQL task cannot handle those complex SQL queries in the Spider dataset.
- The dataset contains 200 databases (∼138 domains), and different databases are used for training and testing. Unlike most previous semantic parsing tasks (e.g., ATIS), this task requires models to generalize to new, unseen databases.

In sum, we train and test models on different complex SQL queries from different databases in this task. This aims to ensure that models can make the correct prediction only when they truly understand the meaning of the questions under the given database, rather than by mere memorization.

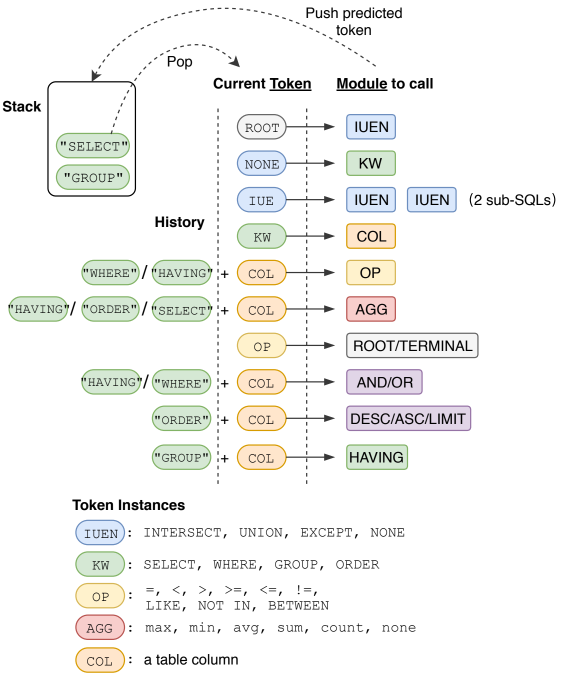


Figure 2: Our modules and SQL grammar used in decoding process. A round symbol represents a SQL tokens, a table column, etc. A square symbol indicates a module that predicts the next SQL token from its corresponding token instances with the same color.

4 Methodology

Similar to (Rabinovich et al., 2017), our model structures the decoder as a collection of recursive modules. However, as we discussed in the related work section, we make use of a SQL specific grammar to guide the decoding process, which allows us to take advantage of SQL queries' well-defined structure. [1]

4.1 Module Overview

Our model decomposes the SQL decoding process into 9 modules to handle the prediction of different SQL components such as keywords, operators, and columns. We provide the overview in this section and more details in later sections.

Figure 2 illustrates our modules and SQL grammar used in decoding process. A round symbol represents a SQL token, such as `SELECT`, `WHERE`, a table column, etc. A square symbol indicates a module that predicts the next SQL token from its corresponding token instances with the same color. Specifically, we have the following modules.

- **IUEN Module**, predicting `INTERCEPT`,

---

[1] Please check out our website for the latest updates on the model at `https://yale-lily.github.io/seq2sql/spider`

`UNION`, `EXCEPT`, and `NONE`, which determines if we need to call itself again to generate nested queries.

- **KW Module**, predicting keywords from `WHERE`, `GROUP BY`, and `ORDER BY`. All queries in our dataset have `SELECT`.
- **COL Module**, predicting table columns.
- **OP Module**, for $=$, $>$, $<$, $>=$, $<=$, $!=$, `LIKE`, `NOT IN`, `IN`, `BETWEEN`.
- **AGG Module**, predicting aggregators from `MAX`, `MIN`, `SUM`, `COUNT`, `AVG`, and `NONE`.
- **Root/Terminal Module**, predicting the `ROOT` of a new subquery or terminal value. It also enables our model to generate nested queries.
- **AND/OR Module**, predicting the presence of AND or OR operator between two conditions.
- **DESC/ASC/LIMIT Module**, predicting the keywords associated with `ORDER BY`. It is invoked only when `ORDER BY` is predicted before.
- **HAVING Module**, predicting the presence of `HAVING` for `GROUP BY` clause. It is invoked only when `GROUP BY` is predicted earlier.

4.2 SQL Grammar

In order to structure our decoder to generate complex queries, we consider a SQL grammar. It determines which module to be invoked at each recursive decoding step. Figure 2 illustrates our SQL grammar. During decoding process, given the current SQL token and the SQL history (the tokens we have gone over to reach the current token), we determine which module to invoke, and predict the next SQL token to generate.

To invoke some modules such as HAVING and OP during decoding, we not only check the type of current token instance but also see whether the type of the previously decoded SQL token is `GROUP` for HAVING module, and `WHERE` or `HAVING` for OP module.

In the grammar, IUEN and Root/Terminal modules are able to generate `ROOT`, which can activate IUEN module again. In this way, our model can recursively generate nested subqueries, and can also predict two or more subqueries in queries that have `EXCEPT`, `INTERSECT`, and `UNION`.

4.3 Input Encoder

Our inputs of each module consist of three types of information: question, table schema, and current SQL decoding history path. We encode a question sentence by a bi-directional LSTM, BiLSTM^{Q}. We encode table schema and history path in the manners described below.

4.3.1 Table-Aware Column Representation

In order to generalize to new databases in testing, it is important to make our model learn to obtain necessary information from a database schema. While SQLNet (Xu et al., 2017) only needed the column names as WikiSQL dataset only contained one table per question-SQL pair, *Spider*'s databases contain multiple tables. To address this setting, we propose to use both table and column names to construct column embeddings.

Specifically, given a database, we first obtain embedding for each table by taking the average embedding of the words constituting the table name (e.g., for table name `student_id`, we average the word embeddings for `student` and `id`). Next, for each column, we obtain the initial column name embedding in the same manner, and then concatenate the corresponding table embedding, and the type information of the column (string, or number, primary/foreign key) in a way similar to (Yu et al., 2018a) to produce a column embedding. On top, we apply another level of BiLSTM ($\text{BiLSTM}^{\text{COL}}$) that connects all columns in the database, to obtain high-level column embeddings. This way, our encoding scheme can effectively capture both the global (table names) and local (column names and types) information in the database schema to understand the question in the context of the given database.

Similarly to (Yu et al., 2018a), while the the order of column names or table names does not matter in practice, the use of BiLSTM performed better than the direct use of input column embeddings.

4.3.2 SQL Decoding History

In addition to question and column information, we also pass the SQL query's current decoding history as an input to each module. This enables us to use the information of previous decoding states to predict the next SQL token. For example, in Figure 1, the COL module would be more likely to predict `salary` in the subquery by considering the path history which contains `salary` for `HAVING`, and `SELECT` in the main query.

In contract, each module in SQLNet does not consider the previous decoded SQL history.

Hence, if directly applied to our recursive SQL decoding steps, each module would just predict the same output every time it is invoked. By passing the SQL history, each module is able to predict a different output according to the history every time it is called during the recursive SQL generation process. Also, the SQL history can improve the performance of each module on long and complex queries because the history helps the model capture the relations between clauses.

Predicted SQL history is used during test decoding. For training, we first traverse each node in the the gold query tree in pre-order to generate gold SQL path history for each training example used in different modules.

4.3.3 Attention for Input Encoding

For each module, like SQLNet, we apply the attention mechanism to encode question representation. We also employs this technique on SQL path history encoding. The specific formulas used are described in the next section.

4.4 Module Details

Similarly to SQLNet (Xu et al., 2017), we employ a sketch-based approach for each module. We apply a seq2set prediction framework introduced by (Xu et al., 2017), to avoid the order issue that happens in seq2seq based models for SQL generation. For example, in Figure 1, `SELECT salary, dept_name` is the same as `SELECT dept_name, salary`. The traditional seq2seq decoder generates each of them one by one in order; hence the model could get penalized even if the prediction and gold label are the same as sets. To avoid this problem, SQLNet predicts them together in one step so that their order does not affect the model's training process. For instance, in Figure 1, our model invokes the COL module to predict `salary` and `dept_name` and push to stack at the same time. However, SQLNet trains each modules independently, so no information passes through each component.

We first describe how to compute the conditional embedding $\mathbf{H}_{1/2}$ of an embedding $\mathbf{H}_1$ given another embedding $\mathbf{H}_2$:

$$\mathbf{H}_{1/2} = \mathbf{softmax}(\mathbf{H}_1 \mathbf{W} \mathbf{H}_2^\top)\mathbf{H}_1.$$

Here $\mathbf{W}$ is a trainable parameter. Moreover, we get a probability distribution from a given score matrix $\mathbf{U}$ by

$$\mathcal{P}(\mathbf{U}) = \mathbf{softmax}\left(\mathbf{V}\mathbf{tanh}(\mathbf{U})\right),$$

where $\mathbf{V}$ is a trainable parameter.

We denote the hidden states of LSTM on question embeddings, path history, and columns embeddings as $\mathbf{H}_{\text{Q}}$, $\mathbf{H}_{\text{HS}}$, and $\mathbf{H}_{\text{COL}}$ respectively. In addition, we denote the hidden states of LSTM on multiple keywords embeddings and keywords embeddings as $\mathbf{H}_{\text{MKW}}$ and $\mathbf{H}_{\text{KW}}$ respectively. Finally, we use $\mathbf{W}$ to denote trainable parameters that are not shared between modules. The output of each module is computed as follows:

IUEN Module In the IUEN module, since only one of the multiple keywords from {`INTERCEPT`, `UNION`, `EXCEPT`, `NONE`} will be used, we compute the probabilities by

$$P_{\text{IUEN}} = \mathcal{P}\left(\mathbf{W}_1\mathbf{H}_{\text{Q/MKW}}^\top + \mathbf{W}_2\mathbf{H}_{\text{HS/MKW}}^\top + \mathbf{W}_3\mathbf{H}_{\text{MKW}}^\top\right)$$

KW Module In the KW module, we first predict the number of keywords in the SQL query and then predict the keywords from {`SELECT`, `WHERE`, `GROUP BY`, `ORDER BY`}.

$$P_{\text{KW}}^{\text{num}} = \mathcal{P}\left(\mathbf{W}_1^{\text{num}}\mathbf{H}_{\text{Q/KW}}^{\text{num}}{}^\top + \mathbf{W}_2^{\text{num}}\mathbf{H}_{\text{HS/KW}}^{\text{num}}{}^\top\right)$$

$$P_{\text{KW}}^{\text{val}} = \mathcal{P}\left(\mathbf{W}_1^{\text{val}}\mathbf{H}_{\text{Q/KW}}^{\text{val}}{}^\top + \mathbf{W}_2^{\text{val}}\mathbf{H}_{\text{HS/KW}}^{\text{val}}{}^\top + \mathbf{W}_3^{\text{val}}\mathbf{H}_{\text{KW}}{}^\top\right)$$

COL Module Similarly, in the COL module, we first predict the number of columns in the SQL query and then predict which ones to use.

$$P_{\text{COL}}^{\text{num}} = \mathcal{P}\left(\mathbf{W}_1^{\text{num}}\mathbf{H}_{\text{Q/COL}}^{\text{num}}{}^\top + \mathbf{W}_2^{\text{num}}\mathbf{H}_{\text{HS/COL}}^{\text{num}}{}^\top\right)$$

$$P_{\text{COL}}^{\text{val}} = \mathcal{P}\left(\mathbf{W}_1^{\text{val}}\mathbf{H}_{\text{Q/COL}}^{\text{val}}{}^\top + \mathbf{W}_2^{\text{val}}\mathbf{H}_{\text{HS/COL}}^{\text{val}}{}^\top + \mathbf{W}_3^{\text{val}}\mathbf{H}_{\text{COL}}{}^\top\right)$$

OP Module In the OP module, for each predicted column from the COL module that is in the `WHERE` clause, we first predict the number of operators on it then predict which operators to use from $\{=, >, <, >=, <=, !=$, `LIKE`, `NOT IN`, `IN`, `BETWEEN`$\}$. We use $\mathbf{H}_{\text{CS}}$ to denote the embedding of one of the predicted columns from the COL module.

$$P_{\text{OP}}^{\text{num}} = \mathcal{P}\left(\mathbf{W}_1^{\text{num}}\mathbf{H}_{\text{Q/CS}}^{\text{num}}{}^\top + \mathbf{W}_2^{\text{num}}\mathbf{H}_{\text{HS/CS}}^{\text{num}}{}^\top + \mathbf{W}_3^{\text{num}}\mathbf{H}_{\text{CS}}{}^\top\right)$$

$$P_{\text{OP}}^{\text{val}} = \mathcal{P}\left(\mathbf{W}_1^{\text{val}}\mathbf{H}_{\text{Q/CS}}^{\text{val}}{}^\top + \mathbf{W}_2^{\text{val}}\mathbf{H}_{\text{HS/CS}}^{\text{val}}{}^\top + \mathbf{W}_3^{\text{val}}\mathbf{H}_{\text{CS}}{}^\top\right)$$

AGG Module In the AGG module, for each predicted column from the COL module that is in the `SELECT` clause, we first predict the number of aggregators on it then predict which aggregators to use from {`MAX`, `MIN`, `SUM`, `COUNT`, `AVG`, `NONE`}

$$P_{\text{AGG}}^{\text{num}} = \mathcal{P}\left(\mathbf{W}_1^{\text{num}}\mathbf{H}_{\text{Q/CS}}^{\text{num}}{}^\top + \mathbf{W}_2^{\text{num}}\mathbf{H}_{\text{HS/CS}}^{\text{num}}{}^\top + \mathbf{W}_3^{\text{num}}\mathbf{H}_{\text{CS}}{}^\top\right)$$

$$P_{\text{AGG}}^{\text{val}} = \mathcal{P}\left(\mathbf{W}_1^{\text{val}}\mathbf{H}_{\text{Q/CS}}^{\text{val}}{}^\top + \mathbf{W}_2^{\text{val}}\mathbf{H}_{\text{HS/CS}}^{\text{val}}{}^\top + \mathbf{W}_3^{\text{val}}\mathbf{H}_{\text{CS}}{}^\top\right)$$

Root/Terminal Module To predict nested subqueries, we add a module to predict if there is a new "ROOT" after an operator, which allows the model to decode queries recursively. For each predicted column from the COL module that is in the `WHERE` clause, we first call OP module, and then predict whether the next decoding step is a "ROOT" node or a value terminal node by

$$P_{\text{RT}} = \mathcal{P}\left(\mathbf{W}_1\mathbf{H}^{\top}_{\text{Q/CS}} + \mathbf{W}_2\mathbf{H}^{\top}_{\text{HS/CS}} + \mathbf{W}_3\mathbf{H}^{\top}_{\text{CS}}\right)$$

AND/OR Module For each condition column predicted from the COL module with number bigger than 1, we predict from {`AND`, `OR`} by

$$P_{\text{AO}} = \mathcal{P}\left(\mathbf{W}_1\mathbf{H}^{\top}_{\text{Q}} + \mathbf{W}_2\mathbf{H}^{\top}_{\text{HS}}\right)$$

DESC/ASC/LIMIT Module In the DAL module, for each predicted column from the COL module that is in the `ORDER BY` clause, we predict from {`DESC`, `ASC`, `DESC LIMIT`, `ASC LIMIT`} by

$$P_{\text{DAL}} = \mathcal{P}\left(\mathbf{W}_1\mathbf{H}^{\top}_{\text{Q/CS}} + \mathbf{W}_2\mathbf{H}^{\top}_{\text{HS/CS}} + \mathbf{W}_3\mathbf{H}^{\top}_{\text{CS}}\right)$$

HAVING Module In the HAVING module, for each predicted column from the COL module that is in the `GROUP BY` clause, we predict whether it is in the `HAVING` clause by

$$P_{\text{HAVING}} = \mathcal{P}\left(\mathbf{W}_1\mathbf{H}^{\top}_{\text{Q/CS}} + \mathbf{W}_2\mathbf{H}^{\top}_{\text{HS/CS}} + \mathbf{W}_3\mathbf{H}^{\top}_{\text{CS}}\right)$$

4.5 Recursive SQL Generation

The SQL generation process is a process of activating different modules recursively. As illustrated in Figure 2, we employ a stack to organize our decoding process. At each decoding step, we pop one SQL token instance from the stack, and invoke a module based on the grammar to predict the next token instance, and then push the predicted instance into the stack. The decoding process continues until the stack is empty.

More specifically, we initialize a stack with only `ROOT` at the first decoding step. At the next step, the stack pops `ROOT`. As illustrated in Figure 2, `ROOT` actives the `IUEN` module to predict if there is `EXCEPT`, `INTERSECT` or `UNION`. If so, there are two subqueries to be generated in the next step. If the model predicts `NONE` instead, it will be pushed into the stack. The stack pops `NONE` at next step. For example, in Figure 2, the current popped token is `SELECT`, which is a instance of keyword (KW) type. It calls the COL module to predict a column name, which will be pushed to the stack.

4.6 Data Augmentation

Even though *Spider* already has a significantly larger number of complex queries than existing datasets, the number of training examples for some complex SQL components is still limited. A widely used way is to conduct data augmentation to generate more training examples automatically. Many studies (Berant and Liang, 2014; Iyer et al., 2017; Su and Yan, 2017) have shown that data augmentation can bring significant improvement in performance. In prior work, data augmentation was typically performed within a single domain dataset. We propose a cross-domain data augmentation method to expand our training data for complex queries. Cross-domain data augmentation is more difficult than the in-domain setting because question-program pairs tend to have domain specific words and phrases. To tackle this issue, we first create a list of universal patterns for question-SQL pairs, based on the human labeled pairs from all the different training databases in *Spider*. To do so, we use a script to remove (and later fill in) all the table/column names and value tokens in the labeled question-SQL pairs, and then group together the same SQL query patterns. Consequently, each SQL query pattern has a list of about 5-20 corresponding questions. In our task, we want to generate more complex training examples. Thus, we filter out simple SQL query patterns by measuring the length and the number of SQL keywords used. We obtain about 280 different complex SQL query patterns from the 4,000+ SQL labels in the train set of our corpus. We then select the 50 most frequent complex SQL patterns that contain multiple SQL components and nested subqueries. After this, we manually edit the selected SQL patterns and their corresponding list of questions to make sure that the table/column/value slots in the questions have one-to-one correspondence to the slots in the corresponding SQL query. For each slot, we also add column type or table information. Thus, for example, columns with string type do not appear in the column slot with integer type during data augmentation (i.e., slot refilling) process. In this way, our question-SQL patterns are generated based on existing human labeled examples, which ensures that the generated training examples are natural.

Once we have the one-to-one slot mapping between questions and SQL queries, we apply a script that takes a new database schema with type information and generates new question-SQL examples by filling empty slots. Specifically, for each database in WikiSQL, we first randomly sample 10 question-SQL patterns. We randomly sample columns from the database schema based on its type: for example, if the slot type in the pattern is "number", and then we only sample from columns with "real" type in the current database. We then refill the slots in both the question and SQL query with the selected column names. Similarly, we also refill table/value slots.

By this data augmentation method, we finally obtain about 98,000 question and SQL pairs using about 18,000 WikiSQL databases with one single table. Additionally, we also use the original WikiSQL training dataset in experiments.

5 Experiments

Dataset In our experiments, we use Spider (Yu et al., 2018b), the new large-scale human annotated text-to-SQL dataset with complex SQL queries and cross-domain databases. In addition to their originally annotated data, their training split includes 752 queries and 1659 questions from six existing datasets: Restaurants (Tang and Mooney, 2001; Popescu et al., 2003b), GeoQuery (Zelle and Mooney, 1996), Scholar (Iyer et al., 2017), Academic (Li and Jagadish, 2014), Yelp and IMDB (Yaghmazadeh et al., 2017). In total, this dataset consists of 11,840 questions, 6,445 unique complex SQL queries, and 206 databases with multiple tables. We follow (Yu et al., 2018b), and use 130, 36, 40 databases for train, development, test, respectively (randomly split).

5.1 Evaluation

We use evaluation metrics including SQL Component matching and Exact matching. To compute the component matching scores, we first decompose predicted queries on SQL clauses including `SELECT`, `WHERE`, `GROUP BY`, `ORDER BY`, and `KEYWORDS` separately. After that, we evaluate each predicted clause and the ground truth as bags of several sub-components, and check whether or not these two sets of components match exactly. F1 scores are reported for each of the above 5 clauses. Exact matching score is 1 if the model predicts all clauses correctly for a given example.

To better understand model performance on different queries, (Yu et al., 2018b) divide SQL queries into 4 levels: easy, medium, hard, extra hard. The definition of difficulty is based on the number of SQL components, selections, and conditions. Queries that contain more SQL keywords are considered harder.

5.2 Experimental Settings

Our model is implemented in PyTorch (Paszke et al., 2017). We build each module based on the TypeSQL (Yu et al., 2018a) implementation. We use pre-trained GloVe (Pennington et al., 2014) embeddings for all question, SQL history, and schema tokens. All word embeddings are fixed. For each experiment, the dimension and dropout rate of all hidden layers is set to 120 and 0.3 respectively. We use Adam (Kingma and Ba, 2015) with the default hyperparameters for optimization, with a batch size of 64. The same loss functions in (Xu et al., 2017) are used.

- **Training data:** *Spider* (plus examples from 6 existing datasets) + WikiSQL + data augmentation
- **Model architecture:** history path + table-aware column encoding

We will conduct ablation studies to analyze the effect of each of the proposed techniques.

5.3 Baseline Models

To demonstrate the efficacy of our model in addressing the complex, cross-domain text-to-SQL task, we compare the performance of our model with several previous state-of-the-art models in the text-to-SQL task. As the dataset and task definition used in this work are fundamentally different from prior work using datasets such as GeoQuery, WikiSQL, we adapted these models to our task in the same way as (Yu et al., 2018b). Specifically:

Seq2Seq with Attention or Copying In order to make the models aware of the table schema information, Yu et al. (2018b) pass the models with a vocabulary that contains SQL keywords and column names of the given database.

(Iyer et al., 2017) Iyer et al. (2017) apply an attention based seq2seq model similar to (Luong et al., 2015) to text-to-SQL tasks. Yu et al. (2018b) adapt their model without user interaction to the task.

SQLNet & TypeSQL Xu et al. (2017) introduce SQLNet, which employs a column attention mechanism and a sketch-based method to generates SQL queries as a slot-filling task. Yu et al. (2018a) improves SQLNet by utilizing word types extracted from a knowledge graph or table content

Method	Easy	Medium	Hard	Extra Hard	All
Seq2Seq	17.9%	2.7%	1.3%	0.6%	5.4%
Seq2Seq+Attention (Dong and Lapata, 2016)	17.9%	2.9%	1.8%	1.3%	5.7%
Seq2Seq+Copying	15.1%	3.4%	1.0%	1.3%	5.2%
Iyer et al. (2017)	7.9%	2.1%	1.3%	1.1%	3.1%
SQLNet (Xu et al., 2017)	23.7%	5.9%	2.3%	0.3%	8.3%
TypeSQL (Yu et al., 2018a)	29.6%	6.1%	2.3%	0.3%	9.7%
SyntaxSQLNet	**43.1%**	**19.2%**	**17.8%**	**4.8%**	**22.0%**
-augment	36.9%	16.7%	9.5%	1.6%	17.6%
-wikiSQL -augment	34.1%	11.2%	9.0%	2.2%	14.5%
-table -wikiSQL -augment	30.1%	7.3%	4.5%	1.9%	10.9%
-history -table -wikiSQL -augment	18.8%	4.5%	0.0%	0.0%	6.1%

Table 1: Exact match accuracy on SQL queries with different hardness levels.

Method	`SELECT`	`WHERE`	`GROUP BY`	`ORDER BY`	`KEYWORDS`
Seq2Seq	13.7%	3.7%	3.2%	4.9%	8.9%
Seq2Seq+Attention	14.0%	5.0%	3.2%	6.1%	9.4%
Seq2Seq+Copying	12.0%	2.7%	5.2%	6.9%	6.7%
Iyer et al. (2017)	6.3%	1.9%	3.0%	3.6%	3.5%
SQLNet	24.0%	18.0%	11.8%	47.1%	61.9%
TypeSQL	36.2%	14.7%	6.4%	49.5%	59.4%
SyntaxSQLNet	**48.2%**	**31.6%**	**28.9%**	**58.4%**	**68.9%**
-augment	45.3%	29.2%	22.0%	47.3%	67.5%
-wikiSQL -augment	39.0%	20.6%	17.1%	50.2%	65.8%
-table -wikiSQL -augment	29.0%	15.0%	13.1%	45.5%	67.0%
-history -table -wikiSQL -augment	18.6%	10.5%	4.1%	30.0%	49.1%

Table 2: F1 scores of Component Matching on all SQL queries.

to help the model better understand entities and numbers in natural language inputs. As they are originally designed for WikiSQL, to conduct experiments on Spider, Yu et al. (2018b) extend their `SELECT` and `WHERE` modules to other SQL components.

6 Results and Discussion

Table 1 presents our test results on the *Spider* dataset with database splitting. Our model with full history and data augmentation achieves 22.0% exact matching on all SQL queries, which is a 12.3% absolute increase compared to the previous best model, TypeSQL.

6.1 Comparison with Baselines

Even though our individual modules are similar to SQLNet and TypeSQL, our syntax-aware decoder allows the modules to incorporate the SQL decoding history, which helps to achieve a significant gain in exact matching for queries of all hardness levels. Specifically, even without our data augmentation technique, SyntaxSQLNet outperforms the previous best, TypeSQL, by 5%. This result suggests that the syntax and history information is beneficial for this complex text-to-SQL task.

Moreover, the tree-based decoder enables SyntaxSQLNet to systematically generate nested queries, boosting the performance for Hard/Extra Hard. As Table 1 shows, SyntaxSQLNet achieves particularly high scores 17.8% and 4.8% for Hard and Extra Hard, which contain nested queries. The Seq2Seq models suffer from generating ungrammatical queries, yielding very low exact matching accuracy on Hard and Extra Hard SQL queries. In contrast, our model generates valid SQL queries by enforcing the syntax.

For the detailed component matching results in Table 2, our model consistently outperforms other previous work by significant margins. Specifically, our model improve F1 score for most of the SQL components by more than 10%.

6.2 Ablation Study

In order to understand the techniques that are responsible for the performance of our model, we perform an ablation study where we remove one of the proposed techniques from our model at a time. The exact match scores are shown in the same tables as other baselines.

6.2.1 Data Augmentation

Our model's exact matching performance on all queries drops 4.4% by excluding data augmentation technique. This drop is particularly large for `GROUP BY` and `ORDER BY` components (Table 2), for which the original Spider dataset has a relatively small number of training examples. Thus, our cross-domain data augmentation technique significantly benefits the model performance by extending to a much larger training dataset.

6.2.2 SQL Decoding History

In order to gain more insight into how our SQL decoding history addresses complex SQL, we report our model's performance without SQL path history. As shown in the Table 1, the model's performance drops about 4.8% on exacting matching metric without the SQL history input. More importantly, its performance on hard and extra hard SQL queries decreases to 0%. This indicates that our model is able to predict nested queries thanks to the SQL decoding history.

6.2.3 Column Encoding

To see how our table-aware column encoding affects performance of our model, we also report the model's result without using table information for our column encoding. After excluding the table embedding from column embeddings, the test performance goes down by about 4%. This drop is especially large for Medium/Hard SQL queries and `SELECT` component, where the correct column prediction is a key. This result shows that the table-aware encoding is very important to predict the correct columns in unseen, complex dasebases (with many foreign keys).

7 Conclusion

In this paper, we presented a syntax tree-based model to address complex and cross-domain text-to-SQL task. Utilizing a SQL specific syntax decoder, as well as SQL path history and table-aware column attention encoders, our model outperforms previous work by a significant margin. The ablation study demonstrates that our proposed techniques are able to predict nested, complex SQL queries correctly even for unseen databases.

Abstract

We introduce the task of cross-lingual decompositional semantic parsing: mapping content provided in a source language into a decompositional semantic analysis based on a target language. We present: (1) a form of decompositional semantic analysis designed to allow systems to target varying levels of structural complexity (shallow to deep analysis), (2) an evaluation metric to measure the similarity between system output and reference semantic analysis, (3) an end-to-end model with a novel annotating mechanism that supports intra-sentential coreference, and (4) an evaluation dataset on which our model outperforms strong baselines by at least 1.75 F_1 score.

1 Introduction

We are concerned here with representing the semantics of multiple natural languages in a single semantic analysis. Renewed interest in semantic analysis has led to a surge of proposed new frameworks, e.g., GMB (Basile et al., 2012), AMR (Banarescu et al., 2013), UCCA (Abend and Rappoport, 2013), and UDS (White et al., 2016), as well as further calls to attend to existing efforts, e.g., Episodic Logic (EL) (Schubert and Hwang, 2000; Schubert, 2000; Hwang and Schubert, 1994; Schubert, 2014), or Discourse Representation Theory (Kamp, 1981; Heim, 1988).

Many of these efforts are limited to the analysis of English, but with a number of exceptions, e.g., recent efforts by Bos et al. (2017), ongoing efforts in Minimal Recursion Semantics (MRS) (Copestake et al., 1995), multilingual FrameNet annotation and parsing (Fung and Chen, 2004; Padó and Lapata, 2005), among others. For many languages, semantic analysis cannot be performed directly, owing to a lack of training data. While there is active work in the community focused on rapid construction of resources for low resource languages (Strassel and Tracey, 2016), it remains an expensive and perhaps infeasible solution to assume in-language annotated resources for developing semantic parsing technologies. In contrast, bitext is easier to get: it occurs often without researcher involvement,[1] and even when not available, it may be easier to find bilingual speakers that can translate a text, than it is to find experts that will create in-language semantic annotations. In addition, we are simply further along in being able to automatically understand English than we are other languages, resulting from the bias in investment in English-rooted resources.

Therefore, we propose the task of cross-lingual decompositional semantic parsing, which aims at transducing a sentence in the source language (e.g., Chinese sentence in Fig. 1b) into a decompositional semantic analysis derived based on English, via bitext. The efforts of decompositional semantics (White et al., 2016) focus on approaches to annotating meaning based on fine-grained scalar judgments which reflect the ambiguity of language, and the underspecification of meaning in context. Our contributions include:

(1) A form of decompositional semantic analysis allowing systems to target varying levels of structural complexity.

(2) An evaluation metric to measure the similarity between system and reference semantic analysis.

(3) An encoder-decoder model for cross-lingual decompositional semantic parsing. With a coreference annotating mechanism, the model solves intra-sentential coreference explicitly.

(4) The first evaluation dataset for cross-lingual decompositional semantic parsing.[2]

Experiments demonstrate our model achieves 38.78% F_1, outperforming strong baselines.

(b) Chinese sentence with Leipzig gloss.

Figure 1: Input and output of cross-lingual decompositional semantic parsing.

2 Semantic Analysis

The goal of cross-lingual decompositional semantic parsing is to provide a semantic analysis which can be used for various types of deep and shallow processing on the target language side. Many forms of semantic analysis are potentially suitable for this goal, e.g., AMR (Banarescu et al., 2013), UCCA (Abend and Rappoport, 2013), and Universal Decompositional Semantics (White et al., 2016). Here we choose Universal Decompositional Semantics (UDS), but note that our approach is applicable to other potential graph semantic formalisms.

The reasons for choosing UDS are three-fold: (1) **Compatibility**: UDS relates to Robust Minimal Recursion Semantics (RMRS) (Copestake, 2007), aiming for a maximal degree of semantic compatibility. With UDS, shallow analysis, such as predicate-argument extraction (Zhang et al., 2017a), can be regarded as producing a semantics which is underspecified and reusable with respect to deeper analysis, such as lexical semantics and inference (White et al., 2016). (2) **Robustness and Speed**: There exists a robust framework, PredPatt (White et al., 2016), for automatically creating UDS from raw sentences and their Universal Dependencies. PredPatt has been shown to be fast and accurate enough to process large volumes of text (Zhang et al., 2017c). (3) **Cross-lingual validity**: PredPatt is based purely on non-lexical and linguistically well-founded patterns from Universal Dependencies, which is designed to be cross-linguistically consistent.

There are three forms to represent UDS: flat, graph, or linearized representations. They are created for different purposes, and are inter-convertible. Flat representation relates to RMRS (Copestake, 2007), and we defer its description to Appendix A.

2.1 Graph Representation

The graph representation as shown in Fig. 1a is developed to improve ease of readability, parser evaluation, and integration with lexical semantics. The structure of the graph representation is a tuple $\mathcal{G} = \langle V, E \rangle$: a set of variables V (e.g., p_1 and x), and a set of edges E. There are 3 types of edges: (1) Argument edges describe argument relations between variable pairs. Deeper analysis such as Semantic Proto-Role (SPR) properties (Reisinger et al., 2015) can be attached to argument edges. SPR analysis can be considered as a scalar regression problem (White et al., 2016), where each predicate-argument pair is annotated with scalar values for different SPR properties. (2) Instance

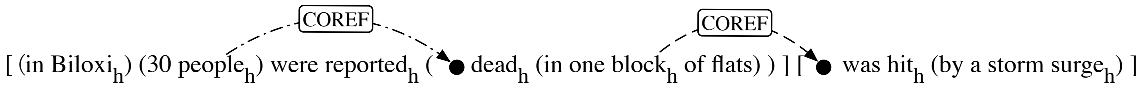

Figure 2: UDS linearized representation. Deeper analysis such as SPR and factuality is not shown.

edges describe instances of variables in the target language. The subscript "h" indicates the syntactic head of an instance. (3) Attribute edges are unary, which describe various attributes of variables, such as event factuality (Saurí and Pustejovsky, 2009) and word senses (Miller, 1995). The graph representation can be viewed as an underspecified version of Dependency Minimal Recursion Semantics (DMRS) (Copestake, 2009) due to the underspecification of scope. Different from DMRS, the graph representation is linked cleanly to Universal Dependency syntax via PredPatt.

2.2 Linearized Representation

The linearized representation aims to facilitate learning of semantic parsers. Recently parsers based on RNN that make use of linearized representation have achieved state-of-the-art performance in constituency parsing (Choe and Charniak, 2016), logical form prediction (Dong and Lapata, 2016; Jia and Liang, 2016), and AMR parsing (Barzdins and Gosko, 2016; Peng et al., 2017). There was also work on predicting linearized semantic representations before RNN based approaches (Wong and Mooney, 2006).

Fig. 2 shows an example of UDS linearized representation. Intra-sentential coreference occurs when an instance refers to an antecedent, where we replace the instance with a special symbol "•" and add a COREF link between "•" and its antecedent. The linearized representation can be viewed as a sequence of tokens with a list of COREF links. Brackets, parentheses, and the special symbol "•" are all considered as tokens in this representation. The COREF links are drawn as a visual convenience, and the actual linearized representation achieves this via co-indexing, and is thus fully linear. We describe the procedure of converting graph representation to linearized representation in Appendix B.

3 Related Work

Our work synthesizes two strands of research, semantic analysis and cross-lingual learning.

The semantic analysis targeted in this work is akin to that of Hobbs (2003), but our eventual goal is to transduce texts from arbitrary human languages into a *"...broad, language-like, inference-enabling [semantic representation] in the spirit of Montague..."* (Schubert, 2015). Unlike efforts such as by Schubert and colleagues that directly target such an analysis, we are pursuing a strategy that incrementally increases the complexity of the target analysis in accordance with our ability to fashion models capable of producing it.[3] Embracing underspecification in the name of tractability is exemplified by MRS (Copestake et al., 2005; Copestake, 2009), the so-called *slacker semantics*, and we draw inspiration from that work. Analyses such as AMR (Banarescu et al., 2013) also make use of underspecification, but usually this is only implicit: certain aspects of meaning are simply not annotated. Unlike AMR, but akin to decisions made in PropBank (Palmer et al., 2005) (which forms the majority of the AMR ontological backbone), we target an analysis with a close correspondence to natural language syntax. Unlike interlingua (Mitamura et al., 1991; Dorr and Habash, 2002) that maps the source language into an intermediate analysis, and then maps it into the target language, we are not concerned with generating text from the semantic analysis. Substantial prior work on semantic analyses exists, including HPSG-based analyses (Copestake et al., 2005), CCG-based analyses (Steedman, 2000; Baldridge and Kruijff, 2002; Bos et al., 2004), and Universal Dependencies based analyses (White et al., 2016; Reddy et al., 2017). See (Schubert, 2015; Abend and Rappoport, 2017) for further discussion.

Cross-lingual learning has previously been applied to various NLP tasks. Yarowsky et al. (2001); Padó and Lapata (2009); Evang and Bos (2016); Faruqui and Kumar (2015) focused on projecting existing annotations on source-language text to the target language. Zeman and Resnik (2008); Ganchev et al. (2009); McDonald et al. (2011); Naseem et al. (2012); Wang and Manning (2014) enabled model transfer by shar-

---

[3] E.g., in Fig. 1a we recognize "*by a storm surge*" as an initial structural unit, with multiple potential analysis, which may be further refined based on the capabilities of a given cross-lingual semantic parser.

ing features or model parameters for different languages. Sudo et al. (2004); Zhang et al. (2017a,b); Mei et al. (2018) worked on cross-lingual information extraction and demonstrated the advantages of end-to-end learning. In this work, we explore end-to-end cross-lingual learning.

4 Evaluation Metric $\boldsymbol{S}$

UDS can be represented in three forms. Evaluating such forms is crucial to the development of parsing algorithms. However, there is no method directly available for evaluation. Related methods come from semantic parsing, whose results are mainly evaluated in three ways: (1) task correctness (Tang and Mooney, 2001), which evaluates on a specific NLP task that uses the parsing results; (2) whole-parse correctness (Zettlemoyer and Collins, 2005), which counts the number of parsing results that are completely correct; and (3) Smatch (Cai and Knight, 2013), which computes the number of exactly matched edges between two semantic structures.

Nevertheless, our task needs an evaluation metric that can be used regardless of specific tasks or domains, and is able to differentiate two UDS graph representations with similar instances, SPR analysis, or attributes. We design an evaluation metric $\boldsymbol{S}$ that computes the similarity between two graph representations.

As described in Section 2.1, the graph representation is a tuple $\mathcal{G} = (V, E)$. For two graphs $\mathcal{G}_1 = (V_1, E_1)$ and $\mathcal{G}_2 = (V_2, E_2)$, we define the score $\boldsymbol{S}$ as the maximum soft edge matching score between $\mathcal{G}_1$ and $\mathcal{G}_2$:

$$\boldsymbol{S}(\mathcal{G}_1, \mathcal{G}_2) = \max_{m \in \mathcal{M}} \Big[\sum_{(e_1^{(i)}, e_2^{(j)}) \in \mathcal{P}} f_T(e_1^{(i)}, e_2^{(j)}) \Big]$$

where m is a mapping from variables in V_1 to variables in V_2. Given a mapping m, $\mathcal{P}$ is a set of edge pairs: for each pair $(e_1^{(i)}, e_2^{(j)})$, variables(s) in $e_1^{(i)}$ are mapped to variables(s) in $e_2^{(j)}$ via m. f_T computes the matching score for a pair of edges belonging to type $T \in \{\text{ARG, INST, ATTR}\}$. The matching score is normalized to $[0, 1]$.

The precision and recall are computed by $\boldsymbol{S}(\mathcal{G}_1, \mathcal{G}_2)/|E_1|$, and $\boldsymbol{S}(\mathcal{G}_1, \mathcal{G}_2)/|E_2|$ respectively.

In this work, $f_{\text{ARG}} = f_{\text{ATTR}} = e^{-\text{MAE}}$, where MAE computes the mean absolute error between two set of scores s_1 and s_2: $\sum_i^n |s_1^{(i)} - s_2^{(i)}|/n$. $f_{\text{INST}} = \text{BLEU}$ (Papineni et al., 2002) which compute the BLEU score of an instance pair.[4]

Finding an optimal variable mapping m that yields the highest $\boldsymbol{S}$ is NP-complete. We instead adopt a strategy used in Smatch (Cai and Knight, 2013) that does a hill-climbing search with smart initialization plus 4 random restarts, and has been shown to give the best trade-off between accuracy and speed. Smatch for evaluating semantic structures can be considered as a special case of $\boldsymbol{S}$, where $f_T = \delta$, the Kronecker delta.

5 Model

We formulate the task of cross-lingual decompositional semantic parsing as a joint problem of sequence-to-sequence learning, coreference resolution and decompositional semantic analysis. The input is a sentence X in the source language, e.g., the Chinese sentence in Fig. 1b. The output is a UDS linearized representation (Y, C, D) based on the target language: Y is a sequence of tokens; C is a set of COREF links; and D is a set of scores for decompositional analysis, such as SPR and factuality.

The goal is to learn a conditional probability distribution $P(Y, C, D|X)$ whose most likely configuration, given the input sentence, outputs the true UDS linearized representation with decompositional analysis. While the standard encoder-decoder framework shows the state-of-the-art performance in sequence-to-sequence learning (Choe and Charniak, 2016; Jia and Liang, 2016; Barzdins and Gosko, 2016), it cannot directly solve intra-sentential conference and decompositional semantic analyses in our task. To achieve this goal, we propose an encoder-decoder architecture incorporated with a *coreference annotating* mechanism[5] and *decompositional analysis*. As illustrated in Fig. 3, **Encoder** transforms the input sequence into hidden states; **Decoder** reads the hidden states, and then at each time step generates a token and creates its COREF link; **Decompositional Analysis**, based on the decoder output, performs SPR analysis for predicate-argument pairs, and factuality analysis for predicates.

---

[4] Future work could consider, e.g., a modified BLEU that considers Levenshtein distance between tokens for a more robust partial-scoring in the face of transliteration errors.

[5] Similar coreference mechanism has been proposed by Ji et al. (2017).

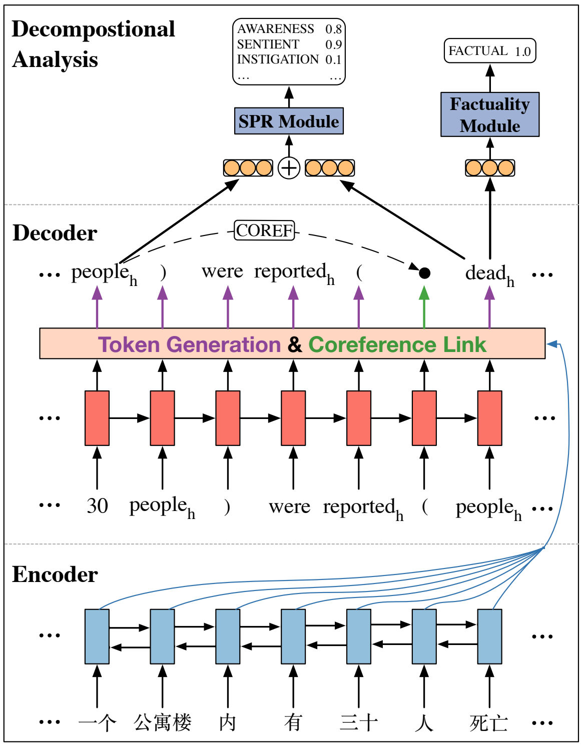

Figure 3: Illustration of the model architecture.

5.1 Encoder

The encoder employs a bidirectional recurrent neural network (Schuster and Paliwal, 1997) with LSTM units (Hochreiter and Schmidhuber, 1997). It encodes the input $X = x_1, \ldots, x_N$[6] into a sequence of hidden states $\boldsymbol{h} = h_1, \ldots, h_N$. Each hidden state h_i is a concatenation of a left-to-right hidden state $\overrightarrow{h_i}$ and a right-to-left hidden state $\overleftarrow{h_i}$,

5.2 Decoder

Given the encoder hidden states, the decoder predicts the linearized representation (as shown in Fig. 2) according to the conditional probability $P(Y, C \mid X)$ which is decomposed as a product of the decoding probabilities at each time step t:

$$P(Y, C \mid X) = \prod_{t=1}^{M} P(y_t, c_t \mid y_{<t}, c_{<t}, X) \quad (1)$$

where y_t is the decoded token at time step t, and c_t is the source of the COREF link for y_t, i.e., the antecedent of y_t. The set of possible antecedents of y_t is $\mathcal{A}(t) = \{\epsilon, y_1, \ldots, y_{t-1}\}$: a dummy antecedent ϵ and all preceding tokens. ϵ represents a scenario, where the token is not a special symbol "•", and it refers to none of the preceding tokens. $y_{<t}$ and $c_{<t}$ are the preceding tokens and their antecedents. We omit $y_{<t}$ and $c_{<t}$ from the notation when the context is unambiguous.

The decoding probability at each time step t is decomposed as

$$P(y_t, c_t) = P(y_t)P(c_t|y_t) \quad (2)$$

where $P(y_t)$ is the token generation probability, and $P(c_t|y_t)$ is the antecedent probability.

Token Generation: The probability distribution of the generated token y_t is defined as

$$P(y_t) = \text{softmax}(\text{FFNN}_\text{g}(s_t, a_t)) \quad (3)$$

where FFNN_g is a two-layer feed-forward neural network over the decoder hidden state s_t and the attention-weighted vector a_t. s_t is computed by

$$s_t = \text{RNN}(y_{t-1}, s_{t-1}), \quad (4)$$

where RNN is a recurrent neural network using LSTM. a_t is computed by the attention mechanism (Bahdanau et al., 2014; Luong et al., 2015),

$$a_t = \sum_{i}^{N} \alpha_{t,i} h_i, \quad (5)$$

$$\alpha_{t,i} = \frac{\exp\left(s_t^\top (W_a h_i + b_a)\right))}{\sum_{j=1}^{N} \exp\left(s_t^\top (W_a h_j + b_a)\right)}, \quad (6)$$

where W_a is a transform matrix and b_a is a bias.

Coref Link: The probability of y_t referring to the preceding token y_k, i.e., $c_t = y_k$, is defined as

$$P(c_t = y_k|y_t) = \frac{\exp\left(\text{SCORE}(y_t, y_k)\right)}{\sum_{y'_k \in \mathcal{A}(t)} \exp\left(\text{SCORE}(y_t, y_{k'})\right)}, \quad (7)$$

$\text{SCORE}(y_t, y_k)$ is a pairwise score for a COREF link from y_k to y_t, defined as:

$$\text{SCORE}(y_t, y_k) = s_\text{c}(y_t) + s_\text{p}(y_k) + s_\text{a}(y_t, y_k) \quad (8)$$

There are three factors in this pairwise score, which is akin to Lee et al. (2017): (1) $s_\text{c}(y_t)$, whether y_t should refer to a preceding instance; (2) $s_\text{p}(y_k)$, whether y_k shoud be a candidate source of such a coreference; and (3) $s_\text{a}(y_t, y_k)$, whether y_k is an antecedent of y_t.

Fig. 4 shows the details of the scoring architecture. At the core of the three factors are vector representations $\gamma(y_t)$ for each token y_t, which is described in detail in the following section. Given

---

[6] For simplicity, we use X (and Y) to represent both tokens as well as their word embeddings.

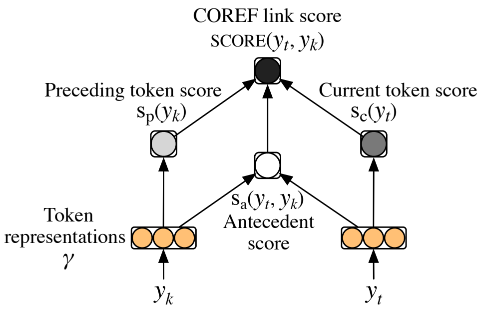

Figure 4: Scoring architecture in the copy mechanism between a preceding token y_k and the currently considered token y_t.

the currently considered token y_t and a preceding token y_k, the scoring functions above are computed via standard feed-foward neural networks:

$$s_{\text{c}}(y_t) = w_{\text{c}} \cdot \text{FFNN}_{\text{c}}(\gamma(y_t)) \quad (9)$$

$$s_{\text{p}}(y_k) = w_{\text{p}} \cdot \text{FFNN}_{\text{p}}(\gamma(y_k)) \quad (10)$$

$$s_{\text{a}}(y_t, y_k) = w_{\text{a}} \cdot \text{FFNN}_{\text{a}}([\gamma(y_t), \gamma(y_k), \gamma(y_t) \circ \gamma(y_k)]) \quad (11)$$

where $\cdot$ denotes dot product, $\circ$ denotes element-wise multiplication, and FFNN denotes a two-layer feed-foward neural network over the input. The input of FFNN_{a} is a concatenation of vector representations $\gamma(y_t)$ and $\gamma(y_k)$, and their explicit element-wise similarity $\gamma(y_t) \circ \gamma(y_k)$.

Token representations: To accurately predict COREF link scores as well as decompositional analysis (which is described in the following section), we consider three types of information in each token representation $\gamma(y_t)$: (1) the token itself y_t, (2) on the decoder side, the preceding context $y_{<t}$, and (3) on the encoder side, the input sequence $X = x_1, \ldots, x_N$.

The lexical information of the token itself y_t is represented by its word embedding e_t. The preceding context $y_{<t}$ is encoded by the decoder RNN in Equation (4). We use the decoder hidden state s_t to represent the preceding context information. The encoder-side context is represented by an attention-weighted weight a_t defined in Equation (6). All the above information is concatenated to produce the final token representation $\gamma(y_t)$:

$$\gamma(y_t) = [e_t, s_t, a_t] \quad (12)$$

5.3 Decompositional Analyses

The decompositional analyses D contains scores for Semantic Proto-Role (SPR) properties D_{SPR}, and scores for event factuality D_{FACT}.

SPR: Given a predicate-argument pair (y_i, y_j), we denote the score for SPR property p as $D^{(y_i,y_j)}_{\text{SPR}_p}$. As shown in Fig. 3, we concatenate the token representations of predicate and argument head tokens $\gamma(y_i)$ and $\gamma(y_j)$ as the input to a SPR module. We employ the state-of-the-art SPR module in Rudinger et al. (2018a), defined as:

$$\hat{D}^{(y_i,y_j)}_{\text{SPR}_p} = W_{\text{SPR}_p}\text{ReLU}(W_{\text{shared}}[\gamma(y_i), \gamma(y_j)]) \quad (13)$$

where $\mathbf{W}_{\text{shared}}$ is the weight matrix shared across all properties. $\mathbf{W}_{\text{SPR}_p}$ is the weight matrix for SPR property p. Then, the log-likelihood of the score of SPR property p is defined as the negative L_2 loss, i.e., $-|\hat{D}^{(y_i,y_j)}_{\text{SPR}_p} - D^{(y_i,y_j)}_{\text{SPR}_p}|^2$.

Factuality: We consider predicting event factuality as a scalar regression problem (White et al., 2016), and denote the factuality score of predicate y_k as $D^{(y_k)}_{\text{FACT}}$. As shown in Fig. 3, we take the token representation of predicate head token $\gamma(y_k)$ as the input to the state-of-the-art factuality module (Rudinger et al., 2018c):

$$\hat{D}^{(y_k)}_{\text{FACT}} = V_2\text{ReLU}\left(V_1\gamma(y_k) + b_1\right) + b_2, \quad (14)$$

where V_1 and V_2 are weight matrices, and b_1 and b_2 are biases. The log-likelihood of factuality score is defined as negative of the Huber loss (Huber, 1964) with $\delta = 1$.

We assume conditional independence among decompositional analysis:

$$P(D|X,Y,C) = \prod_{(y_i,y_j)} \prod_{p} (D^{(y_i,y_j)}_{\text{SPR}_p}|X,Y,C) \prod_{y_k} P(D^{(y_k)}_{\text{FACT}}|X,Y,C) \quad (15)$$

5.4 Learning

Given the input sentence X, the output sequence of tokens Y, and the COREF links C, and the decompositional analysis D, the objective is to minimize the below negative log-likelihood:

$$\begin{aligned}\mathcal{L} &= -\log P(Y, C, D|X) \\ &= -\sum_{t=1}^{M}[\mu_1 \log P(y_t) + \mu_2 \log P(c_t|y_t)] - \\ &\quad \mu_3 \log P(D|X,Y,C)\end{aligned}$$

To increase the convergence rate, we pretrain the model by setting the weights $\mu_1 = 1$ and $\mu_2 = \mu_3 = 0$ to only optimize the token generation accuracy. After the model converges, we set $\mu_2 = \mu_3 = 1$ and lower $\mu_1 = 0.1$.

	S metric			BLEU$_{\text{INST}}$	MAE$_{\text{SPR}}$	MAE$_{\text{FACT}}$

Table 1: Evaluation of results on the **test** set.
(**In-domain test** results are shown in Appendix D.)

6 Experiments

We now describe the evaluation data, baselines, and experimental results. Hyperparameter settings are reported in Appendix C.

6.1 Data

We choose Chinese as the source language and English as the target language. For **test**, we selected 270 sentences from the Universal Dependencies (UD) English Treebank (Silveira et al., 2014) test set, which have human-annotated SPR (White et al., 2016) and factuality (Rudinger et al., 2018c) analyses. We then created linearized representations for these sentences using PredPatt based on their gold UD syntax. Meanwhile, the Chinese translations of these sentences were created by crowdworkers on Amazon Mechanical Turk. The test dataset will be released upon publication. For **training**, we first collected about 1.8M Chinese-English sentence bitexts from the GALE project (Cohen, 2007), then tokenized Chinese sentences with Stanford Word Segmenter (Chang et al., 2008). We created linearized representations for English sentences using PredPatt based on automatic UD syntax generated by SyntaxNet Parser (Andor et al., 2016), and added SPR and factuality annotations using the state-of-the-art models (Rudinger et al., 2018b,c) trained on SPR v2.x and It-happened v2.0 respectively.[7] We hold out 20K training sentences for **validation** and **in-domain test**. Table 2 reports the dataset statistics.

	No. sents	Source
Train	1,879,172	GALE
Validation	10,000	GALE
In-domain Test	10,000	GALE
Test	270	UD Treebank

Table 2: Statistics of the evaluation data.

6.2 Variants

We evaluate our model described in Section 5 and three variants: **(a)** We replace the coreference annotating mechanism by randomly choosing an antecedent from all preceding instances. **(b)** We preprocess the data by replacing the special symbol "●" with the syntactic head of its antecedent. During training and testing, we replace the coreference annotating mechanism with a heuristic that solves coreference by randomly choosing an antecedent among preceding instances which have the same syntactic head. **(c)** We remove the decoder-side information in the token representation $\gamma(y_t)$ defined in Equation (12) and only keep the encoder-side information a_t. We also include a **Pipeline** approach where Chinese sentences are first translated into English by a neural machine translation system (Klein et al., 2017) and are then annotated by a UD parser (Andor et al., 2016). The UDS linearized representation of **Pipeline** are created by PredPatt based the automatic UD parses.

6.3 Results

Table 1 reports the experimental results on the **test** set. Results on the **in-domain test** set are similar and shown in Appendix D. In Table 1, **S metric** (defined in Section 4) measures the similarity between predicted and reference graph representations. Based on the optimal variable mapping provided by the **S metric**, we are able to evaluate our model and the variants in different aspects: **BLEU$_{\text{INST}}$** measures the BLEU score of all matched instance edges; **MAE$_{\text{SPR}}$** measures the

---

[7] Both datasets are available at `http://decomp.net`

mean absolute error of SPR property scores of all matched argument edges; and $\mathbf{MAE}_{\text{FACT}}$ measures the mean absolute error of factuality scores of all matched attribute edges.

Overall, our proposed model outperforms the variants in every aspect. Variants (a) and (b) use simple heuristics to solve coreference, and achieve reasonable results: they both employ sequence-to-sequence models to predict graph representations, which can be considered a replica of state-of-the-art approaches for structured prediction (Choe and Charniak, 2016; Barzdins and Gosko, 2016; Peng et al., 2017). Compared to our model which employs the coreference annotating mechanism, these two variants suffer notable loss in the precision of S metric. As a result, their performance drops on the other metrics. Variant (c) only uses the encoder-side information for token representation, resulting in significant loss in MAE_{SPR} and MAE_{FACT}. In the pipeline approach, each component is trained independently. During test, residual errors from each component are propagated through the pipeline. As expected, it shows a significant performance drop.

	Precision	Recall	F1
Variant (a)	10.38	31.23	15.58
Variant (b)	88.42	50.59	64.36
Variant (c)	84.12	35.99	50.41
Our model	**96.63**	**97.62**	**97.12**

Table 3: Coreference evaluation (MUC) based on forced decoding.

Coreference occurs 589 times in the test set. To evaluate the coreference accuracy of our model, we force the decoder to generate the reference target sequence, and only predict coreference via the copy mechanism, or its variants. In Table 3, we report the precision, recall, and F_1 for the standard MUC using the official coreference scorer of the CoNLL-2011/2012 shared tasks (Pradhan et al., 2014). Since coreference in our setup occurs at the sentence level, our model achieves high performance. Variant (a) randomly choosing antecedents performs poorly, whereas variant (b), which solves coreference only based on syntactic heads, achieves a relatively high score. Variant (c) demonstrates that only using encoder-side information in the coreference annotating mechanism leads a significant performance drop.

	Our Model	Monolingual SOTA

Table 4: Pearson coefficient of each SPR property.

Since our model and the state-of-the-art monolingual SPR model (Rudinger et al., 2018c) use the same test set, we are able to compare the performance of our model against the monolingual model by forcing the decoder and the coreference mechanism to create the reference graph representation and only predicting the SPR property scores. Table 4 shows the Pearson coefficient of each SPR property. While our model only has the access to the sentence in the source language during the encoding stage,[8] the performance is comparable to the state-of-the-art monolingual model.

7 Conclusions

We introduce the task of cross-lingual decompositional semantic parsing, which maps content provided in a source language into decompositional analysis based on a target language. We present: UDS graph/linearized representations as the target semantic interface, the $\boldsymbol{S}$ metric for evaluation, and the Chinese-English decompositional semantic parsing dataset. We propose an end-to-end learning approach with a coreference annotating mechanism which outperforms three strong baselines. We separately evaluate the coreference mechanism and SPR prediction, showing promising results. The representations for cross-lingual decompositional semantics, the evaluation metric, and the evaluation dataset provided in this work

---

[8] The state-of-the-art monolingual SPR model directly encodes the sentence in the target language.

will be beneficial to the increasing interests in semantic analysis and cross-lingual applications.

Abstract

As humans, we often rely on language to learn language. For example, when corrected in a conversation, we may learn from that correction, over time improving our language fluency. Inspired by this observation, we propose a learning algorithm for training semantic parsers from supervision (feedback) expressed in natural language. Our algorithm learns a semantic parser from users' corrections such as *"no, what I really meant was before his job, not after"*, by also simultaneously learning to parse this natural language feedback in order to leverage it as a form of supervision. Unlike supervision with gold-standard logical forms, our method does not require the user to be familiar with the underlying logical formalism, and unlike supervision from denotation, it does not require the user to know the correct answer to their query. This makes our learning algorithm naturally scalable in settings where existing conversational logs are available and can be leveraged as training data. We construct a novel dataset of natural language feedback in a conversational setting, and show that our method is effective at learning a semantic parser from such natural language supervision.

1 Introduction

Semantic parsing is a problem of mapping a natural language utterance into a formal meaning representation, e.g., an executable logical form (Zelle and Mooney, 1996). Because the space of all logical forms is large but constrained by an underlying structure (i.e., all trees), the problem of learning a semantic parser is commonly formulated as an instance of *structured prediction*.

Historically, approaches based on *supervised learning* of structured prediction models have emerged as some of the first and still remain common in the semantic parsing community (Zettlemoyer and Collins, 2005, 2009; Kwiatkowski et al., 2010). A well recognized practical challenge in supervised learning of structured models is that fully annotated structures (e.g., logical forms) that are needed for training are often highly labor-intensive to collect. This problem is further exacerbated in semantic parsing by the fact that these annotations can only be done by people familiar with the underlying logical language, making it challenging to construct large scale datasets by non-experts.

Over the years, this practical observation has spurred many creative solutions to training semantic parsers that are capable of leveraging weaker forms of supervision, amenable to non-experts. One such weaker form of supervision relies on logical form denotations (i.e, the results of a logical form's execution) – rather than the logical form itself, as "supervisory" signal (Clarke et al., 2010; Liang et al., 2013; Berant et al., 2013; Pasupat and Liang, 2015; Liang et al., 2016; Krishnamurthy et al., 2017). In Question Answeing (QA), for example, this means the annotator needs only to know the answer to a question, rather than the full SQL query needed to obtain that answer. Paraphrasing of utterances already annotated with logical forms is another practical approach to scale up annotation without requiring experts with a knowledge of the underlying logical formalism (Berant and Liang, 2014; Wang et al., 2015).

Although these and similar methods do reduce the difficulty of the annotation task, collecting even these weaker forms of supervision (e.g., denotations and paraphrases) still requires a dedicated annotation event, that occurs outside of the normal interactions between the end-user and the semantic parser[1]. Furthermore, expert knowledge may still be required, even if the underlying logi-

User Utterance	Before [September 10th], how many places was [Brad] employed?
System NLG	find employment [Brad] had, prior to [September 10th]
User Feedback	*Yes, but I also want you to count how many placed Brad was employed at.*

Figure 1: Example (i) user's original utterance, (ii) confirmation query generated by inverting the original parse, (iii) user's generated feedback towards the confirmation query (i.e., original parse) .

cal form does not need to be given by the annotator (QA denotations, for example, require the annotator to know the correct answer to the question – an assumption which doesn't hold for end-users who asked the question with the goal of obtaining the answer). In contrast, our goal is to leverage natural language feedback and corrections that may occur naturally as part of the continuous interaction with the non-expert end-user, as training signal to learn a semantic parser.

The core challenge in leveraging natural language feedback as a form of supervision in training semantic parsers, however, is the challenge of correctly parsing that feedback to extract the supervisory signal embedded in it. Parsing the feedback, just like parsing the original utterance, requires its own semantic parser trained to interpret that feedback. Motivated by this observation, our main contribution in this work is a semi-supervised learning algorithm that learns a task parser (e.g., a question parser) from feedback utterances while simultaneously learning a parser to interpret the feedback utterances. Our algorithm relies only on a small number of annotated logical forms, and can continue learning as more feedback is collected from interactions with the user.

Because our model learns from supervision that it simultaneously learns to interpret, we call our approach *learning to learn semantic parsers from natural language supervision*.

2 Problem Formulation

Formally, the setting proposed in this work can be modelled as follows: (i) the user poses a natural language input u_i (e.g., a question) to the system, (ii) the system parses the user's utterance u_i, producing a logical form $\hat{y}_i$, (iii) the system communicates $\hat{y}_i$ to the user in natural language in the form of a confirmation (i.e., *"did you mean . . . "*), (iv) in response to the system's confirmation, the user generates a feedback utterance f_i, which may be a correction of $\hat{y}_i$ expressed in natural language. The observed variables in a single interaction are the task utterance u_i, the predicted task logical form $\hat{y}_i$ and the user's feedback f_i; the true logical form y_i is hidden. See Figure 1 for an illustration.

A key observation that we make from the above formulation is that learning from such interactions can be effectively done in an *offline* (i.e., non-interactive) setting, using only the logs of past interactions with the user. Our aim is to formulate a model that can learn a task semantic parser (i.e., one parsing the original utterance u) from such interaction logs, without access to the true logical forms (or denotations) of the users' requests.

2.1 Modelling conversational logs

Formally, we propose to learn a semantic parser from conversational logs represented as follows:

$$D = \{(u_i, \hat{y}_i, f_i)\}_{i,\dots,N}$$

where u_i is the user's task utterance (e.g., a question), $\hat{y}_i$ is the system's original parse (logical form) of that utterance, f_i is the user's natural language feedback towards that original parse and N is the number of dialog turns in the log. Note that the original parse $\hat{y}_i$ of utterance u_i could come from any semantic parser that was deployed at the time the data was logged – there are no assumptions made on the source of how $\hat{y}_i$ was produced.

Contrast this with the traditional learning settings for semantic parsers, where the user (or annotator) provides the correct logical form y_i or the execution of the correct logical form $[\![y_i]\!]$ (denotation) (Table 1). In our setting, instead of the correct logical form y_i, we only have access to the logical form produced by whatever semantic parser was interacting with the user at the time the data was collected, i.e., $\hat{y}_i$ is *not* necessarily the correct logical form (though it could be). In this work, however, we focus only on corrective feedback (i.e., cases where $\hat{y} \neq y$) as our main objective is to evaluate the ability to interpret rich natural language feedback (which is only given when the original parse is incorrect). Our key hypothesis in this work is that although we do not observe y_i directly, combining $\hat{y}_i$ with the user's feedback f_i should be sufficient to get a better estimate of the correct logical form (closer to y_i), which we can then leverage as a "training example" to improve the task parser (and the feedback parser).

Supervision	**Dataset**
Full logical forms	$\{(u_i, y_i)\}_{i,\ldots,N}$
Denotations	$\{(u_i, [\![y_i]\!])\}_{i,\ldots,N}$
Binary feedback	$\{(u_i, [\![\hat{y}_i = y_i]\!])\}_{i,\ldots,N}$
NL feedback (this work)	$\{(u_i, \hat{y}_i, f_i)\}_{i,\ldots,N}$

Table 1: Different types of supervision used in literature for training semantic parsers, and the corresponding data needed for each type of supervision. Notation used in the table: u corresponds to user utterance (language), y corresponds to a gold-standard logical form parse of u, $\hat{y}$ corresponds to a predicted logical form, $[\![\cdot]\!]$ is the result of executing an expression inside the brackets and f is the user's feedback expressed in natural language in the context of an utterance and a predicted logical form.

3 Natural Language Supervision

3.1 Learning problem formulation

In this section, we propose a learning algorithm for training a semantic parser from natural language feedback. We will use the terms *task parser* and *feedback parser* to refer to the two distinct parsers used for parsing the user's original task utterance (e.g., question) and parsing the user's follow-up feedback utterance respectively. Our learning algorithm does not assume any specific underlying model for the two parsers aside from the requirement that each parser specifies a probability distribution over logical forms given the utterance (for the task parser) and the utterance plus feedback (for the feedback parser):

Task Parser: $P(y \mid u; \theta_t)$
Feedback Parser: $P(y \mid u, f, \hat{y}; \theta_f)$

where θ_t and θ_f parametrize the task and feedback parsers respectively. Note that the key distinction between the task and feedback parser models is that in addition to the user's original task utterance u, the feedback parser also has access to the user's feedback utterance f, and the original parser's prediction $\hat{y}$. We now introduce a joint model that combines task and feedback parsers in a way that encourages the two models to agree:

$$P(y \mid u, f, \hat{y}; \theta_t, \theta_f) = \frac{1}{Z} \underbrace{P(y \mid u; \theta_t)}_{\text{task parser}} \underbrace{P(y \mid u, f, \hat{y}; \theta_f)}_{\text{feedback parser}}$$

At training time, our objective is to maximize the above joint likelihood by optimizing the parser parameters θ_t and θ_f of the task and feedback parsers respectively. The intuition behind optimizing the joint objective is that it encourages the "weaker" model that does not have access to the feedback utterance to agree with the "stronger" model that does (i.e., using the feedback parser's prediction as a noisy "label" to bootstrap the task parser), while conversely encouraging a more "complex" model to agree with a "simpler" model (i.e., using the simpler task parser model as a "regularizer" for the more complex feedback parser; note that the feedback parser generally has higher model complexity compared to the task parser because it incorporates additional parameters to account for processing the feedback input).[2] Note the feedback parser output is not simply the meaning of the feedback utterance in isolation, but instead the revised semantic interpretation of the original utterance, guided by the feedback utterance. In this sense, the task faced by the feedback parser is to both determine the meaning of the feedback, and to apply that feedback to repair the original interpretation of u_i. Note that this model is closely related to co-training (Blum and Mitchell, 1998) (and more generally multi-view learning (Xu et al., 2013)) and is also a special case of a product-of-experts (PoE) model (Hinton, 1999).

3.2 Learning

The problem of maximizing the joint-likelihood $P(y \mid u, f, \hat{y}; \theta_t, \theta_f)$ can be approached as a standard problem of maximum likelihood estimation in the presence of latent variables (i.e., unobserved logical form y), suggesting the application of the Expectation Maximization (EM) algorithm for learning parameters θ_t and θ_f. The direct application of EM in our setting, however, is faced with a complication in the E-step. Because the hidden variables (logical forms y) are structured, computing the posterior over the space of all logical forms and taking the expectation of the log-likelihood with respect to that posterior is generally intractable (unless we assume certain factorized forms for the logical form likelihood).

Instead, we propose to approximate the E-step by replacing the expectation of the log joint-likelihood with its point estimate, using the maximum a posteriori (MAP) estimate of the posterior over logical forms y to obtain that estimate (this is sometimes referred to as "hard-EM"). Obtaining the MAP estimate of the posterior over log-

---

[2] Note that in practice, to avoid locally optimal degenerate solutions (e.g., where the feedback parser learns to trivially agree with the task parser by learning to ignore the feedback), some amount of labeled logical forms would be required to pre-train both models.

ical forms may itself be a difficult optimization problem, and the specific algorithm for obtaining it would depend on the internal models of the task and the feedback parser.

As an alternative, we propose a simple, MCMC based algorithm for approximating the MAP estimate of the posterior over logical forms, that does not require access to the internals of the parser models, i.e., allowing us to conveniently treat both parsers as "black boxes". The only assumption that we make is that it's easy to sample logical forms from the individual parsers (though not necessarily from the joint model), as well as to compute the likelihoods of those sampled logical forms under at least one of the models.

We use Metropolis Hastings to sample from the posterior over logical forms, using one of the parser models as the proposal distribution. Specifically, if we choose the feedback parser as the proposal distribution, and initialize the Markov Chain with a logical form sampled from the task parser, it can be shown that the acceptance probability r for the first sample conveniently simplifies to the following expression:

$$r = \min\left(1, \frac{P(\hat{y}_f \mid u, \theta_t)}{P(\hat{y}_t \mid u, \theta_t)}\right) \tag{1}$$

where $\hat{y}_t$ and $\hat{y}_f$ are logical forms sampled from the task and feedback parsers respectively. Intuitively the above expression compares the likelihood of the logical form proposed by the task parser to the likelihood of the logical form proposed by the feedback parser, but with *both* likelihoods computed under the same *task* parser model (making the comparison fair). The proposed parse is then accepted with a probability proportional to that ratio. See Algorithm 2 for details.

Finally, given this MAP estimate of y, we can perform optimization over the parser parameters θ_t and θ_f using a single step with stochastic gradient descent before re-estimating the latent logical form y. We also approximate the gradients of each parser model by ignoring the gradient terms associated with the log of the normalizer Z. [3]

3.3 Task Parser Model

Our task parser model is implemented based on existing attention-based encoder-decoder models (Bahdanau et al., 2014; Luong et al., 2015). The encoder takes in an utterance (tokenized) u and computes a context-sensitive embedding h_i for each token u_i using a bidirectional Long Short-Term Memory (LSTM) network (Hochreiter and Schmidhuber, 1997), where h_i is computed as the concatenation of the hidden states at position i output by the forward LSTM and the backward LSTM. The decoder generates the output logical form y one token at a time using another LSTM. At each time step j, it generates y_j based on the current LSTM hidden state s_j, a summary of the input context c_j, and attention scores a_{ji}, which are used for attention-based copying as in (Jia and Liang, 2016). Specifically,

$$p(y_j = w, w \in V_{out} | u, y_{1:j-1}) \propto \exp\left(W_o[s_j; c_j]\right)$$

Algorithm 1: Semantic Parser Training from Natural Language Supervision

Algorithm 2: Metropolis Hastings-based MAP estimation of latent semantic parse

```
Input     : $u, \hat{y}, f, \theta_t, \theta_f$
Output    : latent parse $\hat{y}^f$
Parameter: Number of sampling iterations $N$
Function MH-MAP $(u, \hat{y}, f, \theta_t, \theta_f)$ :
    $samples \leftarrow [\,]$
    // sample parse from task parser
    Sample $\hat{y}_t \sim P(y \mid u, \theta_t)$
    $\hat{y}_{curr} \leftarrow \hat{y}_t$
    for $i = 1$ to $N$ do
        // sample parse from feedback parser
        Sample $\hat{y}_f \sim P(y \mid u, f, \hat{y}, \theta_f)$
        $r \leftarrow \min\left(1, \frac{P(\hat{y}_f | u, \theta_t)}{P(\hat{y}_{curr} | u, \theta_t)}\right)$
        Sample $accept \sim$ Bernoulli$(r)$
        if $accept$ then
            $p_t \leftarrow P(\hat{y}_f \mid u, \theta_t)$
            $p_f \leftarrow P(\hat{y}_f \mid u, f, \hat{y}, \theta_f)$
            $samples[\hat{y}_f] \leftarrow p_t \cdot p_f$
            $\hat{y}_{curr} \leftarrow \hat{y}_f$
        end
    end
    $\hat{y}^f \leftarrow$ argmax $samples$
    return $\hat{y}^f$
```

---

[3] We have experimented with a sampling based approximation of the true gradients with contrastive divergence (Hinton, 2002), however, found that our approximation works sufficiently well empirically. See Algorithm 1 for more details of the complete algorithm.

$$p(y_j = u_i | u, y_{1:j-1}) \propto \exp(a_{ji})$$

where $y_j = w$ denotes that y_j is chosen from the output vocabulary V_{out}; $y_j = u_i$ denotes that y_j is a copy of u_i; $a_{ji} = s_j^T W_a h_i$ is an attention score on the input word u_i; $c_j = \sum_i \alpha_i h_i, \alpha_i \propto \exp(a_{ji})$ is a context vector that summarizes the encoder states; and W_o and W_a are matrix parameters to be learned. After generating y_j, the decoder LSTM updates its hidden state s_{j+1} by taking as input the concatenation of the embedding vector for y_j and the context vector c_j.

An important problem in semantic parsing for conversation is resolving references of people and things mentioned in the dialog context. Instead of treating coreference resolution as a separate problem, we propose a simple way to resolve it as a part of semantic parsing. For each input utterance, we record a list of previously-occurring entity mentions $m = \{m_1, ..., m_L\}$. We consider entity mentions of four types: persons, organizations, times, and topics. The encoder now takes in an utterance u concatenated with m[4], and the decoder can generate a referenced mention through copying.

The top parts of Figure 7 and Figure 8 visualize the attention mechanism of the task parser, where the decoder attends to both the utterance and the conversational context during decoding. Note that the conversational context is only useful when the utterance contains reference mentions.

3.4 Feedback Parser Model

Our feedback parser model is an extension of the encoder-decoder model in the previous section. The encoder consists of two bidirectional LSTMs: one encodes the input utterance u along with the history of entity mentions m and the other encodes the user feedback f. At each time step j during decoding, the decoder computes attention scores over each word u_i in utterance u as well as each feedback word f_k based on the decoder hidden state s_j, the context embedding b_k output by the feedback encoder, and a learnable weight matrix W_e: $e_{jk} = s_j^T W_e b_k$. The input context vector c_j in the previous section is updated by adding a context vector that attends to both the utterance and the feedback:

$$c'_j = \sum_i \alpha_i h_i + \sum_k \beta_k b_k$$

where $\alpha_i \propto \exp(a_{ji})$ and $\beta_k \propto \exp(e_{jk})$. Accordingly, the decoder is allowed to copy words from the feedback:

$$p(y_j = f_k | u, f, y_{1:j-1}) \propto \exp(e_{jk})$$

The bottom parts of Figure 7 and Figure 8 visualize the attention mechanism of the feedback parser, where the decoder attends to the utterance, the conversational context, and the feedback during decoding.

Note that our feedback model does not explicitly incorporate the original logical form $\hat{y}$ that the user was generating their feedback towards. We experimented with a number of ways to incorporate $\hat{y}$ in the feedback parser model, but found it most effective to instead use it during MAP inference for the latent parse y. In sampling a logical form in Algorithm 2, we simply reject the sample if the sampled logical form matches $\hat{y}$.

4 Dataset

In this work we focus on the problem of semantic parsing in a conversational setting and construct a new dataset for this task. Note that a parser is required to resolve references to the conversational context during parsing, which in turn may further amplify ambiguity and propagate errors to the final logical form. Conveniently, the same conversational setting also offers a natural channel for correcting such errors via natural language feedback users can express as part of the conversation.

4.1 Dataset construction

We choose *conversational search* in the domain of email and biographical research as a setting for our dataset. Large enterprises produce large amounts of text during daily operations, e.g., emails, reports, and meeting memos. There is an increasing need for systems that allow users to quickly find information over text through search. Unlike regular tasks like booking airline tickets, search tasks often involve many facets, some of which may or may not be known to the users when the search begins. For example, knowing where a person works may triggers a followup question about whether the person communicates with someone internally about certain topic. Such search tasks will often be handled most naturally through dialog.

Figure 1 shows example dialog turns containing the user's utterance (question) u, system's confirmation of the original parse $\hat{y}$, and the user's feedback f. To simplify and scale data collection, we

---

[4] The mentions are ordered based on their types and each mention is wrapped by special boundary symbols [and].

decouple the dialog turns and collect feedback for each dialog turn in isolation. We do that by showing a worker on Mechanial Turk the original utterance u, the system's natural language confirmation generated by inverting the original logical form $\hat{y}$, and the dialog context summarized in a table. See Figure 2 for a screenshot of the Mechanical Turk interface. The dialog context is summarized by the entities (of types person, organization, time and topic) that were mentioned earlier in the conversation and could be referenced in the original question u shown on the screen[5]. The worker is then asked to type their feedback given $(u, \hat{y})$ and the dialog context displayed on the screen. Turkers are instructed to write a natural language feedback utterance that they might otherwise say in a real conversation when attempting to correct another person's incorrect understanding of their question.

We recognize that our data collection process results in only an approximation of a true multi-turn conversation, however we find that this approach to data collection offers a convenient trade-off for collecting a large number of controlled and diverse context-grounded interactions. Qualitatively we find that turkers are generally able to imagine themselves in the hypothetical ongoing dialog, and are able to generate realistic contextual feedback utterances using only the context summary table provided to them.

The initial dataset of questions paired with original logical form parses $\{u_i, \hat{y}_i\}_{1,\ldots,N}$ that we use to solicit feedback from turkers, is prepared offline. In this separate offline task we collect a dataset of 3556 natural language questions, annotated with gold standard logical forms, in the same domain of email and biographical research. We parse each utterance in this dataset with a floating grammar-based semantic parser trained using a structured perceptron algorithm (implemented in SEMPRE (Berant et al., 2013)) on a subset of the questions. We then construct the dataset for feedback collection by sampling the logical form $\hat{y}$ from the first three candidate parses in the beam produced by the grammar-based parser. We use this grammar-based parser intentionally as a very different model from the one that we would ultimately train (LSTM-based parser) on the conversational logs produced by the original parser.

We retain 1285 out of the 3556 annotated questions to form a test set. The rest 2271 questions we pair with between one and three predicted parses $\hat{y}$ sampled from the beam produced by the grammar-based parser, and present each pair of original utterance and predicted logical form $(u_i, \hat{y}_i)$ to a turker who then generates a feedback utterance f_i. In total, we collect 4321 question/original parse/feedback triples $(u_i, \hat{y}_i, f_i)$ (averaging approximately 1.9 feedback utterances per question).

5 Experiments

The key hypothesis that we aim to evaluate in our experiments is whether natural language feedback is an effective form of supervision for training a semantic parser. To achieve this goal, we control and measure the effect that the number of feedback utterances used during training has on the resulting performance of the task semantic parser on a held-out test set. Across all our experiments we also use a small seed training set (300 questions) that contains gold-standard logical forms to pre-train the task and feedback parsers. The number of "unlabeled" questions[6] (i.e., questions not labeled with gold standard logical forms but that have natural language feedback) ranges from 300, 500, 1000 to 1700 representing different experimental settings. For each experimental setting, we rerun the experiment 10 times, re-sampling the questions in both the training and unlabeled sets, and report the averaged results. The test-set remains fixed across all experiments and contains 1285 questions labeled with gold-standard logical forms. The implementation details for the task parser and the feedback parser are included in the appendix.

---

[5] zero or more of the context entities may actually be referenced in the original utterance

[6] Note that from hereon we will refer to the portion of the data that contains natural language feedback as the only form of supervision as "unlabeled data", to emphasize that it is not labeled with gold standard logical forms (in contrast to the seed training set).

5.1 Models and evaluation metrics

In our evaluations, we compare the following four models:

- **MH (full model)** Joint model described in Section 3 and in Algorithm 1 (using Metropolis Hastings-based MAP inference described in Algorithm 2).

- **MH (no feedback)** Same as the full model, except we ignore the feedback f and the original logical form $\hat{y}$ information in the feedback model. Effectively, this reduces the model of the feedback parser to that of the task parser. Because during training, both models would be initialized differently, we may still expect the resulting model averaging effects to aid learning.

- **MH (no feedback + reject $\hat{y}$)** Same as the above baseline without feedback, but we incorporate the knowledge of the original logical form $\hat{y}$ during training. We incorporate $\hat{y}$ using the same method as described in Section **??**.

- **Self-training** Latent logical form inference is performed using only the task parser (using beam search). Feedback utterance f and original logical form $\hat{y}$ are ignored. Task parser parameters θ_t are updated in the same way as in Algorithm 1.

Note that all models are exposed to the same training seed set, and differ only in the way they take advantage of the unlabeled data. We perform two types of evaluations of each model:

- **Generalization performance** we use the learned task parser to make predictions on held-out data. This type of evaluation tests the ability of the parser trained with natural language feedback to generalize to unseen utterances.

- **Unlabeled data performance** we use the learned task parser to make predictions on the unlabeled data that was used in training it. Note that for each experimental condition, we perform this evaluation only on the portion of the unlabeled data that was used during training. This ensures that this evaluation tests the model's ability to "recover" correct logical forms from the questions that have natural language feedback associated with them.

6 Results

6.1 Generalization performance

Figure 3a shows test accuracy as a function of the number of unlabeled questions (i.e., questions containing only feedback supervision without gold standard logical forms) used during training, across all four models. As expected, using more unlabeled data generally improves generalization performance. The **self-training** baseline is the only exception, where performance starts to deteriorate as the ratio of unlabeled to labeled questions increases beyond a certain point. This behavior is not necessarily surprising – when the unlabeled examples significantly outnumber the labeled examples, the model may more easily veer away to local optima without being strongly regularized by the loss on the small number of labeled examples.

Interestingly, the **MH (no feedback)** baseline is very similar to **self-training**, but has a significant performance advantage that does not deteriorate with more unlabeled examples. Recall that the **MH (no feedback)** model modifies the full model described in Algorithm 1 by ignoring the feedback f and the original logical form $\hat{y}$ in the feedback parser model $P(y \mid u, \hat{y}, f; \theta_f)$. This has the effect of reducing the model of the feedback parser into the model of the task parser $P(y \mid u; \theta_t)$. The training on unlabeled data proceeds otherwise in the same way as described in Algorithm 1. As a result, the principle behind the **MH (no feedback)** model is the same as that behind **self-training**, i.e., a single model learns from its own predictions. However, different initializations of the two copies of the task parser, and the combined model averaging appears to improve the robustness of the model sufficiently to keep it from diverging as the amount of unlabeled data is increased.

The **MH (no feedback + reject $\hat{y}$)** baseline also does not observe the feedback utterance f, but incorporates the knowledge of the original parse $\hat{y}$. As described in Section **??**, this knowledge is incorporated during MAP inference of the latent parse, by rejecting any logical form samples that match $\hat{y}$. As expected, incorporating the knowledge of $\hat{y}$ improves the performance of this baseline over the one that does not.

Finally, the full model that incorporates both, the feedback utterance f and the original logical form $\hat{y}$ outperforms the baselines that incorporate only some of that information. The performance gain over these baselines grows as more questions with natural language feedback supervision are made available during training. Note that both this and the **MH (no feedback + reject $\hat{y}$)** model incorporate the knowledge of the original logical form $\hat{y}$, however, the performance gain from incorporating the knowledge of $\hat{y}$ without the feedback is relatively small, indicating that the gains from the model that observes feedback is primarily from its ability to interpret it.

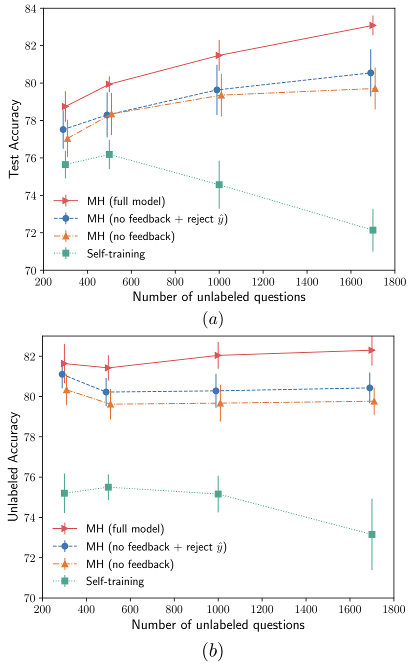
6.2 Performance on unlabeled data

Figure 3*b* shows accuracy on the unlabeled data, as a function of the number of unlabeled questions used during training, across all four models. The questions used in evaluating the model's accuracy on unlabeled data are the same unlabeled questions used during training in each experimental condition. The general trend and the relationship between baselines is consistent with the generalization performance on held-out data in Figure 3*a*. One of the main observations is that accuracy on unlabeled training examples remains relatively flat, but consistently high ($> 80\%$), across all models regardless of the amount of unlabeled questions used in training (within the range that we experimented with). This suggests that while the models are able to accurately recover the underlying logical forms of the unlabeled questions regardless of the amount of unlabeled data (within our experimental range), the resulting generalization performance of the learned models is significantly affected by the amount of unlabeled data (more is better).

6.3 Effect of feedback complexity on performance

Figure 4 reports parsing accuracy on unlabeled questions as a function of the number of corrections expressed in the feedback utterance paired with that question. Our main observation is that the performance of the full model (i.e., the joint model that uses natural language feedback) deteriorates for questions that are paired with more complex feedback (i.e., feedback containing more corrections). Perhaps surprisingly, however, is that all models (including those that do not incorporate feedback) deteriorate in performance for questions paired with more complex feedback. This is explained by the fact that more complex feedback is generally provided for more difficult-to-parse questions. In Figure 4, we overlay the parsing performance with the statistics on the average length of the target logical form (number of predicates).

A more important take-away from the results in Figure 4, is that the model that takes advantage of natural language feedback gains an even greater advantage over models that do not use feedback when parsing more difficult questions. This means that the model is able to take advantage of more complex feedback (i.e., with more corrections) even for more difficult to parse questions.



(a)

(b)

Figure 3: *(a)* Parsing accuracy on held-out questions as a function of the number of unlabeled questions used during training. *(b)* Parsing accuracy on unlabeled questions as a function of the number of unlabeled questions used during training. In both panels, all parsers were initialized using 300 labeled examples consisting of questions and their corresponding logical form.

7 Related Work

Early semantic parsing systems map natural language to logical forms using inductive logical programming (Zelle and Mooney, 1996). Modern systems apply statistical models to learn from pairs of sentences and logical forms (Zettlemoyer and Collins, 2005, 2009; Kwiatkowski et al., 2010). As hand-labeled logical forms are very costly to obtain, different forms of weak supervision have been explored. Example works include learning from pairs of sentences and answers by querying a database (Clarke et al., 2010;

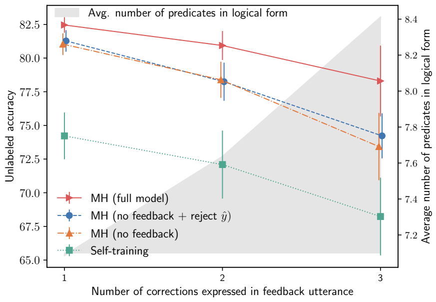


Figure 4: Parsing accuracy on unlabeled questions, partitioned by feedback complexity (i.e., number of corrections expressed in a single feedback utterance).

Liang et al., 2013; Berant et al., 2013; Pasupat and Liang, 2015; Liang et al., 2016; Krishnamurthy et al., 2017); learning from indirect supervision from a large-scale knowledge base (Reddy et al., 2014; Krishnamurthy and Mitchell, 2012); learning from conversations of systems asking for and confirming information (Artzi and Zettlemoyer, 2011; Thomason et al., 2015; Padmakumar et al., 2017); and learning from interactions with a simulated world environment (Branavan et al., 2009; Artzi and Zettlemoyer, 2013; Goldwasser and Roth, 2014; Misra et al., 2015). The supervision used in these methods is mostly in the form of binary feedback, partial logical forms (e.g., slots) or execution results. In this paper, we explore a new form of supervision – natural language feedback. We demonstrate that such feedback not only provides rich and expressive supervisory signals for learning but also can be easily collected via crowd-sourcing. Recent work (Iyer et al., 2017) trains an online language-to-SQL parser from user feedback. Unlike our work, their collected feedback is structured and is used for acquiring more labeled data during training. Our model jointly learns from questions and feedback and can be trained with limited labeled data.

There has been a growing interest on machine learning from natural language instructions. Much work has been done in the setting where an autonomous agent learns to complete a task in an environment, for example, learning to play games by utilizing text manuals (Branavan et al., 2012; Eisenstein et al., 2009; Narasimhan et al., 2015) and guiding policy learning using high-level human advice (Kuhlmann et al., 2004; Squire et al., 2015; Harrison et al., 2017). Recently, natural language explanations have been used to augment labeled examples for concept learning (Srivastava et al., 2017) and to help induce programs that solve algebraic word problems (Ling et al., 2017). Our work is similar in that natural language is used as additional supervision during learning, however, our natural language annotations consist of user feedback on system predictions instead of explanations of the training data.

8 Conclusion and Future Work

In this work, we proposed a novel task of learning a semantic parser directly from end-users' open-ended natural language feedback during a conversation. The key advantage of being able to learn from natural language feedback is that it opens the door to learning continuously through natural interactions with the user, but it also presents a challenge of how to interpret such feedback. In this work we introduced an effective approach that simultaneously learns two parsers: one parser that interprets natural language questions and a second parser that also interprets natural language feedback regarding errors made by the first parser.

Our work is, however, limited to interpreting feedback contained in a single utterance. A natural generalization of learning from natural language feedback is to view it as part of an integrated dialog system capable of both interpreting feedback and asking appropriate questions to solicit this feedback (e.g., connecting to the work by (Padmakumar et al., 2017)). We hope that the problem we introduce in this work, together with the dataset that we release, inspires the community to develop models that can learn language (e.g., semantic parsers) through flexible natural language conversation with end users.

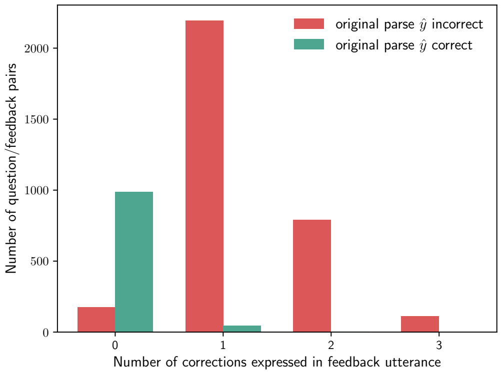

Figure 5: A histogram of the number of corrections expressed in a natural language feedback utterance in our data (0 corrections means that the user affirmed the original parse as correct). We partition the feedback utterances according to whether the original parse $\hat{y}$ that the feedback was provided towards is known to be correct (i.e., matches the gold standard logical form parse).

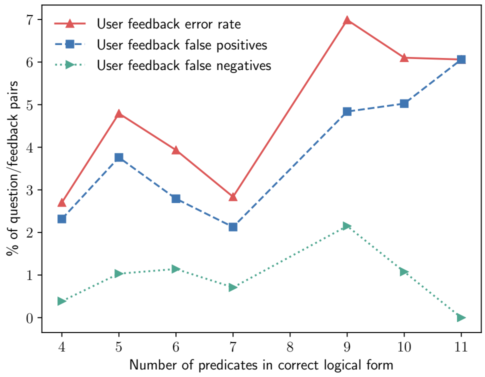

Figure 6: Analysis of noise in feedback utterances contained in our dataset. *Feedback false positives* refers to feedback that incorrectly identifies the wrong original parse $\hat{y}$ as correct. *Feedback false negatives* refers to feedback that incorrectly identifies a correct original parse $\hat{y}$ as wrong. Users are more likely to generate false positives (i.e., miss the error) in their feedback for parses of more complex utterances (as measured by the number of predicates in the gold-standard logical form).

A Analysis of natural language feedback

The dataset we collect creates a unique opportunity to study the nature and the limitations of the corrective feedback that users generate in response to an incorrect parse. One of our hypotheses stated in Section 1 is that natural language affords users to express richer feedback than for example possible with binary (correct/incorrect) mechanism, by allowing users to explicitly refer to and fix what they see as incorrect with the original prediction. In this section we analyze the feedback utterances in our dataset to gain deeper insight into the types of feedback users generate, and the possible limitations of natural language as a source of supervision for semantic parsers.

Figure 5 breaks down the collected feedback by the number of corrections expressed in the feedback utterance. The number of corrections ranges from 0 (no corrections, i.e., worker considers the original parse $\hat{y}$ to be the correct parse of u) to more than 3 corrections.[7] The number of corrections is self-annotated by the workers who write the feedback – we instruct workers to count a correction constrained to a single predicate or a single entity as a single correction, and tally all such corrections in their feedback utterance after they have written it[8]. Because we also know the ground truth of whether the original parse $\hat{y}$ (i.e., parse that the user provided feedback towards) was correct (i.e., $\hat{y}$ matches gold standard parse y), we can partition the number of corrections by whether the original parse $\hat{y}$ was correct (green bars in Figure 5) or incorrect (red bars), allowing us to evaluate the accuracy of some of the feedback.

From Figure 5, we observe that users provide feedback that ranges in the number of corrections, with the majority of feedback utterances making one correction to the original logical form $\hat{y}$ (only 4 feedback utterances expressed more than 3 corrections). Although we do not have gold-standard annotation for the true number of errors in the original logical form $\hat{y}$, we can nevertheless obtain some estimate of the noise in natural language feedback by analyzing cases where we know that the original logical form $\hat{y}$ was correct, yet the user generated feedback with at least one correction. We will refer to such feedback instances as *feedback false negatives*. Similarly, cases where the original logical form $\hat{y}$ is incorrect, yet the user provided no corrections in their feedback, we refer to as *feedback false positives*. The number of feedback false negatives and false positives can be

---

[7] Note that in cases where the user indicates that they made 0 corrections, the feedback utterance that they write is often a variation of a confirmation such as *"that's right"* or *"that's correct"*

[8] we give these instructions to workers in an easy to understand explanation without invoking technical jargon

obtained directly from Figure 5. Generally, we observe that users are more likely to provide more false negatives ($\approx 4\%$ of all feedback) than false positives ($\approx 1\%$) in the feedback they generate.

It is also instructive to consider what factors may contribute to the observed noise in user generated natural language feedback. Our hypothesis is that more complex queries (i.e., longer utterances and longer logical forms) may result in a greater cognitive load to identify and correct the error(s) in the original parse $\hat{y}$. In Figure 6 we investigate this hypothesis by decomposing the percentage of feedback false positives and false negatives as a function of the number of predicates in the gold standard logical form (i.e., one that the user is trying to recover by making corrections in the original logical form $\hat{y}$). Our main observation is that users tend to generate more false positives (i.e., incorrectly identify an originally incorrect logical form $\hat{y}$ as correct) when the target logical form is longer (i.e., the query utterance u is more complex). The number of false negatives (i.e., incorrectly identifying a correct logical form as incorrect) is relatively unaffected by the complexity of the query (i.e., number of predicates in the target logical form). One conclusion that we can draw from this analysis is that we can expect user-generated feedback to miss errors in more complex queries, and models that learn from users' natural language feedback need to have a degree of robustness to such noise.

B Implementation Details

We tokenize user utterances (questions) and feedback using the Stanford CoreNLP package. In all experiments, we use 300-dimensional word embeddings, initialized with word vectors trained using the Paraphrase Database PPDB (Wieting et al., 2015), and we use 128 hidden units for LSTMs. All parameters are initialized uniformly at random. We train all the models using Adam with initial learning rate 10^{-4} and apply L2 gradient norm clipping with a threshold of 10. In all the experiments, we pre-train the task parser and the feedback parser for 20 epochs, and then switch to semi-supervised training for 10 epochs. Pre-training takes roughly 30 minutes and the semi-supervised training process takes up to 7 hours on a Titan X GPU.

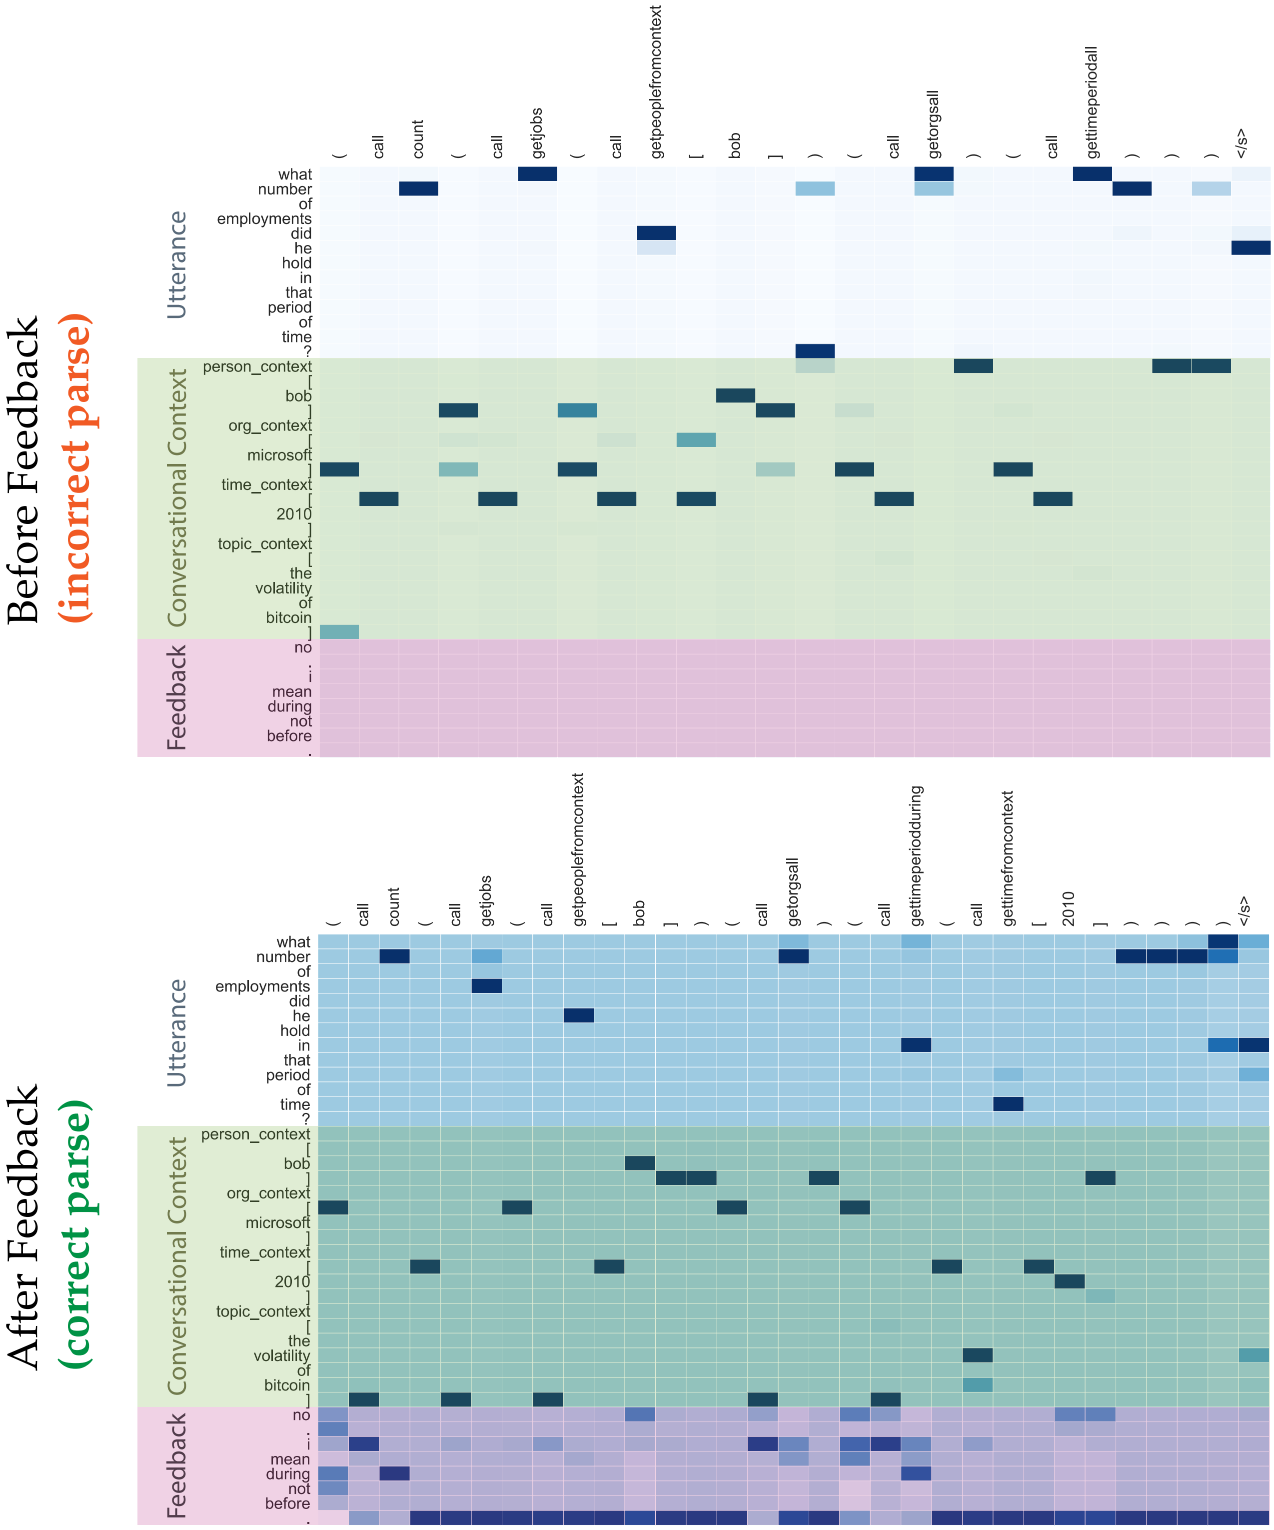

Figure 7: Visualization of the attention mechanism in the task parser (top) and the feedback parser (bottom) for parsing the same utterance. We partition the input to the parser into three groups: the original utterance u being parsed (blue), the conversational context (green) and the feedback utterance f (red). This example was parsed incorrectly before incorporating feedback, but parsed correctly after its incorporation.

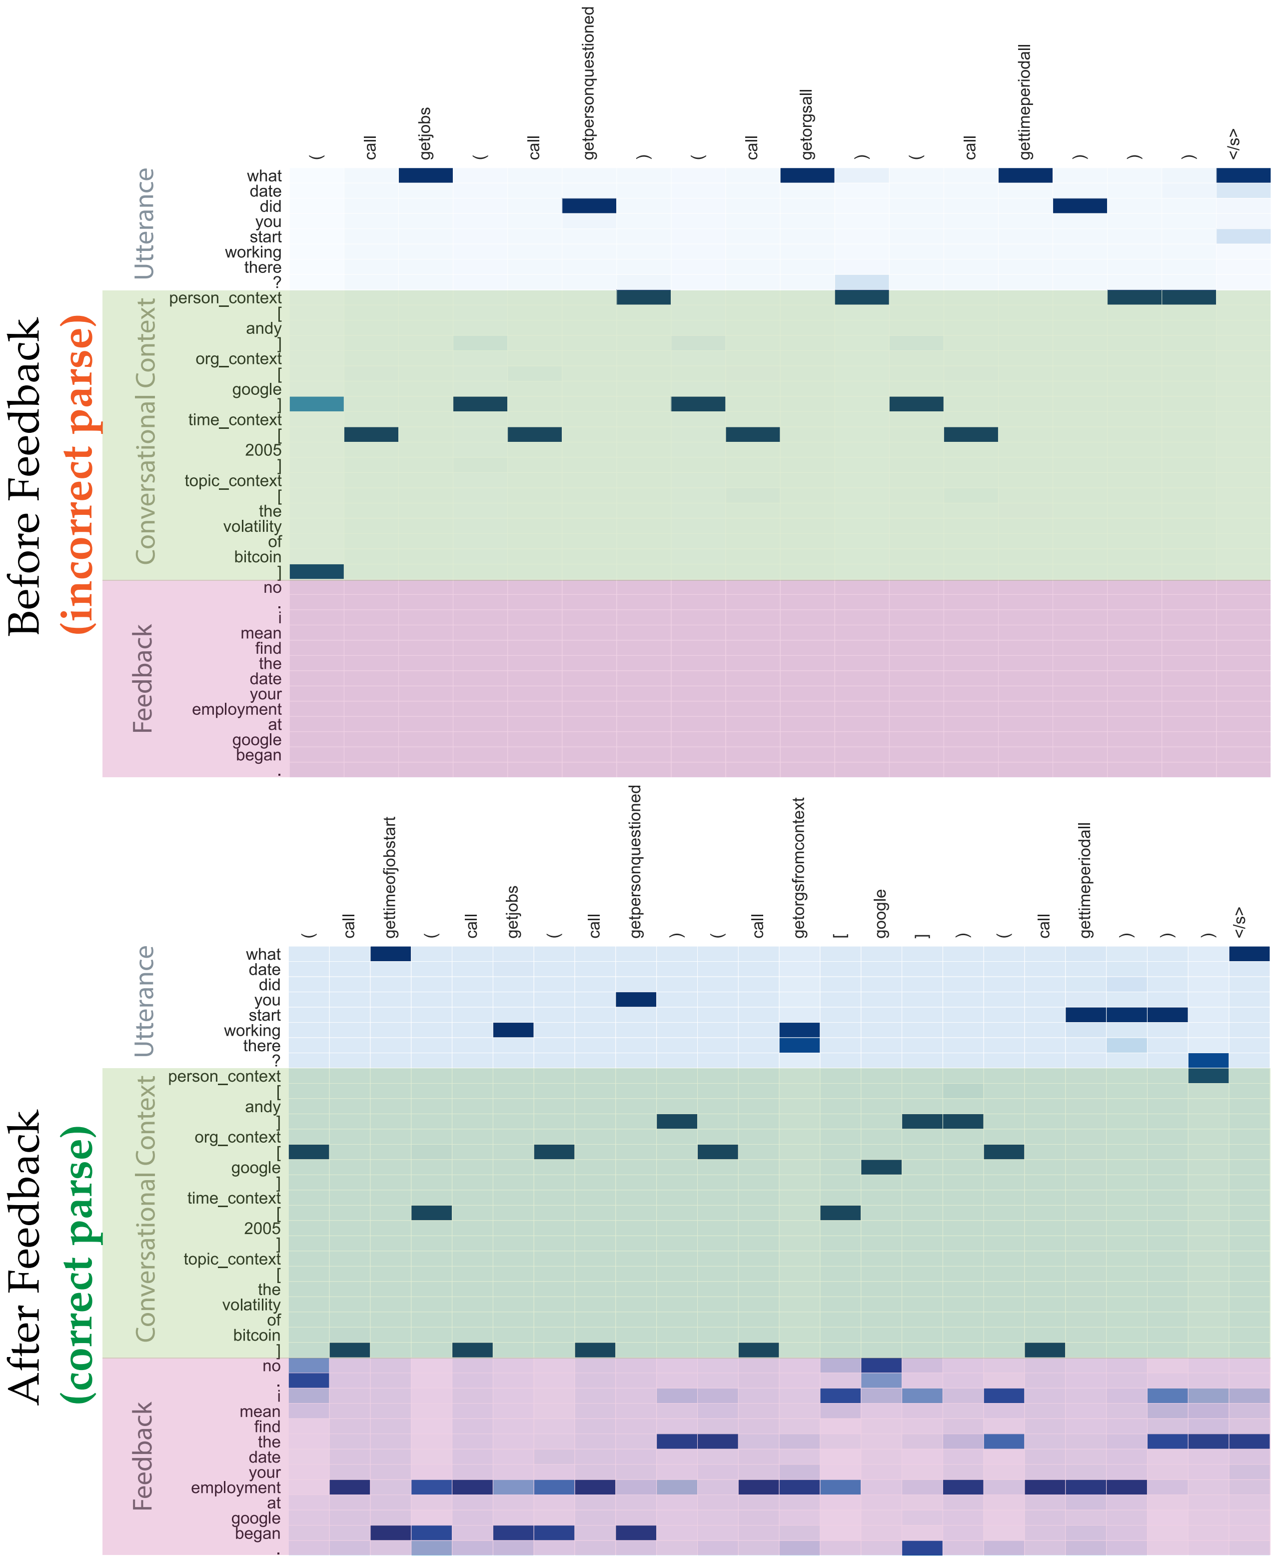

Figure 8: Visualization of the attention mechanism in the task parser (top) and the feedback parser (bottom) for parsing the same utterance. We partition the input to the parser into three groups: the original utterance u being parsed (blue), the conversational context (green) and the feedback utterance f (red). This example was parsed incorrectly before incorporating feedback, but parsed correctly after its incorporation.

DeepCx: A transition-based approach for shallow semantic parsing with complex constructional triggers

Abstract

This paper introduces the SURFACE CONSTRUCTION LABELING (SCL) task, which expands the coverage of Shallow Semantic Parsing (SSP) to include frames triggered by complex constructions. We present DeepCx, a neural, transition-based system for SCL. As a test case for the approach, we apply DeepCx to the task of tagging causal language in English, which relies on a wider variety of constructions than are typically addressed in SSP. We report substantial improvements over previous tagging efforts on a causal language dataset. We also propose ways DeepCx could be extended to still more difficult constructions and to other semantic domains once appropriate datasets become available.

(1) WE must `regulate` to **inhibit** *unsound practices*.
(2) THIS **opens the way to** *applying the law more widely*.
(3) Judy's comments were **SO** OFFENSIVE that *I left*.

(4) We headed out **in spite of** the bad weather.
(5) We value any contribution, **no matter** its size.
(6) Strange **as** it seems, there's been a run of crazy dreams!

(7) **More** boys wanted to play **than** girls.

(9) I'm poor**er than** I'd like.

Table 1: Examples of causal (1–3), concessive (4–6), and comparative (7–9) constructions, with triggers bolded. Arguments of causal examples are annotated as in the BECAUSE annotation scheme, with CAUSES in blue small caps, *effects* in red italics, and `means` in purple typewriter text.

1 Introduction

Shallow semantic parsing (SSP) aims to tag the triggers of semantic relations and the phrases between which those relations hold. However, words are not the only bearers of relational meaning: multi-word expressions (MWEs) and even arbitrarily complex constructions can express relations and evoke semantic frames (see, e.g., Fillmore et al., 2012). For example, causation, concession, and comparison are frequently expressed using complex constructions (see Table 1). MWE research has made strides in identifying MWE strings (see, e.g., Baldwin and Kim, 2010), but little work has addressed tagging arguments of such constructional triggers; many of the examples in Table 1 remain a challenge for conventional SSP.

This paper introduces the broader task of SURFACE CONSTRUCTION LABELING (SCL; §3). Like SSP, SCL aims to tag the surface elements of a sentence that express and participate in relational meanings. But in SCL, triggers are not just words or lexical units, but instances of constructions of the sort described by CONSTRUCTION GRAMMAR (CxG; Fillmore et al., 1988; Goldberg, 1995): arbitrarily complex sets of tokens that carry meaning. These constructions can consist of single words, fixed MWEs, gappy MWEs, or even grammatical patterns.

We propose a transition system for SCL that can tag multi-word, possibly gappy sequences of tokens as triggers and arguments (§4). As a test case for the approach, we address English causal language, a valuable target for semantic analysis in its own right. (Extensions to arbitrary frame and role types would be straightforward with appropriate data; see §8.) The transitions can handle most types of constructions, including those with multiple arguments, missing arguments, and even triggers that overlap or are interleaved with arguments. We present DeepCx, a neural network that tags causal language using this transition system (§5). We also describe experiments applying DeepCx to the BECAUSE corpus (§6), showing that DeepCx significantly outperforms prior construction-based work on predicting causal frames (§7). Finally, we discuss how the transition system and tagger model could be adapted to more difficult SCL tasks (§8).

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1691–1701
Brussels, Belgium, October 31 - November 4, 2018.

2 Background and related work

2.1 Shallow semantic parsing

SCL of course inherits from SSP, which has a venerable tagging tradition. For PropBank data, dozens of taggers have been developed (see Carreras and Màrquez, 2004, 2005; Surdeanu et al., 2008; Hajič et al., 2009). These typically focus on argument tagging, since PropBank triggers are readily identified by their POS tags. One popular design is a multi-stage pipeline that identifies argument spans and then labels them. Another alternative is BIO-style classification of argument words, either with conventional classifiers or with neural networks (e.g., Collobert et al., 2011; Foland and Martin, 2015). More recent systems (e.g., Täckström et al., 2015; Roth and Lapata, 2016) use neural networks to score and label possible argument spans or heads.

FrameNet-based tagging is more difficult, as triggers must be identified and disambiguated. Many FrameNet taggers have taken a pipeline approach (see, e.g., Baker et al., 2007; Das et al., 2014) in which targets are first identified with a whitelist or simple rules. They are then assigned frames, which determine the available frame elements, and finally the frame elements are identified and labeled. Again, neural networks have also been used to score argument spans and heads (Täckström et al., 2015; FitzGerald et al., 2015; Roth, 2016).

Systems in both paradigms are constrained by their underlying representations. PropBank covers only verbs and certain nominal and adjectival predicates. FrameNet's frame-evoking elements are broader, including verbs, prepositions, adverbs, conjunctions, and even some MWEs, but must still be single words or MWEs that act like words. As Table 1 demonstrates, some semantic domains, such as causality, demand a more flexible approach.

2.2 Construction grammar

CxG, which posits that the fundamental units of language are CONSTRUCTIONS—pairings of meanings with arbitrary linguistic forms. For instance, *so X that Y* (example 3) is characterized by a single construction, where the form is *so* $\langle$*adjective* $X\rangle$ $\langle$*finite clausal complement* $Y\rangle$ and the meaning is X *to an extreme that causes* Y. Following Dunietz et al. (2017a,b), we borrow two core insights of CxG: first, that morphemes, words, MWEs, and grammar are **all on equal footing** as "learned pairings of form and function" (Goldberg, 2013); and second, that constructions pair patterns of surface forms **directly with meanings**. Thus, we can tag any surface realizations of constructions as meaning-bearing triggers (hence "surface construction labeling").

2.3 Causal language

To test the SCL approach, we examine causal language, which conveys essential semantic information and is especially rich in constructional triggers.

Our data representation for causal language comes from the BECAUSE 2.1 corpus (Dunietz et al., 2017b), which focuses on what causal meanings are explicitly stated in the text. It defines causal language as any construction which presents one event, state, action, or entity as promoting or hindering another, and which includes at least one lexical trigger to anchor the annotation. For each instance of causal language, up to three spans are annotated: the **causal connective** (the trigger of the causal relation), the **cause** span, the **effect** span, and occasionally a **means** span (if a means by which the cause produces the effect is specified). See Table 1 for examples of analyses of causal language under the BECAUSE scheme. The corpus includes 4,867 sentences (123,674 tokens) of news articles and Congressional hearing transcripts fully annotated for causal language.

The only prior work on construction-based semantic parsing that we know of is Causeway (Dunietz et al., 2017a), also based on the BECAUSE corpus. Causeway detects causal connectives using lexico-syntactic patterns, then applies heuristics and classifiers to tag arguments and remove false positives. It achieves moderate performance, but requires extensive tuning and feature engineering.

2.4 Transition-based systems

Transition-based systems have primarily been used for dependency parsing (e.g., Nivre et al., 2007; Nivre, 2008; Chen et al., 2014; Choi and Palmer, 2011a). Indeed, our system borrows many implementation elements from Dyer et al. (2015), who describe a shift-reduce parser that embeds the stack and buffer as LSTMs. This parser employs the novel STACK LSTM data structure—an LSTM augmented with a stack pointer, enabling it to be rewound to a previous state.

Transition systems have been developed for semantic tasks, as well. Titov et al. (2009), Henderson et al. (2008), and Swayamdipta et al. (2016) explore extensions of dependency parsing that interleave semantic parsing actions with syntactic parsing actions. Google's SLING (Ringgaard et al., 2017) applies a custom-designed transition scheme for frame-based parsing and coreference resolution. Vilares and Gómez-Rodríguez (2018) develop a transition system for Abstract Meaning Representation parsing, and TUPA (Hershcovich et al., 2017) does the same for Universal Conceptual Cognitive Annotation. Both can handle discontinuous or reentrant graph structures. Most directly relevant to DeepCx is Choi and Palmer's (2011b) work, which defines a novel transition system for PropBank parsing. Our similar scheme for parsing causal constructions builds on this one, extending it for cases where the spans are not contiguous.

3 The SCL task for causal language

An SCL task closely resembles an SSP task, except that the triggers can be complex constructions. As a corollary, the arguments can also be discontinuous and/or overlap with each other or the trigger.

In the case of causal language, we define the task as reproducing the core elements of the BECAUSE scheme: connective, cause, effect, and means spans. Following Dunietz et al. (2017a), we split the task into two parts: discovering causal connectives (**connective discovery**) and delimiting and labeling the arguments (**argument ID**). Producing the additional metadata that BECAUSE records for each instance is left to future work.

Each span is defined as a set of tokens. This excludes sublexical constructions; we return to this limitation in §8.

4 Transition system

Like Choi and Palmer, DeepCx's transition system first searches for a connective word, and once it has found one, compares it with each word to the right and to the left. In each comparison, it selects a transition that labels the word as unrelated to the current connective word, as another connective word (or FRAGMENT), or as a member of some argument span(s). Once all words have been compared to the current connective, the system advances to the next possible initial connective word. In the worst case, then, each sentence takes $O(n^2)$ transitions.

Table 2 gives the full set of transitions. The transitions act on a state tuple $(\lambda_1, \lambda_2, a, \lambda_3, \lambda_4, s, A)$. a is the index of the current possible "connective anchor"—the word being tentatively treated as the initial (i.e., leftmost) word of a connective. λ_1 is the list of word indices to a's left that have not yet been compared with it, and λ_2 represents the words to the left of a that have already been compared. Likewise, λ_3 and λ_4 contain the indices of compared and uncompared words, respectively, to the right. Thus, words move from λ_1 to λ_2 and from λ_4 to λ_3 as they are compared with a. s is a boolean indicating whether we are currently comparing words in the sentence to a, i.e., whether a has been confirmed as a connective anchor. A is a set of partially-constructed causal language instances. Each instance consists of a set of connective word indices plus one set of argument word indices for each argument type. For formal description, we represent A as a set of labeled arcs. The head a of each arc is the connective anchor of a causal language instance i (an arbitrary identifier). The label of the arc indicates what role the tail t plays with respect to i: Cause, Effect, or Means if t is a member of the corresponding argument span, and Frag if t is a connective fragment other than a.

As the algorithm scans from left to right, it assigns a to each word index in turn. If it decides a is not a connective anchor, it issues a NO-CONN and moves on. If a is deemed to start a connective, a new instance is initialized with a NEW-CONN. DeepCx proceeds to compare a with each word to its left, in right-to-left order (i.e., starting from the closest word), then each word to the right (in left-to-right order). For each comparison, it issues a LEFT/RIGHT-ARC, CONN-FRAG, or NO-ARC, depending on whether the comparison word is deemed part of an argument, part of the connective, or neither. For simplicity, we always consider the leftmost connective word to anchor the connective, so all CONN-FRAG transitions occur between a connective word and a word to its right. After all words have been compared with a (i.e., once λ_1 and λ_4 are empty), an automatic SHIFT transition advances a to the next connective anchor candidate.

The initial state is: $\lambda_1 = \lambda_2 = \lambda_3 = []$, $a = 1$, $\lambda_4 = [w_1 \mathinner{..} w_n]$, $s = \mathsf{f}$, and $A = \varnothing$, where w_i is the ith word in the sentence. The algorithm terminates when $a = n$ and either $\lambda_3 = \lambda_4 = []$ or s is false—i.e., when no words remain to a's right, and either a is not a connective anchor or all words in the sentence have been compared with it. An example transition sequence is shown in Table 3.

Some transitions have preconditions, shown inline Table 2 in a smaller font. In addition, several transitions have constraints on their ordering to ensure semantic well-formedness. These constraints

Transition schema	**Effect and preconditions**
NO-CONN	$(\boldsymbol{\lambda_1}, \lambda_2{=}[\,], \boldsymbol{a}, \lambda_3{=}[\,], [\boldsymbol{w} \mid \boldsymbol{\lambda_4}], s{=}\mathsf{f}, A) \Rightarrow ([\boldsymbol{\lambda_1} \mid \boldsymbol{a}], \lambda_2, \boldsymbol{w}, \lambda_3, \boldsymbol{\lambda_4}, s, A)$
NEW-CONN	$(\lambda_1, \lambda_2, a, \lambda_3, \lambda_4, \boldsymbol{s}{=}\mathsf{f}, A) \Rightarrow (\lambda_1, \lambda_2, a, \lambda_3, \lambda_4, \mathbf{t}, A)$

RIGHT-ARC$_x$	$(\lambda_1{=}[\,], \lambda_2, a, \boldsymbol{\lambda_3}, [\boldsymbol{w} \mid \boldsymbol{\lambda_4}], s{=}\mathsf{t}, \boldsymbol{A}) \Rightarrow (\lambda_1, \lambda_2, a, [\boldsymbol{\lambda_3} \mid \boldsymbol{w}], \boldsymbol{\lambda_4}, s, \boldsymbol{A} \cup \{\boldsymbol{a} \xrightarrow{\boldsymbol{x_i}} \boldsymbol{w}\})$
CONN-FRAG	$(\lambda_1{=}[\,], \lambda_2, a{\neq}\,w, \lambda_3, [w \mid \lambda_4], s{=}\mathsf{t}, \boldsymbol{A}) \Rightarrow (\lambda_1, \lambda_2, a, \lambda_3, [w \mid \lambda_4], s{=}\mathsf{t}, \boldsymbol{A} \cup \{\boldsymbol{a} \xrightarrow{\mathsf{FRAG}_i} \boldsymbol{w}\})$
SHIFT	$(\boldsymbol{\lambda_1}{=}[\,], \boldsymbol{\lambda_2}, \boldsymbol{a}, [\boldsymbol{w} \mid \boldsymbol{\lambda_3}], \boldsymbol{\lambda_4}{=}[\,], \boldsymbol{s}{=}\mathsf{t}, A) \Rightarrow (\boldsymbol{\lambda_2}, [\,], \boldsymbol{w}, [\,], \boldsymbol{\lambda_3}, \mathbf{f}, A)$
SPLIT	See text (§4.1)

Table 2: The DeepCx transitions. Pre- and post-transition states are expressed as tuples $(\lambda_1, \lambda_2, a, \lambda_3, \lambda_4, s, A)$. x stands for Cause, Effect, Means, or any combination thereof. i indicates the instance under construction; thus, x_i denotes an argument or fragment arc of instance i. Elements changed by the transition are bolded. Preconditions (small font in the starting states) enforce a consistent transition order by delaying rightward actions until all leftward actions are completed.

Table 3: The sequence of oracle transitions and states for *Well*$_1$*, they*$_2$ *moved*$_3$ *because*$_4$ *of*$_5$ *the*$_6$ *schools*$_7$. Elements altered by the transition are bolded. Causal language instances are notated as connective(Cause, Effect).

are listed in the supplementary material (§A.3).

4.1 SPLIT transitions

In BECAUSE, a word from one connective can also be part of another connective. This most often occurs with conjoined arguments where portions of the connective are repeated. For example, in *it'll take luck **for** us **to** succeed or even **to** survive, succeed* and *survive* are considered Effects of two different causal instances whose connectives share the *for*. The SPLIT action handles such cases by completing the current causal language instance and starting a new one, copying all connective and argument words up to the repeated connective word.

4.2 Differences from Choi and Palmer

Our scheme differs fourfold from Choi and Palmer:

1. They assume oracle PropBank predicates. DeepCx, lacking oracle connectives, starts new causal language instances with NEW-CONNs, and adds s to the state to track whether such a transition has occurred.
2. Unlike PropBank, BECAUSE allows a connective to include multiple content words. Our system therefore adds a CONN-FRAG transition.
3. A connective word can be part of an argument—e.g., in *enough food to live,* the connective and Cause both include *enough.* DeepCx therefore

compares each connective anchor with itself. (This is why for each new connective anchor a, λ_4 starts out with a as its first element. It is also why the CONN-FRAG action does not advance to the next potential argument word: a connective fragment can be part of an argument.)

4. PropBank never posits two predicates for a single verb, but in BECAUSE, multiple connectives can share a connective word. This case is handled by the new SPLIT transition (see §4.1).

5 DeepCx neural network architecture

Given the experience of previous shallow semantic parsers (e.g., Roth, 2016), we expected performance to depend heavily on syntactic information. We therefore built our system on top of Dyer et al.'s LSTM parser, allowing us to directly incorporate the parser's embeddings. For example, a token's embedding can incorporate the parser's internal embedding of the subtree rooted at that token.

At each step, the network computes a high-dimensional state vector summarizing the internal data structures. That state feeds into a k-dimensional output layer, where k is the number of transition types seen in training. Each vector component is the predicted log probability that the corresponding transition should come next. At test time, the highest-scoring predicted action is taken; in training, gold-standard actions are executed instead.

Figure 1 shows a schematic of the neural network structure. We elaborate on its components below.

5.1 Final state and prediction layers

Beyond λ_{1-4}, the inputs to the state vector are:

- h, the history of actions so far for the sentence.
- d, the path in the dependency parse tree between anchor a and the token being compared with it.
- The lists of tokens making up the connective (o), Cause (c), Effect (e), and Means (m) spans for the causal instance currently under construction.

The parser state $\mathbf{s}$ at each timestep is defined as:

$$\mathbf{s} = \max\left\{\mathbf{0}, \mathbf{W}_s\left[\boldsymbol{\lambda}_1; \boldsymbol{\lambda}_2; \mathbf{a}; \boldsymbol{\lambda}_3; \boldsymbol{\lambda}_4; \mathbf{o}; \mathbf{c}; \mathbf{e}; \mathbf{m}; \mathbf{d}; \mathbf{h}\right] + \mathbf{b}_s\right\},$$

where $\mathbf{b}_s$ is a bias term, $\mathbf{W}$ is a learned parameter matrix, and any other bold variable $\mathbf{x}$ indicates an embedding of a variable x (described in §5.2). max indicates a component-wise ReLU.

The predicted probability of each transition T is computed from $\mathbf{s}$ using a softmax unit:

$$p\left(T \mid \mathbf{s}\right) = \exp\left(\mathbf{g}_T^\top \mathbf{s} + q_T\right)/z,$$

where $\mathbf{g}_T$ is a learned embedding of T, q_T is a bias for T, and z is a normalizing constant.

5.2 Embedding the inputs to the state

5.2.1 Embedding a token

Following Dyer et al. (2015), each token t is represented as a concatenation of three vector inputs:

- $\tilde{\mathbf{w}}_t$, a fixed word embedding for t's surface form.
- $\mathbf{w}_t$, a small additional word embedding of t, which allows the network to learn task-specific representations of words related to causality. This is the only component of a token's representation that is trained specifically for this task (i.e., that does not use an embedding from a pretrained language model or a syntactic parsing model).
- $\mathbf{p}_t$, the LSTM parser's internal embedding of the POS tag it assigned to t in preprocessing.

The concatenation is passed through a linear transformation $\mathbf{V}$ (with a bias $\mathbf{b}_t$) and a ReLU:

$$\mathbf{t} = \max\left\{\mathbf{0}, \mathbf{V}\left[\tilde{\mathbf{w}}_t; \mathbf{w}_t; \mathbf{p}_t\right] + \mathbf{b}_t\right\}$$

5.2.2 Embedding a list of tokens

For each input to the final state vector that is a list of tokens, we add an LSTM cell to the network.

For the spans of the instance under construction—i.e., the connective, Cause, Effect, and Means spans—embedding token lists is straightforward: whenever a transition adds a token to one of these lists, that token's embedding is added to the corresponding LSTM's input sequence. The LSTM's updated output is then used for all subsequent actions until another transition modifies the span.

The procedure for embedding the λ's is more involved. As transitions are taken, tokens may need to be moved between lists—e.g., the argument token is moved from λ_1 to λ_2 after a LEFT-ARC transition, and the connective anchor token is moved from λ_4 to λ_1 on a NO-CONN.

We implement these transfers using stack LSTMs. Initially, all tokens' embeddings are input to λ_4, but in **reverse order**, so that the leftmost token is added last. Then, whenever λ_4's leftmost token t is to be moved—i.e., on a SHIFT, NO-CONN,

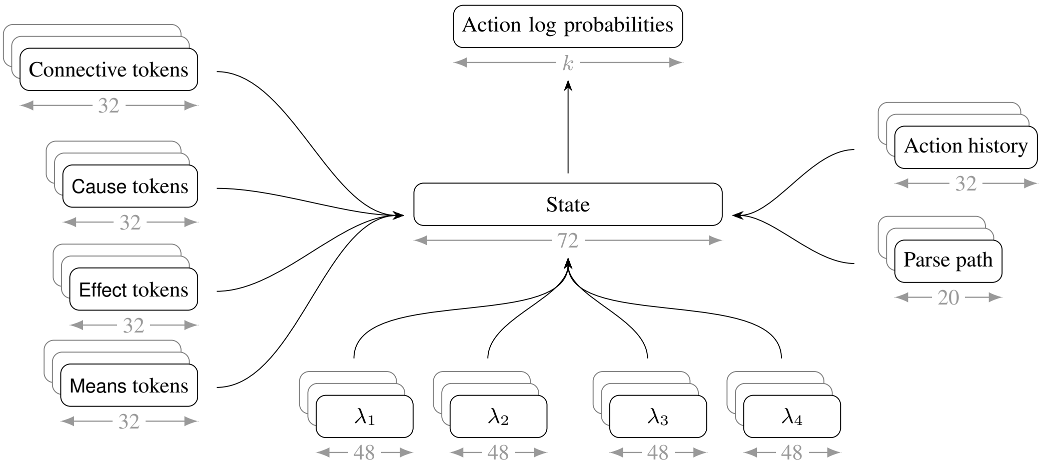

Figure 1: Schematic of the overall neural network architecture. Each lone box represents a vector. Stacked boxes represent LSTMs: at any given time, the state is a single vector, but that state encodes a series of inputs.

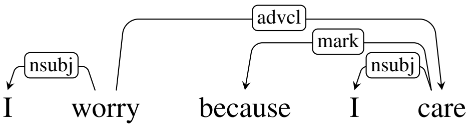
RIGHT-ARC, or NO-ARC-RIGHT—the λ_4 LSTM is rewound one step to its state before t was added. Storing λ_4 in reverse order offers the added benefit of tokens closer to the anchor holding greater sway, since LSTMs favor recently added inputs.

λ_1 and λ_2 are a mirror image of λ_4 and λ_3, respectively. Tokens are added to λ_1 on either a SHIFT or a NO-CONN. Thus, the λ_1 LSTM ends up representing an in-order list of tokens up to the current a. If a is then flagged as a connective anchor, tokens to its left are moved from λ_1 to λ_2 as they are compared. The rightmost token t in λ_1 is the first to be compared, so the λ_1 LSTM is rewound to remove t. t's embedding is then added to λ_2, leaving λ_2 with a reversed list of compared tokens.

5.2.3 Embedding a dependency path

The syntactic relationship between the connective anchor a and a candidate argument word t is given to the network as a DEPENDENCY PATH—the series of labels on the dependency arcs between a and t. For instance, consider the dependency parse below:



Here, the path from the first *I* to *because* would be $\bigcirc \xleftarrow{\text{nsubj}} \bigcirc \xrightarrow{\text{advcl}} \bigcirc \xrightarrow{\text{mark}} \bigcirc$, where the blank nodes take the place of the words *I, worry, care,* and *because* in the dependency graph.

To embed a dependency path, we again use the output of an LSTM cell, where each input is an embedding of a dependency label: for a label x, we directly use the LSTM parser's embedding for the **syntactic** parse action LEFT-ARC(x), if available, or RIGHT-ARC(x) otherwise. We add one extra bit to each arc's embedding to indicate whether it was traversed forward or backward in this path.[1]

5.2.4 Embedding the action history

During training, DeepCx learns vector representations of each action. To embed the action history, these action embeddings are fed as inputs into yet another LSTM cell. This LSTM's output is the embedding of the history thus far.

5.3 Implementation details

DeepCx is implemented using a refactored version of the LSTM parser codebase that performs identically to the original.[2] The neural network framework, which also underlies the LSTM parser, is an early version of DyNet (Neubig et al., 2017). The LSTM parser model is pretrained on the usual Penn Treebank (Marcus et al., 1994) sections (training: 02–21; development: 22).

For $\tilde{\mathbf{w}}$, we use the same "structured skip n-gram" word embeddings as the LSTM parser. See Dyer et al. (2015) for details about the embedding approach, hyperparameters, and training corpora. DeepCx gives no special treatment to out-of-vocabulary items, other than using the $\mathbf{0}$ vector for words not included in the pretrained embeddings.

---

[1] This embedding is similar to that proposed by Roth and Lapata (2016). However, their dependency paths include the words encountered along the way and their POS tags. We experimented with adding these elements to our dependency paths, but found that they consistently reduced performance.

[2] `https://github.com/clab/lstm-parser/tree/easy-to-use`.

The code for DeepCx is available on GitHub.[3]

5.3.1 Dimensionalities

The pretrained LSTM parser model uses the same dimensionalities as the original LSTM parser.

Token embeddings are 48-dimensional; $\mathbf{w}$ is 10-dimensional. The remaining DeepCx neural network dimensionalities used in the experiments reported below are shown in Figure 1. All LSTM cells use two layers of LSTMs before the final output. These values were chosen as an intuitive balance between values that worked well for other projects and what we could reasonably expect to train with the amount of data we have. Early experiments showed little sensitivity to dimensionality.

6 Experiments

6.1 Experimental setup and training setup

Due to the small corpus size, all experiments use 20-fold cross-validation, split by sentence. Within each fold, the available data—i.e., everything but the fold's held-out test set—is randomized, then split into 80% training and 20% development. After each sentence has been fed through the network, taking gold-standard transitions (see §5), backpropagation is run on all predictions for the sentence. Development set performance is evaluated every 2500 sentences. After each epoch, the training and development sets are re-randomized and re-split.[4] Training ends when either the connective-level F_1 score[5] on the development data hits 0.999 or 85% of the past five epochs' evaluations have yielded lower scores than their immediate predecessors. All systems used the same folds. See the supplementary materials (§A.4) for training parameters.

6.2 Network variants tested in experiments

Ablation studies In addition to the vanilla configuration described above, we examined which non-essential model components contribute to performance. We were particularly interested in the effects of parse information. We tested eliminating the following components of the DeepCx model: (1) $\mathbf{w}$, the task-specific word embeddings, which could contribute to overfitting; (2) $\mathbf{a}$, the action history; and (3) $\mathbf{d}$, the parse path between the connective anchor and the current comparison token.

Argument identification alone DeepCx has no separate argument tagging phase, so we tested performance on the subtask of argument identification by providing DeepCx with oracle transitions only for actions that act on the connective—i.e., NO-CONN, NEW-CONN, CONN-FRAG, and SPLIT. The system was then responsible for deciding between NO-ARC, LEFT-ARC, and RIGHT-ARC transitions.

Restricting generalization One of the strengths of the transition-based approach is its ability to recognize previously unseen forms of causal language that resemble known connectives semantically and/or linguistically. Given our relatively small dataset, however, it seemed possible that the system would not have enough data to make meaningful generalizations. We therefore tested a variant where DeepCx would refuse to allow a test-time NEW-CONN or CONN-FRAG transition unless adding the putative connective word would match the initial word sequence of some connective seen in training.

6.3 Evaluation metrics

For connective discovery we measure precision, recall, and F_1, requiring connectives to match exactly. For argument ID, we split metrics for Causes and Effects (we omit Means, as there are too few in the corpus to evaluate reliably). For each argument type, we report F_1 of connective/argument pairs, where matches must match exactly; F_1 of connective/argument pairs, where half of the larger span's tokens must match; and the average Jaccard index for gold vs. predicted spans, **given a correct connective**. Punctuation is excluded from evaluation.

Jaccard indices convey how close argument tagging is when it does not match exactly. This metric is computed only over true positive connectives, as argument overlap cannot be evaluated automatically for false positives. Thus, Jaccard indices are **not directly comparable** between systems—they represent how well argument ID works given the previous stage, rather than in an absolute sense.

7 Results and analysis

Results are shown in Table 4. For comparison, we also report on the best Causeway configurations.

All significance tests below are paired, two-tailed t-tests on the results from all 20 folds.

---

[3] `https://github.com/duncanka/lstm-causality-tagger`.

[4] Reusing the development data means the network can end up memorizing. However, early experiments with dedicated development data showed lower scores, presumably because too much training data was lost from each fold. Of course, our final evaluation is still performed on the fold's held-out data.

[5] For the experiment with oracle connectives, action-level prediction accuracy is used instead of F_1 score.

	Connectives			Causes			Effects		
System variant	**P**	**R**	$\mathbf{F_1}$	$\mathbf{F_1}$	$\mathbf{F_1@.5}$	**J**	$\mathbf{F_1}$	$\mathbf{F_1@.5}$	**J**
Best Causeway-S	62.8	46.2	*53.1*	37.9	42.5	81.0	24.8	38.7	73.3
Best Causeway-L	63.4	45.1	52.5	*38.8*	*43.5*	83.7	*30.4*	*40.7*	78.4
Vanilla DeepCx	*63.4*	55.8	*59.2*	*43.9*	*50.6*	83.0	41.0	*51.7*	82.2
No $\mathbf{w}$	62.7	56.2	59.1	42.8	49.0	81.9	*41.8*	*51.7*	82.5
No $\mathbf{d}$	62.7	***56.5***	*59.2*	42.7	49.1	80.9	39.6	51.1	80.5
No $\mathbf{a}$	61.3	54.1	57.3	40.3	48.3	81.6	36.9	50.4	81.1
No novel connectives	65.4	**56.5**	**60.5**	**44.7**	***51.0***	82.6	**42.8**	***52.6***	82.1
Oracle connectives	–	–	–	73.5	80.9	79.7	67.8	82.8	80.7

Table 4: Results for all variants of DeepCx tested. As before, J indicates Jaccard index. For $P/R/F_1$ scores, the best non-oracle results are bolded, and the best results within each of the top two sections are italicized.

7.1 Overall performance

The results show the DeepCx transition system to be a promising approach for SCL.

The vanilla configuration unmistakably eclipses Causeway at connective discovery with a margin of 6.1 F_1 points, driven primarily by recall. Both F_1 scores have high standard deviations across folds (3.6–4.7 points), but the scores covary; some folds are simply harder. DeepCx usually leads Causeway by at least 5 points, making the difference highly statistically significant ($p \ll 0.001$). The gap comes primarily from recall, where DeepCx averages 9.6–10.7 points higher than Causeway. [6]

On end-to-end argument identification, DeepCx again outperforms Causeway, particularly on recall, with a 5–6-point gap in F_1. The Jaccard indices for Causes and Effects are in the low 80's, indicating extensive overlap with gold-standard spans. They are on par with Causeway for Causes and higher for Effects, despite the fact that DeepCx's higher recall gives it more chances to be docked for mismatches.

7.2 Argument identification alone

Argument ID scores remain high when oracle connectives are provided. Naturally, the end-to-end argument scores improve dramatically compared to non-oracle connectives, but the more important question is what fraction of the previous errors remain when connective discovery is no longer a source of error. With oracle connectives, DeepCx achieves 73.5% F_1 on Causes and 67.8% on Effects, implying that the vanilla configuration's argument error was split roughly half and half between connective discovery failures and argument ID failures.

However, the F_1 metrics reflect exact span matches; it is counted as a mismatch if even a single word is off. Because in this experiment the system's entire task is to tag arguments, the Jaccard indices give an absolute measure of overlap between predicted and gold argument spans. By that measure, the neural network's treatment of argument identification transitions looks quite robust. Jaccard indices do drop by a few points compared to non-oracle connectives, as expected: with the oracle, arguments are evaluated for every gold-standard instance, including more difficult ones that the vanilla configuration misses. But despite the more exhaustive assessment, DeepCx maintains Jaccard indices of $\sim$80% for Causes and Effects.

7.3 Model ablation studies

No pieces of the model beyond the bare essentials improved connective scores. Removing these components did marginally lower argument ID scores, but few differences were statistically significant.

The meager effects of parse paths came as a surprise; indeed, our reason for building on the LSTM parser was to lean on its parse embeddings. That these paths made little difference suggests that the bulk of the information they provide is available in some isomorphic form from simpler inputs.

7.4 Constraining to known connectives

Constraining DeepCx to known connectives yields an interesting tradeoff. On the one hand, it boosts precision ($p < 0.036$) and raises F_1 slightly ($p < 0.09$). Inspecting the vanilla system's outputs accentuates the risks of letting it run wild inventing connectives: its odder proposals included *an unfair effort to, is insanity, eight,* and the dollar sign.

On the other hand, some generalizations were surprisingly perceptive. For instance, the phrase *allowing states greater opportunity to regulate* was not marked by annotators because *allowing* here seems to mean "providing." But DeepCx proposed

---

[6] Recall should perhaps have even been higher: in at least three cases, DeepCx was penalized for correctly flagging connectives that had been missed by annotators.

allowing opportunity to as a connective—a plausible candidate for annotation. Elsewhere DeepCx tagged *catalyst for* and *fuel* (as in *fueled skepticism*), both arguably annotator omissions.

Ultimately, then, whether to permit novel connectives depends on the user's prioritization of precision, recall, and discovery.

8 What's needed for other constructions and domains?

Although the DeepCx transitions were designed for BECAUSE, it would be straightforward, given appropriate corpora, to extend the transition scheme and model structure to arbitrary frames and role labels as in PropBank and FrameNet. The scheme's arc transitions would need variants for each possible role type, as is standard in existing transition-based SSP (e.g., SLING, Choi and Palmer). Likewise, NEW-CONN could be changed to NEW-CONN(frame); the space of arc transitions for constructing the rest of that instance could then be pruned to those relevant to the frame. As for the tagger state, there are several straightforward ways to modify it for open-ended role and frame labels. One option is to represent each instance's arguments as a list of ⟨*role label*, *list of tokens*⟩ tuples, and to add a frame label variable that is embedded as part of the state. Alternatively, we could follow SLING in providing the tagger a list of ⟨*frame label*, *role label*, *token*⟩ tuples.

Applying SCL to domains beyond causality would be particularly useful for relations like comparison and concession (see Table 1), where complex constructions abound. But as Fillmore et al. (2012) observe, many frames possess the odd non-lexical-unit trigger. For example, the Motion frame can be evoked by the "verb-way" construction (*sang our way across Europe*), and Measurement by the abstract pattern ⟨*number*⟩ ⟨*unit*⟩ ⟨*noun*⟩ (as in *twelve-inch-thick*). Expanding SSP to cover constructions would allow parsing these cases, which are individually rare but collectively form a fat tail of frame instances.

DeepCx already covers most constructional quirks that interfere with SSP, including discontinuous trigger and argument spans, overlaps between arguments, overlaps between trigger words and arguments, and overlaps between triggers. Still, several extensions might be needed for the full gamut of arbitrary constructions. Most notably, our scheme operates on words, but plenty of constructions are sub-lexical (e.g., the comparative *-er*). One solution would be to operate on morphemes instead. Unfortunately, tagging would then be subject to errors in morphological analysis, and morpheme- or character-based embeddings would be needed. A simpler but less elegant solution would be to tag the entire word containing the morpheme (e.g., *bigger*) as part of the construction.

A second challenge is constructions with no lexical trigger, as in *I can't come; I have rehearsal*. The simplest fix would be to add a JUXT transition as a sibling of NEW-CONN. This transition would anchor a new relation instance at the boundary between the words currently being compared, indicating that the mere juxtaposition of two argument spans conveys a relation between them.

Cross-sentential constructions—e.g., discourse connectives whose arguments can be in another sentence—pose a third challenge: our sentence-oriented scheme ignores sentential juxtaposition and cross-sentential grammatical relations as construction possibilities. While it would not be too difficult to alter the scheme to allow, say, arguments in the previous k sentences, it might make randomized training more difficult.

Finally, SPLITs make strong assumptions about how two connectives sharing words will interact. Constructions violating these assumptions may require more drastic surgery on the scheme.

9 Contributions and takeaways

This paper has introduced surface construction labeling as an expansion of shallow semantic parsing. It has also presented DeepCx, a neural transition framework unifying connective discovery and argument ID for causal constructions. DeepCx achieves strong performance on parsing such constructions. Although the transition system targets causal language, its flexibility makes it promising for other domains, as well. We hope DeepCx will inspire further work on SCL. This includes applying more sophisticated tagging techniques such as bidirectional LSTMs, attention, and dynamic oracles, but most importantly developing new data and tasks to which the approach can be applied.

What It Takes to Achieve 100% Condition Accuracy on WikiSQL

`{syavuz,izzeddingur,ysu,xyan}@cs.ucsb.com`

Abstract

WikiSQL is a newly released dataset for studying the natural language sequence to SQL translation problem. The SQL queries in WikiSQL are simple: Each involves one relation and does not have any join operation. Despite of its simplicity, none of the publicly reported structured query generation models can achieve an accuracy beyond 62%, which is still far from enough for practical use. In this paper, we ask two questions, "Why is the accuracy still low for such simple queries?" and "What does it take to achieve 100% accuracy on WikiSQL?" To limit the scope of our study, we focus on the `WHERE` clause in SQL. The answers will help us gain insights about the directions we should explore in order to further improve the translation accuracy. We will then investigate alternative solutions to realize the potential ceiling performance on WikiSQL. Our proposed solution can reach up to 88.6% condition accuracy on the WikiSQL dataset.

1 Introduction

A large amount of world's data is stored in relational databases, which require users to master structured query languages such as SQL to query data. It might not be convenient for many users who do not have programming background. Towards removing this huge barrier between non-expert users and data, building reliable natural language interfaces to databases has been a long-standing open problem (Woods, 1973; Androutsopoulos et al., 1995; Popescu et al., 2003).

Recently, there is a renewed interest in natural language interfaces to databases due to the advance in deep learning and the new release of large-scale annotated data such as WikiSQL (Zhong et al., 2017). WikiSQL includes a large collection of questions and their corresponding SQL queries. While the queries in WikiSQL are quite simple: Each involves one relation and does not have join operations, none of the publicly reported SQL generation models (Zhong et al., 2017; Xu et al.) can achieve an accuracy beyond 62%, which is far from enough for practical use. It is not clear yet what level of parsing capabilities are needed to achieve high performance, ideally close to 100% accuracy, on this task.

In this paper, we aim to figure out the level of language understanding required to perform well on the WikiSQL task. Specifically, we focus on the `WHERE` clause generation, which is the most challenging part of this task as reported in (Xu et al.): The accuracies for other clauses like `SELECT` and `AGGREGATE` are over 90% whereas the accuracy for `WHERE` is only around 70%. We aim to conduct the following two studies: (i) Understanding the difficulties of the task and (ii) Investigating alternative solutions to realize the potential ceiling performance.

To this end, we first conduct a careful analysis on a subset of the WikiSQL data to identify the main challenges. This analysis leads to two important observations: (i) ∼17% of the questions are either too ambiguous (hard) or require external knowledge to answer, (ii) ∼68% of the questions can be answered by exact match or simple paraphrasing, however we surprisingly find that the current best system (Xu et al.) can only get less than 80% accuracy on such simple questions. Deeper analysis on the second observation leads to the conclusion that most of the errors in this category are due to wrongly generated condition values as shown by the example in Figure 1. One can resort to soft/hard look-up based approaches over table content as in previous work (Mou et al., 2017; Iyer et al., 2017) or user interaction (which is also applicable to the first observation) to more accurately recognize the entities in questions for better condition value generation.

1986	Drama Desk Award	Outstanding Director of a Musical	Bob Fosse	Nominated
1986	Drama Desk Award	Outstanding Choreography	Bob Fosse	Won

Question:

Which award has the category of the best direction of a musical?

Correct SQL:

SELECT award
WHERE category = best direction of a musical

SQLNet Prediction:

SELECT award
WHERE category = the best direction award a musical

Figure 1: An example from WikiSQL. SQLNet makes a wrong prediction on the condition value of the `WHERE` clause.

As a second contribution, we propose to use table content as additional data source to address the aforementioned wrongly generated condition value problem, and investigate solutions to realize the potential performance limit (upper bound) on WikiSQL. Note that neither Seq2SQL (Zhong et al., 2017) nor SQLNet (Xu et al.) utilize table content. However, we show that it is not straightforward to achieve a high accuracy even in the scenario where table content is available as an optimal external knowledge through our model ablation results and error analysis. We demonstrate that our proposed solutions can reach up to 88.6% `WHERE` condition accuracy, almost matching the performance on `SELECT` and `AGGREGATE`.

2 Background

The WikiSQL dataset introduced in (Zhong et al., 2017) is created from a large number of tables extracted from Wikipedia, employing Amazon Mechanical Turk for annotation. An example from the dataset is provided in Figure 1: It consists of a table t, a SQL query s, and its corresponding natural language question q. There can be multiple conditions in the `WHERE` clause of a SQL query, each of which consists of a table column, an operator ($=, <, >$, etc.), and a condition value.

Instead of asking annotators to write SQL queries for given questions and tables, the authors (Zhong et al., 2017) facilitate the annotation process by paraphrasing generated questions. This raises concerns that the resulting dataset is limited to only simple queries. We acknowledge this concern. However, it is still a large, valuable dataset towards the goal of building ultimate natural language interfaces to databases. If the existing or newly proposed solutions can not solve this task with high accuracy, how can we advance to more complicated ones? Any insight and solution to this task can help us build more advanced SQL synthesis algorithms in future.

3 WikiSQL Data Analysis

In this section, we aim to deliver a thorough analysis of the WikiSQL dataset. (Zhong et al., 2017; Xu et al.) made an assumption that only table schema is available to the model, and table content (i.e., table cell values) is not available. We want to answer the following question: As the dataset creation process involves several heuristics and predefined templates to simplify the annotation task, what kind of capabilities does it still require to answer the resulting questions successfully? To this end, we randomly sample 100 examples from the development set of WikiSQL for analysis.

3.1 Categorization

We manually categorize these 100 examples in terms of the capability needed to predict the correct `WHERE` clause as described below. We also provide illustrative examples for each category in Table 1. If an example belongs to multiple categories, we include it in all the categories that apply. In Table 2, we present the break down of the examples over these categories.

Exact match. For each condition in the SQL query, its column name appears in the question around the neighborhood of its condition value with exactly the same surface form.

Paraphrase. For at least one of the conditions in the SQL query, its column name is paraphrased in the question, hence the inference requires certain paraphrasing capabilities.

Partial clue. For at least one of the conditions in the SQL query, its column name is not explicitly mentioned in the question, not even in paraphrased form. However, there are still partial semantic clues for inference.

External knowledge. For at least one of the conditions in the SQL query, there is no clue in the question to infer its column name. Inferring this column name from the question requires external knowledge regarding the type of its condition

Category	Question	Pseudo SQL Query	Table Columns
Exact match	In what state was the **electorate** fowler?	SELECT state WHERE **electorate** EQL fowler	member, party, **electorate**, state, term in office
Paraphrase	What was the date of the game after week 5 **against the Houston Oilers?**	SELECT date WHERE week GT 5 AND **opponent EQL houston oilers**	week, date, **opponent**, result, attendance
Partial clue	Who had the most points in the game **on March 7**?	SELECT high points WHERE **date EQL march 7**	game, **date**, team, score, high points, ...
External-knowledge	Name the callback date **for amway arena**	SELECT callback date WHERE **audition venue EQL amway arena**	episode air data, audition city, **audition venue**, callback date, ...
Ambiguous	List the branding **for krca-tv**	SELECT branding WHERE **callsign EQL krca-tv**	branding, **callsign**, channel, power (kw), ...

Table 1: Representative examples for each category. **EQL** and **GT** correspond to the = and > operators. Highlighted parts of the question and the pseudo SQL query are provided to indicate clues for the category.

Category	# Questions	Percentage
Exact match	59	54.1%
Paraphrase	16	14.7%
Partial clue	15	13.8%
External knowledge	11	10.1%
Ambiguous	8	7.3%

Table 2: Number of examples in different categories.

Category	Seq2set+CA	Seq2set+CA+WE
Exact match	67.8%	72.9%
Paraphrase	75.0%	68.8%
Partial clue	80.0%	80.0%
External knowledge	54.6%	45.5%
Ambiguous	37.5%	37.5%
Total	67.0%	67.9%

Table 3: Accuracy breakdown of SQLNet.

value that can be detected from the question.

Ambiguous. For this category, even with the external knowledge it is almost impossible (even for humans) to confidently infer the correct condition column from the question.

3.2 Performance Breakdown of SQLNet

In Table 3, we show the performance breakdown of SQLNet (Xu et al.), the state-of-the-art model for WikiSQL, on the selected 100 examples. It has two variants with comparable performance, so we show both of them. As expected, both variants of SQLNet perform poorly on examples that are either too ambiguous or require external knowledge. However, it is surprising that the accuracy on examples that need only exact matching or simple paraphrasing is also not very high, especially considering the paraphrasing capabilities of deep learning models gained from distributed representations. We find that most of these errors are due to wrongly generated condition values as illustrated in Figure 1, where SQLNet fails to even produce a valid phrase. This is indeed important prior knowledge that can be effectively outsourced by resorting to soft/hard look-up based approaches (Mou et al., 2017; Iyer et al., 2017) instead of fully relying on models to precisely generate it.

The above observations exhibit an opportunity to incorporate external knowledge in the condition generation process. We opt to use the table content as the knowledge source to address the wrong condition value problem, which is not used in the existing models (Zhong et al., 2017; Xu et al.). Next we will show that it is not trivial to leverage table content.

4 Our Solutions

As motivated in the previous sections, our main objective here is to investigate solutions to realize the potential ceiling performance on WikiSQL when using the table content as an additional knowledge source. We first describe an attentional RNN-based model that serves as our baseline, and propose several variants for `WHERE` clause generation, each addressing a specific weakness.

4.1 Task Formulation

Given a question q and a table t, our objective is to generate the `WHERE` clause of the SQL query corresponding to the question. In addition, we assume that the table t can be queried while generating the `WHERE` clause. Each condition in the `WHERE` clause is represented as a triple of (`COLUMN`, `OP`, `VALUE`). SQLNet (Xu et al.) generates each of these individual components by first predicting `COLUMN` and `OP`, and then generating `VALUE` using pointer networks (Vinyals et al.). In

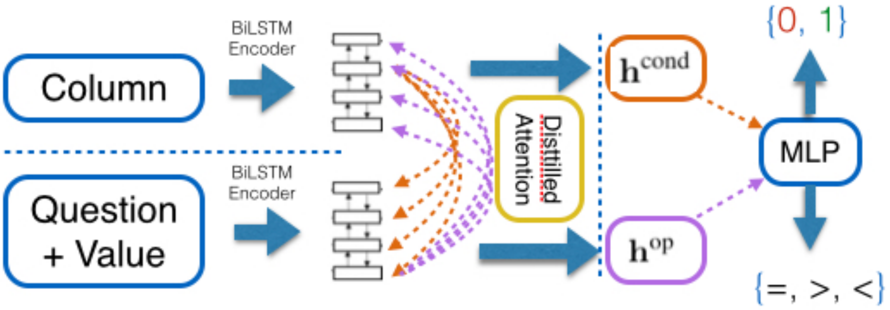

Figure 2: Model overview.

contrast, we propose a two step approach to tackle this problem in the reverse way, taking advantage of the content of table t as additional knowledge: (i) Generate the condition `VALUE` from the question, and (ii) predict which `COLUMN` and `OP` apply to this `VALUE`.

4.1.1 Candidate Generation

Our objective in candidate generation process is to produce a set of $(\texttt{COLUMN}, \texttt{VALUE})$ pairs from question q and table t, where `VALUE` is an *n-gram* in q and `COLUMN` is a column in t. Similar to prior work (Zhong et al., 2017; Xu et al.), we assume that `VALUE` occurs in the question.

We first generate the set $\mathcal{N}$ of all *n-grams* from the question. Then, for each candidate $v \in \mathcal{N}$ and each column $c \in t$, we query table t to check whether value v is contained in any row of column c. Then, we create a set $\mathcal{C} = \{(c, v) \colon v \in c\}$ of $(\texttt{COLUMN}, \texttt{VALUE})$ pairs as our final candidates for the `WHERE` clause. We note here that `VALUE` may not necessarily be an *n-gram* in question for other potential external knowledge or NLIDB tasks. In such scenarios, we can alternatively resort to soft look-up based approaches like the ones proposed in (Mou et al., 2017; Bordes et al., 2015).

4.1.2 Condition Prediction

Given a question q, SQL table t, and a set $\mathcal{C}$ of $(\texttt{COLUMN}, \texttt{VALUE})$ pair as candidates for `WHERE` clause, our objective is to learn two mappings:

$$f_{\text{cond}} : (q, c, v) \mapsto \{0, 1\} \qquad (1)$$

$$f_{\text{op}} : (q, c, v) \mapsto \{=, >, <\} \qquad (2)$$

where f_{cond} determines whether to select $(c, v) \in \mathcal{C}$ as a condition in `WHERE` clause and f_{op} predicts the operator `OP` $\in \{=, >, <\}$. These two mappings together can fully determine the final `WHERE` clause. Note that there can be multiple conditions in the `WHERE` clause.

4.2 Model Overview

We design a neural network model (Figure 2) to instantiate the mappings f_{cond} and f_{op}. We first describe the general structure of the model, consisting of the following steps:

Value Context. We define *value context* as the context of the value in the question for a given pair of question q and value v. Later the question encoder will condition on this information to make predictions. We will investigate different options for value context in Section 4.3. For now, we define it as a transformation g_{context} which maps each (q, v) to its value context.

Value Abstraction. Inspired by (Yavuz et al., 2016), we define *value abstraction* as a transformation g_{abstract} that replaces the surface form of `VALUE` in the question with a single token `ENTITY`. For the running example in Figure 1, applying value abstraction maps the question to "*Which award has the category of the ENTITY?*" It further informs the question encoder regarding the location of the `VALUE` in the question.

Encoding. Given question $q = (q_1, q_2, \ldots, q_m)$, column $c = (c_1, c_2, \ldots, c_n)$, and value $v = (v_1, v_2, \ldots, v_k)$. Before encoding, we first apply the aforementioned textual transformations and obtain value context

$$q' = (q'_1, q'_2, \ldots, q'_l) = g_{\text{context}} \circ g_{\text{abstract}}(q, v).$$

We first encode all the words into a vector space using an embedding matrix $E \in \mathbb{R}^{d \times |\mathcal{V}|}$, where $\mathcal{V}$ denotes the vocabulary and d is the embedding dimension. Let $\mathbf{q'}_i$ denote the embedding of word q'_i. To obtain the contextual embeddings, we use a bi-directional LSTM with hidden unit size h:

$$\overrightarrow{\mathbf{h}^{\text{q}}}_i = LSTM^{\text{q}}_{\text{fwd}}(\overrightarrow{\mathbf{h}^{\text{q}}}_{i-1}, \mathbf{q'}_i) \qquad (3)$$

$$\overleftarrow{\mathbf{h}^{\text{q}}}_i = LSTM^{\text{q}}_{\text{bwd}}(\overleftarrow{\mathbf{h}^{\text{q}}}_{i+1}, \mathbf{q'}_i) \qquad (4)$$

with $\overrightarrow{\mathbf{h}}_0 = \mathbf{0}$ and $\overleftarrow{\mathbf{h}}_{l+1} = \mathbf{0}$. We combine forward and backward contextual embeddings for each word in the question to obtain $\mathbf{h}^{\mathrm{q}}_i = \mathbf{concat}(\overrightarrow{\mathbf{h}^{\mathrm{q}}}_i, \overleftarrow{\mathbf{h}^{\mathrm{q}}}_i) \in \mathbb{R}^{2h}$.

Similarly, we obtain the contextual embedding $\mathbf{h}^{\mathrm{col}}_j \in \mathbb{R}^{2h}$ for each word c_j in column c with another bi-directional LSTM but shared word embedding matrix.

Distilled Attention. The objective of this step is to distill the most relevant information from both the value context and the column for the final prediction. We first compute the attention score of each word $c_j \in c$ on the words $q'_i \in q'$:

$$S^{(\mathrm{col}\rightarrow\mathrm{q})}_{j,i} = \mathbf{h}^{\mathrm{col}}_j \mathbf{W}^{(\mathrm{col}\rightarrow\mathrm{q})} \mathbf{h}^{\mathrm{q}}_i \tag{5}$$

$$P^{(\mathrm{col}\rightarrow\mathrm{q})}_j = \mathrm{softmax}_i \; S^{(\mathrm{col}\rightarrow\mathrm{q})}_{j,i} \tag{6}$$

where $\mathbf{W}^{(\mathrm{col}\rightarrow\mathrm{q})} \in \mathbb{R}^{2h\times 2h}$ is a model parameter to be learned and $P^{(\mathrm{col}\rightarrow\mathrm{q})}_j \in \mathbb{R}^{l}$ represents an attention probability distribution of word c_j over the words of value context q'. Let $P^{(\mathrm{col}\rightarrow\mathrm{q})} \in \mathbb{R}^{n\times l}$ denote the column-wise concatenation of $P^{(\mathrm{col}\rightarrow\mathrm{q})}_j$ indicating the unified representation of attention matrix from column words onto value context. Similarly, we compute the attention from value context (question) to column and get $P^{(\mathrm{q}\rightarrow\mathrm{col})} \in \mathbb{R}^{l\times n}$.

The intuition behind *distilled attention* is to allow two-way comparison to clean up the attention weights. To exemplify this point better, consider a scenario where a word $c_j \in c$ attends on a word $q'_i \in q'$ with high probability, but q'_i is much more relevant to another word $c_{j'} \in c$. We leverage reverse attention $P^{(\mathrm{q}\rightarrow\mathrm{col})}$ to distill the attention weights of column words on the value context. To this end, we define distilled attention weights as

$$P = (P^{(\mathrm{q}\rightarrow\mathrm{col})})^{\top} \odot P^{(\mathrm{col}\rightarrow\mathrm{q})} \tag{7}$$

where $P \in \mathbb{R}^{n\times l}$ becomes our final attention weights and $\odot$ indicates the Hadamard product.

Value Context and Column Representations. Having defined how the encodings and attention weights are computed, we now describe the final value context and column representations. First, we compute a value context vector for each word $c_j \in c$ using the distilled attention weights by

$$\mathbf{h}^{(\mathrm{q}\rightarrow\mathrm{col})}_j = \sum_{i=1}^{l} P_{j,i}\, \mathbf{h}^{\mathrm{q}}_i \tag{8}$$

and fuse it with the corresponding column context vector by

$$\mathbf{h}^{\mathrm{cond}}_j = \tanh(\mathbf{W}^{\mathrm{cond}}_0 \mathbf{h}^{\mathrm{col}}_j + \mathbf{W}^{\mathrm{cond}}_1 \mathbf{h}^{(\mathrm{q}\rightarrow\mathrm{col})}_j) \tag{9}$$

$$\mathbf{h}^{\mathrm{op}}_j = \tanh(\mathbf{W}^{\mathrm{op}}_0 \mathbf{h}^{\mathrm{col}}_j + \mathbf{W}^{\mathrm{op}}_1 \mathbf{h}^{(\mathrm{q}\rightarrow\mathrm{col})}_j) \tag{10}$$

where $\mathbf{W}^{\mathrm{cond}}_0, \mathbf{W}^{\mathrm{cond}}_1, \mathbf{W}^{\mathrm{op}}_0, \mathbf{W}^{\mathrm{op}}_1 \in \mathbb{R}^{2h\times 2h}$ are trainable model parameters. Finally, we apply a pooling layer to obtain fixed-size representations

$$\mathbf{h}^{\mathrm{cond}} = \frac{1}{n}\sum_j \mathbf{h}^{\mathrm{cond}}_j \text{ and } \mathbf{h}^{\mathrm{op}} = \frac{1}{n}\sum_j \mathbf{h}^{\mathrm{op}}_j \tag{11}$$

for *condition* and *operator* predictions.

Prediction. So far we have obtained two different representations $\mathbf{h}^{\mathrm{cond}} \in \mathbb{R}^{2h}$ and $\mathbf{h}^{\mathrm{op}} \in \mathbb{R}^{2h}$ as the latent unified representations of question, column, and value triple (q, c, v). We than use these representations to make the final predictions:

$$\mathbf{p}^{\mathrm{cond}} = \mathrm{softmax}(\mathbf{U}^{\mathrm{cond}}\, \mathbf{h}^{\mathrm{cond}}) \in \mathbb{R}^2 \tag{12}$$

$$\mathbf{p}^{\mathrm{op}} = \mathrm{softmax}(\mathbf{U}^{\mathrm{op}}\, \mathbf{h}^{\mathrm{op}}) \in \mathbb{R}^3 \tag{13}$$

where $\mathbf{U}^{\mathrm{cond}} \in \mathbb{R}^{2\times 2h}$ and $\mathbf{U}^{\mathrm{op}} \in \mathbb{R}^{3\times 2h}$ are model parameters. The final prediction mappings are then defined as:

$$f_{\mathrm{cond}}(q, c, v) = \arg\max_i \mathbf{p}^{\mathrm{cond}}_i \tag{14}$$

$$f_{\mathrm{op}}(q, c, v) = \arg\max_i \mathbf{p}^{\mathrm{op}}_i \tag{15}$$

Training Objective. Let $\mathcal{T} = \{(q, c, v, l, o)\}$ denote a set of training tuples where $l \in \{0, 1\}$ denotes whether to include a condition with (c, v) as $(\texttt{COLUMN}, \texttt{VALUE})$ pair and if so, $o \in \{=, >, <\}$ indicates which `OP` to apply. Our loss function consists of two components:

$$J(\Theta) = J_{\mathrm{cond}}(\Theta) + l\; J_{\mathrm{op}}(\Theta) \tag{16}$$

where $J_{\mathrm{cond}}(\Theta) = -\log(\mathbf{p}^{\mathrm{cond}}_l)$ and $J_{\mathrm{op}}(\Theta) = -\log(\mathbf{p}^{\mathrm{op}}_o)$ are simply negative log-likelihood losses for *condition* and *operator* predictions.

Inference. We also employ an inference schema where we make a simple assumption that a condition value v may be a part of *only one* condition. Hence, we group candidate $\{(c, v)\}$ pairs by value v, and create a candidate column set $C_v\colon \{c\colon (c, v)\}$ for each unique candidate value v. Based on the probabilities $p^{\mathrm{cond}}(c, v)$ computed by the trained model, we select the column $c \in C_v$ with the maximum probability for each candidate value v, hence form the set of $(\texttt{COLUMN}, \texttt{VALUE})$ pairs to be included in condition this way.

4.3 Model Variants

In this section, we discuss variants of our model with different choices for the value context. Consider the running example in Figure 1 and assume

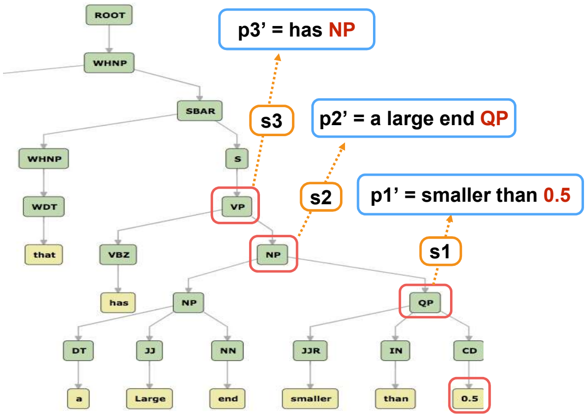

Figure 3: Partial view of parse tree for question "*Which taper/ft that has a Large end smaller than 0.5*" illustrating parse tree based value contexts.

hypothetically that *award* is a candidate condition column for value *best direction of a musical*. When we use the whole question as the value context, eliminating *award* from being a condition `COLUMN` for this `VALUE` becomes very challenging for the model as it is not informed enough regarding the finer context of the value.

4.3.1 Base Model

The base model simply uses identity mapping for value context. More precisely, we use the whole question as the context for the candidate condition `VALUE`. So, $g_{\text{context}}(q, v) = q$.

4.3.2 Window-based model

The objective of *window-based* model is to get value contexts that can provide more clean context information by leveraging the context window around the candidate value. In this case, we first identify the span $[start, end]$ for value v in the question q. Based on its span and a predetermined context window size w, we define $g_{\text{context}}(q, v) = (q_{start-w}, \ldots, q_{start}, \ldots, q_{end}, \ldots, q_{end+w})$.

4.3.3 Parse tree-based model

We also analyze a simple parse tree based model that hierarchically split up the value context into multiple contexts based on the constituency parse tree of the question. To motivate this, consider the question in Figure 3. Window-based value context for 0.5 is *"a large end smaller than ENTITY"* and candidate table columns to apply this value are *"large end"* and *"small end"*. Based on this context, a model will likely assign a higher probability to *"large end"* than *"small end"*. The syntactic structure of the question can potentially help reduce such ambiguities.

Parse tree-based value contexts. As highlighted in Figure 3, we use nested phrase-level subtrees that contain the candidate `VALUE`. Moreover, to better inform the model regarding the type of phrases, we use phrase level constituent tags of subtrees in two ways: (i) to inform the parent tree with the type of its subtree containing candidate `VALUE`, (ii) to apply a tag-specific affine transformation on phrase representations. To this end, we first select the r-lowest subtrees $s_1 \subset s_2 \subset \ldots \subset s_r$ of the question's parse tree containing `VALUE` along with their corresponding phrase-level constituency tags[1] $t_1, t_2, \ldots, t_r$, respectively. We then iteratively form multiple values contexts as nested phrases of $p'_1, p'_2, \ldots, p'_r$ shown in Figure 3 as follows: (i) p'_1 is equal to the phrase formed by the words at the leaf nodes of subtree s_1, and then (ii) iteratively form p'_i as the phrase formed by the words under subtree s_i by replacing its subphrase corresponding to subtree s_{i-1} with its constituency tag t_{i-1} for $i > 1$.

Modifications to General Model. We now describe how the general model defined in Section 4.2 is adapted to accommodate the multiple nested value contexts of different types. In this process, we aim to capture two types of important information: (i) syntactic phrase-level types of value contexts, and (ii) their distance to `VALUE`.

We first compute a value context vector $\mathbf{h}_{j,k}^{(\text{q}\rightarrow\text{col})} \in \mathbb{R}^{2h}$ for each word $c_j \in c$ and each value context p'_k as in Eq. 8 using the same encoding and attention mechanisms. However, we replace the affine transformation layers defined in Eq. 9 and 10 with tag and distance specific ones as follows:

$$\mathbf{h}_j^{\text{cond}} = \tanh(\mathbf{W}_0^{\text{cond}}\mathbf{h}_j^{\text{col}} + \frac{1}{r}\sum_{k=1}^{r}\mathbf{W}_{k,t_k}^{\text{cond}}\mathbf{h}_{j,k}^{(\text{q}\rightarrow\text{col})}) \tag{17}$$

$$\mathbf{h}_j^{\text{op}} = \tanh(\mathbf{W}_0^{\text{op}}\mathbf{h}_j^{\text{col}} + \frac{1}{r}\sum_{k=1}^{r}\mathbf{W}_{k,t_k}^{\text{op}}\mathbf{h}_{j,k}^{(\text{q}\rightarrow\text{col})}) \tag{18}$$

where $\mathbf{W}_0^{\text{cond}}, \mathbf{W}_{k,t_k}^{\text{cond}}, \mathbf{W}_0^{\text{op}}, \mathbf{W}_{k,t_k}^{\text{op}} \in \mathbb{R}^{d\times 2h}$ for $k = 1, 2, \ldots, r$ are model parameters. It is important to note here that k determines the distance of value context to `VALUE` and t_k indicates its tag, effectively making the fusion layers above *tag* and

---

distance specific. The rest of the model exactly follows the Eq. from 11 through 15 with the same training objective and inference schemes.

5 Experiments

In this section, we discuss the details of the experiments and present our main results.

5.1 Training Details

For training our neural networks, we only keep the words appearing at least 3 times in the whole training data and the rest of the words are replaced with `UNK` token. Word embeddings are initialized with pretrained GloVe (Pennington et al., 2014) vectors[2], and updated during the training. We take the dimension of word embeddings and the size of LSTM hidden layer both equal to 100. The model parameters are optimized using Adam (Kingma and Ba, 2015) with batch size of 32 and a decaying learning rate starting with 0.001. We apply gradient clipping to 5 when its norm exceeds this value. We use early stopping based on the model accuracy on the development set. We report our results with a model snapshot achieving the best accuracy on the development set. Our models are implemented in *tensorflow* (Abadi et al., 2016). The code is available at `https://github.com/semihyavuzz/sql_master`.

Table 5: Full query-match (QM) accuracy. For SqlMaster, we combine our WHERE clause predictions with the SELECT and AGGREGATE clause predictions of SQLNet. QM result for TypeSql + TC (w/o Freebase) is not reported.

5.2 Main Results

In Table 4, we present our main results in comparison with the related works. Baseline refers to a baseline for our models where the `WHERE` clause accuracy is computed by assuming that each candidate $(\texttt{COLUMN}, \texttt{VALUE})$ pair is included with corresponding `OP` being equality. On the other hand, UpperBound accuracy is computed by assuming f_{cond} and f_{op} makes 100% correct mapping of whether to include a candidate $(\texttt{COLUMN}, \texttt{VALUE})$ pair and which `OP` to apply on this condition. In other words, errors in UpperBound exist due to wrong candidate generation.

As shown in Table 4, our models surpass the previous results by a large margin as well as its variants improving upon each other. A portion of these improvements definitely come from assuming and using the table itself as the optimal external knowledge. Acknowledging this fact, we make the following more important conclusions from Table 4, 5, and 6: (i) Comparison of the performance results across scenarios (SqlNet vs. SqlMaster or TypeSql) reveals that there is a large room for improvement when an external knowledge base is used, (ii) Comparison of our own models with its variants demonstrates that each component/extension incorporated brings a considerable performance improvement, justifying its potential power to be used in other related NLP tasks, (iii) Comparing our models with SqlNet and TypeSql+TC within our scenario provides further clues/justifications towards effectiveness of our proposed Tree-Based model, (iv) SqlMaster performs comparably to TypeSql + TC (Yu et al., 2018) on WHERE condition predictions despite the fact that we do not use Freebase, which is exploited in (Yu et al., 2018) to identify named entities of certain Freebase types (e.g., *person*, *place*, *country*, *organization*, *sport*), (v) Our SqlMaster (Tree-Based) + VA model achieves 88.6% on test portion of WikiSQL, which almost reaches the upper bound of 91.4%, demonstrating a great promise for future work in this do-

main, and finally (vi) When the performance of our model is compared to SQLNET over the categories as shown in Table 6, we observe that it consistently improves the performance of over all the categories, but most noticeably on EXTERNAL KNOWLEDGE and AMBIGUOUS ones which were the main categories inspiring this work and proposed approaches motivated by the analysis provided in Section 3.

Evaluation in Our Scenario. We adapt SQLNet (Xu et al.) results to our scenario via a post-processing step as follows: For each of their predicted condition in `WHERE` clause, if column c and operator o are both correct, but value v is wrong, then we replace this value with the one in our generated candidates that maps to the column c when the mapping is unique (only one value maps to c).

5.3 Error Analysis

In this section, we provide an error analysis of our models to better understand what are the remaining challenges to achieve UPPERBOUND performance. To this end, we analyzed 100 randomly sampled examples from development set on which our best model fails. 41% of these errors are due to our models not being able to perform a good semantic understanding of the value context. 36% of the errors correspond to ambiguous questions that lack sufficient information to disambiguate between correct and wrong column. A good representative example for this category is "*Who was the director of king's speech?*", where our model predicts "*winner and nominees*" column for the condition value "*king's speech*" while the correct column is "*original title*". The remaining 18% and 5% of the errors are caused by sparsity of column names and wrong labelling problems, respectively.

6 Related Work

Research on natural language interfaces to databases (NLIDBs) and semantic parsing has spanned several decades. Early rule-based NLIDBs (Woods, 1973; Androutsopoulos et al., 1995; Popescu et al., 2003) employ carefully designed rules to map natural language questions to formal representations like SQL queries. While having a high precision, rule-based systems are brittle when facing with language variations and usually only admit inputs from a restricted vocabulary. The rise of statistical models (Zettlemoyer and Collins, 2005; Kate et al., 2005; Berant et al., 2013) and neural network models (Yih et al., 2015; Dong and Lapata, 2016; Sun et al., 2016; Zhong et al., 2017; Xu et al.) has enabled NLIDBs that are more robust to language variations. Such systems allow users to formulate questions with greater flexibility instead of having to probe and adapt to the boundary of rule-based systems.

Along with the advance in modeling is the development of benchmarks for training and testing NLIDB models. Early benchmarks are mostly curated by experts (Zelle and Ray, 1996; Zettlemoyer and Collins, 2007). State-of-the-art models (Dong and Lapata, 2016) have achieved a high accuracy of 80% to 90% on these benchmarks. In the recent years, a number of large-scale, crowd-sourced benchmarks have been constructed with the goal to train and test NLIDBs in a more real-world setting, notably WebQuestions (Berant et al., 2013) and GraphQuestions (Su et al., 2016) for knowledge bases, and WikiSQL (Zhong et al., 2017) for SQL queries to relational databases. The best accuracies on these benchmarks are still far from enough for real use, typically in the range of 20% to 60%.

Besides releasing WikiSQL, Zhong et al. (2017) propose an approach (Seq2SQL) to solve this task. Seq2SQL leverages the pointer-networks (Vinyals et al.) to generate linearized SQL queries token-by-token using the input question and table schema. They report significant performance improvement over (Dong and Lapata, 2016), a generic sequence-to-tree approach proposed for semantic parsing. More recently, Xu et al. propose a sketch-based sequence-to-set approach (SQLNet) eliminating sequence-to-sequence structure employed in (Zhong et al., 2017), when the order does not matter. In our work, we provide a careful analysis of SQLNet results to better understand the limitations of this model on the WikiSQL task. Inspired by this analysis, we propose novel solutions to realize close to upper-bound condition accuracy in the scenario where SQL table is available as an optimal external knowledge. Another recent work (Yu et al., 2018) also focuses on using external knowledge (Freebase) along with the table content to generate SQL queries in a type aware fashion. A concurrent line of related work exploits graph-to-sequence neural models with the aim to better exploit syntactic information in the input question (Xu et al., 2018a,b). On the other hand, Gur et al. (2018) takes an orthogonal approach and introduces a dialogue-based query refinement mechanism where a candidate SQL query (generated by any black-box model) is refined by interactively validating and updating modular segments of the query with users. The authors show that by having successful interactions with users, not only the accuracy of the candidate queries can be improved but also new insights into limitations of current query generation systems can be gained.

There are also a number of recent studies on semantic parsing for semi-structured tables. For example, Pasupat and Liang (2015) develop the WikiTableQuestions benchmark, where the task is to find table cells in HTML table to answer questions, while Jauhar et al. (2016) focus on multi-choice questions. On the other hand, Sun et al. (2016) study how to answer user questions with table cells from millions of HTML tables. These studies directly find cells of semi-structured tables as answers, instead of generating SQL queries for relational databases.

7 Conclusion

In this paper, we thoroughly analyzed the recently released WikiSQL dataset and the performance breakdown of SQLNet. Through the analysis, we identified an opportunity/need to further explore the potentials of incorporating external knowledge in the structured query generation process. In this direction, we developed alternative solutions to explore the potential performance limits for this task in the scenario where table content can be used. We showed that our proposed systems can reach up to 88.6% accuracy in condition generation and provided a discussion regarding what the remaining challenges were through an error analysis. We consider solving the WikiSQL task as a necessary preliminary step towards realizing natural language interfaces to databases in full fledge.

Better Transition-Based AMR Parsing with a Refined Search Space

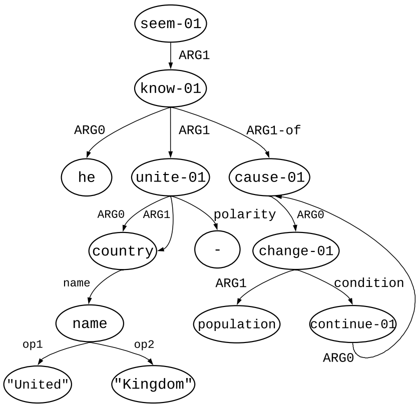
Abstract

This paper introduces a simple yet effective transition-based system for Abstract Meaning Representation (AMR) parsing. We argue that a well-defined search space for a transition system is crucial for building an effective parser. We propose to conduct the search in a refined search space based on a new compact AMR graph and an improved oracle. Our end-to-end parser achieves the state-of-the-art performance on various datasets with minimal additional information.[1]

1 Introduction

Abstract Meaning Representation (AMR) (Banarescu et al., 2013) is a formalism that captures the semantics of a sentence with a rooted directed graph, in which nodes represent the *concepts* and edges represent the *relations* between concepts. An example AMR graph together with its corresponding sentence are illustrated in Figure 1.

AMR parsing, the task of transforming a sentence into its AMR graph, is a challenging task as it requires the parser to learn to predict not only concepts, which consist of predicates, lemmas, named entities, wiki-links and co-references, but also a large number of relation types based on relatively sparse training data (Peng et al., 2017). Given the challenges, many state-of-the-art AMR parsers employ various external resources and adopt a pipeline approach (Flanigan et al., 2016; Wang and Xue, 2017; Foland and Martin, 2017; van Noord and Bos, 2017). Recently, Damonte et al. (2016); Ballesteros and Al-Onaizan (2017); Peng et al. (2018) have successfully developed AMR parsers in an end-to-end fashion using a transition-based approach.



It seems that he knows under the population changes (if it continues) that United Kingdom will not unite.

Figure 1: An example AMR graph for a sentence.

The transition-based approach (Yamada and Matsumoto, 2003; Nivre, 2003, 2004) has been popular among many NLP tasks, including syntactic parsing (Zhang and Clark, 2011; Chen and Manning, 2014), named entity recognition (Lample et al., 2016), and semantic parsing (Cheng et al., 2017). Different from the graph-based approach for structured prediction (e.g., conditional random fields (Lafferty et al., 2001)), such an approach is able to maintain a good balance between efficiency and accuracy (Nivre and McDonald, 2008), and has achieved state-of-the-art results on a number of tasks (Swayamdipta et al., 2016; Shi et al., 2017; Cheng et al., 2017).

While the transition-based approach is promising for AMR parsing, existing transition-based AMR parsers still cannot attain the state-of-the-art results on such a task. We observe that the key to the development of an effective transition-based system is a properly defined search space, and argue that the search space used in existing transition systems needs to be refined. Inspired by (Wang et al., 2015), we design a new compact AMR graph representation. Transition actions designed based on such a compact graph enable our parser to generate the target structure with fewer actions and to better capture the correspondence

---

[1] Dynet (Neubig et al., 2017) is used to implement our parser. We make the supplementary material and code available at `http://statnlp.org/research/sp`

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1712–1722
Brussels, Belgium, October 31 - November 4, 2018.

between concepts and tokens in the sentence.

Oracle, the algorithm used at the training time for specifying the action sequence that can recover the gold AMR graph, is also crucial for the transition-based system. A good oracle will be able to teach the parser how to find a proper path in the search space. The oracle requires alignment information between words and concepts. We identify limitations associated with current practice for finding such alignment information, and propose a new approach that integrates both rules and unsupervised learning.

Experiments show that our system that makes use of POS tags as the only external resource performs competitively on benchmark datasets. To the best of our knowledge, the parser achieves the highest score on the standard LDC2014T12 dataset. Our parser also yields competitive scores on the LDC2015E86 dataset and the more recent LDC2017T10 dataset. On the popular newswire section of LDC2014T12 dataset, our parser outperforms the previous best system by around 3 points in terms of F_1 measure.

2 Related Work

Since the AMR graph encodes rich information, it has been explored for many downstream applications such as language generation (Song et al., 2016), information extraction (Huang et al., 2016) and machine comprehension (Sachan and Xing, 2016). Currently, most parsers can be categorized into 4 classes: 1) *Tree*: such approaches incrementally convert a dependency tree into its corresponding AMR graph (Wang et al., 2015; Goodman et al., 2016; Barzdins and Gosko, 2016); 2) *Graph*: the graph-based models calculate scores of edges and then use a maximum spanning connected subgraph algorithm to select edges that will constitute the graph (Werling et al., 2015; Flanigan et al., 2016); 3) *Seq2seq*: the models adapted from sequence-to-sequence (Sutskever et al., 2014) methods (Peng et al., 2017; Konstas et al., 2017); 4) *Transition*: the transition-based methods, whose input is the plain text sentence and the output is the corresponding graph (Zhou et al., 2016; Damonte et al., 2016; Ballesteros and Al-Onaizan, 2017; Peng et al., 2018).

Apart from these models, Peng et al. (2015) introduce a synchronous hyperedge replacement grammar solution. Pust et al. (2015) regard the task as a machine translation problem, while Artzi et al. (2015) adapt combinatory categorical grammar (Steedman and Baldridge, 2011) for it. Foland and Martin (2017) decompose the parsing task into many subtasks. Then they use multiple bidirectional LSTMs for identifying different types of concepts and relations and iteratively combine these components to form the AMR graph.

Because the mapping between AMR concepts and tokens in the input sentence is latent, external aligners have been developed for training purpose. The most popular aligner is JAMR (Flanigan et al., 2016), which greedily aligns input tokens to graph fragments by using a static template. Another aligner is ISI (Pourdamghani et al., 2014), which is a statistical approach that borrows techniques from statistical machine translation.

3 Approach

We adopt a transition-based approach for AMR parsing. We first propose a new compact representation for AMR graph. Based on our new representation, we further present a novel technique for constructing the action sequence used for training our model. As we will see later, both newly introduced techniques are crucial for building an improved transition-based system within our refined search space.

3.1 Compact AMR Graph

Inspired by (Wang et al., 2015), we design a representation called *compact AMR graph* to simplify concepts and relations of an AMR graph, which makes the learning of our transition system easier. The construction of our compact AMR graph involves removing concepts and relations from an original AMR graph.

Remove Concepts: First we categorize AMR concepts into 2 types:

- **Lexical**: concepts which are converted directly from tokens in the sentence into certain expressions ranging from predicates with sense tags, lemmas to tokens with quotation marks. One example is the concept seem-01 shown in Figure 1, which is converted from the token *seems* with 01 as the sense tag.
- **Non-Lexical**: concepts which are invoked by their child concepts rather than from tokens in the sentence directly. Examples include country and name in Figure 1.[2]

A non-lexical concept is invoked by its child concepts, while a lexical concept corresponds to

---

[2] A list of non-lexical concepts are provided in the supplementary material.

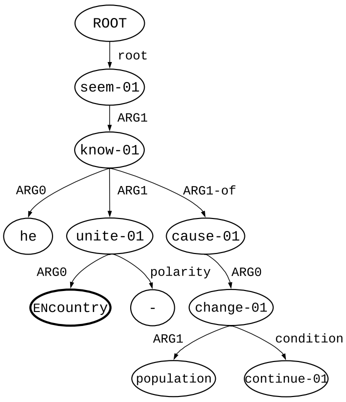


Figure 2: The compact AMR graph for the example in Figure 1.

a certain token in the input sentence. Inspired by (Lu et al., 2008) which learns a semantic parser by aligning words and semantic units, we compress a subgraph rooted by a non-lexical concept into a new concept, which directly corresponds to a contiguous span in the sentence.

For example, a subgraph that consists of non-lexical concepts: country, name and lexical concepts "United", "Kingdom" in Figure 1 can be compressed into one non-lexical concept ENcountry, which can be aligned to the span *"United Kingdom"* in the input sentence as shown in Figure 2.

Removing concepts in the graph enables the parser to build it with fewer actions. Empirically we find that 9% fewer actions are required in LDC2015E86 on average. Also, all concepts can be invoked by a contiguous span in the sentence, which helps the parser to capture the correspondence between concepts and tokens better.

Remove Relations: We also refine the search space by eliminating certain relations in the original AMR graph. The number of relation types is relatively large in the AMR corpus, which leads to a large search space. In order to introduce *reentrancy*[3], attached concepts have to stay in the stack rather than being removed as in most of transition-based AMR parsers.

Take cause-01 shown in the Figure 1 as an example, which is a reentrancy node headed by know-01 and continue-01. After it has been attached to its parent know-01 and child change-01, it still needs to stay in the stack and wait for another relation headed by continue-01. These two concepts are potentially far away from each other in the input sentence, which means cause-01 has to stay in the stack for a long time. In general, the longer a word has to wait to get assigned the more opportunities there are for something to go awry (Manning and Schütze, 1999).

During the testing phase, the parser does not know whether cause-01 is a reentrancy node. Therefore, the parser needs to add all possible relation attachment actions (nearly half of the action space) into the valid action set as long as cause-01 exists in the stack, which makes the parser harder to train.

Thus, we define several properties that the compact graph should respect to further refine the search space[4]:

- **Acyclicity**: cycles are forbidden. The relation ARG0 between cause-01 and continue-01 shown in Figure 1 is removed in the compact AMR graph Figure 2.
- **Simple**: for each parent-child concept pair, only one relation is attached. There exist two relations ARG0 and ARG1 between concepts unite and country shown in Figure 1. One of them is removed in Figure 2.
- **Non-terminal restricted**: only a subset of concepts are allowed to have children. For example, lexical concept – in Figure 1 can only be a terminal node in the compact AMR graph, which means that it can be removed from the stack once it has been attached.
- **Reentrancy restricted**: reentrancy is forbidden for certain concepts, which means these concepts only have one parent concept. An example is that lexical concepts – cannot be reentrancy in the compact AMR graph.

After incorporating these constraints, relation attachment actions are forbidden at many states, which refines the search space. Even though such constraints might prevent us from generating some valid AMR graphs, in practice we can convert the compact AMR graph back to the AMR graph without much loss[5].

3.2 Oracle

Another key to successful search is the oracle, an algorithm that produces a sequence of actions that lead to the gold AMR graph. The action sequence generated by the oracle is significant as it tells

---

[3] One concept can participate in multiple relations as concept country in Figure 1.

[4] In practice, we impose constraints on the valid action set of the parser for each state to ensure the growing structure always respect these properties. Details are provided in supplementary material.

[5] 95% of graphs in the training set of LDC2015E86 dataset satisfy these constraints, which means no relation needs to be removed for most of the graphs.

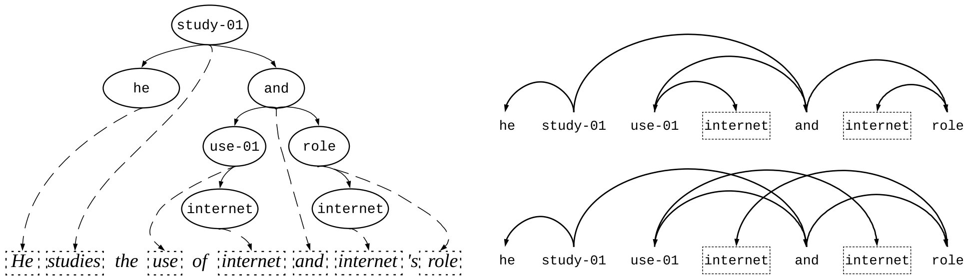

Figure 3: An alignment example for a sentence that has two identical tokens *internet* and the relation arcs between concepts if we put them on a semi-plane.

the model which actions should be taken during training. The oracle requires, as input, the alignment between tokens in the sentences and concepts in the graph. Almost all prior transition-based parsers have used the JAMR aligner for identifying such alignment information. However, we find that the JAMR aligner suffers from two issues, which may lead to errors that may be propagated to the parser through the oracle.

Non-Projectivity Caused by Alignment Error: Consider a sentence that has two identical tokens–*internet*. Figure 3 illustrates the alignments between concepts and tokens. Since our parser predicts the concepts from left to right, we can draw edges between aligned concepts on a semi-plane to verify whether it has crossing arcs.

If the alignment is correct, the AMR graph is projective as shown at the top right of Figure 3. However, the JAMR is a rule-based aligner, which uses a set of heuristics to do fuzzy matching. Its matching mechanism tends to make mistakes when there exist multiple identical words. Such alignment errors may lead to crossing arcs that our parser may not be able to handle.

Assume an alignment error occurs as illustrated in the bottom right of Figure 3. Such an error will force the parser to attach relations between wrong concepts. Sometimes these concepts are far from each other, which potentially leads to more crossing arcs. For example, ARG1 is attached to the wrong internet, causing the undesired crossing arc.

Empty Alignments:Another issue is that as the corpus gets larger, the JAMR aligner yields more empty alignments as shown in Table 3. Since the set of matching rules is static, unseen patterns in a larger corpus may result in sub-optimal alignment information.

Hybrid Aligner: In order to address these issues, we first try the ISI aligner (Pourdamghani et al., 2014). According to preliminary results (Table 3), we find that the performance of such an unsupervised model is not as good as the JAMR aligner when aligning relation and non-lexical concepts. Therefore, we propose a hybrid aligner, which combines unsupervised learning and rule-based strategy[6].

JAMR does not consider information about the structure whereas the unsupervised models can capture *locality* (Wang and Xue, 2017) – the assumption that words that are adjacent in the source sentence tend to align to words that are closer in the target sentence (Vogel et al., 1996). Structural information can also be incorporated into the model to allow it to capture locality beyond linearity (Wang and Xue, 2017). This property of the unsupervised aligner can alleviate the problem of non-projectivity caused by alignment error. Similar to what is done in the JAMR aligner, we also design rules based on properties of AMR graphs to improve alignments of non-lexical concepts.

In the preprocessing stage of the hybrid aligner, we remove all relations. As non-lexical concepts can be aligned to their child concepts in the compact graph, we then remove all non-lexical concepts. Our unsupervised method is based on IBM word alignment models (Brown et al., 1993).

In the postprocessing stage, we align non-lexical concepts iteratively to the same span that its child concepts are aligned to. For example, non-lexical concepts country and name shown in Figure 1 are removed in preprocessing. During postprocessing, their alignments come from child concepts “United” and “Kingdom”, they are aligned to the 16th token *“United”* and the 17th token *“Kingdom”* respectively. Therefore, non-lexical concepts country and name can be aligned to the span 16-17, which is *“United Kingdom”*.

3.3 Transition System

The transition system consists of a stack S containing words that have been processed, a buffer

---

[6] Details of the rules and how to apply them in the hybrid aligner are provided in the supplementary material.

Action	$State_t \rightarrow State_{t+1}$
SHIFT	$(S, u\|B) \rightarrow (u\|S, B)$
REDUCE	$(u\|S, B) \rightarrow (S, B)$
RIGHTLABEL(r)	$(u\|S, v\|B) \rightarrow (g_r(u, v, r)\|S, v\|B)$
LEFTLABEL(r)	$(u\|S, v\|B) \rightarrow (u\|S, g_r(v, u, r)\|B)$
SWAP	$(u, v\|S, B) \rightarrow (v, u\|S, B)$
MERGE	$(u\|S, v\|B) \rightarrow (S, g_m(u, v)\|B)$
PRED(n)	$(S, u\|B) \rightarrow (S, n\|B)$
ENTITY(ℓ)	$(S, u\|B) \rightarrow (S, g_\ell(u, \ell)\|B)$
GEN(n)	$(S, u\|B) \rightarrow (S, u, n\|B)$

Table 1: Definition of actions. $(u|S)/(u, v|S)$: item u (or u, v) is at the top of the stack. g_r, g_m and g_ℓ represent composition functions described in Section 4.3.

B containing words to be processed. Initially, S_1 is empty and B_1 contains the whole input sentence and a end-of-sentence symbol at the end. Execution ends on time step t such that B_t is empty and S_t contains a single structure.

Motivated by (Henderson et al., 2013; Ballesteros and Al-Onaizan, 2017), we design 9 types of actions summarized in Table 1. An example for parsing a sentence into its compact AMR graph shown in Figure 4 is provided in Table 2.

- **SHIFT**: removes an item from the front of the buffer and pushes it to the stack.
- **REDUCE**: pops the item on top of the stack.
- **RIGHTLABEL(r)**: creates a relation arc from the item on top of the stack to the item at the front of the buffer. Since these two items are not removed, they can be attached by another relation arc in the future. Therefore, reentrancy is allowed.
- **LEFTLABEL(r)**: creates a relation in the reverse direction as RIGHTLABEL.
- **SWAP**: swaps the top two items on the stack. This action allows non-projective relations (Nivre, 2009) and helps to introduce reentrancy. Repetitive SWAP actions are disallowed to avoid infinite swapping.
- **PRED(n)**: predicts the predicate and lemma concepts corresponding to the item at the front of the buffer. This action requires a look-up table M generated during the training phase. For example, *meet* is mapped to concepts such as meet, meet-01 and meet-02 in M. If the token *meet* is at the front of the buffer, then we add all its corresponding concepts based on M to the valid action sets.
- **MERGE**: removes the item at the front of the buffer and the item on top of the stack, then a composition function is applied to merge them into a new item. The item will be pushed back to the front of the buffer. This action serves to generate non-lexical concepts, whose corresponding span is larger than two. For example, if *"Iftik"* is on top of the stack and *"Ahmed"* is at the front of the buffer, a MERGE action will be applied. This action can be applied recursively if the span is larger than two.
- **ENTITY(ℓ)**: pops the item at the front of the buffer, and labels it with an entity label. This action is designed for named entities in non-lexical concepts. For example, after merging *"Iftik"* and *"Ahmed"*, ENTITY(ENperson) will be used to label the item.
- **GEN(n)**: creates a non-lexical concept invoked by the item at the front of the buffer, which can be any type of concept or composed representation after MERGE transition. Then the non-lexical concept is pushed back to the buffer right after the item. This action can be applied recursively. An example is that concept have-org-role-91 is invoked by *official*. If token *official* is at the front of the buffer, GEN(have-org-role-91) will be applied.

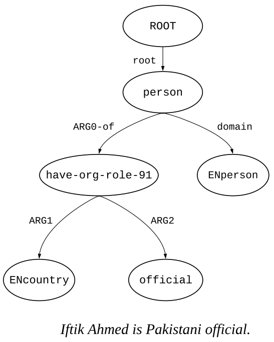

Figure 4: An example sentence with its compact AMR graph.

4 Stack LSTMs

A classifier is required to decide which action to take at each time step, given the current state.

4.1 Stack LSTMs for AMR parsing

Stack LSTMs (Dyer et al., 2015) are LSTMs (Hochreiter and Schmidhuber, 1997) that allow stack operations. Using stack LSTMs, each state can be represented using the contents of the stack, buffer and a list with the history of actions.

Let $\mathbf{s}_t$, $\mathbf{b}_t$ and $\mathbf{a}_t$ denote the summaries of stack, buffer and the history of actions at time step t respectively. The parser state $\mathbf{y}_t$ is given by:

$$\mathbf{y}_t = \max\{\mathbf{0}, \mathbf{W}[\mathbf{s}_t; \mathbf{b}_t; \mathbf{a}_t] + \mathbf{d}\} \quad (1)$$

Table 2: Example action sequence for parsing the sentence: *Iftik Ahmed is Pakistani official.* Here *$* is the end-of-sentence symbol.

where $\mathbf{W}$ is a learned parameter matrix, and $\mathbf{d}$ is a bias term. To learn a better representation, we apply the attention mechanism (Bahdanau et al., 2014) to the words the buffer contains. After getting the representation, we can use it to compute the probability of the next action:

$$p(z|\mathbf{y}_t) = \frac{\exp(g_{z_t}^{\top}\mathbf{y}_t + q_{z_t})}{\sum_{z' \in \mathcal{A}} \exp(g_{z'}^{\top}\mathbf{y}_t + q_{z'})} \quad (2)$$

where g_z is a vector representing the embedding of the action z and q_z is a bias term. The set $\mathcal{A}$ represents the valid action set in each time step. This set varies for different parsing states due to the constraints we made for the compact AMR graph.

4.2 Representations and UNK strategy

Following (Dyer et al., 2015), we concatenate three vector representations: pretrained word vector (Ling et al., 2015), learned word vector and learned vector for the POS tag, followed by a linear map to get the representation of each input token. For relation label representations and generated concepts, we simply use the learned embedding of the parser action that was applied to construct the relation.

Dyer et al. (2015) show that these representations can deal flexibly with out-of-vocabulary (OOV) words[7]. We extend this UNK strategy to AMR parsing. Apart from stochastically replacing (with $p = 0.2$) each singleton in the training data, we also replace the original PRED(n) as PRED(*UNK*) if the token should be selected as a concept. At the postprocessing stage, if an AMR concept is generated by PRED(*UNK*) we will use its lemma form for nouns or the most frequent sense for verbs to replace the "UNK" placeholder. This strategy makes the classifier trained not only to predict whether an OOV word should be selected as an AMR concept but also to predict the correct concept for the in-vocabulary word.

4.3 Composition Functions

We use recursive neural networks (Socher et al., 2013) to compute the representations of partially constructed structures.

For relation attachments, a composition function g_r is used to combine representations of AMR parent concept ($\mathbf{h}$), child concept ($\mathbf{d}$) and the corresponding relation label ($\mathbf{r}$) as:

$$g_r(\mathbf{h}, \mathbf{d}, \mathbf{r}) = \tanh(\mathbf{U}_r[\mathbf{h}; \mathbf{d}; \mathbf{r}] + \mathbf{b}_r) \quad (3)$$

where $\mathbf{U}_r$ and $\mathbf{b}_r$ are parameters in the model, as $\mathbf{U}_m$, $\mathbf{b}_m$, $\mathbf{U}_\ell$ and $\mathbf{b}_\ell$ in equation (4) and (5).

For generated non-lexical concepts, if terminal concepts are lexical concepts as shown in Figure 4 we will use a composition function g_m to get their ($\mathbf{c}_1$ and $\mathbf{c}_2$) merged representation:

$$g_m(\mathbf{c}_1, \mathbf{c}_2) = \tanh(\mathbf{U}_m[\mathbf{c}_1; \mathbf{c}_2] + \mathbf{b}_m) \quad (4)$$

---

[7] Both OOV words in the parsing data and OOV words in the pretraining language model can be represented.

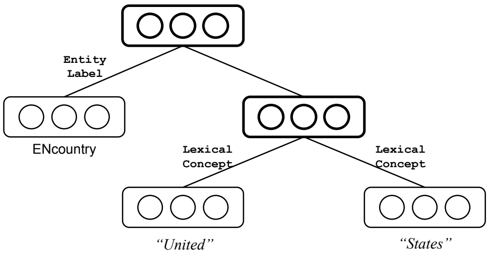

Figure 5: Example of a partial structure rooted by a non-lexical concept. *"United"* and *"States"* are merged by g_m. Then g_ℓ is applied to combine the merged representation and the label representation of ENcompany to arrive at the final representation.

Next, another composition function g_ℓ is applied to get the representation of the labeled generated concept ($\mathbf{e}$ and its entity label $\mathbf{l}$):

$$g_\ell(\mathbf{e}, \mathbf{l}) = \tanh(\mathbf{U}_\ell[\mathbf{e}; \mathbf{l}] + \mathbf{b}_\ell) \qquad (5)$$

5 Experiments and Results

We first evaluate the effectiveness of our hybrid aligner. Then we report the final results by incorporating it into our parser. We conduct experiments on the datasets LDC2014T12, LDC2015E86 and LDC2017T10. The newswire section of LDC2014T12 is popular so we also report the performance on it. All AMR parsing results are evaluated by using Smatch (Cai and Knight, 2013).

5.1 Aligner Evaluation

As the hybrid aligner is designed to tackle non-projectivity caused by alignment error and null alignment, our experiments focus on these aspects.

Non-Projectivity Issue: From Table 3, we find that the percentage of graphs that our hybrid aligner cannot recover is significantly less on these datasets when compared to the use of the JAMR and ISI aligners. We find that the percentage drops less on LDC2017T10. The reason behind this is that many AMR concepts do not have alignments (11.1%) if we use JAMR aligner. The probability of crossing arcs drops owing to the decrease of identified concepts. The ISI aligner shares the same issue. It yields the lowest crossing arcs rate since lots of concepts are not aligned.

Empty Alignment Issue: On the other hand, our hybrid aligner yields less empty alignments. This potentially helps our parser to achieve better performance, since it predicts lexical concepts solely relying on the look-up table generated by the aligner. If we do not have alignment between a certain token and its concept on the training set, the parser is less likely to predict that token as a concept during the testing phase.

Dataset	Aligner	F_1(%)	CR(%)	Null(%)
2014N	JAMR	92.70	14.4	5.1
	Hybrid	**96.12**	**8.8**	**2.0**
2014	JAMR	89.99	16.9	7.0
	Hybrid	**95.27**	**10.5**	**2.6**
2015	JAMR	86.23	16.5	8.9
	Hybrid	**93.05**	11.9	**2.9**
	ISI	71.92	**3.4**	20.1
2017	JAMR	84.41	13.6	11.1
	Hybrid	**92.69**	10.2	**3.4**
	ISI	75.31	**3.2**	18.2

Table 3: Alignment results evaluation. F_1 indicates the final score obtained by the action sequence generated by the aligner during training process. CR(%) indicates the portion that the parser cannot handle because of non-projectivity. Null(%) indicates the percentage of AMR concepts that are not aligned. As the ISI alignments did not include in the LDC2014T12, we can not compare on this dataset.

Improvements on these two aspects allow the aligner to yield better action sequences for the purposes of training our parser. From Table 3, we can see that if we follow the action sequence generated by the hybrid aligner, our parser will achieve a higher Smatch score consistently. Improvement gain gets larger as the corpus gets larger.

5.2 Parser Evaluation

Then we evaluate our parser on the same datasets. As illustrated in Table 4, most models incorporate additional features such as dependency trees, named entities, non-lexical role labels and external corpora. As stack LSTMs use POS tags to get the representation of the input, our parser does not use external resources other than POS tags obtained by using NLTK (Loper and Bird, 2002). We also try to evaluate our parser by removing the POS tags. The performance drops around 1.2 F_1 points on average. POS tags help the parser to select the correct sense when PRED action is applied.

Comparison with other parsers: Currently, all state-of-the-art models either have a relatively high complexity or adopt a pipeline approach. Wang and Xue (2017) incorporate a module called Factor Concept Labels consisting of Bi-LSTMs and CNN based on CAMR (Wang et al., 2016). Another popular parser is JAMR (Flanigan et al., 2016). The relation identification stage of JAMR has the complexity of $O(|V|^2 \log |V|)$, where $|V|$ is the number of concepts. RIGA (Barzdins and Gosko, 2016) is an ensemble system that combines CAMR and seq2seq model. Johnson et al. (2018) view AMR graph as the structure *AM alge-*

Table 4: Comparison with other parsers on LDC2014T12, LDC2015E86 and LDC2017T10 datasets. 2014N refers to the newswire section of LDC2014T12. We categorize parsers based on their types as discussed in Section 2. We also list down the features used by each system. POS: POS tags; DEP: dependency trees; NER: named entities; SRL: semantic role labels. Other features include: Word (WordNet for concept identification), GIGA (20M unlabeled Gigaword), and Silver (100k additional training pairs created by using CAMR and JAMR). "JAMR aligner" indicates that the parser is trained by action sequence generated by the JAMR aligner. "no UNK strategy" shows results without our UNK strategy. "no compact AMR graph" shows results without constraints on the compact AMR graph. Following several previous work, we also report standard deviation for the full model.

bra defined in (Groschwitz et al., 2017). Since *AM algebra* can be viewed as dependency trees over the sentence, they can train a dependency parser to map the sentence into this structure. Different from the structure used in CAMR (Wang et al., 2015), this structure can be directly transformed to AMR graph by using postprocessing rather than relying on another transition-based system. The complexity of their projective decoder is $O(n^5)$, where n is the length of the sentence. Zhou et al. (2016) is also a transition-based parser, which adopts and improves beam search strategy. In contrast, our system does not use a beam, but we anticipate improved results when a beam is used.

For seq2seq models, they generally require less features and build the AMR graph in an end-to-end way. However, these models usually suffer from data sparsity issue (Peng et al., 2017). In order to address this issue, these models utilize external corpora. Konstas et al. (2017) achieves 62.1 score by using 20M unlabeled Gigaword sentences for paired training. van Noord and Bos (2017) use an additional training corpus of 100k sentences called Silver generated by an ensemble system consisting of JAMR and CAMR parsers. Without training on this additional dataset, the performance of their model is 64.0 on LDC2015E86.

Our end-to-end parser has *linear* time complexity and it exhibits competitive results on the datasets with only POS tags as additional features. Foland and Martin (2017) only use named entities as an external resource and they report the second highest F_1 on LDC2015E86. Their system also adopts a pipeline approach. The concept identification phase requires 5 different LSTMs to discover different kinds of concepts based on carefully designed features. Then they connect these components into a single graph. Unlike previous work, the very recent work by Lyu and Titov (2018) treat the alignments as latent variables in a joint probabilistic model, which improves the parsing performance substantially. They report the highest scores on LDC2015E86 and LDC2017T10 datasets. Their parser requires 5 different BiLSTMs for concept identification, alignment prediction, relation identification and root identification. Though our parser constructs the AMR graph in an end-to-end fashion, it can achieve 68.7 and 69.8 Smatch score respectively on the same test set with a simple architecture.

Table 5: Detailed results for the LDC2015E86 and LDC2017T10 test set. W'15 is Wang et al. (2015)'s parser. F'16 is Flanigan et al. (2016)'s parser, D'16 is Damonte et al. (2016)'s parser. V'18 is Vilares and Gómez-Rodríguez (2018)'s parser. J'18 is Johnson et al. (2018)'s parser. vN'17 is van Noord and Bos (2017)'s parser with 100K additional training pairs. L'18 is Lyu and Titov (2018)'s parser.

In order to investigate how our parser performs on predicting *Named Entities*, *Reentrancies*, *Concepts*, *Negations*, etc, we also use the fine-grained evaluation tool (Damonte et al., 2016) and compare to systems which reported these scores. The results are shown in Table 5. We obtain relatively high results for *Concepts*, *Named Entities* and *Wikification*. Also, we achieve good performance on reentrancy identification though we remove many reentrant edges during training. This indicates that the compact AMR graph encodes necessary information. On the other hand, our model does not perform so well on predicating *Negations*. We believe one reason is that our parser is a word-level model. It is hard for it to capture morphological features such as prefixes "un", "in", "il", etc. We anticipate better performance when the character-based representations are used.

Does the compact AMR graph help: In order to better investigate the effect of different modules used in the parser, we also evaluate our parser by removing certain modules. Because our transition system is built based on the compact AMR graph, we could not evaluate the parser by isolating this representation completely. Therefore, we choose to remove some constraints defined on the compact AMR graph to investigate its effect. We can see that our representation improves the performance of our parser on three datasets, which indicates that a refined search space is beneficial to our system. When our parser is trained on the action sequence generated by the JAMR aligner as previous models, it still achieves a competitive score especially on the newswire section.

Impact of the hybrid aligner: Experiments also illustrate that the hybrid aligner consistently helps our parser. When we train our parser by using the action sequence generated by the JAMR aligner, we still achieve competitive results on the newswire section. However, the performance drops as the corpus gets larger. The largest drop occurs when we apply the parser on LDC2017T10, on which correct senses of predicates cannot be selected for many unseen words. We hypothesize that it is because the quality of alignment degrades as the corpus gets larger, which prevents the parser from learning how to find a good path in the search space during training. The hybrid aligner can alleviate this issue by generating a look-up table that has broader coverage. After incorporating the hybrid aligner, our parser achieves the best results of 68.3 on the full test set of LDC2014T12.

6 Conclusion and Future Work

We present a novel transition-based system which refines the search space. Experiments show that our parser is able to achieve state-of-the-art performance with a simple architecture and minimal additional resources. We believe our end-to-end system is helpful in practical settings. In the future, we would also like to investigate if it is possible for alignments to be treated as latent variables, which can be learned in a joint manner within the current framework.

Acknowledgments

We would like to thank the anonymous reviewers for their thoughtful comments. We would also like to thank Zhiyang Teng, Zhanming Jie, Bailin Wang, Aldrian Obaja Muis, Miguel Ballesteros, Swabha Swayamdipta, Bill Yuchen Lin and Yujian Wu for their helpful suggestions. Abstract

Depending on the surrounding context, an idiomatic expression may be interpreted figuratively or literally. This paper proposes an unsupervised learning method for recognizing the intended usages of idioms. We treat the possible usages as a latent variable in probabilistic models and train them in a linguistically motivated feature space. Crucially, we show that distributional semantics serves as a helpful heuristic for formulating a *literal usage metric* to estimate the likelihood that the idiom is intended literally. This information can then guide the unsupervised training process for the probabilistic models. Experiments show that our overall model performs competitively against supervised methods.

1 Introduction

Many idiomatic expressions may be interpreted both figuratively or literally. Their intended usages depend on how they fit with their contexts. For example, the idiom ”spill the beans” is used figuratively in the first instance below, and literally in the second:

> *(1)* [fig.] *The* ***beans have been spilled****. From what I've read on Twitter I could probably fill out the forms and submit it to the FISA court. I don't know what the big secret is.*[1]
>
> *(2)* [lit.] ***Spill the beans****, flip the fruit, bust open a box of hot pockets. Make a general mess of the kitchen.*[2]

This type of ambiguity is commonplace – prior work suggests that about half out of a sample of 60 idioms have a clear literal meaning as well as a figurative one (Fazly et al., 2009). Being able to distinguish the intended usage of an idiom in context has been shown to benefit many natural language processing (NLP) applications, e.g., machine translation and sentiment analysis (Salton et al., 2014; Williams et al., 2015).

While supervised models for idiom usage recognition have had some successes, they require appropriately annotated training examples (Peng et al., 2014; Byrne et al., 2013; Liu and Hwa, 2017). A more challenging problem is to recognize idiom usages without a dictionary or some annotated examples (Korkontzelos et al., 2013). Some previous unsupervised models tried to exploit linguistic differences in usages. For example, Fazly et al.(2009) observed that an idiom appearing in its canonical form is usually used figuratively; Sporleder and Li(2009) relied on the break in lexical coherence between the idioms and the context to signal a figurative usage. These heuristics, however, are not always applicable because the distinctions they depend upon may not be present or obvious. To improve generalization across different idioms and usage contexts, we need a more reliable heuristic, and appropriately incorporate it into an unsupervised learning framework.

We propose a heuristic that differentiates usages based on distributional semantics (Harris, 1954; Turney and Pantel, 2010). Our key insight is that when an idiom is used literally, its relationship with its context is more predictable than when it is used figuratively. This is because the literal meaning of an idiom is compositional (Katz and Giesbrecht, 2006), and the constituent words that make up the idiom are also meant literally. For example, in instance (2), *spill* is meant literally and can take on objects other than *beans*; moreover, one of the context words, *mess*, can often be seen to co-

occur with *spill* in other text, even without *beans*. Our strategy is to represent an idiom's literal usage in terms of the word embeddings of the idiom's constituent words and other words they frequently co-occur with. Then, for any instance in which the idiom's usage is not known, we only need to determine the semantic similarity between that instance and the idiom's literal representation. We define a *literal usage metric* that estimates the likelihood that an instance would be labeled ”literal”.

While the literal usage metric captures the distributional semantic information of the context, we find that some other linguistic cues are also significant for usage detection (such as whether the subject of the sentence is a person); therefore, we allow our model to further refine through unsupervised methods. Specifically, we treat the usage (*figurative* or *literal*) as a hidden variable in probabilistic latent variable models, and we define a set of features that are linguistically relevant for idiom usage detection as observables. We integrate our literal usage metric with the latent variable models by treating the metric outputs as *soft labels* to guide the latent variable models toward grouping by usages.

We hypothesize that unsupervised learning in a more linguistically motivated feature space, informed by soft labels from a semantically driven metric, will produce more robust classifiers. We conduct experiments comparing our approach against other supervised and unsupervised baselines. Results suggest that our approach achieves performances that are competitive to supervised models.

2 Related Work

Despite the common perception that idioms are mainly used figuratively, many can also be meant literally. A number of models have been proposed in the literature to recognize an idiom's usages under different context. Many rely on specific linguistic property to draw a clear-cut decision boundary between literal and figurative usages. For example, Fazly et al. (2009) proposed a method that relies on the concept of *canonical form*. Based on the observation that while literal usages are less syntactically restricted, figurative usages tend to occur in a small number of canonical form(s). As shown in the examples above, however, this rule of thumb does not always hold. Sporleder and Li (2009) proposed a method by building a cohesion graph to include all content words in the context; if removing the idiom improves cohesion, they assume the instance is figurative. Later, Li and Sporleder (2009) used their cohesion graph method to label a subset of the test data with high confidence. This subset is then passed on as training data to the supervised classifier, which then labels the remainder of the dataset.

When manually annotated examples are available, supervised classifiers are effective. Rajani et al. (2014) extracted all non-stop-words in the context and used them as ”bag of words” features to train a L2 regularized Logistic Regression (L2LR) classifier (Fan et al., 2008). As local context of an idiom holds clues for discriminating between its literal and figurative usages, Liu and Hwa (2017) find that context representation also plays a significant role in idiom usage recognition. They took an adaptive approach, applying supervised ensemble learning over three classifiers based on different context representations (Peng et al., 2014; Birke and Sarkar, 2006; Rajani et al., 2014).

3 Our Approach

Given a target idiomatic expression and a collection of instances in which the idiom occurs, our proposed system (Figure 1) determines whether the idiom in each instance is meant figuratively or literally. We first build a **Literal Usage Representation** for each idiom by leveraging the distributional semantics of its constituents (Sec 3.1). Given an instance of idiom, we can determine its usage by the semantic similarity between the context of the instance and the **Literal Usage Representation**. We define a **Literal Usage Metric** to transform the semantic similarity score into soft label, i.e., an initial rough estimation of the instance's usage (Sec 3.2). Finally, we treat the soft labels as distant supervision for downstream probabilistic latent variable models, in which the usages are considered as the hidden variables and are represented over a set of features.

3.1 Literal Usage Representation

An idiom co-occurs with different sets of words depending on whether it is meant literally or figuratively. For example, when used literally, *get wind* is more likely to co-occur with words such as *rain*, *storm* or *weather*; in contrast, when used figuratively, it frequently co-occurs with *rumor* or

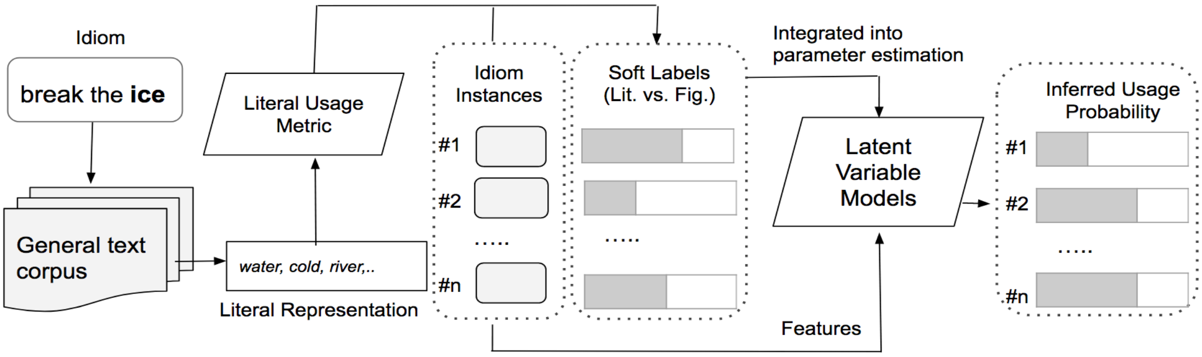

Figure 1: An overview of our unsupervised idiom usage recognition model

story, etc. Comparing the two sets of words associated with the idiom, we see that the literal set of words also tend to co-occur with just *wind*, a constituent word within the idiom. Therefore, even without annotated data or dictionary, we may still approximate a representation for the literal meaning of an idiom by the idiom's constituent words and their semantic relationship to other words. To do so, we begin by initializing a *literal meaning set* to just the idiom's main constituent words[3]; we then grow the set by adding two types of semantically related words. First, we look for co-occuring words in a large textual corpus (e.g., (David et al., 2005)): for each constituent word w, we randomly sample s sentences that contain w from the corpus; we extract the top n most frequent words (excluding stop words) and add them to the literal meaning set. Second, we look for words that are semantically close in a word embedding space: we train a continuous bag-of-words (CBOW) embedding model (Mikolov et al., 2013) and add additional t words that are the most related to w using cosine similarity.

All together, the literal usage representation is a collection of vectors, i.e., the embeddings of the words in the final extended literal meaning set. The size of the set depends on parameters s, n, and t; if the chosen values are too small, we do not end up with a word collection that is representative enough; if the numbers are too large, we would only be wasting computing resources chasing Zipfian tails. Parameter setting choices are discussed further in the experiment section.

3.2 Literal Usage Metrics

Among all the instances to be classified, we expect the context words of the literal cases to be more semantically close to the literal usage representation we just formed. Let L denote the set of words in the literal usage representation for the target idiom. For each instance, let C be the set of non-stop context words in the instance. We calculate s, the semantic similarity score between the context of the instance and the literal usage representation as follows:

$$s = \frac{1}{|C|} \sum_{c \in C} \frac{1}{|L|} \sum_{l \in L} sim(c, l) \qquad (1)$$

where c denotes a word in C, l denotes a word in L and $sim(c, l)$ refers to the cosine similarity between the word embeddings of c and l.

Let $S = \{s_1, s_2, ...s_n\}$ be the set of semantic similarity scores for all the instances we wish to classify. Instances with higher scores are more likely to use the idiom literally. A naive literal usage metrics is to choose a predefined threshold for all idioms and label all the instances with score above the threshold as literal usages. This approach is unlikely to work well in practice. As noted by previous work, idioms have different levels of **semantic analyzability** (Gibbs et al., 1989; Cacciari and Levorato, 1998). When an idiom has a high degree of semantic analyzability, its contextual words will be more semantically close to the literal usage representation, thus a higher threshold is needed.

In this work, we select a different decision threshold for each idiom adaptively based on the similarity scores distribution. And most importantly, rather than generate a hard label, we transform these scores into a probabilistic metric,

---

[3] We observe that the nouns tend to be the most indicative of the idiom's literal meaning, but if the idiom does not contain any noun, we back off to any constituent word that is not a stop word.

where 0 means the usage in the instance is almost certainly figurative while 1.0 means it is literal.

We propose a metric based on the principle of **Minimum Variance (MinV)**. That is, we first sort the scores in S and choose the threshold (from these scores) that minimizes the sum of variances of the two resulting clusters. For each instance i, we then apply the following metric to estimate the probability that the idiom in instance i is meant **literally** based on its semantic similarity score s_i :

$$Pr_i = \frac{1}{1 + e^{-k*(s_i - t)}} \tag{2}$$

where k is a constant weighting factor and t indicates the learned threshold. The intuition is that the larger the difference between s_i and the threshold is, the more likely the instance i is literal; the probability of literal usage is not linearly correlated to the difference, we use the sigmoid function to account for this non-linearity. We incorporate *k* to scale the value of the difference since it is generally very small (close to 0). Without *k*, all the Pr values gravitate toward 0.5, rendering the soft label being equivalent to random guess. We set k to 5 for all the idioms based on a development set.

3.3 Heuristically Informed Usage Recognition

The soft label, generated by MinV (the literal usage metric), captures the distributional semantic information of the context. In practice, there are a variety of other linguistic features which are also informative of the intended usage of idiom. We explore probabilistic latent variable models over a collection of features that are linguistically relevant for idiom usage detection. The soft label is integrated into the unsupervised learning of hidden usages as a distant supervision. In this section, we will describe the proposed features in the latent variable models and how we integrate the soft label into the learning process.

3.3.1 Latent Variable Models

To predict an idiom's usage in instances, we consider two representative probabilistic latent variable models: Latent Dirichlet Allocation (LDA) (Blei et al., 2003)[4] and unsupervised Naive Bayes (NB). For both models, the latent variable is the idiom usage (figurative vs. literal); the observables are linguistic features that can be extracted from the instances, described below:

Subordinate Clause We encode a binary feature indicating whether the target expression is followed by a subordinate clause (the Stanford Parser (Chen and Manning, 2014) is used). This feature is useful for some idioms such as *in the dark*. It usually suggests a figurative usage as in *You've kept us totally in the dark about what happened that night*.

Selectional Preference Violation of selectional preference is normally a signal of figurative usage (e.g., having an abstract entity as the subject of *play with fire*). We encode this feature if the head word of the idiom is a verb and focus on the subject of the verb. We apply Stanford Name Entity tagger (Finkel et al., 2005) with 3 classes ("Location", "Person", "Organization") on the sentence containing the idiom. If the subject is labeled as an Entity, its class will be encoded in the feature vector. Pronouns such as "I" and "he" also indicate the subject is a "Person". However, they are normally not tagged by Stanford Name Entity tagger. To overcome this issue, we add Part-of-Speech of the subject into the feature vector.

Abstractness Abstract words refer to things which are hard to perceive directly with our senses. Abstractness has been shown to be useful in the detection of metaphor, another type of figurative language (Turney et al., 2011). A figurative usage of an idiomatic phrase may have relatively more abstract contextual words. For example, in the sentence *She has lived life in the fast lane*, the word *life* is considered as an abstract word. This is a useful indicator that *in the fast lane* is used figuratively. We use the MRC Psycholinguistic Database Machine Usable Dictionary (Coltheart, 1981) which contains a list of 4295 words with their abstractness measure between 100 and 700. We calculate the average abstractness score for all the contextual words (with stop words being removed) in the sentence containing the idiom. The score is then transformed into categorical feature to overcome sparsity problem based on the following criteria: concrete (450 - 700), medium (350 - 450), abstract (100 - 350).

Neighboring Words Words preceding and following the idiomatic expression can be very informative in terms of usage recognition. For example, words such as *relax* or *shower* before the idiom *in hot water* often signal a literal usage.

---

[4] Although originally conceived for modeling document content, LDA can be applied to any kind of discrete input

Part-of-Speech of the Neighboring Words Class of neighboring words might be useful as well. For example, a pronoun preceding *dog's age* generally indicates a literal usage, as in *I think my dog's age is starting to catch up. She sometimes needs help to jump on to my bed*, while a determiner usually marks a figurative usage, as in *It's been a dog's age since I've used Twitter.*

3.3.2 Incorporating Soft Label into Usage Recognition

Given a collection of instances and their features, either LDA or NB can separate the instances into two groups (hopefully, by usages), but it does not associate the right label (i.e., "figurative" or "literal") to the groups. We do not want to rely on any manual annotations for this step. Therefore, we integrate the automatically generated soft labels (based on MinV, our literal usage metric) into the unsupervised learning procedure as a weak form of supervision. Formally, we want to estimate each instance's posterior distribution over (literal/figurative) usages θ_{du} and usage-feature distribution ϕ_{uf}. For LDA, we derive a Gibbs sampling algorithm which incorporates the soft label into the learning procedure. We refer it as informed Gibbs sampling (infGibbs). For unsupervised naive Bayes model, we adapt the classical Expectation-Maximization algorithm to integrate the soft label. We refer it as informed Expectation-Maximization (infEM).

Informed Gibbs Sampling The Gibbs sampling algorithm (Griffiths and Steyvers, 2004) used in traditional LDA initializes each word token a random hidden topic. The system needs to interpret the learned topics post-hoc, e.g., by human annotation. In our case, for each feature f in each instance, an initial random usage **biased** by the instance's soft label is assigned to f (i.e., a Bernoulli trial). Since the soft label explicitly encodes an instance's literal and figurative usage distribution, we do not need to interpret the learned usages at the end of the algorithm. Based on these assignments, we build a feature-usage counting matrix C^{FU} and instance-usage counting matrix C^{DU} with dimensions $|F| \times 2$ and $|D| \times 2$ respectively ($|F|$ is the feature size and $|D|$ is the number of instances): $C^{FU}_{i,j}$ is the count of feature i assigned to usage j; $C^{DU}_{d,j}$ is the count of features assigned to usage j in instance d. Then for each feature f in each instance, we resample a new usage for f and matrices C^{FU} and C^{DU} will be updated accordingly. This step will be repeated for T times. The resampling equation is:

$$p(u_i = j | u_{-i}, f) \propto p_j \cdot \frac{C^{f_i}_{-i,j} + \beta}{C^{(*)}_{-i,j} + |F|\beta} \cdot \frac{C^{d_i}_{-i,j} + \alpha}{C^{d_i}_{-i,*} + |U|\alpha} \tag{3}$$

where i indexes features in the instance d, j is an index into literal and figurative usages, $*$ indicates a summation over that dimension and $-$ means excluding the corresponding instance. The first factor p_j is the soft label encoding prior usage distribution. The second factor represents the probability of feature f under usage j ($C^{f_i}_{-i,j}$ is the count of the feature f assigned to usage j, excluding the current usage assignment u_i). The third factor represents the probability of usage j in the current instance ($C^{d_i}_{-i,j}$ is the count of linguistic features which are assigned to usage j in the current instance, excluding the current feature f). The value of $|U|$ is 2, representing the number of usages (i.e., figurative and literal). α and β are the hyper-parameters from the Dirichlet priors (we set both of them to 1). The core idea of Equation 3 is to integrate both distribution semantic information (soft label, the first factor) and linguistically motivated features (the second and third factors) into the inference procedure.

The matrices of C^{FU} and C^{DU} from the last $10\% * T$ iterations are averaged and then normalized to approximate the true usage-feature distribution ϕ_{uf} and instance-usage distribution θ_{du} respectively. The final result is determined by θ_{du}, i.e., assigning each instance with the usage of probability higher than 0.5. We do average to have a more stable result because an accidental bad sampling would affect our model negatively if we only use the C^{FU} and C^{DU} from the last iteration. This procedure is important for some idioms if their feature space is sparse. The iteration number T is set to 500 based on a development set.

Informed Expectation Maximization Combining a Naive Bayes classifier with the EM algorithm has been widely used in text classification and word sense disambiguation (Hristea, 2013; Nigam et al., 2000). In our case, we want to construct a model to recover the missing literal and figurative labels of the instances of the target idiom. This section describes two extensions to the basic EM algorithm for idiom usage recognition. The extensions help improve parameter estimation by taking the automatically learned soft labels into consideration.

Our informed EM method extends a basic version for NB (Hristea, 2013), where the initial parameter values θ_{du} and ϕ_{uf} are chosen randomly. At each iteration, the E-step of the algorithm estimates the expectations of the missing values (i.e. the literal and figurative usage) given the latest iteration of the model parameters; the M-step maximizes the likelihood of the model parameters using the previously-computed expectations of the missing values. As we've done with extending Gibbs sampling for LDA, we also perform two similar adaptations on conventional EM for NB to incorporate soft labels. First, we assign each instance an initial usage distribution θ_{du} directly using the soft label, and then initialize the usage-feature distribution ϕ_{uf} using these assignments. We refer it as informed initialization. Second, in the E-step, we multiply the expectation result of the basic EM with the soft label as the new expected usage for each instance (i.e., updating θ_{du}). The M-step is the same as basic EM to update the usage-feature distribution ϕ_{uf}.

4 Evaluation

We conduct experiments to address three questions:

1. How effective is our overall approach? How does it compare against previous work?

2. How effective is our literal usage metric (i.e., MinV) compared to other heuristics?

3. How effective is our literal usage metric at informing downstream learning processes?

4.1 Experimental Setup

Models Our main experiments will evaluate the two variants of the proposed fully unsupervised model as described in section 3: MinV+infGibbs and MinV+infEM. We report the average performance of our models over 5 runs. Performing multiple runs is necessary because we have a sampling process. They are compared with three baseline unsupervised models: Sporleder and Li (2009), Li and Sporleder (2009)[5] and Fazly et al. (2009); and two baseline supervised models: Rajani et al. (2014) and Liu and Hwa (2017) (using 5-fold cross validation).

Parameter setting Recall that in order to build the literal usage representation of an idiom, we need to sample s sentences that contain each constituent word w from an external corpus; extract from them the top n most frequently co-occurring words with w; then separately find t words that are semantically similar to w using word embeddings. To set parameters with values in reasonable ranges, we evaluated MinV on a small development set. We picked 10 idioms that are different from the evaluation set, scraped 50 instances from the web for each idiom, and labeled them ourselves. We find that $s >= 100$, n=10, and t=5 yield good results.

We use the gensim toolkit (Řehůřek and Sojka, 2010) and train our word embedding model using the continuous bag of word model on Text8 Corpus[6]. Negative sampling is applied as the training method; the min_count is set to 2. For the other parameters, we use the default settings in gensim.

Evaluative Data Our goal is to compare all the methods under two public available corpora: SemEval 2013 Task 5B corpus (Korkontzelos et al., 2013), which is used by prior supervised methods (Liu and Hwa, 2017; Rajani et al., 2014) and verb–noun combination (VNC) dataset (Cook et al., 2008), which is used by a prior unsupervised method (Fazly et al., 2009). However, there are some methods-datasets conflicts that have to be resolved. Because the idioms in the SemEval dataset are all in their canonical forms, and because the idioms are not restricted to the verb-noun combination, we cannot evaluate the method by Fazly et al. on this dataset (as their method is tailored to verb-noun combination). Some idioms from the VNC dataset are almost always used figuratively (or literally), which presents a problem for supervised methods. To facilitate full comparisons, we select the subset of idioms from the VNC corpus whose number of literal and figurative instances are both higher than 10. A summary of the two corpora is shown in Table 1. Note that each instance in SemEval corpus has about 3∼5 sentences; for consistency, we use 3 sentences as the context: the sentence with the target idiom and two neighboring sentences.

Evaluation metric Following the convention in prior works, we report the F-score for the recognition of figurative usages and the overall accuracy.

---

[5] We replace Normalized Google Distance (NGD) with word embeddings to measure the semantic relatedness between words due to the query frequency restriction on the API of NGD.

Table 1: Statistics of the two corpora

4.2 The Performance of Our Full Models

Table 2 shows the result of our models and the other comparative methods. Our proposed models show consistent performance across the two corpora, outperforming the unsupervised baselines from Sporleder and Li (2009), Li and Sporleder (2009) and the supervised model from Rajani et al. (2014). Moreover, there is no statistical significance in the F-score difference between the supervised ensemble model from Liu and Hwa (2017) and our models.

On the VNC corpus, our models have comparable average scores as that of Fazly et al. (2009); our scores are more stable across different idioms. While the method of Fazly et al. is nearly perfect for some idioms (0.98 on ”take heart”), it performs poorly for others (e.g., 0.33 on ”pull leg”). Their algorithm has trouble with idioms whose canonical and non-canonical forms can appear frequently both in literal and figurative usages.

4.3 Effectiveness of MinV

The core of our approach is MinV, the literal usage metric we developed to generate soft labels to guide the unsupervised learning. This experiment examines its effectiveness by creating usage classifications directly from it (i.e., if MinV predicts a probability of >0.5, predict ”literal”). We compare MinV against two alternative heuristics.

MinV is based on two core ideas. First, if an idiom is used figuratively, we expect to see a big difference (low similarity scores) between its context and the semantic representation of idiom’s literal usage. The idea is similar to that of Sporleder and Li (2009), but they relied on lexical chain instead of distributional semantics. Second, instead of choosing a predefined threshold to separate the raw semantic similarity scores, we select a different decision threshold for each idiom adaptively based on the distribution of the scores. So as an alternative, we compare MinV against a Fixed-Threshold heuristic that labels an instance as ”literal” if its raw score is higher than some global threshold (set to 0.346 based on development data).

In Table 3, we observe that Minv outperforms both Sporleder and Li’s model as well as Fixed-Threshold, but using MinV by itself is not sufficient. It has great fluctuations, e.g., the F-Score for individual idioms varies from 0.43 to 0.88. Recall that MinV +infGibbs has a smaller fluctuation across different idioms in Table 2. These results suggest that the subsequent learning process is effective.

Through error analysis, we find two major factors contributing to the performance fluctuation. First, the context itself could be misleading. An error case of **play ball** by MinV is:

All 10-year-old Minnie Cruttwell wants to do is play with the boys , but the ***Football Association*** *are not playing ball. She is a* ***member*** *of a mixed* ***team*** *called Balham Blazers , but the FA say she must* ***join*** *a girls’* ***team*** *when she is 12.*

The context words in bold (which are related to the word ”ball”) mislead MinV to predict a ”literal” usage when it is actually a ”figurative” usage (since an organization such as the Football Association cannot literally *play ball*). Second, not all content words in the context are relevant for distinguishing the idiom’s usage. A future direction is to prune contextual words more intelligently.

4.4 Integration of MinV into Learning

We have argued that an advantage of using a metric with a probabilistic interpretation instead of a binary class heuristic is that its scores can be incorporated into subsequent learning models as soft labels. In this set of experiments, we evaluate the impact of the metric on the learning methods. First, we consider unsupervised learning without input from the literal usage metric. We cluster the instances with the original Gibbs sampling and EM algorithms and then label the two clusters with the majority usage within the clusters. Second, we explore using the information from the literal usage metric as ”noisy gold standard” to perform supervised training on a nearest neighbors (NN) classifier. Specifically, the literal and figurative instances labeled by MinV with high confidence (top 30%) are used as example set. Then for each test instance, we calculate its cosine similarity (in feature space) to the literal and figurative example sets and assign the label of the closest set. We refer this model as MinV +NN.

		SemEval		VNC

Table 3: A comparison of classifying by different heuristics. Results are averaged across all the idioms in the two corpora.

Model	Avg. F_{fig}	Avg.Acc
Gibbs	0.58 (0.31 $\sim$ 0.78)	0.57 (0.4 $\sim$ 0.78)
EM	0.56 (0.31 $\sim$ 0.71)	0.6 (0.42 $\sim$ 0.77)
MinV+NN	0.68 (0.41 $\sim$ 0.83)	0.67 (0.55 $\sim$ 0.86)

Table 4: The performance of MinV+NN and models without soft label on all the idioms in the two corpora

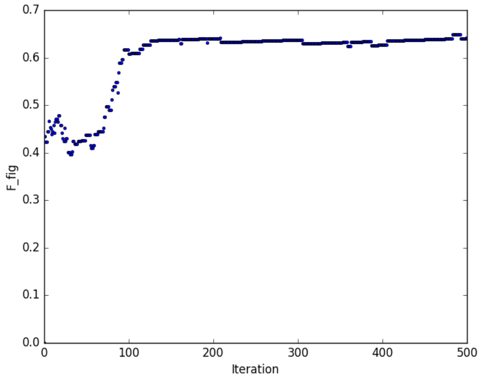

Figure 2: The performance of MinV+infGibbs on the idiom ”break a leg”

Table 4 shows the performances of the new models, which are all worse than our full models MinV +infGibbs and MinV +infEM. This highlights the advantage of integrating distributional semantic information and local features into one single learning procedure. Without the informed prior (encoded by the soft labels), the Gibbs sampling and EM algorithms only seek to maximize the probability of the observed data, and may fail to learn the underlying usage structure.

The model MinV +NN is not as competitive as our full models. It is too sensitive to the selected instances. Even though the training examples are instances that MinV is the most confident about, there are still mislabelled instances. These ”noisy training examples” would lead the NN classifier to make unreliable predictions. In contrast, our unsupervised learning is less sensitive to the performance of MinV; it can achieve a decent performance for an idiom even when the quality of the soft labels is poor. For example, when using MinV as a stand-alone model for *break a leg*, its figurative F-score is only 0.43, but through further training, the full model MinV+infGibbs achieves 0.64. Fig. 2 shows the training curve. A possible reason for this phenomenon is that the soft label is integrated into the learning process by biasing the sampling procedure (see Equation 3). We only encourage our model to follow the distributional semantic evidence captured by soft label and do not force it. So if there are strong evidences encoded by the linguistically motivated features in the instances to overcome the soft label it still has the freedom to do so.

5 Conclusion

We have presented an unsupervised method for idiom usage recognition built upon the heuristic that instances that use the idiom literally are semantically closer to constituent words of the idiom. Experimental results on two different corpora suggest that our models are competitive against supervised methods and prior unsupervised methods.

Abstract

The point of departure of this article is the claim that sense-specific vectors provide an advantage over normal vectors due to the polysemy that they presumably represent. This claim is based on performance gains observed in gold standard evaluation tests such as word similarity tasks. We demonstrate that this claim, at least as it is instantiated in prior art, is unfounded in two ways. Furthermore, we provide empirical data and an analytic discussion that may account for the previously reported improved performance. First, we show that ground-truth polysemy degrades performance in word similarity tasks. Therefore word similarity tasks are not suitable as an evaluation test for polysemy representation. Second, random assignment of words to senses is shown to improve performance in the same task. This and additional results point to the conclusion that performance gains as reported in previous work may be an artifact of random sense assignment, which is equivalent to sub-sampling and multiple estimation of word vector representations. Theoretical analysis shows that this may on its own be beneficial for the estimation of word similarity, by reducing the bias in the estimation of the cosine distance.

1 Introduction

Polysemy is a fundamental feature of natural languages, which typically have many polysemic words. *Chair*, for example, can refer to either a piece of furniture or to a person in charge of a meeting. Therefore both theoretical linguistics and computational linguistics seek to establish principled methods of identifying the senses that together constitute the meaning of words.

It is commonly assumed or claimed that standard word embeddings are unable to capture polysemy (Iacobacci et al., 2015), which results in sub-optimal performance in gold standard evaluation tests such as word similarity tasks, and potentially hamper performance in downstream tasks. The corollary assumption is that sense-specific representations will lead to improved performance on these evaluation tests. This assumption is conceptually attractive, since it makes sense that sense-specific representations are more accurate than global representations which conflate the different senses of a word into a single representation. For example, in translating 'chair,' it is reasonable that performance should improve if the two senses are represented separately. This view is supported by several studies (Huang et al., 2012; Neelakantan et al., 2014; Chen et al., 2014; Li and Jurafsky, 2015; Iacobacci et al., 2015; Mancini et al., 2017), which argue that sense-specific representations lead to improved performance in word similarity tasks.

Ideally, such claims about polysemy should be evaluated using a gold standard evaluation set that is tailored specifically for polysemous words. As this set does not exist, tasks involving word similarity tests have been used as a proxy (see Section 2). The underlying hypothesis is that enriching word vector representations with polysemic information should express itself in performance gains in these tasks. However, this hypothesis has never been tested directly, and the ability of word similarity tasks to directly benefit from polysemic information must first be validated if they are to serve as genuine evaluation sets in polysemy research. Until then, the validity of any reported positive effects of sense-specific representations on evaluation tests is to be treated with caution.

In this paper our first aim is to assess the validity of *word similarity tasks* as proper evaluation tests for polysemic word representations. We use two independent corpora in order to obtain polysemic vectors: (i) a sense-annotated corpus, and (ii) an artificially-induced annotated corpus, constructed

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1732–1740
Brussels, Belgium, October 31 - November 4, 2018.

by using an established method that we modify for our purposes. Surprisingly, our analyses show that even the most accurate sense-specific word vectors do not improve performance. In fact, peak performance is achieved when polysemic information is *ignored*, i.e., when all different annotated senses are collapsed to a single word, as they naturally appear in a text. These counter-intuitive results indicate that the word similarity tasks are not a suitable test to evaluate polysemic representations.

Although these negative results point to the inadequacy of the evaluation test, they also stress a necessary critical analysis of the sense-specific vectors. Specifically, they give rise to the following question: why might previously reported polysemic representations show superior performance in these inadequate evaluation tests?

One explanation for the reported effects may lie in an inherent property of sense-specific representations. The procedure of assigning a word occurrence to a particular sense amounts to a sampling procedure. This sampling procedure itself, regardless of its validity (whether its sense assignments are correct or not), may be the true source of the reported performance gains. To test this hypothesis, we created a control condition in which word occurrences are randomly assigned to different senses. Determining that an effect is attributable to *genuine polysemy* can only be established if a similar effect is lacking or significantly reduced in this control condition.

We demonstrate that performance gains are indeed obtained for a corpus with randomly assigned senses. In addition, we modify two models for sense-specific polysemy representation (Li and Jurafsky, 2015; Mancini et al., 2017) to randomly assign words to senses, and observe that the effect size remains unchanged between the original and random conditions.

In support of our empirical findings, we discuss the difficulty of obtaining an unbiased estimator for the cosine distance between two normalized random variable vectors. This distance is the basis of all word similarity tasks that serve to evaluate performance, and thus it may provide a partial explanation for the empirical findings, under the assumption that words are better represented as a population of vectors. Specifically, the true source of the reported performance gains may be an artifact of a purely statistical benefit that derives from the assignment of words to particular senses, or separate sub-samples, which subsequently reduces the bias of the similarity estimator.

We thus identify two independent pitfalls in NLP research on polysemy representation. First, the inadequacy of currently-used evaluation tests to properly assess polysemic representations. And second, the essence of polysemic representations, whose reported benefits might not come from polysemic information per se, but rather from other unrelated sources.

2 Background

Previous attempts to use polysemic information for enriching word representation used normal unannotated corpora, and therefore disambiguated the different senses of words before exploiting any sense-specific information. Prior art has either taken an automatic approach to detect word senses based on the statistics extracted from texts (Huang et al., 2012; Neelakantan et al., 2014; Li and Jurafsky, 2015), or relied on external lexical resources (e.g., WordNet or BabelNet) which guarantee that the detected senses are mapped to true sense distinctions in natural language (Chen et al., 2014; Iacobacci et al., 2015; Mancini et al., 2017). Importantly, both types of models report marked performance gains in evaluation tests.

This kind of approach produces (i) global vectors that represent a word's meaning as a single vector (with no subdivision into distinct senses), as well as (ii) sense-specific vectors representing individual senses of words, determined in the disambiguation step, as separate vectors. For example, such approaches would represent the meaning of *chair* as a single vector, as well as distinct vectors for each of its multiple senses, e.g., "chair (person)" and "chair (furniture)".

In order to evaluate performance, the vectors created by the models are standardly evaluated using word similarity tasks (the most common are WordSim-353 (Finkelstein et al., 2001) and Stanford's Contextual Word Similarities (SCWS) (Huang et al., 2012)). These tasks comprise pairs of words and the similarity scores assigned to them by human annotators. For example, the similarity between *table* and *chair* might be rated as 0.8 (i.e., human annotators found these words to be very similar, but not perfectly so), while the similarity between *table* and *tree* might be rated as 0.3 (not very similar). The embedding models produce similarity scores for each word pair by computing the cosine-distance between the word vectors for each pair. The model's performance is then evaluated as the rank-order similarity in the order of pairs (Spearman correlation) between the human annotators' scores and the scores produced by the model. In line with the assumption discussed above, one would predict that the rank-order similarity produced by the sense-specific vectors should outperform the one produced by the global vectors. In particular, more accurate sense-specific vectors should produce better results in these tasks; conversely, better performance on these tasks is interpreted as indicating that polysemy has been captured more accurately. We directly test these two predictions in this paper.

Computing word similarity is straightforward when each word is represented as a single vector, but it is less so when the meaning of a polysemic word is represented by multiple sense-specific vectors. This problem of *matching* the senses relevant for a specific word pair, i.e., matching the "person" sense of *chair* with the correct sense of the word *meeting*, poses a major hurdle for meaningful comparison, and has been tackled in three different ways: (i) *average* over all similarity scores between all the different possible pairs; (ii) *weighted average* over these scores according to the probability of senses assigned by the disambiguation model; or (iii) *selection* of the most suitable sense according to the disambiguation model, and using only the corresponding similarity score.

Intuitively, the third approach should outperform the others, as it is based on the clearest distinction between the relevant and non-relevant senses. However, this naïve prediction is not supported by previous studies. Rather, the best results are usually obtained for *average* and *weighted average*, followed by *global* (ignoring polysemy), while *selection* falls far behind the others. This counter-intuitive finding suggests that the observed benefit may be less related to sense disambiguation than previously supposed[1].

3 Task validation

Generally, before any task can be used as an evaluation testbed for polysemy discovery algorithms or polysemous representations, we argue that the *task* itself should be validated as suitable (or not) for the intended purpose. We propose the following **task validation** methodology: (i) Start by identifying a corpus where polysemic information is known for a significant number of words. (ii) Compute two sets of word representations: $\mathcal{A}_1$ - which computes a single representation for all words in the corpus, and $\mathcal{A}_2$ - which computes multiple representations for each polysemic word in the corpus based on the different *known* senses of the word. (iii) Evaluate the task using the two representation sets $\mathcal{A}_1$ and $\mathcal{A}_2$. Only if significant performance gains can be shown when using $\mathcal{A}_2$ as compared to $\mathcal{A}_1$, the task can be used to evaluate polysemy representation.

3.1 Polysemy induction

A major drawback of the proposed methodology is that such annotated corpora are scarce, and the largest among them are still small (OntoNotes (Weischedel et al., 2013) comprises 1.5 million words, cf. unannotated corpora (e.g. Wikipedia) which are about 1000 times larger). We therefore articulate a methodology to generate a *task validation test* from **any corpus** and **evaluation task**, even without prior annotation of polysemy, that is based on the *pseudo-words* approach (Gale et al., 1992; Pilehvar and Navigli, 2014).

More specifically, we induce polysemy in a natural corpus by pairing words, and collapsing every pair of words into a single word-form while keeping their "original identity" as *polysemy annotation*. For example *ring* and *table* may be collapsed to a single word with two senses, *table*^{1} and *table*^{2} respectively. The new corpus is polysemic with respect to the collapsed words, while all other words keep a single sense. This corpus has most of the features of a natural corpus, but unlike most natural corpora (and all large corpora), it contains polysemy annotation. Subsequently, the relevant items in the *word similarity tasks* are collapsed in the same way, making the items polysemous, and thus the tasks suitable as *validation tests*.

With these polysemy-induced corpus and word similarity tasks, we follow the methodology for *task validation* described above. Only if a model that is based on multiple representations per polysemous word leads to a significant performance gain in the task as compared to a model with single representation for each word then the task un-

---

[1] Iacobacci et al. (2015) and Mancini et al. (2017) only reported results on *selection*, for which they found performance gains. For consistent comparison with other models we report *average* (but using their code), noting that it also provides performance gains over *global* vectors.

der examination should be considered adequate to evaluate the utility of polysemy representation of word senses.

3.2 Methods

Word embedding model *word2vec-SkipGram* model (Mikolov et al., 2013) is used to obtain vector representations for words and senses. The model is separately trained over the corpus: first producing sense-specific vectors according to the annotated senses, and next producing global vectors by ignoring the annotated senses and collapsing all their occurrences to a single word. Throughout the analyses we use an embedding size of 300d, a window size of 5 words from each side of the target word, negative-sampling of 5 words, and an initial learning rate of 0.025.

Sense-annotated corpus We use OntoNotes (Weischedel et al., 2013), the largest available corpus annotated for word senses. This allows us to circumvent the problem of first disambiguating the words' senses, and thus to directly test the utility of using polysemic information in word vector representations. The corpus contains 1.5 million English tokens, comprising about 50k English word types, of which 8675 word types are sense-annotated. Because the annotation is not uniform throughout the corpus (words are not annotated every time they appear), which can bias the analysis described below, we extract a subset of the corpus by removing sentences where polysemous words are not annotated, thus removing 40% of the corpus. Stopwords as well as words occurring less than 10 times are ignored by the word embedding models. All words are lowercased.

Sense-induced corpus Wikipedia dump (04/2017) is the original corpus from which a polysemic version is induced. We separately used a list of semantically-aware pseudowords (Pilehvar and Navigli, 2013), in addition to random pairs from the 6000 most frequent words to collapse them into a single word-form (see Section 3.1). Stopwords and infrequent words (<300 tokens) are ignored by the word embedding models.

Evaluation Polysemic word representations are evaluated on the two word similarity tasks described. Crucially, the problem of *matching* the relevant sense in these tests (described in Section 2) is tackled by taking the *average* of the sense-specific representations and comparing it to the *global* word representations[2].

3.3 Results

Results clearly demonstrate that global representations are significantly superior to sense-specific representations in both evaluation tests and across corpora, as shown in Table 1 and Figure 1.

	OPTIMAL	GLOBAL	AVERAGE
WS-353			
OntoNotes		44.7	41.3
Induced Rand.	70	68.7	66.4
Induced S.A.	70	70.2	67.1
SCWS			
OntoNotes		64.0	62.6
Induced Rand.	66	64.3	55.2
Induced S.A.	66	65.9	65.7

Table 1: Word similarity scores for OntoNotes and induced-polysemy Wikipedia. OPTIMAL: performance obtained for the original Wikipedia (apply only for the induced method), GLOBAL: sense information ignored, AVERAGE: sense-specific vectors averaged. S.A. & Rand.: pairing methods for polysemy induction, semantically-aware and random, respectively.

The critical comparison between the *global* and *average* conditions is expected to show better performance for the latter under the assumption that polysemic information improves performance. This difference (marked as *actual gain* in Figure 1), surprisingly shows an opposite outcome, which means that word similarity tasks fail to demonstrate the value of polysemy representation in improving performance.

Complementarily, we report performance for the *optimal* condition. In this condition, word similarity scores are obtained for a model that was trained on the the original Wikipedia corpus (before polysemy induction), and thus represents an upper bound for the performance of any polysemy model that would be trained on an induced polysemy version of the same corpus (i.e., the maximum *ideal gain* a model can achieve over its *global* vectors). The fact that performance is highest for that condition is thus expected, and reassures us that the induced polysemy procedure has worked as planned for both kinds of induction.

Overall, our results points to a failure of polysemy models to improve performance over *global* vectors by *averaging* sense-specific vectors. This worsening in performance of the sense-specific

Color (dark and white) marks the tasks.

3.4 Discussion

The main result described above is negative, demonstrating that *word similarity tasks* are not suitable to evaluate polysemy representation. However, the methodology we proposed for *polysemy induction* constitutes a positive contribution, as it can be used to effectively test any task for its utility in the evaluation of polysemy representation while using any corpora. This may aid in finding tasks which are more suitable to serve as gold standard evaluation tests for polysemy. Moreover, the use of polysemy induction for these purposes adds yet another type of control to the NLP toolbox; such controls are scarcely implemented in NLP studies (but see Dubossarsky et al. (2017)).

Importantly, the inability of the induced polysemy models to produce positive performance gains as reported in prior art may indicate that these reported gains do not reflect benefits from true polysemy, but rather from an unknown factor that boosts performance.

4 The statistical signature of polysemy

In order to further investigate the reason for the lack of performance gains, we analyzed the properties of the sense-specific vectors in the induced polysemy conditions, and compared them to those obtained by previous studies.

We looked at the pairwise similarity between the different sense-specific representations of the same word. We start from the observation that polysemy is inherently defined by word senses that are distinguishable from each other. Importantly, we compared the models that did not produce performance gains in word similarity tasks to those which did report such gains.

4.1 Analysis and results

We tested four sets of sense-specific representations: two from our polysemy induction models (see Section 3.2) and two from Li and Jurafsky (2015)[3] and Mancini et al. (2017)[4] which reported performance gains. For each word in each set, the average cosine-distance between its different sense-specific vectors is computed. The distribution of these average distances within a specific set is defined as its ”polysemic signature”, which is then compared across sets.

The results shown in Figure 2 reveal marked differences in the polysemic signature between the four sets. A high polysemic signature is seen for the two induced polysemy sets, which are the only sets with guaranteed semantically different senses. In these sets, the polysemy model that is based on the random pairing of words has a higher polysemic signature than the one based on semantically-aware pairing. This is well expected, as semantically-aware pseudowords are designed to simulate ”true polysemy” in which the different senses of a word are still semantically related, unlike random pairing which produces a ”coarse” distinction more similar to homonymy (Pilehvar and Navigli, 2014).

The critical comparison to the two sets of polysemy models that did find performance gains

---

[3] https://github.com/jiweil/mutli-sense-embedding

[4] http://lcl.uniroma1.it/sw2v/

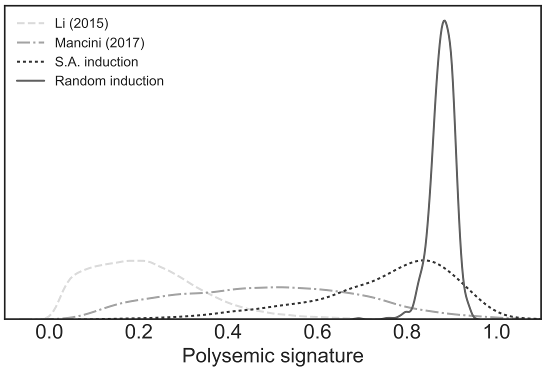

Figure 2: Density distribution of polysemic signatures for the four sets, see text for details.

shows that these models exhibit a smaller polysemic signature, as the different senses seem to be more similar to one another. Crucially, even the polysemic signature of Mancini et al. (2017), which exhibit an intermediate polysemic signature, shows greater similarity in its senses as compared to the sense-aware polysemy induction model, which presumably represents a more subtle (and ecological) model for polysemy.

4.2 Discussion

The broader implications of these results on our research hypothesis can be understood in the context of the findings reported in Section 3.3. The results described in Figure 1 demonstrate a marked difference between previously *reported gains* and the *actual gain* condition which shows a **worsening** of performance in the same task when polysemic information is included. The results demonstrated in Figure 2 can be described as a negative image of those presented in Figure 1. Specifically, the *actual gain* condition of the induced-polysemy has the largest polysemic signature as compared to the other conditions.

Together, these results indicate that the condition that demonstrates polysemy most clearly shows the poorest performance in the evaluation tests. The converse is also true: the conditions that diverge from the clearest polysemic representation show heightened performance in the evaluation tests. A gold standard for polysemy representation should entail that given optimal vector representations, performance on the evaluation tests would be optimal, and vice versa. Since our results demonstrate that the directions of optimal vector representation and optimal test performance are opposite, we are led to the following conclusions: First, polysemy models which provide improvement in word similarity tasks may not necessarily be suitable for polysemous vector representations. Second, word similarity tasks are not suitable evaluation tests for polysemy representation.

5 Theoretical discussion

In this section we recall and analyze some properties of the cosine distance, and describe how they may partially account for the empirical observations discussed in this article. The crucial point is to model the contextual representation of words as a distribution over some vector space.

Let X_i denote the random variable which captures the contextual representation of word i. Let $\{X_i^l, X_j^l \in \mathbb{R}^d\}_{l=1}^L$ denote a sample of such representations for words i, j respectively, where L denotes the sample size. d corresponds to the dimension of the vector space when using word2vec representations, or the number of words in the dictionary when using explicit representations (e.g., PPMI) (see Section 3.2). To simplify the analysis, we further assume that $\|X^l\| = 1 \; \forall l$.

The similarity between two words i, j can be plausibly measured (as customarily done) by the cosine distance between their contextual representations, namely, $\mathbb{E}\left[X_i X_j\right]$:

$$\mathbb{E}\left[X_i X_j\right] = \mathbb{E}\left[X_i\right] \mathbb{E}\left[X_j\right] + \operatorname{cov}(X_i, X_j) \quad (1)$$

Thus the average distance is not equivalent to the distance between the average representations alone, but has to include an additional bias term - $\operatorname{cov}(X_i, X_j)$ - which reflects the statistical dependence between the two vector representations X_i, X_j. This term is significant, because the contextual representation of two words is likely to exhibit strong dependence, especially when the words are more similar.

This is where the problem lies. In the process of generating words' representations, we start from a sample of sentences and generate a single representation. This representation is essentially our estimate of $\mathbb{E}\left[X_i\right]$ for word i. When multiplying two such representations in order to compute the cosine distance between them, we obtain an estimate for $\mathbb{E}\left[X_i\right] \mathbb{E}\left[X_j\right]$, which is *not* a good estimate for $\mathbb{E}\left[X_i X_j\right]$ because of the bias term in (1).

Ideally, in order to provide an unbiased estimate of $\mathbb{E}\left[X_i X_j\right]$, we should divide the sample of sentences into mini-batches, compute the appropriate contextual representation for both words

i, j from each mini-batch, and then directly estimate $\mathbb{E}[X_i X_j]$ by taking the average multiplication of the corresponding representations in each mini-batch. Interestingly, in the process of generating polysemous representations, whether relying on true polysemy or arbitrary polysemy, we essentially accomplish the same goal: for each word, a mini-batch is replaced by the subset of sentences in which only one of the word's meanings is present[5].

If sense matching (see Section 2) is achieved by way of *average* or *weighted average*, it implies that our estimate of word similarity should improve with the number of senses used in the analysis, especially when the assignment is arbitrary. Of course, any improvement is hampered by the deterioration in the quality of the contextual representation computed from the smaller mini-batch sample, and therefore improvement is only expected for a small number of real or artificial ”senses”.

6 Performance gains revisited

The empirical findings presented so far converge on the conclusion that the performance gains reported in prior art may not stem from the utility of polysemic information, as previously claimed, but are the result of an alternative source. In the theoretical discussion we argue that random sense annotation is equivalent to sub-sampling and multiple estimation of contextual vector representations, and that this alone may be beneficial for the task performance of word similarity. It is reasonable to conclude that these repeated sampling procedures may have produced the reported performance gains. Here we test this hypothesis directly.

We propose a simple control condition, in which senses are randomly assigned to words in a corpus, and sense-specific vectors are produced in the same way as before. Determining that an effect is reliably attributed to *genuine polysemy* can only be established if a similar effect is lacking or significantly reduced in this control condition.

6.1 Random sense assignment

We achieve random sense assignments in 2 ways:

Sampling from a known distribution. For the entire corpus and vocabulary (100k words, and note that Neelakantan et al. (2014) and Li and Jurafsky (2015) also took this entire vocabulary approach), we assigned senses at random from a categorical distribution under two conditions. In the first we used a uniform prior which produced equal sense probabilities for each word, and in the second condition we used a biased prior in which one sense predominates. We also experimented with different number of senses per word. We found that the results differed only slightly between the conditions and across the different number of senses. The same regular embedding model was trained as before.

Sampling from an unknown distribution. To test the hypothesis more directly against the sense distributions used in prior work, we reproduced sense-specific vectors of two models using their code: (1) for Li and Jurafsky (2015) we kept their Chinese-Restaurant-Process probabilistic mechanism, where senses are assigned to words based on the similarity of their contexts. We only shuffled the elements of the final vector of sense assignments produced by the model, and (2) for Mancini et al. (2017) we shuffled between the sense tags of each word in their original sense-annotated Wikipedia. For further comparisons we used the original code unchanged to reproduce another set of global and sense-specific vectors for each model separately to serve as a baseline.

6.2 Performance boost due to word sampling

Table 3 shows the results of these simulations. Regular embedding with random sense assignments shows marked performance gains of the sense-specific vectors over the global vectors. In fact, the effect reported in Neelakantan et al. (2014) (which report the highest score in the SCWS task, see Table 2) is replicated almost exactly, perhaps due to the fact that they also used a fixed number of senses for each word as we did in this simulation. Furthermore, the reanalysis of previous models lead to almost identical results in the original and random conditions, which means that randomly assigning words to senses does not weaken the effect.

Together, these three control simulations clearly show that an effect of the same magnitude as previously reported in several studies emerges under random sense assignment. Therefore, our findings strongly undermine the assumption that the reported effects are in any way related to actual polysemy, and strongly suggests that it is repeated sub-sampling that boosts performance.

---

[5] For the purpose of this discussion we ignore sentences in which a word appears more than once.

7 Summary and Discussion

Here we investigate the common-held view that polysemy representation improves performance. Specifically, we question the validity of word similarity tasks as a suitable evaluation test that would allow drawing such conclusions. To test the claim that resolving the polysemy of words improves performance in these tasks, as was repeatedly reported in prior art, we used real-world polysemy in two independent conditions: (i) a human sense-annotated corpus and (ii) a corpus in which polysemy was induced in a controlled artificial fashion. In both conditions, the performance in word similarity tasks *deteriorated*. We claim that this negative finding alone may suffice to determine that word similarity tasks are not suitable tests for evaluating polysemy representation.

However, if the word similarity task is inadequate to evaluate polysemy, why would it show high gains for polysemic representations as reported in many previous studies? To investigate this question we first ask whether polysemic information per se is required to drive such effects, or whether these effects are artificially caused by the procedures by which polysemous representations are created. To test this, we set out to demonstrate that even representations that bear no genuine polysemic information could nonetheless yield improved performance due to a methodological artifact. We thus created control conditions, in which we randomly assign word occurrences to senses, and found that randomly-produced sense-specific vectors indeed show marked improvements in performance. Since this effect cannot stem from polysemy (which is lacking in these conditions), it may only be the result of a methodological artifact - the sampling procedure entailed by the assignment of words to senses.

The existence of a sampling artifact is supported by our theoretical discussion, showing that multiple vector sampling can lower the bias of the estimator of the cosine distance between two vectorial random variables. The underlying assumption is that a better model for contextual word representation should employ a population of vectors. Interestingly, the conclusion that word vectors are better if constructed from multiple representations might apply to word vectors in general, and not just to sense-specific vectors. However, such a claim is outside the scope of this study and remains for future research.

This account is further supported by our *polysemic signature* analysis, which shows that the similarity between the senses in the polysemic models that produced performance gains is greater than in the models that did not produce this effect (the polysemy-induced models). This finding is in line with the sampling artifact account, as sense-specific vectors which are based on random sense assignments are expected to be more similar compared to sense-specific vectors which are based on true polysemic distinctions.

We stress that our analysis does not argue for or against the accuracy of sense-specific vectors in capturing true polysemy (other tests exist for that purpose). Instead, it focuses only on the true source of previously reported performance gains of this kind of representation, and on the validity of word similarity tasks for their evaluation.

All in all, we provide converging evidence, both experimental and theoretical, that word similarity tasks do not provide a marker for the utility of polysemic information. Rather, performance gains in word similarity tasks are an artifact of the procedure by which polysemic representations are created. These conclusions join a general skepticism expressed in the literature about the use of word similarity tasks for the evaluation of word vectors (Hill et al., 2015; Avraham and Goldberg, 2016; Batchkarov et al., 2016; Faruqui et al., 2016).

Essentially, our findings mean that there is no solid empirical foundation to the claim that polysemic information improves performance in evaluation tests. In fact, they corroborate the general impression that polysemic representation does not improve performance on most downstream tasks (Li and Jurafsky, 2015). It may be the case that sense-specific vectors can or will show heightened performance on evaluation tests, or improve downstream tasks. This, however, will have to be demonstrated on the basis of tasks whose suitability has been properly validated. Moreover, any effects reported will have to be supported by demonstrating that these effects are absent or strongly reduced in a properly articulated condition that should control for the sampling artifact.

Critically, until a reliable evaluation test exists, research on polysemic word representation is seriously hampered. In fact, a re-evaluation of past models would be in place, as both ”positive” and ”negative” results that were previously reported are in fact invalid.

Acknowledgments

We thank Matan Ben-Yosef for his invaluable contribution in executing and manipulating the code of Li and Jurafsky (2015).

Abstract

Semantic graphs, such as WordNet, are resources which curate natural language on two distinguishable layers. On the local level, individual relations between synsets (semantic building blocks) such as hypernymy and meronymy enhance our understanding of the words used to express their meanings. Globally, analysis of graph-theoretic properties of the entire net sheds light on the structure of human language as a whole. In this paper, we combine global and local properties of semantic graphs through the framework of Max-Margin Markov Graph Models (M3GM), a novel extension of Exponential Random Graph Model (ERGM) that scales to large multi-relational graphs. We demonstrate how such global modeling improves performance on the local task of predicting semantic relations between synsets, yielding new state-of-the-art results on the WN18RR dataset, a challenging version of WordNet link prediction in which "easy" reciprocal cases are removed. In addition, the M3GM model identifies multirelational motifs that are characteristic of well-formed lexical semantic ontologies.

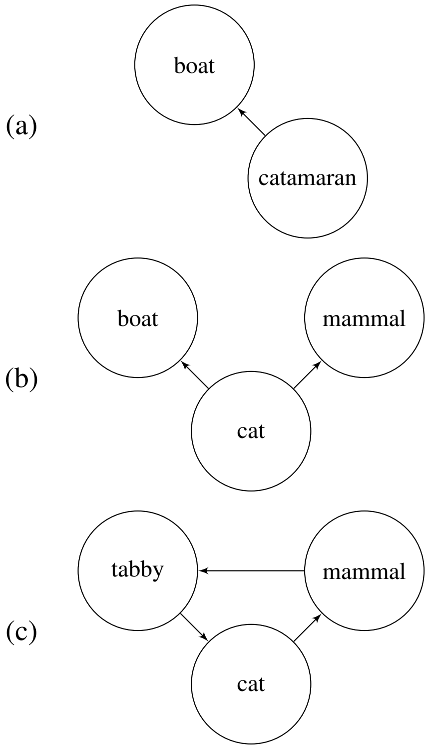

Figure 1: Probable (a) and improbable (b-c) structures in a hypothetical hypernym graph.

1 Introduction

Semantic graphs, such as WordNet (Fellbaum, 1998), encode the structural qualities of language as a representation of human knowledge. On the local level, they describe connections between specific semantic concepts, or **synsets**, through individual edges representing relations such as hypernymy ('is-a') or meronymy ('is-part-of'); on the global level, they encode emergent regular properties in the induced relation graphs. Local properties have been subject to extensive study in recent years via the task of **relation prediction**, where individual edges are found based mostly on distributional methods that embed synsets and relations into a vector space (e.g. Socher et al., 2013; Bordes et al., 2013; Toutanova and Chen, 2015; Neelakantan et al., 2015). In contrast, while the structural regularity and significance of global aspects of semantic graphs is well-attested (Sigman and Cecchi, 2002), global properties have rarely been used in prediction settings. In this paper, we show how global semantic graph features can facilitate in local tasks such as relation prediction.

To motivate this approach, consider the hypothetical hypernym graph fragments in Figure 1: in (a), the semantic concept (synset) 'catamaran' has

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1741–1751
Brussels, Belgium, October 31 - November 4, 2018.

a single hypernym, 'boat'. This is a typical property across a standard hypernym graph. In (b), the synset 'cat' has two hypernyms, an unlikely event. While a local relation prediction model might mistake the relation between 'cat' and 'boat' to be plausible, for whatever reason, a high-order graph-structure-aware model should be able to discard it based on the knowledge that a synset should not have more than one hypernym. In (c), an impossible situation arises: a cycle in the hypernym graph leads each of the participating synsets to be predicted by transitivity as its own hypernym, contrary to the relation's definition. However, a purely local model has no explicit mechanism for rejecting such an outcome.

In this paper, we examine the effect of global graph properties on the link structure via the WordNet relation prediction task. Our hypothesis is that features extracted from the entire graph can help constrain local predictions to structurally sound ones (Guo et al., 2007). Such features are often manifested as aggregate counts of small subgraph structures, known as **motifs**, such as the number of nodes with two or more outgoing edges, or the number of cycles of length 3. Returning to the example in Figure 1, each of these features will be affected when graphs (b) and (c) are evaluated, respectively.

To estimate weights on local and global graph features, we build on the **Exponential Random Graph Model** (ERGM), a log-linear model over networks utilizing global graph features (Holland and Leinhardt, 1981). In ERGMs, the likelihood of a graph is computed by exponentiating a weighted sum of the features, and then normalizing over all possible graphs. This normalization term grows exponentially in the number of nodes, and in general cannot be decomposed into smaller parts. Approximations are therefore necessary to fit ERGMs on graphs with even a few dozen nodes, and the largest known ERGMs scale only to thousands of nodes (Schmid and Desmarais, 2017). This is insufficient for WordNet, which has an order of 10^5 nodes.

We extend the ERGM framework in several ways. First, we replace the maximum likelihood objective with a margin-based objective, which compares the observed network against alternative networks; we call the resulting model the Max-Margin Markov Graph Model (M3GM), drawing on ideas from structured prediction (Taskar et al., 2004). The gradient of this loss is approximated by importance sampling over candidate negative edges, using a local relational model as a proposal distribution. The complexity of each epoch of estimation is thus linear in the number of edges, making it possible to scale up to the 10^5 nodes in WordNet.[1] Second, we address the multi-relational nature of semantic graphs, by incorporating a combinatorial set of labeled motifs. Finally, we link graph-level relational features with distributional information, by combining the M3GM with a dyad-level model over word sense embeddings.

We train M3GM as a re-ranker, which we apply to a a strong local-feature baseline on the WN18RR dataset (Dettmers et al., 2018). This yields absolute improvements of 3-4 points on all commonly-used metrics. Model inspection reveals that M3GM assigns importance to features from all relations, and captures some interesting inter-relational properties that lend insight into the overall structure of WordNet.[2]

2 Related Work

Relational prediction in semantic graphs. Recent approaches to relation prediction in semantic graphs generally start by embedding the semantic concepts into a shared space and modeling relations by some operator that induces a score for an embedding pair input. We use several of these techniques as base models (Nickel et al., 2011; Bordes et al., 2013; Yang et al., 2014); detailed description of these methods is postponed to Section 3.2. Socher et al. (2013) generalize over the approach of Nickel et al. (2011) by using a bilinear tensor which assigns multiple parameters for each relation; Shi and Weninger (2017) project the node embeddings in a translational model similar to that of Bordes et al. (2013); Dettmers et al. (2018) apply a convolutional neural network by reshaping synset embeddings to 2-dimensional matrices. None of these embedding-based approaches incorporate structural information; in general, improvements in embedding-based methods are expected to be complementary to our approach.

---

[1] Although in principle the number of edges could grow quadratically with the number of nodes, Steyvers and Tenenbaum (2005) show that semantic graphs like WordNet tend to be very sparse, so that the number of observed edges grows roughly linearly with the number of nodes.

[2] Our code is available at `http://www.github.com/yuvalpinter/m3gm`.

Some recent works compose single edges into more intricate motifs, such as Guu et al. (2015), who define a task of **path prediction** and compose various functions to solve it. They find that compositionalized bilinear models perform best on WordNet. Minervini et al. (2017) train link-prediction models against an adversary that produces examples which violate structural constraints such as symmetry and transitivity. Another line of work builds on local neighborhoods of relation interactions and automatic detection of relations from syntactically parsed text (Riedel et al., 2013; Toutanova et al., 2015). Schlichtkrull et al. (2017) use Graph Convolutional Networks to predict relations while considering high-order neighborhood properties of the nodes in question. In general, these methods aggregate information over local neighborhoods, but do not explicitly model structural motifs.

Our model introduces interaction features between relations (e.g., hypernyms and meronyms) for the goal of relation prediction. To our knowledge, this is the first time that relation interaction is explicitly modeled into a relation prediction task. Within the ERGM framework, Lu et al. (2010) train a limited set of combinatory path features for social network link prediction.

Scaling exponential random graph models. The problem of approximating the denominator of the ERGM probability has been an active research topic for several decades. Two common approximation methods exist in the literature. In **Maximum Pseudolikelihood Estimation** (**MPLE**; Strauss and Ikeda, 1990), a graph's probability is decomposed into a product of the probability for each edge, which in turn is computed based on the ERGM feature difference between the graph excluding the edge and the full graph. **Monte Carlo Maximum Likelihood Estimation** (**MCMLE**; Snijders, 2002) follows a sampling logic, where a large number of graphs is randomly generated from the overall space under the intuition that the sum of their scores would give a good approximation for the total score mass. The probability for the observed graph is then estimated following normalization conditioned on the sampling distribution, and its precision increases as more samples are gathered. Recent work found that applying a parametric bootstrap can increase the reliability of MPLE, while retaining its superiority in training speed (Schmid and Desmarais, 2017). Despite this result, we opted for an MCMLE-based approach for M3GM, mainly due to the ability to keep the number of edges constant in each sampled graph. This property is important in our setup, since local edge scores added or removed to the overall graph score can occasionally dominate the objective function, giving unintended importance to the overall edge count.

3 Max-Margin Markov Graph Models

Consider a graph $G = (V, E)$, where V is a set of vertices and $E = \{(s_i, t_i)\}_{i=1}^{|E|}$ is a set of directed edges. The ERGM scoring function defines a probability over $\mathcal{G}_{|V|}$, the set of all graphs with $|V|$ nodes. This probability is defined as a log-linear function,

$$P_{\text{ERGM}}(G) \propto \psi_{\text{ERGM}}(G) = \exp\left(\boldsymbol{\theta}^T \mathbf{f}(G)\right), \quad (1)$$

where $\mathbf{f}$ is a feature function, from graphs to a vector of feature counts. Features are typically counts of motifs — small subgraph structures — as described in the introduction. The vector $\boldsymbol{\theta}$ is the parameter to estimate.

In this section we discuss our adaptation of this model to the domain of semantic graphs, leveraging their idiosyncratic properties. Semantic graphs are composed of multiple relation types, which the feature space needs to accommodate; their nodes are linguistic constructs (semantic concepts) associated with complex interpretations, which can benefit the graph representation through incorporating their embeddings in $\mathbb{R}^d$ into a new scoring model. We then present our M3GM framework to perform reliable and efficient parameter estimation on the new model.

3.1 Graph Motifs as Features

Based on common practice in ERGM feature extraction (e.g., Morris et al., 2008), we select the following graph features as a basis:

- Total edge count;
- Number of cycles of length k, for $k \in \{2, 3\}$;
- Number of nodes with exactly k outgoing (incoming) edges, for $k \in \{1, 2, 3\}$;
- Number of nodes with **at least** k outgoing (incoming) edges, for $k \in \{1, 2, 3\}$;
- Number of paths of length 2;

- Transitivity: the proportion of length-2 paths $u \rightarrow v \rightarrow w$ where an edge $u \rightarrow w$ also exists.

Semantic graphs are multigraphs, where multiple relationships (hypernymy, meronymy, derivation, etc.) are overlaid atop a common set of nodes. For each relation r in the relation inventory $\mathcal{R}$, we denote its edge set as E_r, and redefine $E = \bigcup_{r \in \mathcal{R}} E_r$, the union of all labeled edges. Some relations do not produce a connected graph, while others may coincide with each other frequently, possibly in regular but intricate patterns: for example, derivation relations tend to occur between synsets in the higher, more abstract levels of the hypernym graph. We represent this complexity by expanding the feature space to include relation-sensitive **combinatory motifs**. For each feature template from the basis list above, we extract features for all possible combinations of relation types existing in the graph. Depending on the feature type, these could be relation singletons, pairs, or triples; they may be order-sensitive or order-insensitive. For example:

- A combinatory 'transitivity' feature will be extracted for the proportion of paths $u \xrightarrow{hypernym} v \xrightarrow{meronym} w$ where an edge $u \xrightarrow{has\_part} w$ also exists.
- A combinatory '2-outgoing' feature will be extracted for the number of nodes with exactly one *derivation* and one *has_part*.

The number of features thus scales in $O(|\mathcal{R}|^K)$ for a feature basis which involves up to K edges in any feature, and so our 17 basis features (with $K = 3$) generate a combinatory feature set with roughly 3,000 features for the 11-relation version of WordNet used in our experiments (see Section 4.1).

3.2 Local Score Component

In classical ERGM application domains such as social media or biological networks, nodes tend to have little intrinsic distinction, or at least little meaningful intrinsic information that may be extracted prior to applying the model. In semantic graphs, however, the nodes represent synsets, which are associated with information that is both valuable to predicting the graph structure and approximable using unsupervised techniques such as embedding into a common d-dimensional vector space based on copious amounts of available data. We thus modify the traditional scoring function from eq. (1) to include node-specific information, by introducing a relation-specific **association operator** $\mathcal{A}^{(r)} : V \times V \rightarrow \mathbb{R}$:

$$\psi_{\text{ERGM+}}(G) = \\ = \exp\left(\boldsymbol{\theta}^T \mathbf{f}(G) + \sum_{r \in \mathcal{R}} \sum_{(s,t) \in E_r} \mathcal{A}^{(r)}(s,t)\right). \quad (2)$$

The association operator generalizes various models from the relation prediction literature:

TransE (Bordes et al., 2013) embeds each relation r into a vector in the shared space, representing a 'difference' between sources and targets, to compute the association score under a translational objective,

$$\mathcal{A}^{(r)}_{\text{TRANSE}}(s,t) = -\|\boldsymbol{e}_s + \boldsymbol{e}_r - \boldsymbol{e}_t\|.$$

BiLin (Nickel et al., 2011) embeds relations into full-rank matrices, computing the score by a bilinear multiplication,

$$\mathcal{A}^{(r)}_{\text{BILIN}}(s,t) = \boldsymbol{e}_s^T \mathbf{W}_r \boldsymbol{e}_t.$$

DistMult (Yang et al., 2014) is a special case of **BiLin** where the relation matrices are diagonal, reducing the computation to a ternary dot product,

$$\mathcal{A}^{(r)}_{\text{DISTMULT}}(s,t) = \langle \boldsymbol{e}_s, \boldsymbol{e}_r, \boldsymbol{e}_t \rangle = \sum_{i=1}^{d} e_{s_i}\, e_{r_i}\, e_{t_i}.$$

3.3 Parameter Estimation

The probabilistic formulation of ERGM requires the computation of a normalization term that sums over all possible graphs with a given number of nodes, $\mathcal{G}_N$. The set of such graphs grows at a rate that is super-exponential in the number of nodes, making exact computation intractable even for networks that are orders of magnitude smaller than semantic graphs like WordNet. One solution is to approximate probability using a variant of the Monte Carlo Maximum Likelihood Estimation (MCMLE) produce,

$$\log P(G) \approx \log \psi(G) - \log \frac{|\mathcal{G}_{|V|}|}{M} \sum_{\tilde{G} \sim \mathcal{G}_{|V|}}^{M} \psi(\tilde{G}), \quad (3)$$

where M is the number of networks $\tilde{G}$ sampled from $\mathcal{G}_{|V|}$, the space of all (multirelational) edge sets on nodes V. Each $\tilde{G}$ is referred to as a *negative sample*, and the goal of estimation is to assign low scores to these samples, in comparison with the score assigned to the observed network G.

Network samples can be obtained using edgewise negative sampling. For each edge $s \xrightarrow{r} t$ in the training network G, we remove it temporarily and consider T alternative edges, keeping the source s and relation r constant, and sampling a target $\tilde{t}$ from a **proposal distribution** Q. Every such substitution produces a new graph $\tilde{G}$,

$$\tilde{G} = G \cup \{s \xrightarrow{r} \tilde{t}\} \setminus \{s \xrightarrow{r} t\}. \quad (4)$$

Large-margin objective. Rather than approximating the log probability, as in MCMLE estimation, we propose a margin loss objective: the log score for each negative sample $\tilde{G}$ should be below the log score for G by a margin of at least 1. This motivates the hinge loss,

$$\mathcal{L}(\mathbf{\Theta}, \tilde{G}; G) = \Big(1 - \log \psi_{\text{ERGM+}}(G) + \log \psi_{\text{ERGM+}}(\tilde{G})\Big)_+, \quad (5)$$

where $(x)_+ = \max(0, x)$. Recall that the scoring function $\psi_{\text{ERGM+}}$ includes both the local association score for the alternative edge and the global graph features for the resulting graph. However, it is not necessary to recompute all association scores; we need only subtract the association score for the deleted edge $s \xrightarrow{r} t$, and add the association score for the sampled edge $s \xrightarrow{r} \tilde{t}$.

The overall loss function is the sum over $N = |E| \times T$ negative samples, $\{\tilde{G}^{(i)}\}_{i=1}^{N}$, plus an L_2 regularizer on the model parameters,

$$\mathcal{L}(\mathbf{\Theta}; G) = \lambda ||\mathbf{\Theta}||_2^2 + \sum_{i=1}^{N} \mathcal{L}(\mathbf{\Theta}, \tilde{G}^{(i)}). \quad (6)$$

Proposal distribution. The proposal distribution Q used to sample negative edges is defined to be proportional to the local association scores of edges not present in the training graph:

$$Q(\tilde{t} \mid s, r, G) \propto \begin{cases} 0 & s \xrightarrow{r} \tilde{t} \in G \\ \mathcal{A}^{(r)}(s, \tilde{t}) & s \xrightarrow{r} \tilde{t} \notin G \, . \end{cases} \quad (7)$$

By preferring edges that have high association scores, the negative sampler helps push the M3GM parameters away from likely false positives.

4 Relation Prediction

We evaluate M3GM on the relation graph edge prediction task.[3] Data for this task consists of a set of labeled edges, i.e. tuples of the form (s, r, t), where s and t denote source and target entities, respectively. Given an edge from an evaluation set, two prediction instances are created by hiding the source and target side, in turn. The predictor is then evaluated on its ability to predict the hidden entity, given the other entity and the relation type.[4]

4.1 WN18RR Dataset

A popular relation prediction dataset for WordNet is the subset curated as WN18 (Bordes et al., 2013, 2014), containing 18 relations for about 41,000 synsets extracted from WordNet 3.0. It has been noted that this dataset suffers from considerable leakage: edges from reciprocal relations such as hypernym / hyponym appear in one direction in the training set and in the opposite direction in dev / test (Socher et al., 2013; Dettmers et al., 2018). This allows trivial rule-based baselines to achieve high performance. To alleviate this concern, Dettmers et al. (2018) released the **WN18RR** set, removing seven relations altogether. However, even this dataset retains four symmetric relation types: *also see*, *derivationally related form*, *similar to*, and *verb group*. These symmetric relations can be exploited by defaulting to a simple rule-based predictor.

4.2 Metrics

We report the following metrics, common in ranking tasks and in relation prediction in particular: **MR**, the Mean Rank of the desired entity; **MRR**, Mean Reciprocal Rank, the main evaluation metric; and **H@**k, the proportion of Hits (true entities) found in the top k of the lists, for $k \in \{1, 10\}$. Unlike some prior work, we do not type-restrict the possible relation predictions (so, e.g., a *verb group* link may select a noun, and that would count against the model).

4.3 Systems

We evaluate a single-rule baseline, three association models, and two variants of the M3GM re-

---

[3] Sometimes referred to as Knowledge Base Completion, e.g. in Socher et al. (2013).

[4] We follow prior work in excluding the following from the ranked lists: the known entity (no self loops); entities from the training set which fit the instance; other entities in the evaluation set.

ranker trained on top of the best-performing association baseline.

4.3.1 RULE

We include a single-rule baseline that predicts a relation between s and t in the evaluation set if the same relation was encountered between t and s in the training set. All other models revert to this baseline for the four symmetric relations.

4.3.2 Association Models

The next group of systems compute local scores for entity-relation triplets. They all encode entities into embeddings $\boldsymbol{e}$. Each of these systems, in addition to being evaluated as a baseline, is also used for computing association scores in M3GM, both in the proposal distribution (see Section 3.3) and for creating lists to be re-ranked (see below): **TRANSE**, **BILIN**, **DISTMULT**. For detailed descriptions, see Section 3.2.

4.3.3 Max-Margin Markov Graph Model

The M3GM is applied as a re-ranker. For each relation and source (target), the top K candidate targets (sources) are retrieved based on the local association scores. Each candidate edge is introduced into the graph, and the score $\psi_{\text{ERGM+}}(G)$ is used to re-rank the top-K list.

We add a variant to this protocol where the graph score and association score are weighted by α and $1-\alpha$, repsectively, before being summed. We tune a separate α_r for each relation type, using the development set's mean reciprocal rank (MRR). These hyperparameter values offer further insight into where the M3GM signal benefits relation prediction most (see Section 6).

Since we do not apply the model to the symmetric relations (scored by the RULE baseline), they are excluded from the sampling protocol described in eq. (5), although their edges do contribute to the combinatory graph feature vector $\mathbf{f}$.

Our default setting backpropagates loss into only the graph weight vector $\boldsymbol{\theta}$. We experiment with a model variant which backpropagates into the association model and synset embeddings as well.

4.4 Synset Embeddings

For the association component of our model, we require embedding representations for WordNet synsets. While unsupervised word embedding techniques go a long way in representing wordforms (Collobert et al., 2011; Mikolov et al., 2013; Pennington et al., 2014), they are not immediately applicable to the semantically-precise domain of synsets. We explore two methods of transforming pre-trained word embeddings into synset embeddings.

Averaging. A straightforward way of using word embeddings to create synset embeddings is to collect the words representing the synset as surface form within the WordNet dataset and average their embeddings (Socher et al., 2013). We apply this method to pre-trained GloVe embeddings (Pennington et al., 2014) and pre-trained FastText embeddings (Bojanowski et al., 2017), averaging over the set of all wordforms in all lemmas for each synset, and performing a case-insensitive query on the embedding dictionary. For example, the synset '*determine.v.01*' lists the following lemmas: 'determine', 'find', 'find_out', 'ascertain'. Its vector is initialized as

$$\frac{1}{5}(\boldsymbol{e}_{determine} + 2 \cdot \boldsymbol{e}_{find} + \boldsymbol{e}_{out} + \boldsymbol{e}_{ascertain}).$$

AutoExtend retrofitting + Mimick. AutoExtend is a method developed specifically for embedding WordNet synsets (Rothe and Schütze, 2015), in which pre-trained word embeddings are retrofitted to the tripartite relation graph connecting wordforms, lemmas, and synsets. The resulting synset embeddings occupy the same space as the word embeddings. However, some WordNet senses are not represented in the underlying set of pre-trained word embeddings.[5] To handle these cases, we trained a character-based model called MIMICK, which learns to predict embeddings for out-of-vocabulary items based on their spellings (Pinter et al., 2017). We do not modify the spelling conventions of WordNet synsets before passing them to Mimick, so e.g. '*mask.n.02*' (the second synset corresponding to 'mask' as a noun) acts as the input character sequence as is.

Random initialization. In preliminary experiments, we attempted training the association models using randomly-initialized embeddings. These proved to be substantially weaker than distributionally-informed embeddings and we do not report their performance in the results section. We view this finding as strong evidence to support the necessity of a distributional signal in a type-level semantic setup.

---

[5] We use the out-of-the-box vectors supplied in `http://www.cis.lmu.de/~sascha/AutoExtend`.

	System	MR	MRR	H@10	H@1
	Rule	13396	35.26	35.27	35.23

Table 2: Main results on test set. [†] These models were not re-implemented, and are reported as in Nguyen et al. (2018) and in Dettmers et al. (2018).

4.5 Setup

Following tuning experiments, we train the association models on synset embeddings with $d = 300$, using a negative log-likelihood loss function over 10 negative samples and iterating over symmetric relations once every five epochs. We optimize the loss using AdaGrad with $\eta = 0.01$, and perform early stopping based on the development set mean reciprocal rank. M3GM is trained in four epochs using AdaGrad with $\eta = 0.1$. We set M3GM's re-rank list size $K = 100$ and, following tuning, the regularization parameter $\lambda = 0.01$ and negative sample count per edge $T = 10$. Our models are all implemented in DyNet (Neubig et al., 2017).

5 Results

Table 1 presents the results on the development set. Lines 1-3 depict the results for local models using averaged FastText embedding initialization, showing that the best performance in terms of MRR and top-rank hits is achieved by TransE. Mean Rank does not align with the other metrics; this is an interpretable tradeoff, as both BiLin and DistMult have an inherent preference for correlated synset embeddings, giving a stronger fallback for cases where the relation embedding is completely off, but allowing less freedom for separating strong cases from correlated false positives, compared to a translational objective.

Effect of global score. There is a clear advantage to re-ranking the top local candidates using the score signal from the M3GM model (line 4). These results are further improved when the graph score is weighted against the association component per relation (line 5). We obtain similar improvements when re-ranking the predictions from DistMult and BiLin.

The M3GM training procedure is not useful in fine-tuning the association model via backpropagation: this degrades the association scores for true edges in the evaluation set, dragging the re-ranked results along with them to about a 2-point drop relative to the untuned variant.

Table 2 shows that our main results transfer onto the test set, with even a slightly larger margin. This could be the result of the greater edge density of the combined training and dev graphs, which enhance the global coherence of the graph structure captured by M3GM features. To support this theory, we tested the M3GM model trained on only the training set, and its test set performance was roughly one point worse on all metrics, as compared with the model trained on the training+dev data.

Synset embedding initialization. We trained association models initialized on AutoExtend+Mimick vectors (see Section 4.4). Their performance, inferior to averaged FastText vectors by about 1-2 MRR points on the dev set, is somewhat at odds with findings from previous experiments on WordNet (Guu et al., 2015). We believe the decisive factor in our result is the size of the training corpus used to create FastText embeddings, along with the increase in resulting vocabulary coverage. Out of 124,819 lemma tokens participating in 41,105 synsets, 118,051 had embeddings available (94.6%; type-level coverage 88.1%). Only 530 synsets (1.3%) finished this initialization process with no embedding and were assigned random vectors. AutoExtend, fit for embeddings from Mikolov et al. (2013) which were trained on a smaller corpus, offers a weaker signal: 13,377 synsets (32%) had no vector and needed Mimick initialization.

member meronym	0.67	has part	0.33
instance hypernym	0.65		

Table 5: Graph score weights found for relations on the dev set. Zero means graph score is not considered at all for this relation, one means only it is considered.

6 Graph Analysis

As a consequence of the empirical experiment, we aim to find out what M3GM has learned about WordNet. Table 3 presents a sample of top-weighted motifs. Lines 1 and 2 demonstrate that the model prefers a broad scattering of targets for the *member_meronym* and *has_part* relations[6], which are flat and top-downwards hierarchical, respectively, while line 4 shows that a multitude of unique *hypernym*s is undesired, as expected from a bottom-upwards hierarchical relation. Line 5 enforces the asymmetry of the hypernym relation.

Lines 3, 6, and 7 hint at deeper interactions between the different relation types. Line 3 shows that the model assigns positive weights to hypernyms which have derivationally-related forms, suggesting that the derivational equivalence classes in the graph tend to exist in the higher, more abstract levels of the hypernym hierarchy, as noted in Section 3.1. Line 6 captures a semantic conflict: synsets located in the lower, specific levels of the graph can be specified either as *instances* of abstract concepts[7], or as *members* of less specific concrete classes, but not as both. Line 7 may have captured a nodal property – since *part_of* is a relation which holds between nouns, and *verb_group* holds between verbs, this negative weight assignment may be the manifestation of a part-of-speech uniqueness constraint. In addition, in features 3 and 7 we see the importance of symmetric relations (here *derivationally_related_form* and *verb_group*, respectively), which manage to be represented in the graph model despite not being directly trained on.

Table 4 presents examples of relation targets successfully re-ranked thanks to these features. The first false connection created a new unique hypernym, 'garden lettuce', downgraded by the graph score through incrementing the count of negatively-weighted feature 4. In the second case, 'vienna' was brought from rank 10 to rank 1 since it incremented the count for the positively-weighted feature 2, whereas all targets ranked above it by the local model were already *has_part*-s, mostly of 'europe'.

The α_r values weighing the importance of M3GM scores in the overall function, found per relation through grid search over the development set, are presented in Table 5. It appears that for all but two relations, the best-performing model preferred the signal from the graph features to that from the association model ($\alpha_r > 0.5$). Based on the surface properties of the different relation graphs, the decisive factor seems to be that *synset_domain_topic_of* and *has_part* pertain mostly to very common concepts, offering good local signal from the synset embeddings, whereas the rest include many long-tail, low-frequency synsets that require help from global features to detect regularity.

---

[6] Example edges: 'America' → 'American', 'face' → 'mouth', respectively.

[7] Example *instance_hypernym* edge: 'Rome' → 'national capital'.

7 Conclusion

This paper presents a novel method for reasoning about semantic graphs like WordNet, combining the distributional coherence between individual entity pairs with the structural coherence of network motifs. Applied as a re-ranker, this method substantially improves performance on link prediction. Our analysis of results from Table 3, lines 6 and 7, suggests that adding graph motifs which qualify their adjacent nodes in terms of syntactic function or semantic category may prove useful.

From a broader perspective, M3GM can do more as a probabilistic model than predict individual edges. For example, consider the problem of linking a new entity into a semantic graph, given only the vector embedding. This task involves adding multiple edges simultaneously, while maintaining structural coherence. Our model is capable of scoring bundles of new edges, and in future work, we plan to explore the possibility of combining M3GM with a search algorithm, to automatically extend existing knowledge graphs by linking in one or more new entities.

We also plan to explore multilingual applications. To some extent, the structural parameters estimated by M3GM are not specific to English: for example, hypernymy cannot be symmetric in any language. If the structural parameters estimated from English WordNet are transferable to other languages, then the combination of M3GM and multilingual word embeddings could facilitate the creation and extension of large-scale semantic resources across many languages (Fellbaum and Vossen, 2012; Bond and Foster, 2013; Lafourcade, 2007).

Abstract

Adjectives like *warm*, *hot*, and *scalding* all describe temperature but differ in intensity. Understanding these differences between adjectives is a necessary part of reasoning about natural language. We propose a new paraphrase-based method to automatically learn the relative intensity relation that holds between a pair of scalar adjectives. Our approach analyzes over 36k adjectival pairs from the Paraphrase Database under the assumption that, for example, paraphrase pair *really hot* ↔ *scalding* suggests that *hot* < *scalding*. We show that combining this paraphrase evidence with existing, complementary pattern- and lexicon-based approaches improves the quality of systems for automatically ordering sets of scalar adjectives and inferring the polarity of indirect answers to *yes/no* questions.

1 Introduction

Semantically similar adjectives are not fully interchangeable in context. Although *hot* and *scalding* are related, the statement *"the coffee was hot"* does not imply the coffee was *scalding*. *Hot* and *scalding* are scalar adjectives that describe *temperature*, but they are not interchangeable because they vary in intensity. A native English speaker knows that their relative intensities are given by the ranking *hot* < *scalding*. Understanding this distinction is important for language understanding tasks such as sentiment analysis (Pang et al., 2008), question answering (de Marneffe et al., 2010), and textual inference (Dagan et al., 2006).

Existing lexical resources such as WordNet (Miller, 1995; Fellbaum, 1998) do not include the relative intensities of adjectives. As a result, there have been efforts to automate the process of learning intensity relations (e.g. Sheinman and Tokunaga (2009), de Melo and Bansal (2013), Wilkinson (2017), etc.). Many existing approaches rely on *pattern-based* or *lexicon-based* methods to predict the intensity ranking of adjectives. Pattern-based approaches search large corpora for lexical patterns that indicate an intensity relationship – for example, *"not just X, but Y"* implies $X < Y$. As with pattern-based approaches for other tasks (such as hypernym discovery (Hearst, 1992)), they are precise but have relatively sparse coverage of comparable adjectives, even when using web-scale corpora (de Melo and Bansal, 2013; Ruppenhofer et al., 2014). Lexicon-based approaches employ resources that map an adjective to a real-valued number that encodes both intensity and polarity (e.g. *good* might map to 1 and *phenomenal* to 5, while *bad* maps to -1 and *awful* to -3). They can also be precise, but may not cover all adjectives of interest.

particularly pleased	↔	*ecstatic*
quite limited	↔	*restricted*

so silly	↔	*dumb*
completely mad	↔	*crazy*

Figure 1: Examples of paraphrases from PPDB of the form $RB\ JJ_u \leftrightarrow JJ_v$ which can be used to infer pairwise intensity relationships ($JJ_u < JJ_v$).

We propose paraphrases as a new source of evidence for the relative intensity of scalar adjectives. A paraphrase is a pair of words or phrases with approximately similar meaning, such as *really great* ↔ *phenomenal*. Adjectival paraphrases can be exploited to uncover intensity relationships. A paraphrase pair of the above form, where one phrase is composed of an intensifying adverb and an adjective (*really great*) and the other is a single-word adjective (*phenomenal*), provides evidence that *great* < *phenomenal*. By drawing this evidence from large, automatically-generated

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1752–1762
Brussels, Belgium, October 31 - November 4, 2018.

paraphrase resources like the Paraphrase Database (PPDB) [1] (Ganitkevitch et al., 2013; Pavlick et al., 2015), it is possible to obtain high-coverage pairwise adjective intensity predictions at reasonably high accuracy.

We demonstrate the usefulness of paraphrase evidence for inferring relative adjective intensity in two tasks: ordering sets of adjectives along an intensity scale, and inferring the polarity of indirect answers to *yes/no* questions. In both cases, we find that combining the relatively noisy, but high-coverage, paraphrase evidence with more precise but low-coverage pattern- or lexicon-based evidence improves overall quality.

2 Related Work

Noting that adding adjective intensity relations to WordNet (Miller, 1995; Fellbaum, 1998) would be useful, Sheinman et al. (2013) propose a system for automatically extracting sets of same-attribute adjectives from WordNet 'dumbbells' – consisting of two direct antonyms at the poles and satellites of synonymous/related adjectives incident to each antonym (Gross and Miller, 1990) – and ordering them by intensity. The annotations, however, are not in WordNet as of its latest version (3.1).

Work on adjective intensity generally focuses on two related tasks: clustering adjectives based on the attributes they modify, and ranking same-attribute adjectives by intensity. With respect to the former, common approaches involve clustering adjectives by their contexts (Hatzivassiloglou and McKeown, 1993; Shivade et al., 2015). We do not focus on the clustering task in this paper, but concentrate on the ranking task.

Approaches to the task of ranking scalar adjectives by their intensity mostly fall under the paradigms of *pattern-based* or *lexicon-based* approaches. *Pattern-based* approaches work by extracting lexical (Sheinman and Tokunaga, 2009; de Melo and Bansal, 2013; Sheinman et al., 2013) or syntactic (Shivade et al., 2015) patterns indicative of an intensity relationship from large corpora. For example, the patterns "X, but not Y" and "not just X but Y" provide evidence that X is an adjective less intense than Y.

Lexicon-based approaches are derived from the premise that adjectives can provide information about the sentiment of a text (Hatzivassiloglou and McKeown, 1993). These methods draw upon a lexicon that maps adjectives to real-valued scores encoding both sentiment polarity and intensity. The lexicon might be compiled automatically – for example, from analyzing adjectives' appearance in star-valued product or movie reviews (de Marneffe et al., 2010; Rill et al., 2012; Sharma et al., 2015; Ruppenhofer et al., 2014) – or manually. In our experiments we utilize the manually-compiled SO-CAL lexicon (Taboada et al., 2011).

Our paraphrase-based approach to inferring relative adjective intensity is based on paraphrases that combine adjectives with adverbial modifiers. A tangentially related approach is Collex (Ruppenhofer et al., 2014), which is motivated by the intuition that adjectives with extreme intensities are modified by different adverbs from adjectives with more moderate intensities: extreme adverbs like *absolutely* are more likely to modify extreme adjectives like *brilliant* than are moderate adverbs like *very*. Unlike Collex, which requires predetermined sets of 'end-of-scale' and 'normal' adverbial modifiers, our approach learns the identity and relative importance of intensifying adverbs.

Relative intensity is just one of several dimensions of gradable adjective semantics. In addition to intensity scales, a comprehensive model of scalar adjective semantics might also incorporate notions of intensity range (Morzycki, 2015), adjective class (Kamp and Partee, 1995), and scale membership according to meaning (Hatzivassiloglou and McKeown, 1993). In this paper we take the position that relative intensity is worth studying on its own because it is an important component of adjective semantics, usable directly for some NLP tasks such as sentiment analysis (Pang et al., 2008), and as part of a more comprehensive model for other tasks like question answering (de Marneffe et al., 2010).

3 Paraphrase-based Intensity Evidence

Adjectival paraphrases provide evidence about the relative intensity of adjectives. A paraphrase of the form $RB\ JJ_u \leftrightarrow JJ_v$ – where one phrase is comprised of an adjective modified by an intensifying adverb ($RB\ JJ_u$), and the other is a single-word adjective (JJ_v) – is evidence that the first adjective is less intense than the second ($JJ_u < JJ_v$). We propose a new method for encoding this evidence and using it to make pairwise adjective intensity predictions. First, a graph (JJGRAPH) is formed to represent over 36k adjectival paraphrases hav-

Figure 2: Bootstrapping process for identifying intensifying adverbs. The adverbs found in Rounds 1 and 3 are used to build intensifying edges in JJGRAPH.

ing the specified form. Next, data in the graph are used to make pairwise adjective intensity predictions.

3.1 Identifying Intensifying Adverbs

In JJGRAPH, nodes are adjectives, and each directed edge ($\text{JJ}_u \underset{\text{RB}}{\longrightarrow} \text{JJ}_v$) corresponds to an adjectival paraphrase of the form (*RB* $JJ_u \leftrightarrow JJ_v$) – for example, (*very tall* ↔ *large*) – where one 'phrase' (JJ_v) is an adjective and the other (RB JJ_u) is an adjectival phrase containing an adverb and adjective (see Figure 1 for examples).

Adverbs in PPDB can be intensifying or de-intensifying. An *intensifying* adverb (e.g. *very*, *totally*) strengthens the adjectives it modifies. In contrast, a *de-intensifying* adverb (e.g. *slightly*, *somewhat*) weakens the adjectives it modifies. Since edges in JJGRAPH ideally point in the direction of increasing intensity, the first step in the process of creating JJGRAPH is to identify a set of adverbs that are likely intensifiers to be included as edges.

For this purpose, we generate a set R of likely intensifying adverbs within PPDB using a bootstrapping approach (Figure 2). The process starts with a small seed set of adjective pairs having a known intensity relationship. The seeds are pairs (j_u, j_v) from PPDB-XXL[2] such that j_u is a base-form adjective (e.g. *hard*), and j_v is its **comparative** or **superlative** form (e.g. *harder* or *hardest*). Using the seeds, we identify intensifying adverbs by finding adjectival paraphrases in PPDB of the form $(r_i j_u \leftrightarrow j_v)$; because $j_u < j_v$, adverb r_i is inferred to be intensifying (Round 1). All such r_i are added to initial adverb set R_1. The process continues by extracting paraphrases $(r_i j_{u'} \leftrightarrow j_{v'})$ with $r_i \in R_1$, indicating additional adjective pairs $(j_{u'}, j_{v'})$ with intensity direction inferred by r_i (Round 2). Finally, the adjective pairs extracted in this second iteration are used to identify additional intensifying adverbs R_3, which are added to the final set $R = R_1 \cup R_3$ (Round 3).

In all, this process generates a set of 610 adverbs. Examination of the set shows that the process does capture many intensifying adverbs like *very* and *abundantly*, and excludes many de-intensifying adverbs appearing in PPDB like *far less* and *not as*. However, due to the noise inherent in PPDB itself and in the bootstrapping process, there are also a few de-intensifying adverbs included in R (e.g. *hardly*, *kind of*) as well as adverbs that are neither intensifying nor de-intensifying (e.g. *ecologically*). It will be important to take this noise into consideration when using JJGRAPH to make pairwise intensity predictions.

3.2 Building JJGRAPH

JJGRAPH is built by extracting all 36,756 adjectival paraphrases in PPDB of the specified form, where the adverb belongs to R. The resulting graph has 3,704 unique adjective nodes. JJGRAPH is a multigraph, as there are frequently multiple intensifying relationships between pairs of adjectives. For example, the paraphrases (*pretty hard* ↔ *tricky*) and (*really hard* ↔ *tricky*) are both present in PPDB. There can also be contradictory or cyclic edges in JJGRAPH, as in the example depicted in the JJGRAPH subgraph in Figure 3, where the adverb *really* connects *tasty* to *lovely* and vice versa. Self-edges are allowed (e.g. (*really hard* ↔ *hard*)).

3.3 Pairwise Intensity Prediction

Examining the directed adverb edges between two adjectives j_u and j_v in JJGRAPH provides evidence about the relative intensity relationship between them. However, it has just been noted that JJGRAPH is noisy, containing both contradictory/cyclic edges and adverbs that are not uniformly intensifying. Rather than try to eliminate cycles, or manually annotate each adverb with a weight corresponding to its intensity and polarity

---

[2] PPDB comes in six increasingly large sizes from S to XXXL; larger collections have wider coverage but lower precision. Our work uses XXL.

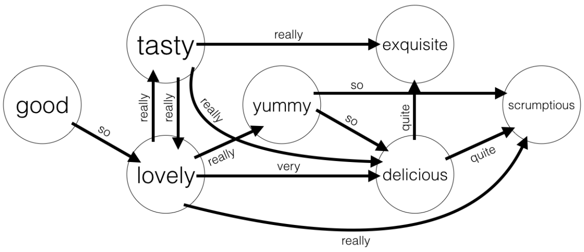

Figure 3: A subgraph of JJGRAPH, depicting its directed graph structure.

(Ruppenhofer et al., 2015; Taboada et al., 2011), we aim to learn these weights automatically in the process of predicting pairwise intensity.

Given adjectives (j_u, j_v), we build a classifier that outputs a score from 0 to 1 indicating the predicted likelihood that $j_u < j_v$. Its binary features correspond to adverb edges from j_u to j_v and from j_v to j_u in JJGRAPH. The feature space includes only adverbs from R that appear at least 10 times in JJGRAPH, resulting in features for $m = 259$ unique adverbs in each direction (i.e. from j_u to j_v and vice versa) for $2m = 518$ binary features total. Note that while all adverb features correspond to predicted intensifiers from R, there are some features that are actually de-intensifying due to the noise inherent in the bootstrapping process (Section 3.1).

We train the classifier on all 36.7k edges in JJGRAPH, based on a simplifying assumption that all adverbs in R are indeed intensifiers. For each adjective pair (j_u, j_v) with one or more direct edges from j_u to j_v, a positive training instance for pair (j_u, j_v) and a negative training instance for pair (j_v, j_u) are added to the training set. A logistic regression classifier is trained on the data, using elastic net regularization and 10-fold cross validation to tune parameters.

The model parameters output by the training process are in a feature weights vector $w \in \mathbb{R}^{2m}$ (with no bias term) which can be used to generate a paraphrase-based score for each adjective pair:

$$score_{\text{pp}}(j_u, j_v) = \frac{1}{1 + \exp^{-wx_{uv}}} - 0.5 \qquad (1)$$

where x_{uv} is the binary feature vector for adjective pair (j_u, j_v). The decision boundary 0.5 is subtracted from the sigmoid activation function so that pairs predicted to have the directed relation $j_u < j_v$ will have a positive score, and those predicted to have the opposite directional relation will have a negative score. Pairs with no connecting edges in JJGRAPH score 0.

4 Other Intensity Evidence

Our experiments compare the proposed paraphrase approach with existing pattern- and lexicon-based approaches.

4.1 Pattern-based Evidence

We experiment with the pattern-based approach of de Melo and Bansal (2013). Given a pair of adjectives to be ranked by their intensity, de Melo and Bansal (2013) cull intensity patterns from Google *n*-Grams (Brants and Franz, 2009) as evidence of their intensity order. Specifically, they identify 8 types of *weak-strong* patterns (e.g. *“X, but not Y”*) and 7 types of *strong-weak* patterns (e.g. *“not X, but still Y”*) that are used as evidence about the directionality of the intensity relationship between adjectives. Given an adjective pair (j_u, j_v), an overall pattern-based *weak-strong* score is calculated:

$$score_{\text{pat}}(j_u, j_v) = \frac{(W_u - S_u) - (W_v - S_v)}{\text{count}(j_u) \cdot \text{count}(j_v)} \qquad (2)$$

where W_u and S_u quantify the pattern evidence for the *weak-strong* and *strong-weak* intensity relations respectively for the pair (j_u, j_v), and W_v and S_v quantify the pattern evidence for the pair (j_v, j_u). W_u and S_u are calculated as:

$$\begin{aligned} W_u &= \frac{1}{P_1} \sum_{p_1 \in P_{ws}} \text{count}(p_1(j_u, j_v)) \\ S_u &= \frac{1}{P_2} \sum_{p_2 \in P_{sw}} \text{count}(p_2(j_u, j_v)) \end{aligned} \qquad (3)$$

W_v and S_v are calculated similarly by swapping the places of j_u and j_v. For example, given pair (*good*, *great*), W_u might incorporate evidence from patterns *“good, but not great”* and *“not only good but great”*, while S_v might incorporate evidence from the pattern *“not great, just good”*. P_{ws} denotes the set of *weak-strong* patterns, P_{sw} denotes the set of *strong-weak* patterns, and P_1 and P_2 give the total counts of all occurrences of any pattern in P_{ws} and P_{sw} respectively. The score is normalized by the frequencies of j_u and j_v in order to avoid bias due to high-frequency adjectives. As with the paraphrase-based scoring mechanism (Equation 1), scores output by this method can be positive or negative, with positive scores being indicative of a *weak-strong* relationship from j_u to j_v. Note that $score(j_u, j_v) = -score(j_v, j_u)$.

4.2 Lexicon-based Evidence

We use the manually-compiled SO-CAL[3] lexicon as our third, lexicon-based method for inferring intensity. The SO-CAL lexicon assigns an integer weight in the range $[-5, 5]$ to 2,826 adjectives. The sign of the weight encodes sentiment polarity (positive or negative), and the value encodes intensity (e.g. *atrocious*, with a weight of -5, is more intense than *unlikable*, with a weight of -3). SO-CAL is used to derive a pairwise intensity prediction for adjectives (j_u,j_v) as follows:

$$score_{\text{socal}}(j_u, j_v) = |L(j_v)| - |L(j_u)|, \quad \text{iff sign}(j_u) = \text{sign}(j_v) \tag{4}$$

where $L(j_v)$ gives the lexicon weight for j_v. Note that $score_{socal}$ is computed only for adjectives having the same polarity direction in the lexicon; otherwise the score is undefined. This is because adjectives belonging to different half scales, such as *freezing* and *steaming*, are frequently incomparable in terms of intensity (de Marneffe et al., 2010).

4.3 Combining Evidence

While the pattern-based and lexicon-based pairwise intensity scores are known to be precise but low-coverage (de Melo and Bansal, 2013; Ruppenhofer et al., 2015), we expect that the paraphrase-based score will produce higher coverage at lower accuracy. Thus we also experiment with scoring methods that combine two or three score types. When combining two metrics **x** and **y** to generate a score for a pair (j_u, j_v), we simply use the first metric **x** if it can be reliably calculated for the pair, and back off to metric **y** otherwise. More formally, the combined score for metrics **x** and **y** is given by:

$$\begin{aligned} score_{\text{x+y}}(j_u, j_v) &= \alpha_{\text{x}} \cdot g_{\text{x}}(score_{\text{x}}(j_u, j_v)) \\ &+ (1 - \alpha_{\text{x}}) \cdot g_{\text{y}}(score_{\text{y}}(j_u, j_v)) \end{aligned} \tag{5}$$

where $\alpha_{\text{x}} \in \{0, 1\}$ is a binary indicator corresponding to the condition that $score_{\text{x}}$ can be reliably calculated for the adjective pair, and $g_{\text{x}}(\cdot)$ is a scaling function (see below). If $\alpha_{\text{x}} = 1$, then $score_{\text{x}}$ is used. Otherwise, if $\alpha_{\text{x}} = 0$, then we default to $score_{\text{y}}$. When combining three metrics x, y, and z, the combined score is given by:

$$\begin{aligned} score_{\text{x+y+z}}(j_u, j_v) &= \alpha_{\text{x}} \cdot g_{\text{x}}(score_{\text{x}}(j_u, j_v)) \\ &+ (1 - \alpha_{\text{x}}) \cdot score_{\text{y+z}}(j_u, j_v) \end{aligned} \tag{6}$$

The criteria for having $\alpha_{\text{x}} = 1$ varies depending on the metric type. For pattern-based evidence (**x**='pat'), $\alpha_{\text{x}} = 1$ when adjectives j_u and j_v appear together in any of the intensity patterns culled from Google *n*-grams (e.g. "j_u, but not j_v" exists). For lexicon-based evidence (**x**='socal'), $\alpha_{\text{x}} = 1$ when both j_u and j_v are in the SO-CAL vocabulary, and have the same polarity (i.e. are both positive or both negative). For paraphrase-based evidence (**x**='pp'), $\alpha_{\text{x}} = 1$ when j_u and j_v have one or more edges directly connecting them in JJGRAPH.

Since the metrics to be combined may have different ranges, we use a scaling function $g_{\text{x}}(\cdot)$ to make the scores output by each metric directly comparable:

$$g_{\text{x}}(w) = \text{sign}(w) \cdot \left(\frac{\log(|w|) - \mu_{\text{x}}}{\sigma_{\text{x}}} + \gamma_{\text{x}} \right) \tag{7}$$

where μ_{x} and σ_{x} are the estimated population mean and standard deviation of $\log(score_{\text{x}})$ (estimated over all adjective pairs in the dataset), and γ_{x} is an offset equal to at least $5\sigma_{\text{x}}$.

5 Ranking Adjective Sets by Intensity

The first experimental application for the different paraphrase evidence is an existing model for predicting a global intensity ordering within a set of adjectives. Global ranking models are useful for inferring intensity comparisons between adjectives for which there is no explicit evidence. For example, in ranking three adjectives like *warm*, *hot*, and *scalding*, there may be direct evidence indicating *warm* < *hot* and *hot* < *scalding*, but no way of directly comparing *warm* to *scalding*. Global ranking models infer that *warm* < *scalding* based on evidence from the other adjective pairs in the scale.

5.1 Global Ranking Model

We adopt the mixed-integer linear programming (MILP) approach of de Melo and Bansal (2013) for generating a global intensity ranking. This model takes a set of adjectives $A = \{a_1, \ldots, a_n\}$

---

[3] `https://github.com/sfu-discourse-lab/SO-CAL`

Dataset	# of Scales	Min/Max/Mean Scale Size	# of Unordered (unequal) Pairs	Example Scale
deMelo	87	3 / 8 / 3.90	524 (466)	$\{\text{clean}\} < \{\text{spotless, immaculate}\}$
Crowd	79	2 / 8 / 3.18	293 (250)	$\{\text{low}\} < \{\text{limited}\} < \{\text{scarce}\}$
Wilkinson	21	2 / 5 / 2.81	61 (61)	$\{\text{dry}\} < \{\text{arid}\} < \{\text{parched}\}$

Table 1: Characteristics of the scalar adjective datasets used for evaluation. The deMelo scale example shows an instance of an equally-intense pair (*spotless*, *immaculate*).

and directed, pairwise adjective intensity scores $score(a_i, a_j)$ as input, and assigns each adjective a_i a place along a linear scale $x_i \in [0, 1]$. The adjectives' assigned values define the global ordering. If the predicted weights used as input are inconsistent, containing cycles, the model resolves these by choosing the globally optimal solution.

Recall that all pairwise scoring metrics produce a positive score for adjective pair (j_u, j_v) when it is likely that $j_u < j_v$, and a negative score otherwise. Consequently, the MILP approach should result in $x_u < x_v$ when $score(j_u, j_v)$ is positive, and $x_u > x_v$ otherwise. This goal is achieved by maximizing the objective function:

$$\sum_{u,v} \text{sign}(x_v - x_u) \cdot score(j_u, j_v) \tag{8}$$

de Melo and Bansal (2013) propose a MILP formulation for maximizing this objective, which we utilize in our experiments. Note that while de Melo and Bansal (2013) incorporate synonymy evidence from WordNet in their ranking method, we do not implement this part of the model.

5.2 Experiments

We experiment with using each of the paraphrase-, pattern-, and lexicon-based pairwise scores as input to the global ranking model in isolation. To examine how the scoring methods perform when used in combination, we also test all possible combinations of 2 and 3 scores.

Experiments are run over three distinct test sets (Table 1). Each dataset contains ordered sets of scalar adjectives belonging to the same *scale*. In general, scalar adjectives describing the same attribute can be ordered along a full scale (e.g. *freezing* to *sweltering*), or a half scale (*warm* to *sweltering*); all three test sets group adjectives into half scales. The three datasets are described here, and their characteristics are given in Table 1.

deMelo (de Melo and Bansal, 2013)[4]. 87 adjective sets are extracted from WordNet 'dumbbell' structures (Gross and Miller, 1990), and partitioned into half-scale sets based on their pattern-based evidence in the Google N-Grams corpus (Brants and Franz, 2009). Sets are manually annotated for intensity relations (<, >, and =).

Wilkinson (Wilkinson and Oates, 2016). Twelve adjective sets are generated by presenting crowd workers with small seed sets (e.g. *huge, small, microscopic*), and eliciting similar adjectives. Sets are automatically cleaned for consistency, and then annotated for intensity by crowd workers. While the original dataset contains full scales, we manually sub-divide these into 21 half-scales for use in this study. Details on the modification from full- to half-scales are in the Supplemental Material.

Crowd. We also crowdsourced a new set of adjective scales with high coverage of the PPDB vocabulary. In a three-step process, we first asked crowd workers whether pairs of adjectives describe the same attribute (e.g. temperature) and therefore should belong along the same scale. Second, sets of same-scale adjectives were refined over multiple rounds. Finally, workers ranked the adjectives in each set by intensity. The final dataset includes 293 adjective pairs along 79 scales.

We measure the agreement between the gold standard ranking of adjectives along each scale and the predicted ranking using three commonly-used metrics:

Pairwise accuracy. For each pair of adjectives along the same scale, we compare the predicted ordering of the pair after global ranking (<, >, or =) to the gold-standard ordering of the pair, and report overall accuracy of the pairwise predictions.

Kendall's tau (τ_b). This metric computes the rank correlation between the predicted ($r_P(J)$) and gold-standard ($r_G(J)$) ranking permutations of each adjective scale J, incorporating a correction for ties. Values for τ_b range from -1 to 1, with extreme values indicating a perfect negative

---

Table 2: Pairwise relation prediction and global ranking results for each score type in isolation, and for the best-scoring combinations of 2 and 3 score types on each dataset. For the global ranking accuracy and average τ_b results, we denote with the † symbol scores for metrics incorporating paraphrase-based evidence that significantly out-perform both $score_{\text{pat}}$ and $score_{\text{socal}}$ under the paired Student's t-test, using the Anderson-Darling test to confirm that scores conform to a normal distribution (Fisher, 1935; Anderson and Darling, 1954; Dror et al., 2018). Example output is also given, with correct rankings starred.

or positive correlation, and a value of 0 indicating no correlation between predicted and gold rankings. We report τ_b as a weighted average over scales in each dataset, where weights correspond to the number of adjective pairs in each scale.

Spearman's rho (ρ). We report the Spearman's ρ rank correlation coefficient between predicted ($r_P(J)$) and gold-standard ($r_G(J)$) ranking permutations. For each dataset, we calculate this metric just once by treating each adjective in a particular scale as a single data point, and calculating an overall ρ for all adjectives from all scales.

5.3 Experimental Results

The results of the global ordering experiment, reported in Table 2, are organized as follows: *Score Accuracy* pertains to performance of the scoring methods alone – prior to global ranking – while *Global Ranking Results* pertains to performance of each scoring method as used in the global ranking algorithm. Within *Score Accuracy* there are two metrics. *Coverage* gives the percent of unique same-scale adjective pairs from the test set that can be directly scored using the given method. For $score_{\text{pat}}$, covered pairs are all those that appear together in any recognized pattern; for $score_{\text{pp}}$, covered pairs are those directly connected in JJGRAPH by one or more direct edges; for $score_{\text{socal}}$, covered pairs are all those for which both adjectives are in the SO-CAL lexicon and the metric is defined. *Pairwise Accuracy* gives the accuracy of the scoring method (before global ranking) on *just the covered pairs*, meaning that the subset of pairs scored by each method varies. Within *Global Ranking Results*, we report pairwise accuracy, weighted average τ_b, and ρ calculated over *all pairs* after ranking – including both pairs that are covered by the scoring method, and those whose pairwise intensity relationship has been inferred by the ranking algorithm.

The results indicate that the pairwise score accuracies (before ranking) for $score_{\text{pat}}$ and $score_{\text{socal}}$ are higher than those of $score_{\text{pp}}$ for all datasets, but that their coverage is relatively limited. The one exception is the deMelo dataset, where $score_{\text{pat}}$ has high coverage because the dataset was compiled specifically by finding adjective pairs that matched lexical patterns in the corpus. For all datasets, highest coverage is achieved using one of the combined metrics that incorporates paraphrase-based evidence.

The impact of these trends is visible on the

Global Ranking Results. When using pairwise intensity scores to compute the global ranking, higher coverage by a metric drives better results, as long as the metric's accuracy is reasonably high. Thus the paraphrase-based $score_{\text{pp}}$, with its high coverage, gets better global ranking results than the other single-method scores for two of the three datasets. Further, we find that boosting coverage with a combined metric that incorporates paraphrase evidence produces the highest post-ranking pairwise accuracy scores overall for all three datasets, and the highest average τ_b and ρ on the Crowd and Wilkinson datasets. We conclude that incorporating paraphrase evidence can improve the quality of this model for ordering adjectives along a scale because it gives high coverage with reasonably high quality.

The performance trends on the deMelo dataset differ from those on the Crowd and Wilkinson datasets. In particular, $score_{\text{pp}}$ and $score_{\text{socal}}$ have substantially lower pre-ranking pairwise accuracy on the pairs they cover in the deMelo dataset than they do for Crowd and Wilkinson: $score_{\text{pp}}$ has an accuracy of just 0.458 on covered pairs in the deMelo dataset, compared with 0.676 and 0.753 on the Crowd and Wilkinson datasets, and score differences for $score_{\text{socal}}$ are similar. The near-random prediction accuracies of $score_{\text{pp}}$ and $score_{\text{socal}}$ on deMelo before ranking lead to near-zero correlation values on this dataset after global ranking. To explore possible reasons for these results, we assessed the level of human agreement with each dataset in terms of pairwise accuracy. For each test set, we asked five crowd workers to classify the intensity direction for each adjective pair (j_u, j_v) in all scales as less than (<), greater than (>), or equal (=). We found that humans agreed with the 'gold standard' direction 65% of the time on the Bansal dataset, versus 70% of the time on the Crowd and Wilkinson datasets. It is possible that the more difficult nature of the Bansal dataset, coupled with its method of compilation (i.e. favoring adjective pairs that co-occur with pre-defined intensity patterns), lead to the lower coverage and lower accuracy of $score_{\text{pp}}$ and $score_{\text{socal}}$ on this dataset.

6 Indirect Question Answering

The second task that we address is answering indirect *yes* or *no* questions. de Marneffe et al. (2010) observed that answers to such polar questions frequently omit an explicit *yes* or *no* response. In some cases the implied answer depends on the relative intensity of adjective modifiers in the question and answer. For example, in the exchange:

Q: *Was he a successful ruler?*
A: *Oh, a tremendous ruler.*

the implied answer is *yes*, which is inferred because *successful* $\leq$ *tremendous* in terms of relative intensity. Conversely, in the exchange:

Q: *Does it have a large impact?*
A: *It has a medium-sized impact.*

the implied answer is *no* because *large* > *medium-sized.*

de Marneffe et al. (2010) compiled an evaluation set for this task by extracting 123 examples of such indirect question-answer pairs (IQAP) from dialogue corpora. In each exchange, the implied answer (annotated by crowd workers to be *yes* or *no*[5]) depends on the relative intensity relationship between modifiers in the question and answer texts. In their original paper, the authors utilize an automatically-compiled lexicon to make a polarity prediction for each IQAP.

6.1 Predicting Answer Polarity

Our goal is to see whether paraphrase-based scores are useful for predicting the polarity of answers in the IQAP dataset. As before, we compare the quality of predictions made using the paraphrase-based evidence with predictions made using pattern-based, lexicon-based, and combined scoring metrics.

To use the pairwise scores for inference, we employ a decision procedure nearly identical to that of de Marneffe et al. (2010). If j_q and j_a are scorable (i.e. have a scorable intensity relationship along the same half-scale), then $j_q \leq j_a$ implies the answer is *yes* (first example above), and $j_q > j_a$ implies the answer is *no* (second example). If the pair of adjectives is not scorable, then the predicted answer is *no*, as the pair could be antonyms or completely unrelated. If either j_q or j_a is missing from the scoring vocabulary, the adjectives are impossible to compare and therefore the prediction is *uncertain*. The full decision procedure is given in Figure 4.

---

[5] The original dataset contains two additional examples where the answer is annotated as *uncertain*, but de Marneffe et al. (2010) exclude them from the results and so do we.

Given: A dialogue exchange consisting of a polar question and answer, where the answer depends on the relative intensities of distinct modifiers j_q and j_a in the question and answer respectively:

1. if j_q or j_a are missing from the score vocabulary, predict "UNCERTAIN"
2. else, if $score(\mathrm{JJ}_q, \mathrm{JJ}_a)$ is undefined, predict "NO"
3. else, if $score(\mathrm{JJ}_q, \mathrm{JJ}_a) \geq 0$, predict "YES"
4. else, predict "NO"
5. If the question or answer contains negation, map a "YES" answer to "NO and a "NO" answer to "YES"

Figure 4: Decision procedure for using pairwise intensity scores for predicting polarity of an IQAP instance, based on de Marneffe et al. (2010).

6.2 Experiments

The decision procedure in Figure 4 is carried out for the 123 IQAP instances in the dataset, varying the score type. We report the accuracy, and macro-averaged precision, recall, and F1-score of the 85 *yes* and 38 *no* instances, in Table 3 alongside the percent of instances with adjectives out of vocabulary. Only the combined scores for the two best-scoring combinations, $score_{\text{socal+pp}}$ and $score_{\text{socal+pat+pp}}$, are reported.

Method	%OOV	Acc.	P	R	F
all-"YES"	.00	**.691**	.346	.500	.409
deMarneffe (2010)	.02	.610	.597	.594	.596
$score_{\text{socal}}$	.33	.504	**.710**	.481	.574
$score_{\text{pp}}$	.09	.496	.568	.533	.550
$score_{\text{pat}}$	.07	.407	.524	.491	.507
$score_{\text{socal+pp}}$	.09	.634	.690	.663	.676
$score_{\text{socal+pat+pp}}$	.06	.642	.684	**.683**	**.684**

Table 3: Accuracy and macro-averaged precision (P), recall (R), and F1-score (F) over *yes* and *no* responses on 123 question-answer pairs. The percent of pairs having one or both adjectives out of the score vocabulary is listed as %OOV.

The simplest baseline of predicting all answers to be "YES" gets highest accuracy in this imbalanced test set, but all score types perform better than the all-"YES" baseline in terms of precision and F1-score. Bouyed by its high precision, the $score_{\text{socal}}$ – which is derived from a manually-compiled lexicon – scored higher than $score_{\text{pp}}$ and $score_{\text{pat}}$. But it mis-predicted 33% of pairs as *uncertain* because of its limited overlap with the IQAP vocabulary. Meanwhile, $score_{pp}$ had relatively high coverage and a mid-level F-score, while $score_{pat}$ scored poorly on this dataset due to its sparsity; while all modifiers in the IQAP dataset are in the Google N-grams vocabulary, most do not have observed patterns and therefore return predictions of "NO" (item 2 in Figure 4). As in the global ranking experiments, the paraphrase-based evidence is complementary to the lexicon-based evidence, and thus the combined $score_{\text{socal+pp}}$ and $score_{\text{socal+pat+pp}}$ produce significantly better accuracy than any score in isolation (McNemar's test, $p < .01$), and also out-perform the original expected ranking method of de Marneffe et al. (2010) (although they do not beat the best-reported score on this dataset, F-score=0.706 (Kim and de Marneffe, 2013)).

7 Conclusion

We have proposed adjectival paraphrases as a new source of evidence for predicting intensity relationships between scalar adjectives. While paraphrase-based intensity evidence produces pairwise predictions that are less precise than those produced by pattern- or lexicon-based evidence, the coverage is substantially higher. Thus paraphrases can be successfully used as a complementary source of information for reasoning about adjective intensity. We will publish the JJGRAPH resource, datasets, and code upon publication.

Abstract

In this paper, we propose a new kernel-based co-occurrence measure that can be applied to sparse linguistic expressions (e.g., sentences) with a very short learning time, as an alternative to pointwise mutual information (PMI). As well as deriving PMI from mutual information, we derive this new measure from the Hilbert–Schmidt independence criterion (HSIC); thus, we call the new measure the pointwise HSIC (PHSIC). PHSIC can be interpreted as a smoothed variant of PMI that allows various similarity metrics (e.g., sentence embeddings) to be plugged in as kernels. Moreover, PHSIC can be estimated by simple and fast (linear in the size of the data) matrix calculations regardless of whether we use linear or nonlinear kernels. Empirically, in a dialogue response selection task, PHSIC is learned thousands of times faster than an RNN-based PMI while outperforming PMI in accuracy. In addition, we also demonstrate that PHSIC is beneficial as a criterion of a data selection task for machine translation owing to its ability to give high (low) scores to a consistent (inconsistent) pair with other pairs.

1 Introduction

Computing the co-occurrence strength between two linguistic expressions is a fundamental task in natural language processing (NLP). For example, in collocation extraction (Manning and Schütze, 1999), word bigrams are collected from corpora and then strongly co-occurring bigrams (e.g., "New York") are found. In dialogue response selection (Lowe et al., 2015), pairs comprising a context and its response sentence are collected from dialogue corpora and the goal is to rank the candidate responses for each given context sentence. In either case, a set of linguistic expression pairs $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^{n}$ is first collected and then the co-occurrence strength of a (new) pair (x, y) is computed.

		Robustness to Sparsity	Learning Time
PMI			
$\log \frac{n \cdot c(x,y)}{\sum_{y'} c(x,y') \sum_{x'} c(x',y)}$	Eq. 1		✓
$\log \frac{\widehat{\mathbf{P}}_{\mathrm{RNN}}(y \mid x)}{\widehat{\mathbf{P}}_{\mathrm{RNN}}(y)}$	Eq. 2	✓	
PHSIC			
$(\phi(x)-\overline{\phi(x)})^\top \widehat{C}_{XY} (\psi(y)-\overline{\psi(y)})$	Sec. 5.1	✓	✓
$(\boldsymbol{a}-\overline{\boldsymbol{a}})^\top \widehat{C}_{\mathrm{ICD}} (\boldsymbol{b}-\overline{\boldsymbol{b}})$	Sec. 5.2	✓	✓

Table 1: The proposed co-occurrence norm, PHSIC, eliminates the trade-off between robustness to data sparsity and learning time, which PMI has (Section 1).

Pointwise mutual information (PMI) (Church and Hanks, 1989) is frequently used to model the co-occurrence strength of linguistic expression pairs. There are two typical types of PMI estimation (computation) method. One is a counting-based estimator using maximum likelihood estimation, sometimes with smoothing techniques, for example,

$$\widehat{\mathrm{PMI}}_{\mathrm{MLE}}(x, y; \mathcal{D}) = \log \frac{n \cdot c(x,y)}{\sum_{y'} c(x,y') \sum_{x'} c(x',y)}, \tag{1}$$

where $c(x, y)$ denotes the frequency of the pair (x, y) in given data $\mathcal{D}$. This is easy to compute and is commonly used to measure co-occurrence between words, such as in collocation extraction[1]; however, when data $\mathcal{D}$ is sparse, i.e., when x or y is a phrase or sentence, this approach is unrealistic. The second method uses recurrent neural networks (RNNs). Li et al. (2016) proposed to em-

---

[1] In collocation extraction, simple counting $c(x, y) \propto \widehat{\mathbf{P}}(x, y)$, rather than PMI, ranks undesirable function-word pairs (e.g., "of the") higher (Manning and Schütze, 1999).

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1763–1775
Brussels, Belgium, October 31 - November 4, 2018.

ploy PMI to suppress *dull* responses for utterance generation in dialogue systems[2]. They estimated $\mathbf{P}(y)$ and $\mathbf{P}(y|x)$ using RNN language models and estimated PMI as follows:

$$\widehat{\mathrm{PMI}}_{\mathrm{RNN}}(x, y; \mathcal{D}) = \log \frac{\widehat{\mathbf{P}}_{\mathrm{RNN}}(y|x)}{\widehat{\mathbf{P}}_{\mathrm{RNN}}(y)}. \quad (2)$$

This way of estimating PMI is applicable to sparse language expressions; however, learning RNN language models is computationally costly.

To eliminate this trade-off between robustness to data sparsity and learning time, in this study we propose a new kernel-based co-occurrence measure, which we call the *pointwise Hilbert–Schmidt independence criterion (PHSIC)* (see Table 1). Our contributions are as follows:

- We formalize PHSIC, which is derived from HSIC (Gretton et al., 2005), a kernel-based dependence measure, in the same way that PMI is derived from mutual information (Section 3).
- We give an intuitive explanation why PHSIC is robust to data sparsity. PHSIC is a "smoothed variant of PMI", which allows various similarity metrics to be plugged in as kernels (Section 4).
- We propose fast estimators of PHSIC, which are reduced to a simple and fast matrix calculation regardless of whether we use linear or nonlinear kernels (Section 5).
- We empirically confirmed the effectiveness of PHSIC, i.e., its robustness to data sparsity and learning time, in two different types of experiment, a dialogue response selection task and a data selection task for machine translation (Section 6).

2 Problem Setting

Let X and Y denote random variables on $\mathcal{X}$ and $\mathcal{Y}$, respectively. In this paper, we deal with the tasks of taking a set of linguistic expression pairs

$$\mathcal{D} = \{(x_i, y_i)\}_{i=1}^{n} \underset{\text{i.i.d.}}{\sim} \mathbf{P}_{XY}, \quad (3)$$

which is regarded as a set of i.i.d. samples drawn from a joint distribution $\mathbf{P}_{XY}$, and then measuring the "co-occurrence strength" for each given pair $(x, y) \in \mathcal{X} \times \mathcal{Y}$. Such tasks include collocation extraction and dialogue response selection (Section 1).

3 Pointwise HSIC

In this section, we give the formal definition of PHSIC, a new kernel-based co-occurrence measure. We show a summary of this section in Table 2. Intuitively, PHSIC is a "kernelized variant of PMI."

3.1 Dependence Measure

As a preliminary step, we introduce the simple concept of dependence (see **Dependence Measure** in Table 2). Recall that random variables X and Y are *independent* if and only if the joint probability density $\mathbf{P}_{XY}$ and the product of the marginals $\mathbf{P}_X\mathbf{P}_Y$ are equivalent. Therefore, we can measure the *dependence* between random variables X and Y via the difference between $\mathbf{P}_{XY}$ and $\mathbf{P}_X\mathbf{P}_Y$.

Both the mutual information and the Hilbert–Schmidt independence criterion, to be described below, are such dependence measures.

3.2 MI and PMI

We briefly review the well-known mutual information and PMI (see **MI & PMI** in Table 2).

The *mutual information (MI)*[3] between two random variables X and Y is defined by

$$\mathrm{MI}(X, Y) := \mathrm{KL}[\mathbf{P}_{XY} \| \mathbf{P}_X\mathbf{P}_Y] \quad (4)$$

(Cover and Thomas, 2006), where $\mathrm{KL}[\cdot\|\cdot]$ denotes the Kullback–Leibler (KL) divergence. Thus, $\mathrm{MI}(X, Y)$ is the degree of dependence between X and Y measured by the KL divergence between $\mathbf{P}_{XY}$ and $\mathbf{P}_X\mathbf{P}_Y$.

Here, by definition of the KL divergence, MI can be represented in the form of the expectation over $\mathbf{P}_{XY}$, i.e., the summation over all possible pairs $(x, y) \in \mathcal{X} \times \mathcal{Y}$:

$$\mathrm{MI}(X, Y) = \underset{(x,y)}{\mathbf{E}}\left[\log \frac{\mathbf{P}_{XY}(x, y)}{\mathbf{P}_X(x)\mathbf{P}_Y(y)}\right]. \quad (5)$$

The shaded part in Equation (5) is actually the *pointwise mutual information (PMI)* (Church and Hanks, 1989):

$$\mathrm{PMI}(x, y; X, Y) := \log \frac{\mathbf{P}_{XY}(x, y)}{\mathbf{P}_X(x)\mathbf{P}_Y(y)}. \quad (6)$$

Therefore, $\mathrm{PMI}(x, y)$ can be thought of as the contribution of (x, y) to $\mathrm{MI}(X, Y)$.

---

[2] In dialogue response selection or generation, a simple conditional probability $\widehat{\mathbf{P}}(y|x)$, rather than PMI, ranks *dull* responses (e.g., "I don't know.") higher (Li et al., 2016).

[3] Conventionally, mutual information is denoted by $I(X; Y)$; in this paper, however, for notational consistency, mutual information is denoted by $\mathrm{MI}(X, Y)$.

	Dependence Measure the dependence between X and Y (the difference between $\mathbf{P}_{XY}$ and $\mathbf{P}_X\mathbf{P}_Y$)	**Co-occurrence Measure** the contribution of (x, y) to the dependence between X and Y
MI & PMI	$\mathrm{MI}(X, Y) = \mathrm{KL}[\mathbf{P}_{XY} \| \mathbf{P}_X\mathbf{P}_Y]$ $= \underset{(x,y)}{\mathbf{E}}\left[\log \frac{\mathbf{P}_{XY}(x,y)}{\mathbf{P}_X(x)\mathbf{P}_Y(y)}\right]$	$\mathrm{PMI}(x, y; X, Y)$ $= \log \frac{\mathbf{P}_{XY}(x,y)}{\mathbf{P}_X(x)\mathbf{P}_Y(y)}$
HSIC & PHSIC	$\mathrm{HSIC}(X, Y; k, \ell) = \mathrm{MMD}^2_{k,\ell}[\mathbf{P}_{XY}, \mathbf{P}_X\mathbf{P}_Y]$ $= \underset{(x,y)}{\mathbf{E}}\left[(\phi(x) - m_X)^\top C_{XY}(\psi(y) - m_Y)\right]$ $= \underset{(x,y)}{\mathbf{E}}\left[\underset{(x',y')}{\mathbf{E}}[\widetilde{k}(x,x')\widetilde{\ell}(y,y')]\right]$	$\mathrm{PHSIC}(x, y; X, Y, k, \ell)$ $= (\phi(x) - m_X)^\top C_{XY}(\psi(y) - m_Y)$ $= \underset{(x',y')}{\mathbf{E}}[\widetilde{k}(x,x')\widetilde{\ell}(y,y')]$

Table 2: Relationship between the mutual information (MI), the pointwise mutual information (PMI), the Hilbert–Schmidt independence criterion (HSIC), and the pointwise HSIC (PHSIC). As well as defining PMI as the contribution to MI, we define PHSIC as the contribution to HSIC. In short, PHSIC is a "kernelized PMI" (Section 3).

3.3 HSIC and PHSIC

As seen in the previous section, PMI can be derived from MI. Here, we consider replacing MI with the Hilbert–Schmidt independence criterion (HSIC). Then, in analogy with the relationship between PMI and MI, we derive PHSIC from HSIC (see **HSIC & PHSIC** in Table 2).

Let $k\colon \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ and $\ell\colon \mathcal{Y} \times \mathcal{Y} \to \mathbb{R}$ denote positive definite kernels on $\mathcal{X}$ and $\mathcal{Y}$, respectively (intuitively, they are similarity functions between linguistic expressions). The *Hilbert–Schmidt independence criterion (HSIC)* (Gretton et al., 2005), a kernel-based dependence measure, is defined by

$$\mathrm{HSIC}(X, Y; k, \ell) := \mathrm{MMD}^2_{k,\ell}[\mathbf{P}_{XY}, \mathbf{P}_X\mathbf{P}_Y], \quad (7)$$

where $\mathrm{MMD}[\cdot, \cdot]$ denotes the maximum mean discrepancy (MMD) (Gretton et al., 2012), which measures the difference between random variables on a kernel-induced feature space. Thus, $\mathrm{HSIC}(X, Y; k, \ell)$ is the degree of dependence between X and Y measured by the MMD between $\mathbf{P}_{XY}$ and $\mathbf{P}_X\mathbf{P}_Y$, while MI is measured by the KL divergence (Equation (4)).

Analogous to MI in Equation (5), HSIC can be represented in the form of the expectation on $\mathbf{P}_{XY}$ by a simple deformation:

$$\begin{aligned}&\mathrm{HSIC}(X, Y; k, \ell)\\ &= \underset{(x,y)}{\mathbf{E}}\left[(\phi(x) - m_X)^\top C_{XY}(\psi(y) - m_Y)\right] && (8)\\ &= \underset{(x,y)}{\mathbf{E}}\left[\underset{(x',y')}{\mathbf{E}}[\widetilde{k}(x,x')\widetilde{\ell}(y,y')]\right], && (9)\end{aligned}$$

where

$$\phi(x) := k(x, \cdot), \quad \psi(y) := \ell(y, \cdot), \quad (10)$$

$$m_X := \mathbf{E}_x[\phi(x)], \quad m_Y := \mathbf{E}_y[\psi(y)], \quad (11)$$

$$C_{XY} := \underset{(x,y)}{\mathbf{E}}\left[(\phi(x) - m_X)(\psi(y) - m_Y)^\top\right], \quad (12)$$

$$\begin{aligned}\widetilde{k}(x, x') &:= k(x, x') - \mathbf{E}_{x'}[k(x, x')]\\ &\quad - \mathbf{E}_x[k(x, x')] + \mathbf{E}_{x,x'}[k(x, x')]. \quad (13)\end{aligned}$$

At first glance, these equations are somewhat complicated; however, the estimators of PHSIC we actually use are reduced to a simple matrix calculation in Section 5. Unlike MI in Equation (5), HSIC has two representations: Equation (8) is the representation in feature space and Equation (9) is the representation in data space.

Similar to the relationship between MI and PMI (Section 3.2), we define the *pointwise Hilbert–Schmidt independence criterion (PHSIC)* by the shaded parts in Equations (8) and (9):

$$\begin{aligned}&\mathrm{PHSIC}(x, y; X, Y, k, \ell)\\ &:= (\phi(x) - m_X)^\top C_{XY}(\psi(y) - m_Y) && (14)\\ &= \underset{(x',y')}{\mathbf{E}}[\widetilde{k}(x,x')\widetilde{\ell}(y,y')]\,. && (15)\end{aligned}$$

Namely, $\mathrm{PHSIC}(x, y)$ is defined as the contribution of (x, y) to $\mathrm{HSIC}(X, Y)$.

In summary, we define PHSIC such that "MI:PMI = HSIC:PHSIC" holds (see Table 2).

4 PHSIC as Smoothed PMI

This section gives an intuitive explanation for the first feature of PHSIC, i.e., the robustness to data sparsity, using Table 3. In short, we show that PHSIC is a "smoothed variant of PMI."

First, the maximum likelihood estimator of PMI

	add scores	deduct scores
$\widehat{\mathrm{PMI}}(x, y; \mathcal{D}) = \boxed{\log \frac{n \cdot \sum_i \mathbb{I}[x = x_i \wedge y = y_i]}{\sum_i \mathbb{I}[x = x_i] \sum_i \mathbb{I}[y = y_i]}}$	$\begin{array}{c} (x, y) \\ \Vert \quad \Vert \\ \mathcal{D} = \{\dots, (x_i, y_i), \dots\} \end{array}$	$\begin{array}{ccc} (x, y) & & (x, y) \\ \Vert \quad \nparallel & & \nparallel \quad \Vert \\ \{\dots, (x_i, y_i), & \dots, & (x_i, y_i), \dots\} \end{array}$
$\widehat{\mathrm{PHSIC}}(x, y; \mathcal{D}, k, \ell) = \boxed{\frac{1}{n} \sum_i \widehat{\widetilde{k}}(x, x_i) \widehat{\widetilde{\ell}}(y, y_i)}$	$\begin{array}{ccc} (x, y) & & (x, y) \\ \wr \quad \wr & & \not\wr \quad \not\wr \\ \{\dots, (x_i, y_i), & \dots, & (x_i, y_i), \dots\} \end{array}$	$\begin{array}{ccc} (x, y) & & (x, y) \\ \wr \quad \not\wr & & \not\wr \quad \wr \\ \{\dots, (x_i, y_i), & \dots, & (x_i, y_i), \dots\} \end{array}$

Table 3: Comparison of estimators of PMI and PHSIC in terms of methods of matching the given (x, y) and the observed (x_i, y_i) in $\mathcal{D}$. PMI matches them in an exact manner, while PHSIC smooths the matching using kernels. Therefore, PHSIC is expected to be robust to data sparsity (Section 4).

in Equation (1) can be rewritten as

$$\widehat{\mathrm{PMI}}(x, y; \mathcal{D}) = \boxed{\log \frac{n \cdot \sum_i \mathbb{I}[x = x_i \wedge y = y_i]}{\sum_i \mathbb{I}[x = x_i] \sum_i \mathbb{I}[y = y_i]}}, \quad (16)$$

where $\mathbb{I}[\text{condition}] = 1$ if the condition is true and $\mathbb{I}[\text{condition}] = 0$ otherwise. According to Equation (16), $\widehat{\mathrm{PMI}}(x, y)$ is the amount computed by repeating the following operation (see the first row in Table 3):

> *collate the given (x, y) and the observed (x_i, y_i) in $\mathcal{D}$ in order, and add the scores if (x, y) and (x_i, y_i) match exactly or deduct the scores if either the x side or the y side (but nor both) matches.*

Moreover, an estimator of PHSIC in data space (Equation (15)) is

$$\widehat{\mathrm{PHSIC}}(x, y; \mathcal{D}, k, \ell) = \boxed{\frac{1}{n} \sum_i \widehat{\widetilde{k}}(x, x_i) \widehat{\widetilde{\ell}}(y, y_i)}, \quad (17)$$

where $\widehat{\widetilde{k}}(\cdot, \cdot)$ and $\widehat{\widetilde{\ell}}(\cdot, \cdot)$ are similarity functions centered on the data[4]. According to Equation (17), $\widehat{\mathrm{PHSIC}}(x, y)$ is the amount computed by repeating the following operation (see the second row in Table 3):

> *collate the given (x, y) and the observed (x_i, y_i) in $\mathcal{D}$ in order, and add the scores if the similarities on the x and y sides are both higher (both $\widehat{\widetilde{k}}(x, x_i) > 0$ and $\widehat{\widetilde{\ell}}(y, y_i) > 0$ hold)[5] or deduct the scores if the similarities on either the x or y sides are similar but those on the other side are not similar.*

As described above, when comparing the estimators of PMI and PHSIC from the viewpoint of "methods of matching the given (x, y) and the observed (x_i, y_i)," it is understood that PMI matches them in an exact manner, while PHSIC smooths the matching using kernels (similarity functions).

With this mechanism, even for completely unknown pairs, it is possible to estimate the co-occurrence strength by referring to observed pairs through the kernels. Therefore, PHSIC is expected to be robust to data sparsity and can be applied to phrases and sentences.

Available Kernels for PHSIC In NLP, a variety of similarity functions (i.e., positive definite kernels) are available. We can freely utilize such resources, such as cosine similarity between sentence embeddings. For a more detailed discussion, see Appendix A.

5 Empirical Estimators of PHSIC

Recall that we have two types of empirical estimator of PMI, the maximum likelihood estimator (Equation (1)) and the RNN-based estimator (Equation (2)). In this section, we describe how to rapidly estimate PHSIC from data. When using the linear kernel or cosine similarity (e.g., cosine similarity between sentence embeddings), PHSIC can be efficiently estimated in feature space (Section 5.1). When using a nonlinear kernel such as the Gaussian kernel, PHSIC can also be estimated efficiently in data space via a simple matrix decomposition (Section 5.2).

5.1 Estimation Using Linear Kernel or Cosine

When using the linear kernel or cosine similarity, the estimator of PHSIC in feature space (14) is as follows:

---

[4] To be exact, $\widehat{\widetilde{k}}(x, x') := k(x, x') - \frac{1}{n}\sum_{j=1}^{n} k(x, x_j) - \frac{1}{n}\sum_{i=1}^{n} k(x_i, x') + \frac{1}{n^2}\sum_{i=1}^{n}\sum_{j=1}^{n} k(x_i, x_j)$, which is an estimator of the centered kernel $\widetilde{k}(x, x')$ in Equation (13).

[5] In addition, the scores are added if the similarity on the x side and that on the y side are both lower, that is, if $\widehat{\widetilde{k}}(x, x_i) < 0$ and $\widehat{\widetilde{\ell}}(y, y_i) < 0$ hold.

$$\widehat{\mathrm{PHSIC}}_{\mathrm{feature}}(x, y; \mathcal{D}, k, \ell) = (\phi(x) - \overline{\phi(x)})^\top \widehat{C}_{XY}(\psi(y) - \overline{\psi(y)}), \tag{18}$$

where

$$\phi(x) = \begin{cases} x & (k(x, x') = x^\top x') \\ x/\|x\| & (k(x, x') = \cos(x, x')) \end{cases}, \tag{19}$$

$$\overline{\phi(x)} := \frac{1}{n}\sum_{i=1}^{n} \phi(x_i), \quad \overline{\psi(y)} := \frac{1}{n}\sum_{i=1}^{n} \psi(y_i), \tag{20}$$

$$\widehat{C}_{XY} := \frac{1}{n}\sum_{i=1}^{n} \phi(x_i)\psi(y_i)^\top - \overline{\phi(x)}\,\overline{\psi(y)}^\top. \tag{21}$$

Generally in kernel methods, a feature map $\phi(\cdot)$ induced by a kernel $k(\cdot, \cdot)$ is unknown or high-dimensional and it is difficult to compute estimated values in feature space[6]. However, when we use the linear kernel or cosine similarity, feature maps can be explicitly determined (Equation (19)).

Computational Cost When learning Equation (18) with feature maps $\phi\colon \mathcal{X} \to \mathbb{R}^d$ and $\psi\colon \mathcal{Y} \to \mathbb{R}^d$, computing the vectors $\overline{\phi(x)}, \overline{\psi(y)} \in \mathbb{R}^d$ and the matrix $\widehat{C}_{XY} \in \mathbb{R}^{d \times d}$ takes $\mathcal{O}(nd^2)$ time and $\mathcal{O}(nd)$ space (linear in the size of the input, n). When estimating PHSIC(x, y), computing $\phi(x), \psi(y) \in \mathbb{R}^d$ and Equation (18) takes $\mathcal{O}(d^2)$ time (constant; does not depend on the size of the input, n).

5.2 Estimation Using Nonlinear Kernels

When using a nonlinear kernel such as the Gaussian kernel, it is necessary to estimate PHSIC in data space. Using a simple matrix decomposition, this can be achieved with the same computational cost as the estimation in feature space. See Appendix B for a detailed derivation.

6 Experiments

In this section, we provide empirical evidence for the greater effectiveness of PHSIC than PMI, i.e., a very short learning time and robustness to data sparsity. Among the many potential applications of PHSIC, we choose two fundamental scenarios, (re-)ranking/classification and data selection.

- In the ranking/classification scenario (measuring the co-occurrence strength of *new data pairs* with reference to observed pairs), PHSIC is applied as a criterion for the dialogue response selection task (Section 6.2).
- In the data selection/filtering scenario (ordering the entire set of *observed data pairs* according to the co-occurrence strength), PHSIC is also applied as a criterion for data selection in the context of machine translation (Section 6.3).

6.1 PHSIC Settings

To take advantage of recent developments in representation learning, we used several pre-trained models for encoding sentences into vectors and several kernels between these vectors for PHSIC.

Encoders As sentence encorders, we used two pre-trained models without fine-tuning. First, the sum of the word vectors effectively represents a sentence (Mikolov et al., 2013a):

$$\boldsymbol{x} = \textstyle\sum_{w \in x} \mathrm{vec}(w), \quad \boldsymbol{y} = \textstyle\sum_{w \in y} \mathrm{vec}(w). \tag{22}$$

For $\mathrm{vec}(\cdot)$, we used the pre-trained **`fastText`** model[7], which is a high-accuracy and popular word embedding model (Bojanowski et al., 2017); models in 157 languages are publicly distributed (Grave et al., 2018). Second, we also used a DNN-based sentence encoder, called the universal sentence encoder (Cer et al., 2018), which utilizes the deep averaging network (**`DAN`**) (Iyyer et al., 2015). The pre-trained model for English sentences we used is publicly available[8].

Kernels As kernels between these vectors, we used cosine similarity (**`cos`**)

$$k(\boldsymbol{x}, \boldsymbol{x}') = \cos(\boldsymbol{x}, \boldsymbol{x}') \tag{23}$$

and the Gaussian kernel (also known as the radial basis function kernel; **`RBF`** kernel)

$$k(\boldsymbol{x}, \boldsymbol{x}') = \exp\left(-\frac{\|\boldsymbol{x} - \boldsymbol{x}'\|_2^2}{2\sigma^2}\right), \tag{24}$$

and similarly for $\ell(\boldsymbol{y}, \boldsymbol{y}')$. The experiments are ran with hyperparameter $\sigma = 1.0$ for the RBF kernel, and $d = 100$ for incomplete Cholesky decomposition (for more detail, see Section B).

6.2 Ranking: Dialogue Response Selection

In the first experiment, we applied PHSIC as a ranking criterion of the task of dialogue response

---

[6] One of the characteristics of kernel methods is that an intractable estimation in feature space is replaced with an efficient estimation in data space.

[7] `https://fasttext.cc/docs/en/english-vectors.html`, `https://fasttext.cc/docs/en/crawl-vectors.html`

[8] `https://www.tensorflow.org/hub/modules/google/universal-sentence-encoder/1`

selection (Lowe et al., 2015); in the task, pairs comprising a context (previous utterance sequence) and its response are collected from dialogue corpora and the goal is to rank the candidate responses for each given context sentence.

The task entails sentence sequences (very sparse linguistic expressions); moreover, Li et al. (2016) pointed out that (RNN-based) PMI has a positive impact on suppressing *dull* responses (e.g., "I don't know.") in dialogue systems. Therefore, PHSIC, another co-occurrence measure, is also expected to be effective for this. With this setting, where the validity of PMI is confirmed, we investigate whether PHSIC can replace RNN-based PMI in terms of both learning time and robustness to data sparsity.

Experimental Settings

Dataset For the training data, we gathered approximately 5×10^5 reply chains from Twitter, following Sordoni et al. (2015)[9]. In addition, we randomly selected $\{10^3, 10^4, 10^5\}$ reply chains from that dataset. Using these small subsets, we confirmed the effect of the difference in the size of the training set (data sparseness) on the learning time and predictive performance.

For validation and test data, we used a small (approximately 2000 pairs each) but highly reliable dataset created by Sordoni et al. (2015)[10], which consists only of conversations given high scores by human annotators. Therefore, this set was not expected to include *dull* responses.

For each dataset, we converted each context-message-response triple into a context-response pair by concatenating the context and message following Li et al. (2016). In addition, to convert the test set (positive examples) to ten-choice multiple-choice questions, we shuffled the combinations of context and response to generate pseudo-negative examples.

Evaluation Metrics We adopted the following evaluation metrics for the task: (i) `ROC-AUC` (the area under the receiver operating characteristic curve), (ii) `MRR` (the mean reciprocal rank), and (iii) `Recall@{1,2}`.

	Config			Size of Training Set n			
				10^3	10^4	10^5	5×10^5
RNN-PMI	*Dim.*	*Init.*					
	300	`fastText`	Total	20.6	99.2	634.3	4042.5
			$\widehat{\mathbf{P}}(y)$	8.0	23.6	294.6	1710.1
			$\widehat{\mathbf{P}}(y\|x)$	12.6	75.6	339.7	2332.4
	1200	`fastText`	Total	49.0	162.0	1751.3	13054.9
			$\widehat{\mathbf{P}}(y)$	16.3	57.2	671.0	5512.1
			$\widehat{\mathbf{P}}(y\|x)$	32.7	104.8	1080.3	7542.8
PHSIC	*Encoder*	*Kernel*					
	`fastText`	`cos`		**0.0**	**0.1**	**0.5**	**2.8**
	`DAN`	`cos`		**0.0**	**0.1**	**0.4**	**1.8**

Table 4: **Learning time** [s] for each model and each size of training set for the dialogue response task. Each row denotes a model; each column denotes the number of training data n. The text appended to each baseline model denotes the number of dimension of hidden layers (*Dim.*) and the method of initialization the embedding layer (*Init.*). The text appended to each proposed model denotes the pre-trained models used to encode sentences into vectors (*Encoder*) and the kernel between these vectors (*Kernel*). The best result (the shortest learning time) in each column is in bold.

Experimental Procedure We used the following procedure: (i) train the model with a set of context-response pairs $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^n$; (ii) for each context sentence x in the test data, rank the candidate responses $\{y_j\}_{j=1}^{10}$ by the model; and (iii) report three evaluation metrics.

Baseline Measures As baseline measures, both (1) an RNN language model $\widehat{\mathbf{P}}_{\mathrm{RNN}}(y)$ (Mikolov et al., 2010) and (2) a conditional RNN language model $\widehat{\mathbf{P}}_{\mathrm{RNN}}(y|x)$ (Sutskever et al., 2014) were trained, and (3) PMI based on these language models, **RNN-PMI**, was also used for experiments (see Equation (2)). We trained these models with all combinations of the following settings: (a) the number of dimensions of the hidden layers being 300 or 1200 and (b) the initialization of the embedding layer being **`random`** (uniform on $[-0.1, 0.1]$) or **`fastText`**. For more detailed settings, see Appendix C.

Experimental Results

Learning Time Table 4 shows the experimental results of the learning time[11]. Regardless of the size of the training set n, the learning time for

---

[9] We collected tweets after 2017 for our training set to avoid duplication with the test set, which contains tweets from the year 2012.

[10] `https://www.microsoft.com/en-us/download/details.aspx?id=52375`

[11] The computing environment was as follows:
(i) CPU: Xeon E5-1650-v3 (3.5 GHz, 6 Cores);
(ii) GPU: GTX 1080 (8 GB).

PHSIC is much shorter than that of the RNN-based method. For example, even when the size of the training set n is 5×10^5, PHSIC is approximately 1400–4000 times faster than RNN-based PMI. This is because the estimators of PHSIC are reduced to a deterministic and efficient matrix calculation (Section 5), whereas neural network-based models involve the sequential optimization of parameters via gradient descent methods.

Robustness to Data Sparsity Table 5 shows the experimental results of the predictive performance. When the size of the training data is small ($n = 10^3, 10^4$), that is, when the data is extremely sparse, the predictive performance of PHSIC hardly deteriorates while that of PMI rapidly decays as the number of data decreases. This indicates that PHSIC is more robust to data sparsity than RNN-based PMI owing to the effect of kernels. Moreover, PHSIC with the simple cosine kernel outperforms the RNN-based model regardless of the number of data, while the learning time of PHSIC is thousands of times shorter than those of the baseline methods (Section 6.2).

Additionally we report Spearman's rank correlation coefficient between models to verify whether PHSIC shows similar behavior to PMI. See Appendix D for more detail.

6.3 Data Selection for Machine Translation

The aim of our second experiment was to demonstrate that PHSIC is also beneficial as a criterion of data selection. To achieve this, we attempted to apply PHSIC to a parallel corpus filtering task that has been intensively discussed in recent (neural) machine translation (MT, NMT) studies. This task was first adopted as a shared task in the third conference on machine translation (WMT 2018)[12].

Several existing parallel corpora, especially those automatically gathered from large-scale text data, such as the Web, contain unacceptable amounts of noisy (low-quality) sentence pairs that greatly affect the translation quality. Therefore, the development of an effective method for parallel corpus filtering would potentially have a large influence on the MT community; discarding such noisy pairs may improve the translation quality and shorten the training time.

We expect PHSIC to give low scores to *exceptional* sentence pairs (misalignments or missing translations) during the selection process because PHSIC assigns low scores to pairs that are highly inconsistent with other pairs (see Section 4). Note that applying RNN-based PMI to a parallel corpus selection task is unprofitable since obtaining RNN-based PMI also has an identical computational cost for training a sequence-to-sequence model for MT, and thus, we cannot expect a reduction of the total training time.

Experimental Settings

Dataset We used the ASPEC-JE corpus[13], which is an official dataset used for the MT-evaluation shared task held in the fourth workshop on Asian translation (WAT 2017)[14] (Nakazawa et al., 2017). ASPEC-JE consists of approximately three million (3M) Japanese–English parallel sentences from scientific paper abstracts. As discussed by Kocmi et al. (2017), ASPEC-JE contains many low-quality parallel sentences that have the potential to significantly degrade the MT quality. In fact, they empirically revealed that using only the reliable part of the training parallel corpus significantly improved the translation quality. Therefore, ASPEC-JE is a suitable dataset for evaluating the data selection ability.

Model For our data selection evaluation, we selected the Transformer architecture (Vaswani et al., 2017) as our baseline NMT model, which is widely-used in the NMT community and known as one of the current state-of-the-art architectures. We utilized `fairseq`[15], a publicly available tool for neural sequence-to-sequence models, for building our models.

Experimental Procedure We used the following procedure for this evaluation: (1) rank all parallel sentences in a given parallel corpus according to each criterion, (2) extract the top K ranked parallel sentences, (3) train the NMT model using the extracted parallel sentences, and (4) evaluate the translation quality of the test data using a typical MT automatic evaluation measure, i.e., BLEU (Papineni et al., 2002)[16]. In our experiments we evaluated PHSIC with K = 0.5M and 1M.

Table 6: **BLEU scores** with the Transformer for each data selection criterion and each size of selected data K for the parallel corpus filtering task.“Random” represents the baseline method of selecting sentences at random.

Baseline Measure As a baseline measure, we utilize a publicly available script[17] of **fast_align** (Dyer et al., 2013), which is one of the state-of-the-art word aligner. We firstly used the fast_align for the training set $\mathcal{D} = \{(x_i, y_i)\}_i$ to obtain the word alignment between each sentence pair (x_i, y_i), i.e., a set of aligned word pairs with its probabilities. We then computed the co-occurrence score of (x_i, y_i) with sentence-length normalization, i.e., the average log probability of aligned word pairs.

Experimental Results

Table 6 shows the results of our data selection evaluation. It is common knowledge in NMT that more data gives better performance in general. However, we observed that PHSIC successfully extracted beneficial parallel sentences from the noisy parallel corpus; the result using 1M data extracted from the 3M corpus by PHSIC was almost the same as that using 3M data (the decrease in the BLEU score was only 0.07), whereas that by random extraction reduced the BLEU score by 1.20.

This was actually a surprising result because PHSIC utilizes only monolingual similarity measures (kernels) without any other language resources. This indicates that PHSIC can be applied to a language pair poor in parallel resources. In addition, the surface form and grammatical characteristics between English and Japanese are extremely different[18]; therefore, we expect that PHSIC will work well regardless of the similarity of the language pair.

7 Related Work

Dependence Measures Measuring independence or dependence (correlation) between two random variables, i.e., estimating dependence from a set of paired data, is a fundamental task in statistics and a very wide area of data science. To measure the complex nonlinear dependence that real data has, we have several choices.

First, information-theoretic MI (Cover and Thomas, 2006) and its variants (Suzuki et al., 2009; Reshef et al., 2011) are the most commonly used dependence measures. However, to the best of our knowledge, there is no practical method of computing MIs for large-multi class high-dimensional

---

[17] `https://github.com/clab/fast_align`

[18] For example, word order; English is an SVO (subject-verb-object) language and Japanese is an SOV (subject-object-verb) language.

(having a complex generative model) discrete data, such as sparse linguistic data.

Second, several kernel-based dependence measures have been proposed for measuring nonlinear dependence (Akaho, 2001; Bach and Jordan, 2002; Gretton et al., 2005). The reason why kernel-based dependence measures work well for real data is that they do not explicitly estimate densities, which is difficult for high-dimensional data. Among them, HSIC (Gretton et al., 2005) is popular because it has a simple estimation method, which is used for various tasks such as feature selection (Song et al., 2012), dimensionality reduction (Fukumizu et al., 2009), and unsupervised object matching (Quadrianto et al., 2009; Jagarlamudi et al., 2010). We follow this line.

Co-occurrence Measures First, In NLP, PMI (Church and Hanks, 1989) and its variants (Bouma, 2009) are the de facto co-occurrence measures between *dense* linguistic expressions, such as words (Bouma, 2009) and simple narrative-event expressions (Chambers and Jurafsky, 2008). In recent years, positive PMI (PPMI) has played an important role as a component of word vectors (Levy and Goldberg, 2014).

Second, there are several studies in which the pairwise ranking problem has been solved by using deep neural networks (DNNs) in NLP. Li et al. (2016) proposed a PMI estimation using RNN language models; this was used as a baseline model in our experiments (see Section 6.2). Several studies have used DNN-based binary classifiers modeling $\mathbf{P}(C = \text{positive} \mid (x, y))$ to solve the given ranking problem directly (Hu et al., 2014; Yin et al., 2016; Mueller and Thyagarajan, 2016) (these networks are sometimes called Siamese neural networks). Our study focuses on comparing co-occurrence measures. It is unknown whether Siamese NNs capture the co-occurrence strength; therefore we did not deal with Siamese NNs in this paper.

Finally, to the best of our knowledge, Yokoi et al. (2017)'s paper is the first study that suggested converting HSIC to a pointwise measure. The present study was inspired by their suggestion; here, we have (i) provided a formal definition (population) of PHSIC; (ii) analyzed the relationship between PHSIC and PMI; (iii) proposed linear-time estimation methods; and (iv) experimentally verified the computation speed and robustness to data sparsity of PHSIC for practical applications.

8 Conclusion

The NLP community has commonly employed PMI to estimate the co-occurrence strength between linguistic expressions; however, existing PMI estimators have a high computational cost when applied to sparse linguistic expressions (Section 1). We proposed a new kernel-based co-occurrence measure, the pointwise Hilbert–Schmidt independent criterion (PHSIC). As well as defining PMI as the contribution to mutual information, PHSIC is defined as the contribution to HSIC; PHSIC is intuitively a "kernelized variant of PMI" (Section 3). PHSIC can be applied to sparse linguistic expressions owing to the mechanism of smoothing by kernels. Comparing the estimators of PMI and PHSIC, PHSIC can be interpreted as a smoothed variant of PMI, which allows various similarity metrics to be plugged in as kernels (Section 4). In addition, PHSIC can be estimated in linear time owing to the efficient matrix calculation, regardless of whether we use linear or nonlinear kernels (Section 5). We conducted a ranking task for dialogue systems and a data selection task for machine translation (Section 6). The experimental results show that (i) the learning of PHSIC was completed thousands of times faster than that of the RNN-based PMI while outperforming it in ranking accuracy (Section 6.2); and (ii) even when using a nonlinear kernel, PHSIC can be applied to a large dataset. Moreover, PHSIC reduces the amount of training data to one third without sacrificing the output translation quality (Section 6.3).

Future Work Using the PHSIC estimator in feature space (Equation (18)), we can generate the most appropriate $\psi(y)$ for a given $\phi(x)$ (uniquely, up to scale). That is, if a DNN-based sentence decoder is used, y (a sentence) can be restored from $\psi(y)$ (a feature vector) so that generative models of strong co-occurring sentences can be realized.

A Available Kernels for PHSIC

Similarity between Sentence Vectors A variety of vector representations of phrases and sentences based on the distributional hypothesis have recently been proposed, including sentence encoders (Kiros et al., 2015; Dai and Le, 2015; Iyyer et al., 2015; Hill et al., 2016; Cer et al., 2018) and the sum of word embeddings; it is known as *additive compositionality* (Mitchell and Lapata, 2010; Mikolov et al., 2013a; Wieting et al., 2015) that we can express the meaning of phrases and sentences well with the sum of word vectors (e.g., `word2vec` (Mikolov et al., 2013b), `GloVe` (Pennington et al., 2014), and `fastText` (Bojanowski et al., 2017)). Note that various pre-trained models of sentence encoders and word embeddings have also been made available.

The cosine of these vectors, which is a positive definite kernel, can be used as a convenient and highly accurate similarity function between phrases or sentences. Other major kernels can also be used, such as the RBF kernel, the Laplacian kernel, and polynomial kernels.

Structured Kernels Various structured kernels for NLP, such as tree kernels, which capture fine structure of sentences such as syntax, were devised in the support vector machine era (Collins and Duffy, 2002; Bunescu and Mooney, 2006; Moschitti, 2006).

Combinations We can freely combine the previously mentioned kernels because the sum and the product of positive definite kernels are also positive definite kernels (Shawe-Taylor and Cristianini, 2004, Proposition 3.22).

B Derivation of Fast PHSIC Estimation in Data Space

Although estimators of HSIC and PHSIC depend on kernels k, ℓ and data $\mathcal{D}$, hereinafter, we use the following notation for the sake of simplicity:

$$\widehat{\mathrm{HSIC}}(X,Y) := \widehat{\mathrm{HSIC}}(X,Y;\mathcal{D},k,\ell), \tag{25}$$

$$\widehat{\mathrm{PHSIC}}(x,y) := \widehat{\mathrm{PHSIC}}(x,y;\mathcal{D},k,\ell). \tag{26}$$

Naïve Estimation Fist, an estimator of PHSIC in the data space (15) is

$$\widehat{\mathrm{PHSIC}}_{\mathrm{kernel}}(x,y) = (\boldsymbol{k}-\overline{\boldsymbol{k}})^\top(\tfrac{1}{n}H)(\boldsymbol{\ell}-\overline{\boldsymbol{\ell}}), \tag{27}$$

where $\boldsymbol{k} := (k(x,x_1),\dots,k(x,x_n))^\top \in \mathbb{R}^n$, so as $\boldsymbol{\ell}$; and vector $\overline{\boldsymbol{k}} := \frac{1}{n}K\mathbf{1}$ denotes empirical mean of $\{\boldsymbol{k}_i\}_{i=1}^n$, so as $\overline{\boldsymbol{\ell}}$. This estimation has a large computational cost. When learning, computing the vectors $\overline{\boldsymbol{k}}, \overline{\boldsymbol{\ell}}$ takes $\mathcal{O}(n^2)$ time and $\mathcal{O}(n)$ space. When estimating PHSIC, computing $\boldsymbol{k}, \boldsymbol{\ell}$ and multiplying the matrix $\frac{1}{n}H$ takes $\mathcal{O}(n)$ time.

Fast Estimation via Incomplete Cholesky Decomposition Equation (27) has a large computational cost because it is necessary to construct the Gram matrices K and $L \in \mathbb{R}^{n\times n}$. In kernel methods, several methods have been proposed for approximating Gram matrices at low cost without constructing them explicitly, such as *incomplete Cholesky decomposition* (Fine and Scheinberg, 2001).

By incomplete Cholesky decomposition, from data points $\{x_1,\dots,x_n\} \subseteq \mathcal{X}$ and a positive definite kernel $k\colon \mathcal{X}\times\mathcal{X} \to \mathbb{R}$, a matrix $A = (\boldsymbol{a}_1,\dots,\boldsymbol{a}_n)^\top \in \mathbb{R}^{n\times d}$ ($d \ll n$) can be obtained with $\mathcal{O}(nd^2)$ time complexity. This makes it possible to approximate the Gram matrix K by vectors $\boldsymbol{a}_i \in \mathbb{R}^d$ without configuring the entire of K:

$$\boldsymbol{a}_i^\top \boldsymbol{a}_j \approx k(x_i,x_j) \tag{28}$$

$$AA^\top \approx K. \tag{29}$$

Also, for HSIC, an efficient approximation method utilizing incomplete Cholesky decomposition has been proposed (Gretton et al., 2005, Lemma 2):

$$\widehat{\mathrm{HSIC}}_{\mathrm{ICD}}(X,Y) = \frac{1}{n^2}\|(HA)^\top B\|_{\mathrm{F}}^2, \tag{30}$$

where $A = (\boldsymbol{a}_1,\dots,\boldsymbol{a}_n)^\top \in \mathbb{R}^{n\times d}$ is a matrix satisfying $AA^\top \approx K$ computed via incomplete Cholesky decomposition, so as B ($BB^\top \approx L$). Equation (30) can be represented in the form of the expectation on data points:

$$\widehat{\mathrm{HSIC}}_{\mathrm{ICD}}(X,Y) = \frac{1}{n}\sum_{i=1}^{n}\Big[(\boldsymbol{a}_i-\overline{\boldsymbol{a}})^\top \widehat{C}_{\mathrm{ICD}}(\boldsymbol{b}_i-\overline{\boldsymbol{b}})\Big] \tag{31}$$

$$\widehat{C}_{\mathrm{ICD}} := \frac{1}{n}(HA)^\top B \in \mathbb{R}^{d\times d}, \tag{32}$$

where vector $\overline{\boldsymbol{a}} := \frac{1}{n}A^\top\mathbf{1} \in \mathbb{R}^d$ denotes empirical mean of $\{\boldsymbol{a}_i\}_{i=1}^n$, so as $\overline{\boldsymbol{b}} := \frac{1}{n}B^\top\mathbf{1}$.

Recall that $\mathrm{PHSIC}(x,y)$ is the contribution of (x,y) to $\mathrm{HSIC}(X,Y)$ (see Section 3.3); PHSIC then can be efficiently estimated by the shaded part of Equation (31):

$$\widehat{\mathrm{PHSIC}}_{\mathrm{ICD}}(x,y) = (\boldsymbol{a}-\overline{\boldsymbol{a}})^\top \widehat{C}_{\mathrm{ICD}}(\boldsymbol{b}-\overline{\boldsymbol{b}}). \tag{33}$$

Here, the vector $\boldsymbol{a} \in \mathbb{R}^d$ corresponding to the new x can be calculated by “performing from halfway”

Models	*Config*			`(A)`	`(B)`	`(C)`	`(D)`
	Dim.	*Init.*					
RNN-PMI	300	`fastText`	`(A)`	–	.42	.12	.27
	1200	`fastText`	`(B)`	.42	–	.12	.26
	Encoder	*Kernel*					
PHSIC	`fastText`	`cos`	`(C)`	.12	.12	–	.16
	`DAN`	`cos`	`(D)`	.27	.26	.16	–

Table 7: **Spearman's** ρ between the co-occurrence scores computed by the models in the dialogue response selection task (Section 6.2). The size of training set n is 5×10^5. The other notation is the same as in Table 4.

on the incomplete Cholesky decomposition algorithm. Let $x^{(1)}, \ldots, x^{(d)}$ denote the dominant x_is adopted during decomposition algorithm. The jth element of $\boldsymbol{a}$ can be computed as follows:

$$\boldsymbol{a}[j] = \Big[k(x, x^{(j)}) - \sum_{m=1}^{j-1} \boldsymbol{a}[m] A_{jm}\Big] \,/\, A_{jj}, \quad (34)$$

so as $\boldsymbol{b} \in \mathbb{R}^d$ corresponding to the new y. The estimation via incomplete Cholesky decomposition (33) is extremely efficient compared to the naive estimation (27); Equation (33)'s computational complexity is equivalent to the estimation in the feature space (18).

C Detailed Settings for Learning RNNs

Detailed settings for learning RNNs used in this research are as follows:

- Hidden layers: single layer LSTMs (Hochreiter and Schmidhuber, 1997)
- Vocabulary: words with a frequency: 10 or more ($n = 5 \times 10^5$), 2 or more (otherwise)
- Dropout rate: 0.1 (300-dim), 0.3 (1200-dim)
- Batch size: 64
- Max epoch number: 5 ($n = 5 \times 10^5$), 30 (otherwise)
- Deep learning framework: `Chainer` (Tokui et al., 2015)

D Correlation Between Models in Dialogue Response Selection Task

Table D shows Spearman's rank correlation coefficient (Spearman's ρ) between the co-occurrence scores on the test set computed by the models in the dialogue response selection task (Section 6.2). This shows that the behavior of RNN-based PMI and PHSIC are considerably different. Furthermore, interestingly, the behavior of PHSICs using different kernels is also different. Possible reasons for these observations are as follows: (1) the difference in the dependence measures (MI or HSIC) on which each model is based; (2) the validity or numerical stability of estimating PMI with RNN language models; and (3) differences in the behavior of PHSIC originating from differences in the plugged in kernels. A more detailed analysis of the compatibility between tasks and measures (or kernels) is attractive future work.

Neural Related Work Summarization with a Joint Context-driven Attention Mechanism

Abstract

Conventional solutions to automatic related work summarization rely heavily on human-engineered features. In this paper, we develop a neural data-driven summarizer by leveraging the seq2seq paradigm, in which a joint context-driven attention mechanism is proposed to measure the contextual relevance within full texts and a heterogeneous bibliography graph simultaneously. Our motivation is to maintain the topic coherency between a related work section and its target document, where both the textual and graphic contexts play a big role in characterizing the relationship among scientific publications accurately. Experimental results on a large dataset show that our approach achieves a considerable improvement over a typical seq2seq summarizer and five classical summarization baselines.

1 Introduction

In scientific fields, scholars need to contextualize their contribution to help readers acquire an understanding of their research papers. For this purpose, the related work section of an article serves as a pivot to connect prior domain knowledge, in which the innovation and superiority of current work are displayed by a comparison with previous studies. While citation prediction can assist in drafting a reference collection (Nallapati et al., 2008), consuming all these papers is still a laborious job, where authors must read every source document carefully and locate the most relevant content cautiously.

As a solution in saving authors' efforts, automatic related work summarization is essentially a topic-biased multi-document problem (Cong and Kan, 2010), which relies heavily on human-engineered features to retrieve snippets from the references. Most recently, neural networks enable a data-driven architecture *sequence-to-sequence* (seq2seq) for natural language generation (Bahdanau et al., 2014, 2016), where an encoder reads a sequence of words/sentences into a context vector, from which a decoder yields a sequence of specific outputs. Nonetheless, compared to scenarios like machine translation with an end-to-end nature, aligning a related work section to its source documents is far more challenging.

To address the summarization alignment, former studies try to apply an attention mechanism to measure the saliency/novelty of each candidate word/sentence (Tan et al., 2017), with the aim of locating the most representative content to retain primary coverage. However, toward summarizing a related work section, authors should be more creative when organizing text streams from the reference collection, where the selected content ought to highlight the topic bias of current work, rather than retell each reference in a compressed but balanced fashion. This motivates us to introduce the contextual relevance and characterize the relationship among scientific publications accurately.

Generally speaking, for a pair of documents, a larger lexical overlap often implies a higher similarity in their research backgrounds. Yet such a hypothesis is not always true when sampling content from multiple relevant topics. Take "DSSM"[1] as an example, from viewpoint of the abstract similarity, those references investigating "Information Retrieval", "Latent Semantic Model" or "Clickthrough Data Mining" could be of more importance in correlation and should be greatly sampled for the related work section. But in reality, this article spends a bit larger chunk of texts (about 58%) to elaborate "Deep Learning" during the literature review, which is quite difficult for machines to grasp the contextual relevance therein. In addi-

tion, other situations like emerging new concepts also suffer from the terminology variation or paraphrasing in varying degrees.

In this study, we utilize a heterogeneous bibliography graph to embody the relationship within a scalable scholarly database. Over the recent past, there is a surge of interest in exploiting diverse relations to analyze bibliometrics, ranging from literature recommendation (Yu et al., 2015) to topic evolvement (Jensen et al., 2016). In a graphical sense, interconnected papers transfer the credit among each other directly/indirectly through various patterns, such as paper citation, author collaboration, keyword association and releasing on series of venues, which constitutes the graphic context for outlining concerned topics. Unfortunately, a variety of edge types may pollute the information inquiry, where a slice of edges are not so important as the others on sampling content. Meanwhile, most existing solutions in mining heterogeneous graphs depend on the human supervision, e.g., *hyperedge* (Bu et al., 2010) and *metapath* (Swami et al., 2017). This is usually not easy to access due to the complexity of graph schemas.

Our contribution is threefold: First, we explore the *edge-type usefulness distribution* (EUD) on a heterogeneous bibliography graph, which enables the relationship discovery (between any pair of papers) for sampling the interested information. Second, we develop a novel seq2seq summarizer for the automatic related work summarization, where a joint context-driven attention mechanism is proposed to measure the contextual relevance within both textual and graphic contexts. Third, we conduct experiments on 8,080 papers with native related work sections, and experimental results show that our approach outperforms a typical seq2seq summarizer and five classical summarization baselines significantly.

2 Related Work

This study touches on several strands of research within automatic related work summarization and seq2seq summarizer as follows.

The idea of creating a related work section automatically is pioneered by Cong and Kan (2010) who design two rule-based strategies to extract sentences for general and detailed topics respectively. Subsequently, Hu and Wan (2014) exploit *probabilistic latent semantic indexing* to split candidate texts into different topic-biased parts, then apply several regression models to learn the importance of each sentence. Similarly, Widyantoro and Amin (2014) transform the summarization problem into classifying rhetorical categories of sentences, where each sentence is represented as a feature vector containing word frequency, sentence length and etc. Most recently, Chen and Hai (2016) construct a graph of representative keywords, in which a *minimum steiner tree* is figured out to guide the summarization as finding the least number of sentences to cover the discriminated nodes. In general, compared to traditional summaries, the automatic related work summarization receives less concerns over the past. However, these existing solutions cannot work without manual intervention, which limits the application scale to an extremely small size (see Table 1).

Authors	Number of papers
Cong and Kan (2010)	20
Hu and Wan (2014)	1,050
Widyantoro and Amin (2014)	50
Chen and Hai (2016)	3

Table 1: Data scales of previous studies on automatic related work summarization.

The earliest seq2seq summarizer stems from Rush et al. (2015) which utilizes a feed-forward network for compressing sentences, and later is expanded by Chopra et al. (2016) with a *recurrent neural network* (RNN). On this basis, Nallapati et al. (2016a,c) and Chen et al. (2016) both present a set of RNN-based models to address various aspects of abstractive summarization. Typically, Cheng and Lapata (2016) propose a general seq2seq summarizer, where an encoder learns the representation of documents while a decoder generates each word/sentence using an attention mechanism. With further research, Nallapati et al. (2016b) extend the sentence compression by trying a hierarchical attention architecture and a limited vocabulary during the decoding phase. Next, Narayan et al. (2017) leverage the side information as an attention cue to locate focus regions for summaries. Recently, inspired by *PageRank*, Tan et al. (2017) introduce a graph-based attention mechanism to tackle the saliency problem. Nonetheless, these methods all discuss the single-document scenario, which is far from the nature of automatic related work summarization.

In this study, derived from the general seq2seq summarizer of Cheng and Lapata (2016), we propose a joint context-driven attention mechanism to measure the contextual relevance within full texts and a heterogeneous bibliography graph simultaneously. To our best knowledge, we make the first attempt to develop a neural data-driven solution for the automatic related work summarization, and the practice of using the joint context as an attention cue is also less explored to date. Besides, this study is launched on a dataset with up to 8,080 papers, which is much greater than previous studies and makes our results more convincing.

Since text summarization via word-by-word generation is not mature at present (Cheng and Lapata, 2016; Nallapati et al., 2016b; Tan et al., 2017), we adopt the extractive sentential fashion for our summarizer, where a related work section is created by extracting and linking sentences from a reference collection. Meanwhile, this study follows the mode of Cong and Kan (2010) who assume that the collection is given as part of the input, and do not consider the citation sentences of each reference.

3 Methodology

3.1 Problem Formulation

To adapt the seq2seq paradigm, we formulate the automatic related work summarization into a sequential text generation problem as follows.

Given an unedited paper $\mathtt{t}$ (target document) and its n-size reference collection $\mathtt{R_t} = \{\mathtt{r}^{\mathtt{t}}_{1:n}\}$, we draw up a related work section for $\mathtt{t}$ by selecting sentences from $\mathtt{R_t}$. To be specific, each reference (source document) will be traversed one time sequentially, and without loss of generality, in the descending order of their significance to $\mathtt{t}$. Consequently, all sentences to be selected are concatenated into an m-length sequence $\mathtt{S_t} = \{\mathtt{s}^{\mathtt{t}}_{1:m}\}$ to feed the summarizer. For each candidate sentence $\mathtt{s}^{\mathtt{t}}_j$, once being visited, a label $\mathtt{y}^{\mathtt{t}}_j \in \{0, 1\}$ will be determined synchronously based on whether or not this sentence should be covered into the output. Our objective is to maximize the log-likelihood probability of observed labels $\mathtt{Y_t} = \{\mathtt{y}^{\mathtt{t}}_{1:m}\}$ under $\mathtt{R_t}$, $\mathtt{S_t}$ and summarizer parameters θ, as shown below.

$$\max \sum_{j=1}^{m} \log \Pr(\mathtt{y}^{\mathtt{t}}_j \mid \mathtt{R_t}; \mathtt{S_t}; \theta) \tag{1}$$

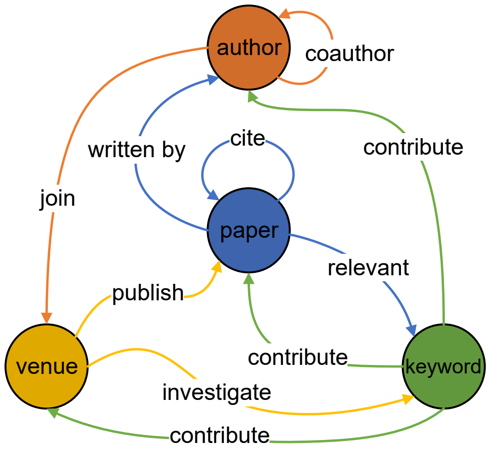

Figure 1: Heterogeneous bibliography graph.

3.2 Random Walk on Heterogeneous Bibliography Graph

Prior works have illustrated that one of the most promising channels for information recommendation is the community network (Guo and Liu, 2015). In this study, we verify this hypothesis toward the content sampling of scientific summarization, by investigating heterogeneous relations among different kinds of objects such as papers, authors, keywords and venues.

For measuring the relationship among scientific publications, we introduce a directed graph $\mathtt{G} = (\mathtt{V}, \mathtt{E})$ to contain various bibliographical connections, as shown in Figure 1, which involves four objects and ten edge types in total. Each edge $\mathtt{e}_{j,i} \in \mathtt{E}$ is assigned a value $\frac{\pi(\mathtt{e}_{j,i})}{z} \in [0, 1]$ to indicate the transition probability between two nodes $\mathtt{v}_j, \mathtt{v}_i \in \mathtt{V}$, where $\pi(\mathtt{e}_{j,i}) \in \mathbb{R}$ returns the unknown edge-type usefulness of $\mathtt{e}_{j,i}$, and $z \in \mathbb{R}$ is a normalizing weight. For most of edge types, we model the weight as one divided by the number of outgoing links of the same kind. But regarding the "contribution" category, the weight modeling is accomplished by *PageRank with Priors* (White and Smyth, 2003). Note that different edge types usually take very uneven importance in one particular task (Yu et al., 2015), and it is quite difficult to enable the classical heterogeneous graph mining without expert defined paths for *random walk* (Bu et al., 2010; Swami et al., 2017).

In this study, we propose an unsupervised approach to capture the connectivity diversity, by introducing an optimal EUD for navigating *random walkers* on the heterogeneous bibliography graph. Given a target document $\mathtt{t}$, the optimized usefulness assignment can help those walkers lock a top-n recommendation $\bar{\mathtt{R}}_\mathtt{t}$ to best match the reference collection $\mathtt{R}_\mathtt{t}$, as shown in Eq. 2. On this basis, a well-performing algorithm *node2vec* (Grover and Leskovec, 2016) is adopted to conduct an unsupervised *random walk* to vectorize every node $\forall \mathtt{v}_* \in \mathtt{V}$ into a d-dimensional embedding $\varphi(\mathtt{v}_*) \in \mathbb{R}^d$ so that any edge $\forall \mathtt{e}_* \in \mathtt{E}$ can be calculated therefrom. Specifically, we employ *evolutionary algorithm* (EA) to tune the EUD, which enjoys advantages over conventional gradient methods in both convergence speed and accuracy.

$$\arg\max \sum_{\mathtt{t}} \sum_{j=1}^{n} \log \Pr(\mathtt{r}_j^\mathtt{t} \in \bar{\mathtt{R}}_\mathtt{t} \mid \text{EUD}) \tag{2}$$

EA Setup We use an array of real numbers $\mathtt{x}_{1:10}$ to code an individual in the population, where $\mathtt{x}_j \in [0,1]$ denotes the usefulness of j-th edge type. Given an EUD, *PageRank* (Page, 1998) runs on graph to infer the relative importance of each node for each target document, and a fitness function is applied to judge how well this EUD satisfies locating the ground truth references as Eq. 3, in which if $\mathtt{r}_j^\mathtt{t}$ belongs to $\bar{\mathtt{R}}_\mathtt{t}$, then $\alpha(\mathtt{r}_j^\mathtt{t}, \bar{\mathtt{R}}_\mathtt{t}) \in \mathbb{N}$ returns the ranking of $\mathtt{r}_j^\mathtt{t}$ within $\bar{\mathtt{R}}_\mathtt{t}$, and otherwise a big penalty coefficient to prevent irrelevant references to be recommended. Like most other optimizations, this procedure starts with a randomly generated population.

$$\max \frac{1}{\sum_{\mathtt{t}} \sum_{j=1}^{n} \left| j - \alpha(\mathtt{r}_j^\mathtt{t}, \bar{\mathtt{R}}_\mathtt{t}) \right|} \tag{3}$$

EA Operator We choose the operator from *differential evolution* (Das and Suganthan, 2011) to generate offsprings for each individual. The basic idea is to utilize the difference between different individuals to disturb each trial object. First, three distinct individuals $\mathtt{x}_{1:10}^{r1}, \mathtt{x}_{1:10}^{r2}, \mathtt{x}_{1:10}^{r3}$ are sampled randomly from current population to create a variant $\mathtt{x}_{1:10}^{\text{var}}$, as shown in Eq. 4, where $f \in \mathbb{R}$ indicates the scaling factor. Next, $\mathtt{x}_{1:10}^{\text{var}}$ is crossed with a trial object $\mathtt{x}_{1:10}^{\text{tri}}$ to build a hybrid one $\mathtt{x}_{1:10}^{\text{hyb}}$ as Eq. 5, in which $c \in [0,1]$ denotes the crossover factor and $u \in [0,1]$ represents an uniform random number. At last, the fitnesses of $\mathtt{x}_{1:10}^{\text{tri}}$ and $\mathtt{x}_{1:10}^{\text{hyb}}$ are compared, and the better one will be saved as the offspring into a new round of evolution.

$$\mathtt{x}_j^{\text{var}} = \mathtt{x}_j^{r1} + f \times (\mathtt{x}_j^{r2} - \mathtt{x}_j^{r3}) \tag{4}$$

$$\mathtt{x}_j^{\text{hyb}} = \begin{cases} \mathtt{x}_j^{\text{var}}, & \text{if} \quad u \le c \\ \mathtt{x}_j^{\text{tri}}, & \text{otherwise} \end{cases} \tag{5}$$

3.3 Neural Extractive Summarization

As Figure 2 shows, we model our seq2seq summarizer with a hierarchical encoder and an attention-based decoder, as described below.

Hierarchical Encoder Our encoder consists of two major layers, namely a *convolutional neural network* (CNN) and a *long-short-term memory* (LSTM)-based RNN. Specifically, the CNN deals with word-level texts to derive sentence-level meanings, which are then taken as inputs to the RNN for handling longer-range dependency within lager units like a paragraph and even a whole paper. This conforms to the nature of document that is composed from words, sentences and higher levels of abstraction (Narayan et al., 2017).

Consider a sentence of p words $\mathtt{s}_j^\mathtt{t} = \{\mathtt{w}_{j,1:p}^\mathtt{t}\}$, where each word $\mathtt{w}_{j,i}^\mathtt{t}$ can be represented by a d-dimensional embedding $\phi(\mathtt{w}_{j,i}^\mathtt{t}) \in \mathbb{R}^d$. Previous studies have illustrated the strength of CNN in presenting sentences, because of its capability to learn compressed expressions and address sentences with variable lengths (Kim, 2014). First, a convolution kernel $k \in \mathbb{R}^{d \times q \times d}$ is applied to each possible window of q words to construct a list of feature maps as:

$$\mathtt{g}_{j,i}^\mathtt{t} = \tanh\left(k \times \phi(\mathtt{w}_{j,i:i+q-1}^\mathtt{t}) + b\right) \tag{6}$$

where $b \in \mathbb{R}^d$ denotes the bias term. Next, *max-over-time pooling* (Collobert et al., 2011) is performed on all generated features to obtain the sentence embedding as:

$$\phi(\mathtt{s}_j^\mathtt{t}) = \max_{1 \le i \le d} \left(\mathtt{g}_{j,1:p-q+1}^\mathtt{t}[i,:]\right) \tag{7}$$

where $[i,:]$ denotes the i-th row of matrix. Given a sequence of sentences $\mathtt{S}_\mathtt{t} = \{\mathtt{s}_{1:m}^\mathtt{t}\}$, we then take the RNN to yield an equal-length array of hidden states, in which LSTM has proved to alleviate the vanishing gradient problem when training long sequences (Hochreiter and Schmidhuber, 1997). Each hidden state can be viewed as a local representation with focusing on current and former sentences together, which is updated as: $\mathtt{h}_j^\mathtt{t} = \text{LSTM}\big(\phi(\mathtt{s}_j^\mathtt{t}), \mathtt{h}_{j-1}^\mathtt{t}\big) \in \mathbb{R}^d$.

In practice, we use multiple kernels with various widths to produce a group of embeddings for each

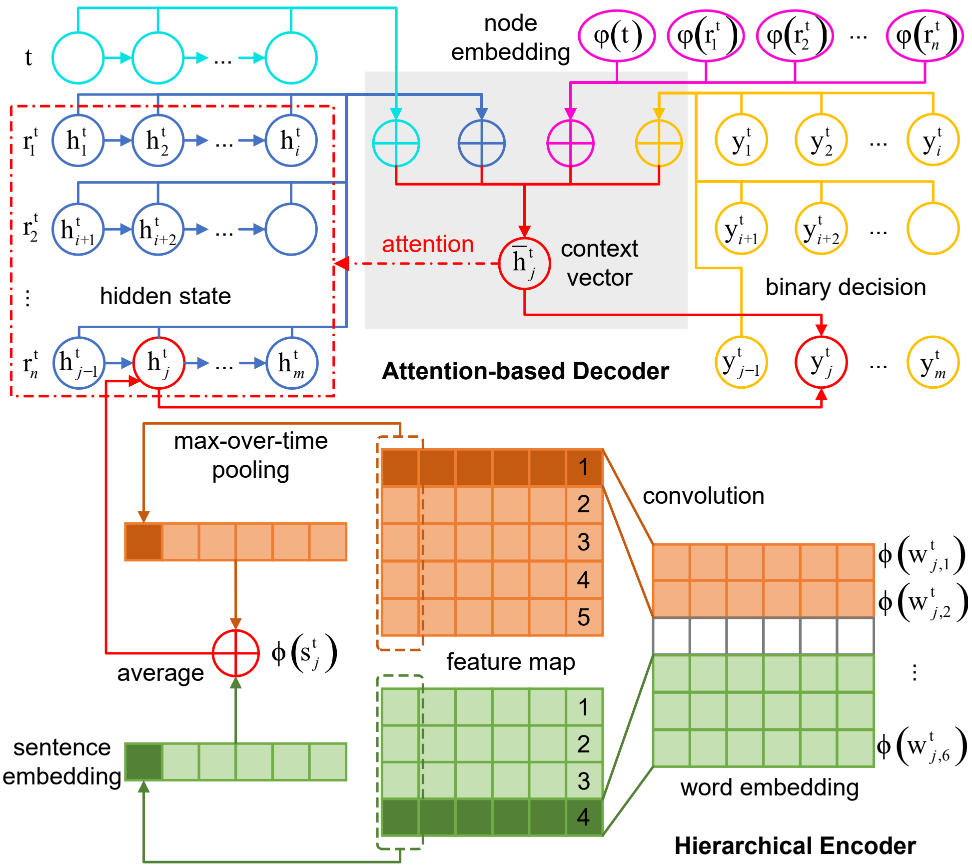

Figure 2: Framework of our seq2seq summarizer.

sentence, and average them to capture the information inside different n-grams. As Figure 2 (bottom) shows, the sentence $\mathtt{s}_j^{\mathtt{t}}$ involves six words, and two kernels of widths two (orange) and three (green) abstract a set of five and four feature maps respectively. Meanwhile, since *rhetorical structure theory* (Mann and Thompson, 2009) points out that association must exist in any two parts of coherent texts, RNN is only applicable to manage the sentence relation within a single document, because we cannot expect the dependency between two sections from different references.

Attention-based Decoder Our decoder labels each sentence $\mathtt{s}_j^{\mathtt{t}}$ as 0/1 sequentially, according to whether it is salient or novel enough, plus if relevant to the target document `t` or not. As shown in Figure 2 (top), the binary decision $\mathtt{y}_j^{\mathtt{t}}$ is made by both the hidden state $\mathtt{h}_j^{\mathtt{t}}$ and the context vector $\bar{\mathtt{h}}_j^{\mathtt{t}}$ from an attention mechanism (grey background). In particular, this attention (red dash line) is acted as an intermediate stage to determine which sentences to highlight so as to provide the contextual information for current decision (Bahdanau et al., 2014). Given $\mathtt{H}_{\mathtt{t}} = \{\mathtt{h}_{1:m}^{\mathtt{t}}\}$, this decoder returns the probability of $\mathtt{y}_j^{\mathtt{t}} = 1$ as below:

$$\Pr(\mathtt{y}_j^{\mathtt{t}} = 1 \mid \mathtt{R}_{\mathtt{t}}; \mathtt{S}_{\mathtt{t}}; \theta) = \text{sigmoid}\big(\delta(\mathtt{h}_j^{\mathtt{t}}, \bar{\mathtt{h}}_j^{\mathtt{t}})\big) \quad (8)$$

$$\bar{\mathtt{h}}_j^{\mathtt{t}} = \sum_{i=1}^{m} \mathtt{a}_{j,i} \mathtt{h}_i^{\mathtt{t}} \quad (9)$$

where $\delta(\mathtt{h}_j^{\mathtt{t}}, \bar{\mathtt{h}}_j^{\mathtt{t}}) \in \mathbb{R}$ denotes a fully connected layer with as input the concatenation of $\mathtt{h}_j^{\mathtt{t}}$ and $\bar{\mathtt{h}}_j^{\mathtt{t}}$, and $\mathtt{a}_{j,i} \in [0, 1]$ is the attention weight indicating how much the supporting sentence $\mathtt{s}_i^{\mathtt{t}}$ contributes to extracting the candidate one $\mathtt{s}_j^{\mathtt{t}}$.

Apart from saliency and novelty two traditional attention factors (Chen et al., 2016; Tan et al., 2017), we focus on the contextual relevance within both textual and graphic contexts to distinguish the relationship from near to far, as shown in Eq. 10 and Eq. 11. To be specific: 1) $\mathtt{h}_j^{\mathtt{t}\,\mathrm{T}} W_{\mathtt{s}} \mathtt{h}_i^{\mathtt{t}}$ represents the saliency of $\mathtt{s}_i^{\mathtt{t}}$ to $\mathtt{s}_j^{\mathtt{t}}$; 2) $-\mathtt{d}_j^{\mathtt{t}\,\mathrm{T}} W_{\mathtt{n}} \mathtt{h}_i^{\mathtt{t}}$ indicates the novelty of $\mathtt{s}_i^{\mathtt{t}}$ to the dynamic output $\mathtt{d}_j^{\mathtt{t}}$; 3) $\phi(\mathtt{t})^{\mathrm{T}} W_{\mathtt{t}} \mathtt{h}_i^{\mathtt{t}}$ denotes the relevance of $\mathtt{s}_i^{\mathtt{t}}$ to `t` from the textual context; 4) $\varphi(\mathtt{t})^{\mathrm{T}} W_{\mathtt{g}} \varphi(\mathtt{h}_i^{\mathtt{t}})$ refers to the relevance from the graphic context. More concretely, $W_* \in \mathbb{R}^d$ characterizes the learnable matrix, $\phi(\mathtt{t})$ returns the average of hidden states from $\mathtt{t}$, $\varphi(\mathtt{t})$ and $\varphi(\mathtt{h}_i^{\mathtt{t}})$ return the node embeddings of both $\mathtt{t}$ and the source document that $\mathtt{h}_i^{\mathtt{t}}$ belongs to respectively. Note that $\phi(\cdot)$ and $\varphi(\cdot)$ represent two distinct embedding spaces, where the former reflects the lexical collocations of corpus, and the latter embodies the connectivity patterns of associated graph.

$$\begin{aligned} \mathtt{a}_{j,i} = \quad & \mathtt{h}_j^{\mathtt{t}\,\mathrm{T}} W_{\mathtt{s}} \mathtt{h}_i^{\mathtt{t}} && \text{\# saliency} \\ & -\mathtt{d}_j^{\mathtt{t}\,\mathrm{T}} W_{\mathtt{n}} \mathtt{h}_i^{\mathtt{t}} && \text{\# novelty} \\ & +\phi(\mathtt{t})^{\mathrm{T}} W_{\mathtt{t}} \mathtt{h}_i^{\mathtt{t}} && \text{\# relevance}_1 \\ & +\varphi(\mathtt{t})^{\mathrm{T}} W_{\mathtt{g}} \varphi(\mathtt{h}_i^{\mathtt{t}}) && \text{\# relevance}_2 \end{aligned} \tag{10}$$

$$\mathtt{d}_j^{\mathtt{t}} = \sum_{i=1}^{j-1} \Pr(\mathtt{y}_j^{\mathtt{t}} = 1 \mid \mathtt{R}_{\mathtt{t}}; \mathtt{S}_{\mathtt{t}}; \theta) \times \mathtt{h}_i^{\mathtt{t}} \tag{11}$$

The basic idea behind our attention mechanism is as follows: if a supporting sentence more resembles a candidate one, or overlaps less with the dynamic output, or is more relevant to the target document, then it can provide more contextual information to facilitate current decision on being extracted or not, thereby taking a higher weight in the generated context vector. This innovative attention will guide our goal related work section to maximize the representativeness of selected sentences (saliency & novelty), while minimizing the semantic distance to the target document (relevance). This is consistent with the way that scholars consume a reference collection, with the min-max objective in their minds.

4 Experiment

4.1 Experimental Setup

This section presents the experimental setup for assessing our approach, including 1) dataset used for training and testing, 2) implementation details, 3) contrast methods and evaluation metrics.

Dataset We conduct experiments on a dataset[2] created from the ACM digital library, where metadata and full texts are derived from PDF files. To be detailed, this dataset includes 371,891 papers, 779,810 authors, 9,204 keywords and 807 venues in total. Note that we ignore the keyword with frequency below a certain threshold, and adopt *greedy matching* of Guo et al. (2013) to generate pseudo keywords for papers lacking topic descriptions. For each target document, the references are traversed by the descending order of the cited number in related work section (primary) and in full paper (secondary) successively. We first apply a series of pre-processings such as lowercasing and stemming to standardize candidate sentences, then remove those which are too short/long ($<$ 7 or $>$ 80 words). On this basis, a total of 8,080 papers are selected to evaluate our approach, each containing more than 15 references found in the dataset and a related work section of at least 500 words. But as for the heterogeneous bibliography graph, all source data have to be imported to ensure the structural integrity of communities. Besides, this graph should be constructed year-by-year to preclude the effect of later publications on earlier ones.

Implementation We use *Tensorflow* for implementation, where both the dimensions of embedding and hidden state are equally 128. For the CNN, *word2vec* (Mikolov et al., 2013) is utilized to initialize the word embeddings, which can be further tuned during the training phase. Meanwhile, we follow the work of Kim (2014) to apply a list of kernels with widths $\{3, 4, 5\}$. As for the RNN, each LSTM module is set to one single layer, and all input documents are padded to the same length, along with a mark to indicate the real number of sentences. Based on these settings, we train our summarizer using *Adam* with the default in Kingma and Ba (2014), and perform *mini-batch cross-entropy* training with a batch of one target document for 20 epochs.

To create training data for our summarizer, each reference needs to be annotated with the ground truth in advance, i.e., candidate sentences are tagged with 0/1 for indicating summary-worthy or not. Specifically, we follow a heuristic practice of Cao et al. (2016) and Nallapati et al. (2016b) to compute ROUGE-2 score (Lin and Hovy, 2003) for each sentence, in terms of the native related work sections (gold standards). Next, those sentences with high scores are chosen as the positive samples, and the rest as the negative ones, such that the total score of selected sentences is maximized with respect to the gold standard. As for

---

[2] To help readers reproduce the experiment outcome, we share part of the experiment data while the copyrighted information is removed. `https://github.com/kuadmu/2018EMNLP`

testing, we relax the number of sentences to be selected, and focus on the classification probability from Eq. 8. In this study, *cross validation* is applied to split the dataset into ten parts equally at random, in which nine are used for training and the other one for testing.

Evaluation We adopt the widely used toolkit ROUGE (Lin and Hovy, 2003) to evaluate the summarization performance automatically. In particular, we report ROUGE-1 and ROUGE-2 (unigram and bigram overlapping) as a way to assess the informativeness, and ROUGE-L (the longest common subsequence) as a means to assess the fluency, in terms of fixed bytes of gold standards.

To validate the proposed attention mechanism, we compare our approach (denoted as $\text{P.}_{\text{S+N+Rteg+EUD}}$) against six variants, including: 1) P._{void}: a plain seq2seq summarizer without attentions; 2) P._{S}: use the saliency as an only attention factor; 3) $\text{P.}_{\text{S+N}}$: leverage both the saliency and novelty; 4) $\text{P.}_{\text{S+N+Rt}}$: incorporate the relevance from the textual context; 5) $\text{P.}_{\text{S+N+Rtog}}$: gain the relevance from the graphic context of a homogeneous citation graph; 6) $\text{P.}_{\text{S+N+Rteg}}$: utilize the heterogeneous bibliography graph, but with each edge type the same usefulness.

In addition, we also select six representative summarization methods as a benchmark group. The first one is the general seq2seq summarizer by Cheng and Lapata (2016), denoted as PointerNet, which employs an attention mechanism to extract sentences directly after reading them. Following are five classical generic solutions, including: 1) Luhn (Luhn, 1958): a heuristic summarization based on word frequency and distribution; 2) MMR (Carbonell and Goldstein, 1998): a diversity-based re-ranking to produce summaries; 3) LexRank (Erkan et al., 2004): a graph-based summary technique inspired by *PageRank* and *HITS*; 4) SumBasic (Nenkova and Vanderwende, 2005): a frequency-based summarizer with duplication removal; 5) NltkSum (Acanfora et al., 2014): a *natural language tookit* (NLTK)-based implementation for summarization.

For clarity, Luhn, LexRank and SumBasic are analogous to the work of Hu and Wan (2014) which extracts sentences scoring the highest in significance, and they are also contrasted in the latest studies on neural summarizers (Chen et al., 2016; Tan et al., 2017). Meanwhile, MMR often serves as a part/post-processing of existing techniques to avoid the redundancy (Cohan and Goharian, 2017), and we introduce NltkSum to investigate the impact of grammatical/semantic analysis to the automatic related work summarization. Note that former studies specially for this task require extensive human involvements (see Table 1), thus we cannot apply them to such a large dataset of this study.

4.2 Results and Discussion

Table 2 reports the evaluation comparison over ROUGE metrics. From the top half, all scores appear a gradual upward trend with incorporation of saliency, novelty, relevance (from both textual and graphic contexts) and EUD into consideration one after another, which demonstrates the validity of our attention mechanism for summarizing related work sections. To be specific, we further reach the following conclusions:

1) P._{void} vs. P._{S} vs. $\text{P.}_{\text{S+N}}$: Both saliency and novelty are two effective factors to locate the required content for summaries, which is consistent with prior studies.

2) $\text{P.}_{\text{S+N}}$ vs. $\text{P.}_{\text{S+N+Rt}}$: Contextual relevance does contribute to address the alignment between a related work section and its source documents.

3) $\text{P.}_{\text{S+N+Rt}}$ vs. $\text{P.}_{\text{S+N+Rtog}}$: Textual context alone cannot provide entire evidence to characterize the relationship among scientific publications exactly.

4) $\text{P.}_{\text{S+N+Rtog}}$ vs. $\text{P.}_{\text{S+N+Rteg}}$: Heterogeneous bibliography graph involves richer contextual information than a homogeneous citation graph.

5) $\text{P.}_{\text{S+N+Rteg}}$ vs. $\text{P.}_{\text{S+N+Rteg+EUD}}$: EUD plays an indispensable role in organizing accurate contextual relevance on a heterogeneous graph.

cluster[3] under different attention factors. It can be seen that only after adding the relevance especially that from the graphic context into attentions, our summarizer can correctly sample the content from "Deep Learning" (yellow line), and eliminate that originated from "Other Sources" by a big margin (green line). As this example falls into the methodology transferring, a host of its involved word collocations are not idiomatic combinations yet, such as "Deep Neural Network" co-occurs with "Clickthrough Data" that is more frequently related to "Latent Semantic Analysis" at that time, which results in a somewhat biased textual context. By contrast, the graphic context will suffer less from this bias because it characterizes the connectivity patterns (real-time setup) instead of n-gram statistics, thus offering a more robust measure for the contextual relevance.

The bottom half of Table 2 illustrates the superiority of our approach over six representative summarization methods. Above all, Luhn, LexRank and MMR three summarizers that simply exploit shallow text features (word frequency and associated sentence similarity) to measure either significance or redundancy fall far behind the plain variant $P._{\text{void}}$, which partly reflects the strength of seq2seq paradigm in summarizing a related work section. Second, with combination of significance and redundancy, SumBasic achieves a drastic increase on ROUGE-1 and a mild raise on ROUGE-2 respectively, but it still cannot improve ROUGE-L marginally. This is because simple text statistics cannot present deeper levels of natural language understanding to catch larger-grained units of co-occurrence. Third, NltkSum benefits from a NLTK library so as to access grammatical/semantic supports, thereby having the best informativeness (ROUGE-1 and ROUGE-2) among the five generic baselines, and meanwhile a comparable fluency (ROUGE-L) with our approach. Finally, as a deep learning solution, although PointerNet takes both hidden states and previously labeled sentences into account, at each decoding step it focuses on only current and just one previous sentences, lacking a comprehensive consideration on saliency, novelty and more importantly the contextual relevance ($< P._{\text{S+N}}$).

To better verify the summarization performance, we also conduct a human evaluation on 35 papers containing more than 30 references in the dataset. We assign a number of raters to compare each generated related work section against the gold standard, and judge by three independent aspects as: 1) How compliant is the related work section to the target document? 2) How intuitive is the related work section for readers to grasp the key content? 3) How useful is the related work section for researchers to prepare their final literature reviews? Note that we do not allow any ties during the comparison, and each property is assessed with a 5-point scale of 1 (worst) to 5 (best).

Table 3 displays how often raters rank each summarizer as the 1st, 2nd and so on, in terms of

---

[3] We pack the references cited in the same subsection of the related work section as one reference cluster.

Methods	1st	2nd	3rd	4th	5th	6th	7th	Mean Ranking
Luhn	0.04	0.07	0.09	0.13	0.17	0.23	0.29	5.26
MMR	0.05	0.07	0.11	0.16	0.19	0.22	0.20	4.82
LexRank	0.06	0.09	0.11	0.14	0.17	0.19	0.27	4.93

PointerNet	0.14	0.20	0.18	0.15	0.13	0.11	0.08	3.54
$\text{P}_{\text{S+N+Rteg+EUD}}$	0.40	0.22	0.14	0.09	0.06	0.04	0.02	2.34

Table 3: Human evaluation (proportion) on 35 papers with more than 30 references in the dataset.

best-to-worst. Specifically, our approach comes the 1st on 40% of the time, which is followed by NltkSum that is considered the best on 21% of the time (almost half of ours), and PointerNet with quite equal proportions on each ranking. Furthermore, the other four summarizers account for obviously lower ratings in general. To attain the statistical significance, *one-way analysis of variance* (ANOVA) is performed on the obtained ratings, and the results show that our approach is better than all six contrast methods significantly ($p < 0.01$), which means that the conclusion drawn by Table 2 is sustained.

5 Conclusion

In this paper, we highlight the contextual relevance for the automatic related work summarization, and analyze the graphic context to characterize the relationship among scientific publications accurately. We develop a neural data-driven summarizer by leveraging the seq2seq paradigm, where a joint context-driven attention mechanism is proposed to measure the contextual relevance within full texts and a heterogeneous bibliography graph simultaneously. Extensive experiments demonstrate the validity of the proposed attention mechanism, and the superiority of our approach over six representative summarization baselines.

In future work, an appealing direction is to organize the selected sentences in a logical fashion, e.g., by leveraging a topic hierarchy tree to determine the arrangement of the related work section (Cong and Kan, 2010). We also would like to take the citation sentences of each reference into consideration, which is another concise and universal data source for scientific summarization (Chen and Hai, 2016; Cohan and Goharian, 2017). At the end of this paper, we believe that extractive methods are by no means the final solutions for literature review generation due to plagiarism concerns, and we are going to put forward a fully abstractive version in further studies.

Abstract

Information selection is the most important component in document summarization task. In this paper, we propose to extend the basic neural encoding-decoding framework with an information selection layer to explicitly model and optimize the information selection process in abstractive document summarization. Specifically, our information selection layer consists of two parts: gated global information filtering and local sentence selection. Unnecessary information in the original document is first globally filtered, then salient sentences are selected locally while generating each summary sentence sequentially. To optimize the information selection process directly, distantly-supervised training guided by the golden summary is also imported. Experimental results demonstrate that the explicit modeling and optimizing of the information selection process improves document summarization performance significantly, which enables our model to generate more informative and concise summaries, and thus significantly outperform state-of-the-art neural abstractive methods.

1 Introduction

Document summarization is the task of generating a fluent and condensed summary for a document while retaining the gist information. There are two prominent approaches: extractive methods and abstractive methods. Extractive methods generate summary for a document by directly selecting salient sentences from the original document. On the contrary, abstractive methods synthesize information from the input document to generate summary using arbitrary words and expressions - as human usually do. Recent neural models enable an end-to-end framework for natural language generation, which inspires the research on abstractive document summarization.

Most existing work directly apply the neural encoding-decoding framework, which first encodes the input into an abstract representation and then decodes the output based on the encoded information. Although the encoding-decoding framework has achieved huge success on some text generation tasks like machine translation (Bahdanau et al., 2014) and image caption (Vinyals et al., 2015), the performance on abstractive document summarization is much less convincing. Since document summarization is a special natural language generation task that requires information selection, the performance of current neural abstractive methods even has a considerable gap from extractive methods.

The most essential prerequisite for a practical document summarization system is that the generated summary must contain the salient information of the original document. Since a document is a long sequence of multiple sentences, both global document information and local inter-sentence relations need to be properly modeled in the information selection process. Although the encoding-decoding framework has implicitly modeled the information selection process via end-to-end training, we argue that abstractive document summarization shall benefit from explicitly modeling and optimizing it by capturing both the global document information and local inter-sentence relations.

In this paper, we propose to extend the encoding-decoding framework to model the information selection process explicitly. We treat the document summarization as a three-phase task: document encoding, information selection and summary decoding. Correspondingly, our model consists of three layers: a document encoder layer, an information selection layer and a

Brussels, Belgium, October 31 - November 4, 2018.

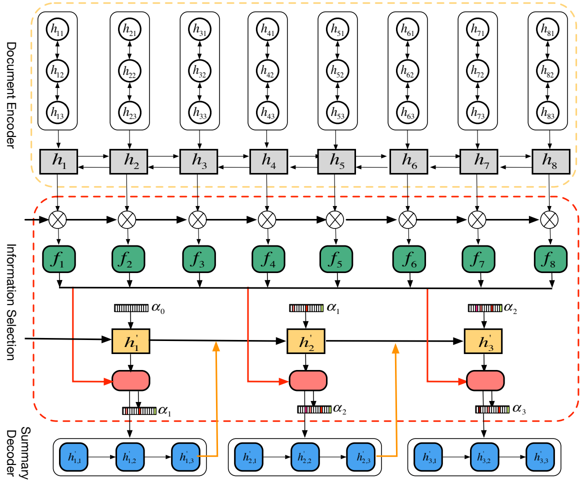

Figure 1: Our abstractive document summarization model, which mainly consists of three layers: document encoder layer (the top part), information selection layer (the middle part) and summary decoder layer (the bottom part).

summary decoder layer, as shown in Figure 1. In our model, both the document and summary are processed sentence by sentence, to better capture the inter-sentence relations. The information selection layer consists of two parts: gated global information filtering and local sentence selection. Unnecessary information in the original document are first globally filtered by a gated network, then important sentences are selected locally while generating each summary sentence sequentially. Moreover, we propose to optimize the information selection process with distantly-supervised training. Our proposed method combines the strengths of extractive methods and abstractive methods, which is able to tackle the factors of saliency, non-redundancy, coherence and fluency under a unified framework. We conduct extensive experiments on benchmark datasets and the results demonstrate that the explicit modeling and distantly-supervised optimizing of the information selection process improves document summarization performance significantly, which enables our model to significantly outperforms previous state-of-the-art neural abstractive methods.

2 Our Model

As shown in Figure 1, our model consists of a hierarchical document encoder, an information selection layer and an attention-equipped decoder. Firstly, the hierarchical encoder encodes the document sentence by sentence, and word by word in each sentence. Then the information selection layer selects and filters the sentence representations based on the global document representation. A sentence selection RNN is used to select salient and relevant sentences while generating each summary sentence sequentially based on the tailored sentence representations. At last, the summary decoder produces the output summary to paraphrase and generalize the selected sentences.

In the following, we denote h_i, $h_{i,j}$ as the hidden state of the i-th sentence and the j-th word of the i-th sentence in the document encoder part, respectively. In the information selection and summary decoder part, we denote h'_t, $h'_{t,k}$ as the hidden state of the t-th summary sentence and the k-th word in the t-th summary sentence, respectively.

2.1 Document Encoder

A document d is a sequence of sentences $d = \{s_i\}$, and each sentence is a sequence of words $s_i = \{w_{i,j}\}$. A hierarchical encoder, which consists of two levels: word level and sentence level similar to (Nallapati et al., 2016), is used to encode the document from both word and sentence level.

The word-level encoder is a bidirectional Gated Recurrent Unit (GRU) (Chung et al., 2014), which encodes the words of a sentence into sentence representation. The word encoder sequentially updates its hidden state after receiving a word, which is formulated as:

$$h_{i,j} = BiGRU(h_{i,j-1}, e_{i,j}) \qquad (1)$$

where $h_{i,j}$ and $e_{i,j}$ denotes the hidden state and embedding of word $w_{i,j}$, respectively.

The concatenation of the forward and backward final hidden states in the word-level encoder is indicated as the vector representation x_i of the sentence s_i, which is used as input to the sentence-level encoder. The sentence encoder is also a bidirectional GRU, which updates its hidden state after receiving each sentence representation by:

$$h_i = BiGRU(h_{i-1}, x_i) \qquad (2)$$

where h_i denotes the hidden state of sentence s_i.

The concatenation of the forward and backward final states in the sentence-level encoder is used as the vector representation of document $\hat{\mathbf{d}}$.

2.2 Information Selection

Document summarization is a special natural language generation task which requires information compression. It needs to remove the unnecessary information and select salient information from the input document to produce a condensed summary. However, it is difficult for the basic encoder-decoder framework to learn the process of salient information selection, which has also been noticed by several previous work (Tan et al., 2017a,b). To tackle the challenge, we extend the basic encoder-decoder framework by adding an information selection layer to model the information selection process explicitly. Our information selection layer consists of two parts: gated global information filtering that used to remove the unnecessary information of a document, and local sentence selection that used to select salient sentences from a document sequentially to produce summary sentences.

Gated Global Information Filtering

Inspired by studies on how human write text summaries by first skimming the document and deleting unnecessary material (Brown and Day, 1983), we design a gated global information filtering network to filter unnecessary information of a document based on the global document representation before the summary decoder generates summary. Concretely, the gated information filtering network makes use of the document representation $\hat{\mathbf{d}}$, which represents the global information of a document, to filter sentences based on the sentence representation h_i.

For each source sentence s_i, the gate network takes the document representation $\hat{\mathbf{d}}$ and sentence representation h_i as inputs to compute the gate vector g_i:

$$g_i = \sigma(W_g h_i + U_g \hat{\mathbf{d}} + b_g) \tag{3}$$

where W_g and U_g denote weight matrices, b_g the bias vector, and σ the sigmoid activation function.

Then each sentence s_i can be filtered by the gate vector g_i as follows:

$$f_i = h_i \odot g_i \tag{4}$$

where f_i indicates the representation of sentence s_i after information filtering, and $\odot$ denotes element-wise multiplication.

Note that, we filter sentences in micro semantic dimensions rather than filtering whole sentences. The tailored sentence representations are used as input to the sentence selection network and summary decoder, which can help to detect salient sentences and improve informativeness of the generated summary.

Local Sentence Selection

We explicitly model the local sentence selection process which selects several target sentences to generate a summary sentence. Concretely, we apply a RNN layer to sequentially select target sentences for each summary sentence, shown as in Figure 1. The sentence-selection RNN uses the document representation $\hat{\mathbf{d}}$ as initial state $h_0^{'}$, and sequentially predicts the sentence selection vector α_t as follows:

$$\alpha_t^i = \frac{e^{\phi(f_i, h_t')}}{\sum_l e^{\phi(f_l, h_t')}} \tag{5}$$

$$\phi(f_i, h_t') = v^T tanh(W_f f_i + W_h h_t' + b). \tag{6}$$

where α_t^i indicates the weight of source sentence s_i when generating the t-th summary sentence, and $h_t^{'}$ denotes the hidden state of sentence selection layer when generating the t-th summary sentence. v, W_f and W_h are weight matrices, and b is the bias vector. Note that, the sentence selection vector α_t is computed based on the tailored sentence representation f_i.

The sentence-selection RNN uses a single unidirectional GRU, which updates its state by:

$$h_t^{'} = GRU(h_{t-1}^{'}, x_t^{'}) \tag{7}$$

where $x_t^{'}$ denotes the input of current sentence-selection step. $x_t^{'}$ combines both the previous sentence selection vector α_{t-1} and the encoded representation of previous generated sentence $r_{t-1}^{'}$ by $x_t^{'} = tanh(W_r r_{t-1}^{'} + W_\alpha \alpha_{t-1} + b_x)$, where W_r, W_α, and b_x denote learnable parameters.

The representation of the selected source sentences is computed by:

$$q_t = \sum_j \alpha_t^j f_j \tag{8}$$

which is used as initial state of the summary decoder to generate a summary sentence to paraphrase and generalize the selected sentences.

2.3 Summary Decoder

On top of the document encoder and the information selection layer, we use GRU with attention as the summary decoder to realize each summary sentence word by word.

At each word decoding step k in the t-th summary sentence, the GRU reads the previous word embedding $e_{t,k-1}$ and context vector $c_{t,k-1}$ as inputs to compute the new hidden state $h'_{t,k}$ by:

$$h'_{t,k} = GRU(h'_{t,k-1}, c_{t,k-1}, e_{t,k-1}) \tag{9}$$

We import attention mechanism to help locate relevant words to be copied or paraphrased within the selected source sentences in each word generation step. The attention distribution $\beta^i_{t,k}$ of the kth word of the tth summary sentence over the sentences in the ith document can be computed as:

$$\beta^{i,j}_{t,k} = \alpha^i_t \frac{e^{\phi(h_{i,j}, h'_{t,k})}}{\sum_l e^{\phi(h_{i,l}, h'_{t,k})}} \tag{10}$$

where α^i_t denotes the weight of the ith source sentence, used to normalize the word attention distributions. Then the word-level context vector when generating the kth word at the tth sentence generation step can be computed as: $\mathbf{c}_{t,k} = \sum_i \sum_j \beta^{i,j}_{t,k} h_{i,j}$, which is also incorporated into the word decoder.

At each word generation step, the vocabulary distribution is calculated from the context vector $\mathbf{c}_{t,k}$ and the decoder state $h'_{t,k}$ by:

$$P_{vocab}(w'_{t,k}) = softmax(W_v(W_c[h'_{t,k}, c_{t,k}] + b_c) + b_v) \tag{11}$$

where W_v and W_c are learned parameters. The copy mechanism based on the word attention is also imported into the decoder to alleviate the OOV problems as in (See et al., 2017).

2.4 Model Learning with Distant Supervision

Despite the end-to-end training for the performance of generated summary, we also directly optimize the sentence selection decisions by importing supervision for the sentence selection vector α_t in Equation 5. While there is no explicit supervision for sentence selection, we define a simple approach for labeling sentences based on the reference summaries. To simulate the sentence selection process on human-written abstracts, we compute the words-matching similarities (based on TF-IDF cosine similarity) between a reference-summary sentence and corresponding source document sentences and normalize them into distantly-labelled sentence selection vector p_t. Then the sentence selection loss is defined as:

$$loss_{sel} = \sum_t D_{KL}(\alpha_t, p_t) \tag{12}$$

where $D_{KL}(\alpha_t, p_t)$ indicates the KL-divergence between distribution α_t and p_t. The sentence selection loss is imported into the final loss function to be optimized with the summary generation component together.

The loss function $\mathcal{L}$ of the model is the mix of the negative log-likelihood of generating summaries over training set $\mathcal{T}$, and the sentence selection loss of distantly-supervised training:

$$\mathcal{L} = \sum_{(X,Y)\in\mathcal{T}} -logP(Y|X;\theta) + \lambda loss_{sel} \tag{13}$$

where λ is a hyper-parameter tuned on the validation set. (X, Y) denotes a document-summary pair in the training set.

3 Experiments

3.1 Dataset

We conduct our experiments on a large-scale corpus of *CNN/DailyMail*, which has been widely used for exploration on summarizing documents with multi-sentence summaries. The corpus are originally constructed in (Hermann et al., 2015) by collecting human generated highlights from news stories in the CNN and DailyMail Website, which contains input document of about 800 tokens on average and multi-sentence summaries of up to 200 tokens. We use the same version of data with (See et al., 2017), which totally has 280,125 training pairs, 13,367 validation pairs and 11,489 test pairs after discarding the examples with empty article text. Some of previous work (Nallapati et al., 2016, 2017; Paulus et al., 2017; Tan et al., 2017a) use the anonymized version of data, which has been pre-processed to replace each named entity with an unique identifier. By contrast, we use the non-anonymized data similar to (See et al., 2017), which is a more favorable and challenging problem because it requires no pre-processing.

3.2 Implementation Details

Model Parameters For all experiments, the word-level encoder and summary decoder both use 256-dimensional hidden states, and the sentence-level encoder and sentence selection network both use 512-dimensional hidden states. We use pre-trained Glove (Pennington et al., 2014) vector for initialization of word embeddings. The dimension of word embeddings is 100, which will be further trained in the model. We use a vocabulary of 50k words for both encoder and decoder.

Method	Rouge-1	Rouge-2	Rouge-L

Seq2seq-b.	3.11^*	2.95^*	3.08^*	3.51^*
Coverage	3.41^*	3.25^*	3.37	3.72
Our Model	3.76	3.49	3.65	3.80

Table 2: Human evaluation results. * indicates the difference between **Our Model** and other models are statistic significant ($p < 0.1$) by two-tailed t-test.

We use dropout (Srivastava et al., 2014) with probability $p = 0.5$. After tuning on the validation set, parameter λ is set as 0.2.

Model Training We use Adagrad (Duchi et al., 2011) algorithm with learning rate 0.1 and an initial accumulator value of 0.1 to optimize the model parameters θ. During training, we use gradient clipping with a maximum gradient norm of 2. Our model is trained on a single Tesla K40m GPU with a batch size of 16 and an epoch is set containing 10,000 randomly sampled documents. Convergence is reached within 300 epochs.

Hierarchical Beam Search To improve information correctness and avoid redundancy during the summary decoding process, we use the hierarchical beam search algorithm with reference mechanism (Tan et al., 2017a) to generate multi-sentence summaries. Similar to (Tan et al., 2017a), the beam sizes for word decoder and sentence decoder are 15 and 2, respectively.

3.3 Baselines

We compare our system with the results of state-of-the-art neural summarization approaches reported in recent papers, which contain both abstractive models and extractive models. The extractive models include **SummaRuNNer** (Nallapati et al., 2017), while **SummaRuNNer-abs** is similar to SummaRuNNer but is trained directly on the abstractive summaries. **Lead-3** is a strong extractive baseline which uses the first 3 sentences of the document as summary. The abstractive models include:

1) **Seq2seq-baseline**, which uses the basic seq2seq encoder-decoder structure with attention mechanism and incorporates with the copy mechanism as in (See et al., 2017).
2) **ABS-temp-attn** (Nallapati et al., 2016), which uses *Temporal Attention* on the seq2seq architecture to overcome the repetition problem.
3) **Graph-attention** (Tan et al., 2017a), which uses a graph-ranking based attention mechanism based on a hierarchical architecture to identify important source sentences.
4) **Deep-reinforced** (Paulus et al., 2017), which trains the seq2seq encoder-decoder model with reinforcement learning techniques.
5) **Coverage** (See et al., 2017), which is an extension of the Seq2seq-baseline model by importing coverage mechanism to control repetitions in summary.

3.4 Evaluation

ROUGE Evaluation

We evaluate our models with the standard ROUGE metric (Lin, 2004) and obtain ROUGE scores using the `pyrouge` package. Results in Table 1 show that our method has significant improvement over state-of-the-art neural abstractive baselines as well as extractive baselines. Note that, the **Deep-reinforced** model achieves the best ROUGE-L performance because it directly optimizes the ROUGE-L metric. Comparing with the current state-of-the-art model **Coverage**, our model achieves significant better performance on ROUGE-1 and ROUGE-2 metrics, and comparable performance on ROUGE-L metric, which demonstrates that our model is more effective in selecting salient information from a document to produce an informative summary while keeping the ability to generate fluent and correct sentences.

Human Evaluation with Case Analysis

In addition to the ROUGE evaluation, we also conducted human evaluation on 50 random samples from CNN/DailyMail test set and compared the summaries generated by our method with the outputs of **Lead-3**, **Seq2seq-baseline** and **Coverage**. Three data annotators were asked to compare the generated summaries with the human summaries, and assess each summary from four independent

Gold Reference: faith and hope howie were born with one body and two faces on may 8 . they tragically died in hospital just 19 days after they were born . parents simon howie and renee young visit their grave at pinegrove in western sydney fortnightly . they arrived on thursday to find the grave bare of all the girls ' mementos . staff had cleared entire baby section and thrown belongings in rubbish .
Seq2Seq-baseline: faith and hope howie were dubbed the miracle twins when they were born on may 8 last year with one body and two faces due to an extremely rare condition known as disrosopus . faith and hope howie were dubbed the miracle twins when they were born on may 8 last year with one body and two faces due to an extremely rare condition known as disrosopus . faith and hope howie were dubbed the miracle twins when they were born on may 8 last year with one body and two faces due to an extremely rare condition known as disrosopus .
Coverage: faith and hope howie were dubbed the miracle twins when they were born on may 8 last year with one body and two faces due to an extremely rare condition known as disrosopus . they died in hospital less than a month after they were born and their parents , simon howie and renee young , laid them to rest at pinegrove memorial park in sydney 's west.
Our Model: faith and hope howie were dubbed the miracle twins when they were born on may 8 last year with one body and two faces due to an extremely rare condition known as disrosopus. they died in hospital less than a month after they were born and their parents , simon howie and renee young , laid them to rest at pinegrove memorial park in sydney 's west. family members have visited the grave every week to leave mementos and flowers for faith and hope , but when mr howie and ms young arrived on thursday they found the site completely bare .

Table 3: Examples of generated summaries. The Seq2Seq-baseline model generates repeated sentences and loses salient information. The Coverage model reduces repetitions, but also loses salient information. Our model can select more salient information from the original document and generate more informative summary.

perspectives: (1) **Informative**: How informative the summary is? (2) **Concise**: How concise the summary is? (3) **Coherent**: How coherent (between sentences) the summary is? (4) **Fluent**: How fluent, grammatical the sentences of a summary are? Each property is assessed with a score from 1(worst) to 5(best) by three annotators. The average results are presented in Table 2.

The results show that our model consistently outperforms the **Seq2seq-baseline** model and the previous state-of-the-art method **Coverage**. An example of comparison of the generated summaries by our model with the two abstractive models (w.r.t the reference summary) is shown in Table 3[1]. The summary generated by **Seq2Seq-Baseline** usually contains repetition of sentences, which seriously affects its informativeness, conciseness as well as coherence. For example, the sentence "*faith and hope howie were dubbed the miracle twins when they were born ...*" is repeated three times in Table 3. The **Coverage** model effectively alleviates the information repetition problem, however, it loses some salient information that should be included in the summary. For example, the information about "**mementos**" and "**family members visit the grave**" is lost in the example shown in Table 3. The summary generated by our method obviously contains more salient information, which shows the effectiveness of the information selection component in our model. According to the results in Table 2, the sentence-level modeling of document and summary in our model also makes the generated summaries achieve better inter-sentence coherence. Compared with the strong extractive baseline **Lead-3**, our model is able to generate more informative and concise summaries, which shows the advantage of abstractive methods. The fluency scores also show the good ability of our model to generate fluent and grammatical sentences. The human evaluation results demonstrate that our model is able to generate more informative, concise and coherent summaries than the baselines.

Figure 2: Visualization of sentence selection vectors. I_i and O_i indicate the i-th sentence of the input and output, respectively. Obviously, our model can detect more salient sentences that are included in the reference summary.

The visualization of the sentence selection vectors of the gold reference summary and the three abstractive models when generating the presented examples in Table 3 are shown in Figure 2[2]. The figure shows that **Seq2Seq-baseline** fails to detect all important source sentences and attend to the same sentences repeatedly, which result in generating repeated summary sentences. **Coverage** learns to reduce repetitions, but fails to detect all the salient information. Obviously, our method is more effective in selecting salient and relevant source sentences from the document to generate more informative summary. Furthermore, our

---

[2] The sentence selection vectors of the Seq2seq-baseline mode and the Coverage model are computed by summing the attention weights of all words in each sentence and then normalized across sentences.

Method	Rouge-1	Rouge-2	Rouge-L
Our Model	**41.54**	**18.18**	**36.47**
– *distS*	40.02	17.54	34.87
– *distS&gateF*	39.26	16.96	33.92
– *infoSelection*	36.64	15.66	33.42

Table 4: Comparison results of removing different components of our method.

method tends to focus on different sets of source sentences when generating different summary sentences. The results verify that the information selection component in our model significantly improves the information selection process in document summarization.

4 Discussion

In this section, we first validate the effectiveness of each component of our model, then compare the performance of information selection of our method with several extractive methods, and finally analyze the effects of golden summary length on the performance of our model.

4.1 Model Validation

To further verify the effectiveness of each component in our model, we conduct several ablation experiments. "– *distS*" denotes removing the distant supervision for sentence selection (set λ as 0). "– *distS&gateF*" denotes removing both the distant supervision for sentence selection training and the global gated information filtering component. "– *infoSelection*" denotes removing the whole information selection layer and do not explicitly modeling the information selection process, which is actually the Seq2seq-baseline model.

Results on the test set are shown in Table 4. Our method much outperforms all the comparison systems and removing each component of our model one by one will leads to sustained significant performance declining, which verifies the effectiveness of each component in our model. The global gated information filtering network removes unnecessary information from the original document and helps generate more informative summary. The distantly-supervised training for sentence selection decisions helps the model learn to detect important and relevant source sentences for each summary sentence. The results verify that explicitly modeling the information selection process significantly improves the document summarization performance.

Method	Rouge-1	Rouge-2	Rouge-L
SummaRuNNer-abs	37.5	14.5	33.4
SummaRuNNer	39.6	16.2	35.3
OurExtractive	**40.41**	**18.30**	36.30
– *distS*	37.06	16.55	33.23
– *distS&gateF*	36.25	16.22	32.59

Table 5: Comparsion results of sentence selection.

length	Method	Rouge-1	Rouge-2	Rouge-L
< 75 (81.82%)	Our Mod.	**39.90**	**16.91**	35.19
	Coverage	38.90	16.81	**35.82**
$[75, 100)$ (12.64%)	Our Mod.	**47.13**	**22.44**	**40.81**
	Coverage	42.89	19.72	39.41
$[100, 125)$ (4.00%)	Our Mod.	**50.49**	**24.23**	**43.68**
	Coverage	41.78	19.00	38.41
> 125 (1.54%)	Our Mod.	**50.25**	**23.98**	**41.19**
	Coverage	39.57	17.93	36.33

Table 6: Comparison results w.r.t different length of reference summary. < 75 indicates the reference summary has less than 75 words (occupy 81.82% of test set), $[75, 100)$ denotes the number of words in reference summary is between 75 and 100 (occupy 12.64% of test set).

4.2 Effectiveness of Information Selection

To verify the performance of sentence selection in our model, we add a comparison system **OurExtractive** which is almost the same as our model, but replaces the summary decoder by a sentence extractor. The sentence extractor extracts the source sentence with the largest weight in each sentence generation step. "– *distS*" denotes removing the distant supervision for sentence selection training in our model. "– *distS&gateF*" denotes removing both the distant supervision for sentence selection training and the gated global information filtering component.

Results in Table 5 show that our simple extractive method **OurExtractive** significantly outperforms state-of-the-art neural extractive baselines, which demonstrates the effectiveness of the information selection component in our model. Moreover, **OurExtractive** significantly outperforms the two comparison systems which remove different components of our model one by one. The results show that both the gated global information filtering and distant supervision training are effective for improving information selection in document summarization. Our proposed method effectively combines the strengths of extractive methods and abstractive methods into a unified framework.

4.3 Effects of Summary Length

We further compare our method with the **Coverage** model by evaluating them on the test set with different length of golden reference summaries. The results are shown in Table 6, which demonstrate that our method is better at generating long summary for long document. As the golden summary becoming longer, our system will obtain larger advantages over the baseline (from +1.0 Rouge-1, +0.1 Rouge-2 and -0.63 Rouge-L for summary less than 75 words, rising to +10.68 Rouge-1, +6.05 Rouge-2 and +4.86 Rouge-L for summaries more than 125 words). The results also verify that our method is more effective in selecting salient information from documents, especially for long documents.

5 Related Work

Existing exploration on document summarization mainly can be categorized to **extractive methods** and **abstractive methods**.

5.1 Extractive Summarization Methods

Neural networks have been widely investigated on extractive document summarization task. Earlier work attempts to use deep learning techniques to improve sentence ranking or scoring (Cao et al., 2015a,b; Yin and Pei, 2015). Some recent work solves the sentence extraction and document modeling in an end-to-end framework. Cheng and Lapata (2016) propose an encoder-decoder approach where the encoder hierarchically learns the representation of sentences and documents while an attention-based sentence extractor extracts salient sentences sequentially from the original document. Nallapati et al. (2017) propose a recurrent neural network-based sequence-to-sequence model for sequential labelling of each sentence in the document. Neural models are able to leverage large-scale corpora and achieve better performance than traditional methods.

5.2 Abstractive Summarization Methods

As the seq2seq learning with neural networks achieve huge success in sequence generation tasks like machine translation, it also shows great potential in text summarization area, especially for abstractive methods. Some earlier researches studied the use of seq2seq learning for abstractive sentence summarization (Takase et al., 2016; Rush et al., 2015; Chopra et al., 2016). These models are trained on a large corpus of news documents which are usually shortened to be the first one or two sentences, and their headlines.

Later, some work explored the seq2seq models on document summarization, which produce a multi-sentence summary for a document. The seq2seq models usually exhibit some undesirable behaviors, such as inaccurately reproducing factual details, unable to deal with out-of-vocabulary (OOV) words and repetitions. To alleviate these issues, copying mechanism (Gu et al., 2016; Gulcehre et al., 2016; Nallapati et al., 2016) has been incorporated into the encoder-decoder architecture. Distraction-based attention model (Chen et al., 2016) and coverage mechanism (See et al., 2017) have also been investigated to alleviate the repetition problem. To better train the seq2seq model on tasks with long documents and multi-sentence summaries, a deep reinforced model was proposed to combine the standard words predication with teacher forcing learning and the global sequence prediction training with reinforcement learning (Paulus et al., 2017). Recently, Tan et al. (2017a) propose to leverage the hierarchical encoder-decoder architecture on generating multi-sentence summaries, and incorporate sentence-ranking into the summary generation process based on the graph-based attention mechanism. Different from these neural-based work, our model explicitly models the information selection process in document summarization by extending the encoder-decoder framework with an information selection layer. Our model captures both the global document information and local inter-sentence relations, and optimize the information selection process directly via distantly-supervised training, which effectively combines the strengths of extractive methods and abstractive methods.

6 Conclusion

In this paper, we have analyzed the necessity of explicitly modeling and optimizing of the information selection process in document summarization, and verified its effectiveness by extending the basic neural encoding-decoding framework with an information selection layer and optimizing it with distantly-supervised training. Our information selection layer consists of a gated global information filtering network and a local RNN sentence selection network. Experimental results demonstrate that both of them are effective for helping select salient information during the summary generation process, which significantly improves the document summarization performance. Our model combines the strengths of extractive methods and abstractive methods, which can generate more informative and concise summaries, and thus achieves state-of-the-art abstractive document summarization performance and is also competitive with state-of-the-art extractive models.

Abstract

We introduce *extreme summarization*, a new single-document summarization task which does not favor extractive strategies and calls for an abstractive modeling approach. The idea is to create a short, one-sentence news summary answering the question "What is the article about?". We collect a real-world, large scale dataset for this task by harvesting online articles from the British Broadcasting Corporation (BBC). We propose a novel abstractive model which is conditioned on the article's topics and based entirely on convolutional neural networks. We demonstrate experimentally that this architecture captures long-range dependencies in a document and recognizes pertinent content, outperforming an oracle extractive system and state-of-the-art abstractive approaches when evaluated automatically and by humans.[1]

SUMMARY: *A man and a child have been killed after a light aircraft made an emergency landing on a beach in Portugal.*

DOCUMENT: Authorities said the incident took place on Sao Joao beach in Caparica, south-west of Lisbon.
The National Maritime Authority said a middle-aged man and a young girl died after they were unable to avoid the plane.
[*6 sentences with 139 words are abbreviated from here.*]
Other reports said the victims had been sunbathing when the plane made its emergency landing.
[*Another 4 sentences with 67 words are abbreviated from here.*]
Video footage from the scene carried by local broadcasters showed a small recreational plane parked on the sand, apparently intact and surrounded by beachgoers and emergency workers.
[*Last 2 sentences with 19 words are abbreviated.*]

Figure 1: An abridged example from our extreme summarization dataset showing the document and its one-line summary. Document content present in the summary is color-coded.

1 Introduction

Automatic summarization is one of the central problems in Natural Language Processing (NLP) posing several challenges relating to *understanding* (i.e., identifying important content) and *generation* (i.e., aggregating and rewording the identified content into a summary). Of the many summarization paradigms that have been identified over the years (see Mani, 2001 and Nenkova and McKeown, 2011 for a comprehensive overview), single-document summarization has consistently attracted attention (Cheng and Lapata, 2016; Durrett et al., 2016; Nallapati et al., 2016, 2017; See et al., 2017; Tan and Wan, 2017; Narayan et al., 2017; Fan et al., 2017; Paulus et al., 2018; Pasunuru and Bansal, 2018; Celikyilmaz et al., 2018; Narayan et al., 2018a,b).

Neural approaches to NLP and their ability to learn continuous features without recourse to pre-processing tools or linguistic annotations have driven the development of large-scale document summarization datasets (Sandhaus, 2008; Hermann et al., 2015; Grusky et al., 2018). However, these datasets often favor extractive models which create a summary by identifying (and subsequently concatenating) the most important sentences in a document (Cheng and Lapata, 2016; Nallapati et al., 2017; Narayan et al., 2018b). Abstractive approaches, despite being more faithful to the actual summarization task, either lag behind extractive ones or are mostly extractive, exhibiting a small degree of abstraction (See et al., 2017; Tan and Wan, 2017; Paulus et al., 2018; Pasunuru and Bansal, 2018; Celikyilmaz et al., 2018).

In this paper we introduce *extreme summariza-*

tion, a new single-document summarization task which is not amenable to extractive strategies and requires an abstractive modeling approach. The idea is to create a short, one-sentence news summary answering the question "What is the article about?". An example of a document and its extreme summary are shown in Figure 1. As can be seen, the summary is very different from a headline whose aim is to encourage readers to read the story; it draws on information interspersed in various parts of the document (not only the beginning) and displays multiple levels of abstraction including paraphrasing, fusion, synthesis, and inference. We build a dataset for the proposed task by harvesting online articles from the British Broadcasting Corporation (BBC) that often include a first-sentence summary.

We further propose a novel deep learning model which we argue is well-suited to the extreme summarization task. Unlike most existing abstractive approaches (Rush et al., 2015; Chen et al., 2016; Nallapati et al., 2016; See et al., 2017; Tan and Wan, 2017; Paulus et al., 2018; Pasunuru and Bansal, 2018; Celikyilmaz et al., 2018) which rely on an encoder-decoder architecture modeled by recurrent neural networks (RNNs), we present a *topic-conditioned* neural model which is based entirely on convolutional neural networks (Gehring et al., 2017b). Convolution layers capture long-range dependencies between words in the document more effectively compared to RNNs, allowing to perform document-level inference, abstraction, and paraphrasing. Our convolutional encoder associates each word with a topic vector capturing whether it is representative of the document's content, while our convolutional decoder conditions each word prediction on a document topic vector.

Experimental results show that when evaluated automatically (in terms of ROUGE) our topic-aware convolutional model outperforms an oracle extractive system and state-of-the-art RNN-based abstractive systems. We also conduct two human evaluations in order to assess (a) which type of summary participants prefer and (b) how much key information from the document is preserved in the summary. Both evaluations overwhelmingly show that human subjects find our summaries more informative and complete. Our contributions in this work are three-fold: a new single document summarization dataset that encourages the development of abstractive systems; corroborated by analysis and empirical results showing that extractive approaches are not well-suited to the extreme summarization task; and a novel topic-aware convolutional sequence-to-sequence model for abstractive summarization.

2 The XSum Dataset

Our extreme summarization dataset (which we call XSum) consists of BBC articles and accompanying single sentence summaries. Specifically, each article is prefaced with an introductory sentence (aka summary) which is professionally written, typically by the author of the article. The summary bears the HTML class "story-body__introduction," and can be easily identified and extracted from the main text body (see Figure 1 for an example summary-article pair).

We followed the methodology proposed in Hermann et al. (2015) to create a large-scale dataset for extreme summarization. Specifically, we collected 226,711 Wayback archived BBC articles ranging over almost a decade (2010 to 2017) and covering a wide variety of domains (e.g., News, Politics, Sports, Weather, Business, Technology, Science, Health, Family, Education, Entertainment and Arts). Each article comes with a unique identifier in its URL, which we used to randomly split the dataset into training (90%, 204,045), validation (5%, 11,332), and test (5%, 11,334) set. Table 1 compares XSum with the CNN, DailyMail, and NY Times benchmarks. As can be seen, XSum contains a substantial number of training instances, similar to DailyMail; documents and summaries in XSum are shorter in relation to other datasets but the vocabulary size is sufficiently large, comparable to CNN.

Table 2 provides empirical analysis supporting our claim that XSum is less biased toward extractive methods compared to other summarization datasets. We report the percentage of novel n-grams in the target gold summaries that do not appear in their source documents. There are 36% novel unigrams in the XSum reference summaries compared to 17% in CNN, 17% in DailyMail, and 23% in NY Times. This indicates that XSum summaries are more abstractive. The proportion of novel constructions grows for larger n-grams across datasets, however, it is much steeper in XSum whose summaries exhibit approximately 83% novel bigrams, 96% novel trigrams, and 98% novel 4-grams (comparison datasets display

Datasets	# docs (train/val/test)	avg. document length		avg. summary length		vocabulary size	
		words	sentences	words	sentences	document	summary
CNN	90,266/1,220/1,093	760.50	33.98	45.70	3.59	343,516	89,051
DailyMail	196,961/12,148/10,397	653.33	29.33	54.65	3.86	563,663	179,966
NY Times	589,284/32,736/32,739	800.04	35.55	45.54	2.44	1,399,358	294,011
XSum	204,045/11,332/11,334	431.07	19.77	23.26	1.00	399,147	81,092

Table 1: Comparison of summarization datasets with respect to overall corpus size, size of training, validation, and test set, average document (source) and summary (target) length (in terms of words and sentences), and vocabulary size on both on source and target. For CNN and DailyMail, we used the original splits of Hermann et al. (2015) and followed Narayan et al. (2018b) to preprocess them. For NY Times (Sandhaus, 2008), we used the splits and pre-processing steps of Paulus et al. (2018). For the vocabulary, we lowercase tokens.

Datasets	% of novel n-grams in gold summary				LEAD			EXT-ORACLE		
	unigrams	bigrams	trigrams	4-grams	R1	R2	RL	R1	R2	RL
CNN	16.75	54.33	72.42	80.37	29.15	11.13	25.95	50.38	28.55	46.58
DailyMail	17.03	53.78	72.14	80.28	40.68	18.36	37.25	55.12	30.55	51.24
NY Times	22.64	55.59	71.93	80.16	31.85	15.86	23.75	52.08	31.59	46.72
XSum	**35.76**	**83.45**	**95.50**	**98.49**	**16.30**	**1.61**	**11.95**	**29.79**	**8.81**	**22.65**

Table 2: Corpus bias towards extractive methods in the CNN, DailyMail, NY Times, and XSum datasets. We show the proportion of novel n-grams in gold summaries. We also report ROUGE scores for the LEAD baseline and the extractive oracle system EXT-ORACLE. Results are computed on the test set.

around 47–55% new bigrams, 58–72% new trigrams, and 63–80% novel 4-grams).

We further evaluated two extractive methods on these datasets. LEAD is often used as a strong lower bound for news summarization (Nenkova, 2005) and creates a summary by selecting the first few sentences or words in the document. We extracted the first 3 sentences for CNN documents and the first 4 sentences for DailyMail (Narayan et al., 2018b). Following previous work (Durrett et al., 2016; Paulus et al., 2018), we obtained LEAD summaries based on the first 100 words for NY Times documents. For XSum, we selected the first sentence in the document (excluding the one-line summary) to generate the LEAD. Our second method, EXT-ORACLE, can be viewed as an upper bound for extractive models (Nallapati et al., 2017; Narayan et al., 2018b). It creates an oracle summary by selecting the best possible set of sentences in the document that gives the highest ROUGE (Lin and Hovy, 2003) with respect to the gold summary. For XSum, we simply selected the single-best sentence in the document as summary.

Table 2 reports the performance of the two extractive methods using ROUGE-1 (R1), ROUGE-2 (R2), and ROUGE-L (RL) with the gold summaries as reference. The LEAD baseline performs extremely well on CNN, DailyMail and NY Times confirming that they are biased towards extractive methods. EXT-ORACLE further shows that improved sentence selection would bring further performance gains to extractive approaches. Abstractive systems trained on these datasets often have a hard time beating the LEAD, let alone EXT-ORACLE, or display a low degree of novelty in their summaries (See et al., 2017; Tan and Wan, 2017; Paulus et al., 2018; Pasunuru and Bansal, 2018; Celikyilmaz et al., 2018). Interestingly, LEAD and EXT-ORACLE perform poorly on XSum underlying the fact that it is less biased towards extractive methods.

In line with our findings, Grusky et al. (2018) have recently reported similar extractive biases in existing datasets. They constructed a new dataset called “Newsroom” which demonstrates a high diversity of summarization styles. XSum is not diverse, it focuses on a single news outlet (i.e., BBC) and a unifrom summarization style (i.e., a single sentence). However, it is sufficiently large for neural network training and we hope it will spur further research towards the development of abstractive summarization models.

3 Convolutional Sequence-to-Sequence Learning for Summarization

Unlike tasks like machine translation and paraphrase generation where there is often a one-to-one semantic correspondence between source and target words, document summarization must distill the content of the document into a few important facts. This is even more challenging for our task, where the compression ratio is extremely

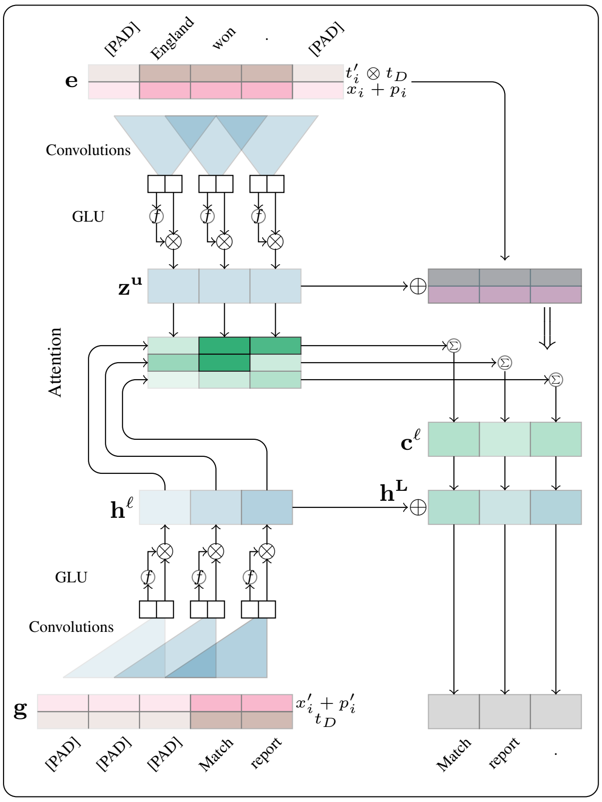

Figure 2: Topic-conditioned convolutional model for extreme summarization.

high, and pertinent content can be easily missed.

Recently, a convolutional alternative to sequence modeling has been proposed showing promise for machine translation (Gehring et al., 2017a,b) and story generation (Fan et al., 2018). We believe that convolutional architectures are attractive for our summarization task for at least two reasons. Firstly, contrary to recurrent networks which view the input as a chain structure, convolutional networks can be stacked to represent large context sizes. Secondly, hierarchical features can be extracted over larger and larger contents, allowing to represent long-range dependencies efficiently through shorter paths.

Our model builds on the work of Gehring et al. (2017b) who develop an encoder-decoder architecture for machine translation with an attention mechanism (Sukhbaatar et al., 2015) based exclusively on deep convolutional networks. We adapt this model to our summarization task by allowing it to recognize pertinent content (i.e., by foregrounding salient words in the document). In particular, we improve the convolutional encoder by associating each word with a vector representing topic salience, and the convolutional decoder by conditioning each word prediction on the document topic vector.

Model Overview At the core of our model is a simple convolutional block structure that computes intermediate states based on a fixed number of input elements. Our convolutional encoder (shown at the top of Figure 2) applies this unit across the document. We repeat these operations in a stacked fashion to get a multi-layer hierarchical representation over the input document where words at closer distances interact at lower layers while distant words interact at higher layers. The interaction between words through hierarchical layers effectively captures long-range dependencies.

Analogously, our convolutional decoder (shown at the bottom of Figure 2) uses the multi-layer convolutional structure to build a hierarchical representation over what has been predicted so far. Each layer on the decoder side determines useful source context by attending to the encoder representation before it passes its output to the next layer. This way the model remembers which words it previously attended to and applies multi-hop attention (shown at the middle of Figure 2) per time step. The output of the top layer is passed to a softmax classifier to predict a distribution over the target vocabulary.

Our model assumes access to word and document topic distributions. These can be obtained by any topic model, however we use Latent Dirichlet Allocation (LDA; Blei et al. 2003) in our experiments; we pass the distributions obtained from LDA directly to the network as additional input. This allows us to take advantage of topic modeling without interfering with the computational advantages of the convolutional architecture. The idea of capturing document-level semantic information has been previously explored for recurrent neural networks (Mikolov and Zweig, 2012; Ghosh et al., 2016; Dieng et al., 2017), however, we are not aware of any existing convolutional models.

Topic Sensitive Embeddings Let D denote a document consisting of a sequence of words $(w_1, \ldots, w_m)$; we embed D into a distributional space $\mathbf{x} = (x_1, \ldots, x_m)$ where $x_i \in \mathbb{R}^f$ is a column in embedding matrix $M \in \mathbb{R}^{V \times f}$ (where V is the vocabulary size). We also embed the absolute word positions in the document $\mathbf{p} = (p_1, \ldots, p_m)$ where $p_i \in \mathbb{R}^f$ is a column in position matrix

$P \in \mathbb{R}^{N \times f}$, and N is the maximum number of positions. Position embeddings have proved useful for convolutional sequence modeling (Gehring et al., 2017b), because, in contrast to RNNs, they do not observe the temporal positions of words (Shi et al., 2016). Let $t_D \in \mathbb{R}^{f'}$ be the topic distribution of document D and $\mathbf{t}' = (t'_1, \ldots, t'_m)$ the topic distributions of words in the document (where $t'_i \in \mathbb{R}^{f'}$). During encoding, we represent document D via $\mathbf{e} = (e_1, \ldots, e_m)$, where e_i is:

$$e_i = [(x_i + p_i); (t'_i \otimes t_D)] \in \mathbb{R}^{f+f'},$$

and $\otimes$ denotes point-wise multiplication. The topic distribution t'_i of word w_i essentially captures how topical the word is in itself (local context), whereas the topic distribution t_D represents the overall theme of the document (global context). The encoder essentially enriches the context of the word with its topical relevance to the document.

For every output prediction, the decoder estimates representation $\mathbf{g} = (g_1, \ldots, g_n)$ for previously predicted words $(w'_1, \ldots, w'_n)$ where g_i is:

$$g_i = [(x'_i + p'_i); t_D] \in \mathbb{R}^{f+f'},$$

x'_i and p'_i are word and position embeddings of previously predicted word w'_i, and t_D is the topic distribution of the input document. Note that the decoder does not use the topic distribution of w'_i as computing it on the fly would be expensive. However, every word prediction is conditioned on the topic of the document, enforcing the summary to have the same theme as the document.

Multi-layer Convolutional Structure Each convolution block, parametrized by $W \in \mathbb{R}^{2d \times kd}$ and $b_w \in \mathbb{R}^{2d}$, takes as input $X \in \mathbb{R}^{k \times d}$ which is the concatenation of k adjacent elements embedded in a d dimensional space, applies one dimensional convolution and returns an output element $Y \in \mathbb{R}^{2d}$. We apply Gated Linear Units (GLU, $v : \mathbb{R}^{2d} \rightarrow \mathbb{R}^{d}$, Dauphin et al. 2017) on the output of the convolution Y. Subsequent layers operate over the k output elements of the previous layer and are connected through residual connections (He et al., 2016) to allow for deeper hierarchical representation. We denote the output of the ℓth layer as $\mathbf{h}^\ell = (h^\ell_1, \ldots, h^\ell_n)$ for the decoder network, and $\mathbf{z}^\ell = (z^\ell_1, \ldots, z^\ell_m)$ for the encoder network.

Multi-hop Attention Our encoder and decoder are tied to each other through a multi-hop attention mechanism. For each decoder layer ℓ, we compute the attention a^ℓ_{ij} of state i and source element j as:

$$a^\ell_{ij} = \frac{\exp(d^\ell_i \cdot z^u_j)}{\sum_{t=1}^{m} \exp(d^\ell_i \cdot z^u_t)},$$

where $d^\ell_i = W^\ell_d h^\ell_i + b^\ell_i + g_i$ is the decoder state summary combining the current decoder state h^ℓ_i and the previous output element embedding g_i. The vector $\mathbf{z^u}$ is the output from the last encoder layer u. The conditional input c^ℓ_i to the current decoder layer is a weighted sum of the encoder outputs as well as the input element embeddings e_j:

$$c^\ell_i = \sum_{j=1}^{m} a^\ell_{ij}(z^u_j + e_j).$$

The attention mechanism described here performs multiple attention “hops” per time step and considers which words have been previously attended to. It is therefore different from single-step attention in recurrent neural networks (Bahdanau et al., 2015), where the attention and weighted sum are computed over $\mathbf{z^u}$ only.

Our network uses multiple linear layers to project between the embedding size $(f + f')$ and the convolution output size $2d$. They are applied to $\mathbf{e}$ before feeding it to the encoder, to the final encoder output $\mathbf{z^u}$, to all decoder layers $\mathbf{h}^\ell$ for the attention score computation, and to the final decoder output $\mathbf{h^L}$ before the softmax. We pad the input with $k-1$ zero vectors on both left and right side to ensure that the output of the convolutional layers matches the input length. During decoding, we ensure that the decoder does not have access to future information; we start with k zero vectors and shift the covolutional block to the right after every prediction. The final decoder output $\mathbf{h^L}$ is used to compute the distribution over the target vocabulary T as:

$$p(y_{i+1}|y_1, \ldots, y_i, D, t_D, \mathbf{t}') = \\ \text{softmax}(W_o h^L_i + b_o) \in \mathbb{R}^T.$$

We use layer normalization and weight initialization to stabilize learning.

Our topic-enhanced model calibrates long-range dependencies with globally salient content. As a result, it provides a better alternative to vanilla convolutional sequence models

(Gehring et al., 2017b) and RNN-based summarization models (See et al., 2017) for capturing cross-document inferences and paraphrasing. At the same time it retains the computational advantages of convolutional models. Each convolution block operates over a fixed-size window of the input sequence, allowing for simultaneous encoding of the input, ease in learning due to the fixed number of non-linearities and transformations for words in the input sequence.

4 Experimental Setup

In this section we present our experimental setup for assessing the performance of our **T**opic-aware **Conv**olutional **S**equence **to** **S**equence model which we call T-CONVS2S for short. We discuss implementation details and present the systems used for comparison with our approach.

Comparison Systems We report results with various systems which were all trained on the XSum dataset to generate a one-line summary given an input news article. We compared T-CONVS2S against three extractive systems: a baseline which randomly selects a sentence from the input document (RANDOM), a baseline which simply selects the leading sentence from the document (LEAD), and an oracle which selects a single-best sentence in each document (EXT-ORACLE). The latter is often used as an upper bound for extractive methods. We also compared our model against the RNN-based abstractive systems introduced by See et al. (2017). In particular, we experimented with an attention-based sequence to sequence model (SEQ2SEQ), a pointer-generator model which allows to copy words from the source text (PTGEN), and a pointer-generator model with a coverage mechanism to keep track of words that have been summarized (PTGEN-COVG). Finally, we compared our model against the vanilla convolution sequence to sequence model (CONVS2S) of Gehring et al. (2017b).

Model Parameters and Optimization We did not anonymize entities but worked on a lower-cased version of the XSum dataset. During training and at test time the input document was truncated to 400 tokens and the length of the summary limited to 90 tokens.

The LDA model (Blei et al., 2003) was trained on XSum documents (training portion). We therefore obtained for each word a probability distribution over topics which we used to estimate $\mathbf{t}'$; the topic distribution t_D can be inferred for any new document, at training and test time. We explored several LDA configurations on held-out data, and obtained best results with 512 topics. Table 3 shows some of the topics learned by the LDA model.

T1:	charge, court, murder, police, arrest, guilty, sentence, boy, bail, space, crown, trial
T2:	church, abuse, bishop, child, catholic, gay, pope, school, christian, priest, cardinal
T3:	council, people, government, local, housing, home, house, property, city, plan, authority
T4:	clinton, party, trump, climate, poll, vote, plaid, election, debate, change, candidate, campaign
T5:	country, growth, report, business, export, fall, bank, security, economy, rise, global, inflation
T6:	hospital, patient, trust, nhs, people, care, health, service, staff, report, review, system, child

Table 3: Example topics learned by the LDA model on XSum documents (training portion).

For SEQ2SEQ, PTGEN and PTGEN-COVG, we used the best settings reported on the CNN and DailyMail data (See et al., 2017).[2] All three models had 256 dimensional hidden states and 128 dimensional word embeddings. They were trained using Adagrad (Duchi et al., 2011) with learning rate 0.15 and an initial accumulator value of 0.1. We used gradient clipping with a maximum gradient norm of 2, but did not use any form of regularization. We used the loss on the validation set to implement early stopping.

For CONVS2S[3] and T-CONVS2S, we used 512 dimensional hidden states and 512 dimensional word and position embeddings. We trained our convolutional models with Nesterov's accelerated gradient method (Sutskever et al., 2013) using a momentum value of 0.99 and renormalized gradients if their norm exceeded 0.1 (Pascanu et al., 2013). We used a learning rate of 0.10 and once the validation perplexity stopped improving, we reduced the learning rate by an order of magnitude after each epoch until it fell below 10^{-4}. We also applied a dropout of 0.2 to the embeddings, the decoder outputs and the input of the convolutional blocks. Gradients were normalized by the number of non-padding tokens per mini-batch. We also

---

[2] We used the code available at `https://github.com/abisee/pointer-generator`.

[3] We used the code available at `https://github.com/facebookresearch/fairseq-py`.

used weight normalization for all layers except for lookup tables.

All neural models, including ours and those based on RNNs (See et al., 2017) had a vocabulary of 50,000 words and were trained on a single Nvidia M40 GPU with a batch size of 32 sentences. Summaries at test time were obtained using beam search (with beam size 10).

5 Results

Automatic Evaluation We report results using automatic metrics in Table 4. We evaluated summarization quality using F$_1$ ROUGE (Lin and Hovy, 2003). Unigram and bigram overlap (ROUGE-1 and ROUGE-2) are a proxy for assessing informativeness and the longest common subsequence (ROUGE-L) represents fluency.[4]

On the XSum dataset, Seq2Seq outperforms the LEAD and RANDOM baselines by a large margin. PtGen, a Seq2Seq model with a "copying" mechanism outperforms EXT-ORACLE, a "perfect" extractive system on ROUGE-2 and ROUGE-L. This is in sharp contrast to the performance of these models on CNN/DailyMail (See et al., 2017) and Newsroom datasets (Grusky et al., 2018), where they fail to outperform the LEAD. The result provides further evidence that XSum is a good testbed for abstractive summarization. PtGen-Covg, the best performing abstractive system on the CNN/DailyMail datasets, does not do well. We believe that the coverage mechanism is more useful when generating multi-line summaries and is basically redundant for extreme summarization.

ConvS2S, the convolutional variant of Seq2Seq, significantly outperforms all RNN-based abstractive systems. We hypothesize that its superior performance stems from the ability to better represent document content (i.e., by capturing long-range dependencies). Table 4 shows several variants of T-ConvS2S including an encoder network enriched with information about how topical a word is on its own (enc$_{t'}$) or in the document (enc$_{(t',t_D)}$). We also experimented with various decoders by conditioning every prediction on the topic of the document, basically encouraging the summary to be in the same theme as the document (dec$_{t_D}$) or letting the decoder decide the theme of the summary.

Models	R1	R2	RL
Random	15.16	1.78	11.27
LEAD	16.30	1.60	11.95
EXT-ORACLE	29.79	8.81	22.66
Seq2Seq	28.42	8.77	22.48
PtGen	29.70	9.21	23.24
PtGen-Covg	28.10	8.02	21.72
ConvS2S	31.27	11.07	25.23
T-ConvS2S (enc$_{t'}$)	31.71	11.38	25.56
T-ConvS2S (enc$_{t'}$, dec$_{t_D}$)	31.71	11.34	25.61
T-ConvS2S (enc$_{(t',t_D)}$)	31.61	11.30	25.51
T-ConvS2S (enc$_{(t',t_D)}$, dec$_{t_D}$)	**31.89**	**11.54**	**25.75**

Table 4: ROUGE results on XSum test set. We report ROUGE-1 (R1), ROUGE-2 (R2), and ROUGE-L (RL) F$_1$ scores. Extractive systems are in the upper block, RNN-based abstractive systems are in the middle block, and convolutional abstractive systems are in the bottom block.

Models	% of novel n-grams in generated summaries			
	unigrams	bigrams	trigrams	4-grams
LEAD	0.00	0.00	0.00	0.00
EXT-ORACLE	0.00	0.00	0.00	0.00
PtGen	27.40	73.33	90.43	96.04
ConvS2S	**31.26**	**79.50**	**94.28**	**98.10**
T-ConvS2S	30.73	79.18	94.10	98.03
GOLD	35.76	83.45	95.50	98.49

Table 5: Proportion of novel n-grams in summaries generated by various models on the XSum test set.

Interestingly, all four T-ConvS2S variants outperform ConvS2S. T-ConvS2S performs best when both encoder and decoder are constrained by the document topic (enc$_{(t',t_D)}$,dec$_{t_D}$). In the remainder of the paper, we refer to this variant as T-ConvS2S.

We further assessed the extent to which various models are able to perform rewriting by generating genuinely abstractive summaries. Table 5 shows the proportion of novel n-grams for LEAD, EXT-ORACLE, PtGen, ConvS2S, and T-ConvS2S. As can be seen, the convolutional models exhibit the highest proportion of novel n-grams. We should also point out that the summaries being evaluated have on average comparable lengths; the summaries generated by PtGen contain 22.57 words, those generated by ConvS2S and T-ConvS2S have 20.07 and 20.22 words, respectively, while GOLD summaries are the longest with 23.26 words. Interestingly, PtGen trained on XSum only copies 4% of 4-grams in the source document, 10% of trigrams, 27% of bigrams, and 73% of unigrams. This is in sharp contrast to Pt-

EXT-ORACLE	Caroline Pidgeon is the Lib Dem candidate, Sian Berry will contest the election for the Greens and UKIP has chosen its culture spokesman Peter Whittle.	[34.1, 20.5, 34.1]
PTGEN	UKIP leader Nigel Goldsmith has been elected as the new mayor of London to elect a new conservative MP.	[45.7, 6.1, 28.6]
CONVS2S	London mayoral candidate Zac Goldsmith has been elected as the new mayor of London.	[53.3, 21.4, 26.7]
T-CONVS2S	Former London mayoral candidate Zac Goldsmith has been chosen to stand in the London mayoral election.	[50.0, 26.7, 37.5]
GOLD	Zac Goldsmith will contest the 2016 London mayoral election for the conservatives, it has been announced.	
Questions	(1) Who will contest for the conservatives? (Zac Goldsmith) (2) For what election will he/she contest? (The London mayoral election)	
EXT-ORACLE	North-east rivals Newcastle are the only team below them in the Premier League table.	[35.3, 18.8, 35.3]
PTGEN	Sunderland have appointed former Sunderland boss Dick Advocaat as manager at the end of the season to sign a new deal.	[45.0, 10.5, 30.0]
CONVS2S	Sunderland have sacked manager Dick Advocaat after less than three months in charge.	[25.0, 6.7, 18.8]
T-CONVS2S	Dick Advocaat has resigned as Sunderland manager until the end of the season.	[56.3, 33.3, 56.3]
GOLD	Dick Advocaat has resigned as Sunderland boss, with the team yet to win in the Premier League this season.	
Questions	(1) Who has resigned? (Dick Advocaat) (2) From what post has he/she resigned? (Sunderland boss)	
EXT-ORACLE	The Greater Ardoyne residents collective (GARC) is protesting against an agreement aimed at resolving a long-running dispute in the area.	[26.7, 9.3, 22.2]
PTGEN	A residents' group has been granted permission for GARC to hold a parade on the outskirts of Crumlin, County Antrim.	[28.6, 5.0, 28.6]
CONVS2S	A protest has been held in the Republic of Ireland calling for an end to parading parading in North Belfast.	[42.9, 20.0, 33.3]
T-CONVS2S	A protest has been held in North Belfast over a protest against the Orange Order in North Belfast.	[45.0, 26.3, 45.0]
GOLD	Church leaders have appealed to a nationalist residents' group to call off a protest against an Orange Order parade in North Belfast.	
Questions	(1) Where is the protest supposed to happen? (North Belfast) (2) What are they protesting against? (An Orange Order parade)	

Table 6: Example output summaries on the XSum test set with [ROUGE-1, ROUGE-2 and ROUGE-L] scores, goldstandard reference, and corresponding questions. Words highlighted in blue are either the right answer or constitute appropriate context for inferring it; words in red lead to the wrong answer.

GEN trained on CNN/DailyMail exhibiting mostly extractive patterns; it copies more than 85% of 4-grams in the source document, 90% of trigrams, 95% of bigrams, and 99% of unigrams (See et al., 2017). This result further strengthens our hypothesis that XSum is a good testbed for abstractive methods.

Human Evaluation In addition to automatic evaluation using ROUGE which can be misleading when used as the only means to assess the informativeness of summaries (Schluter, 2017), we also evaluated system output by eliciting human judgments in two ways.

In our first experiment, participants were asked to compare summaries produced from the EXT-ORACLE baseline, PTGEN, the best performing system of See et al. (2017), CONVS2S, our topic-aware model T-CONVS2S, and the human-authored gold summary (GOLD). We did not include extracts from the LEAD as they were significantly inferior to other models.

The study was conducted on the Amazon Mechanical Turk platform using *Best-Worst Scaling* (BWS; Louviere and Woodworth 1991; Louviere et al. 2015), a less labor-intensive alternative to paired comparisons that has been shown to produce more reliable results than rating scales (Kiritchenko and Mohammad, 2017). Participants were presented with a document and summaries generated from two out of five systems and were asked to decide which summary was *better* and which one was *worse* in order of informativeness (does the summary capture important information in the document?) and fluency (is the summary written in well-formed English?). Examples of system summaries are shown in Table 6. We randomly selected 50 documents from the XSum test set and compared all possible combinations of two out of five systems for each document. We collected judgments from three different participants for each comparison. The order of summaries was

Models	Score	QA
EXT-ORACLE	-0.121	15.70
PTGEN	-0.218	21.40
CONVS2S	-0.130	30.90
T-CONVS2S	**0.037**	**46.05**
GOLD	0.431	97.23

Table 7: System ranking according to human judgments and QA-based evaluation.

randomized per document and the order of documents per participant.

The score of a system was computed as the percentage of times it was chosen as best minus the percentage of times it was selected as worst. The scores range from -1 (worst) to 1 (best) and are shown in Table 7. Perhaps unsurprisingly human-authored summaries were considered best, whereas, T-CONVS2S was ranked 2nd followed by EXT-ORACLE and CONVS2S. PTGEN was ranked worst with the lowest score of -0.218. We carried out pairwise comparisons between all models to assess whether system differences are statistically significant. GOLD is significantly different from all other systems and T-CONVS2S is significantly different from CONVS2S and PTGEN (using a one-way ANOVA with posthoc Tukey HSD tests; $p < 0.01$). All other differences are not statistically significant.

For our second experiment we used a question-answering (QA) paradigm (Clarke and Lapata, 2010; Narayan et al., 2018b) to assess the degree to which the models retain key information from the document. We used the same 50 documents as in our first elicitation study. We wrote two fact-based questions per document, just by reading the summary, under the assumption that it highlights the most important content of the news article. Questions were formulated so as not to reveal answers to subsequent questions. We created 100 questions in total (see Table 6 for examples). Participants read the output summaries and answered the questions as best they could without access to the document or the gold summary. The more questions can be answered, the better the corresponding system is at summarizing the document as a whole. Five participants answered questions for each summary.

We followed the scoring mechanism introduced in Clarke and Lapata (2010). A correct answer was marked with a score of one, partially correct answers with a score of 0.5, and zero otherwise. The final score for a system is the average of all its question scores. Answers again were elicited using Amazon's Mechanical Turk crowdsourcing platform. We uploaded the data in batches (one system at a time) to ensure that the same participant does not evaluate summaries from different systems on the same set of questions.

Table 7 shows the results of the QA evaluation. Based on summaries generated by T-CONVS2S, participants can answer 46.05% of the questions correctly. Summaries generated by CONVS2S, PTGEN and EXT-ORACLE provide answers to 30.90%, 21.40%, and 15.70% of the questions, respectively. Pairwise differences between systems are all statistically significant ($p < 0.01$) with the exception of PTGEN and EXT-ORACLE. EXT-ORACLE performs poorly on both QA and rating evaluations. The examples in Table 6 indicate that EXT-ORACLE is often misled by selecting a sentence with the highest ROUGE (against the gold summary), but ROUGE itself does not ensure that the summary retains the most important information from the document. The QA evaluation further emphasizes that in order for the summary to be felicitous, information needs to be embedded in the appropriate context. For example, CONVS2S and PTGEN will fail to answer the question "Who has resigned?" (see Table 6 second block) despite containing the correct answer "Dick Advocaat" due to the wrong context. T-CONVS2S is able to extract important entities from the document with the right theme.

6 Conclusions

In this paper we introduced the task of "extreme summarization" together with a large-scale dataset which pushes the boundaries of abstractive methods. Experimental evaluation revealed that models which have abstractive capabilities do better on this task and that high-level document knowledge in terms of topics and long-range dependencies is critical for recognizing pertinent content and generating informative summaries. In the future, we would like to create more linguistically-aware encoders and decoders incorporating co-reference and entity linking.

Acknowledgments We gratefully acknowledge the support of the European Research Council (Lapata; award number 681760), the European Union under the Horizon 2020 SUMMA project (Narayan, Cohen; grant agreement 688139), and Huawei Technologies (Cohen).

Abstract

Abstractive text summarization aims to shorten long text documents into a human readable form that contains the most important facts from the original document. However, the level of actual abstraction as measured by novel phrases that do not appear in the source document remains low in existing approaches. We propose two techniques to improve the level of abstraction of generated summaries. First, we decompose the decoder into a contextual network that retrieves relevant parts of the source document, and a pretrained language model that incorporates prior knowledge about language generation. Second, we propose a novelty metric that is optimized directly through policy learning to encourage the generation of novel phrases. Our model achieves results comparable to state-of-the-art models, as determined by ROUGE scores and human evaluations, while achieving a significantly higher level of abstraction as measured by n-gram overlap with the source document.

1 Introduction

Text summarization concerns the task of compressing a long sequence of text into a more concise form. The two most common approaches to summarization are *extractive* (Dorr et al., 2003; Nallapati et al., 2017), where the model extracts salient parts of the source document, and *abstractive* (Paulus et al., 2017; See et al., 2017), where the model not only extracts but also concisely paraphrases the important parts of the document via generation. We focus on developing a summarization model that produces an increased level of abstraction. That is, the model produces concise summaries without only copying long passages from the source document.

A high quality summary is shorter than the original document, conveys only the most important and no extraneous information, and is semantically and syntactically correct. Because it is difficult to gauge the correctness of the summary, evaluation metrics for summarization models use word overlap with the ground-truth summary in the form of ROUGE (Lin, 2004) scores. However, word overlap metrics do not capture the *abstractive* nature of high quality human-written summaries: the use of paraphrases with words that do not necessarily appear in the source document.

The state-of-the-art abstractive text summarization models have high word overlap performance, however they tend to copy long passages of the source document directly into the summary, thereby producing summaries that are not abstractive (See et al., 2017).

We propose two general extensions to summarization models that improve the level of abstraction of the summary while preserving word overlap with the ground-truth summary. Our first contribution decouples the extraction and generation responsibilities of the decoder by factoring it into a contextual network and a language model. The contextual network has the sole responsibility of extracting and compacting the source document whereas the language model is responsible for the generation of concise paraphrases. Our second contribution is a mixed objective that jointly optimizes the n-gram overlap with the ground-truth summary while encouraging abstraction. This is done by combining maximum likelihood estimation with policy gradient. We reward the policy with the ROUGE metric, which measures word overlap with the ground-truth summary, as well as a novel abstraction reward that encourages the generation of words not in the source document.

We demonstrate the effectiveness of our contributions on a encoder-decoder summarization

Article
(cnn) to allay possible concerns, boston prosecutors released video friday of the shooting of a police officer last month that resulted in the killing of the gunman. the officer wounded, john moynihan, is white. angelo west, the gunman shot to death by officers, was black. after the shooting, community leaders in the predominantly african-american neighborhood of (...)
Human-written summary
boston police officer john moynihan is released from the hospital. video shows that the man later shot dead by police in boston opened fire first. moynihan was shot in the face during a traffic stop.
Generated summary (See et al., 2017)
boston prosecutors released video friday of the shooting of a police officer last month. the gunman shot to death by officers , was black . one said the officers were forced to return fire. he was placed in a medically induced coma at a boston hospital.
Generated summary (Liu et al., 2018)
boston prosecutors released video of the shooting of a police officer last month . the shooting occurred in the wake of the boston marathon bombing. the video shows west sprang out and fired a shot with a pistol at officer's face.
Our summary (ML+RL ROUGE+Novel, with LM)
new: boston police release video of shooting of officer , john moynihan. new: angelo west had several prior gun convictions , police say. boston police officer john moynihan, 34, survived with a bullet wound . he was in a medically induced coma at a boston hospital , a police officer says.

Table 1: Summaries generated by different models for the same CNN/Daily Mail article. The highlighted spans indicate phrases of 3 tokens or more that are copied word-by-word from the original article.

model. Our model obtains state-of-the-art ROUGE-L scores, and ROUGE-1 and ROUGE-2 performance comparable to state-of-the-art methods on the CNN/DailyMail dataset. Moreover, we significantly outperform all previous abstractive approaches in our abstraction metrics. Table 1 shows a comparison of summaries generated by our model and previous abstractive models, showing less copying and more abstraction in our model.

2 Model

2.1 Base Model and Training Objective

The base model follows the encoder-decoder architecture with temporal attention and intra-attention proposed by Paulus et al. (2017). Let $E \in \mathbb{R}^{n \times d^{\text{emb}}}$ denote the matrix of d^{emb} dimensional word embeddings of the n words in the source document. The encoding of the source document h^{enc} is computed via a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) whose output has dimension d^{hid}.

$$h^{\text{enc}} = \text{BiLSTM}\left(E\right) \in \mathbb{R}^{n \times d^{\text{hid}}} \tag{1}$$

The decoder uses temporal attention over the encoded sequence that penalizes input tokens that previously had high attention scores. Let h_t^{dec} denote the decoder state at time t. The temporal attention context at time t, c_t^{tmp}, is computed as

$$s_{ti}^{\text{tmp}} = \left(h_t^{\text{dec}}\right)^{\intercal} W^{\text{tmp}} h_i^{\text{enc}} \in \mathbb{R} \tag{2}$$

$$q_{ti}^{\text{tmp}} = \frac{\exp(s_{ti}^{\text{tmp}})}{\sum_{j=1}^{t-1} \exp(s_{ji}^{\text{tmp}})} \in \mathbb{R} \tag{3}$$

$$\alpha_{ti}^{\text{tmp}} = \frac{q_{ti}^{\text{tmp}}}{\sum_{j=1}^{n} q_{tj}^{\text{tmp}}} \in \mathbb{R} \tag{4}$$

$$c_t^{\text{tmp}} = \sum_{i=1}^{n} \alpha_{ti}^{\text{tmp}} h_i^{\text{enc}} \in \mathbb{R}^{d^{\text{hid}}} \tag{5}$$

where we set q_{ti}^{tmp} to $\exp(s_{ti}^{\text{tmp}})$ for $t = 1$.

The decoder also attends to its previous states via intra-attention over the decoded sequence. The intra-attention context at time t, c_t^{int}, is computed as

$$s_{ti}^{\text{int}} = \left(h_t^{dec}\right)^{\intercal} W^{\text{int}} h_i^{\text{dec}} \in \mathbb{R} \tag{6}$$

$$c_t^{\text{int}} = \sum_{i=1}^{t-1} \left(\frac{s_{ti}^{\text{int}}}{\sum_{j=1}^{n} s_{tj}^{\text{int}}} \right) h_i^{\text{dec}} \in \mathbb{R}^{d^{\text{hid}}} \tag{7}$$

The decoder generates tokens by interpolating between selecting words from the source document via a pointer network as well as selecting words from a fixed output vocabulary. Let z_t denote the ground-truth label as to whether the tth

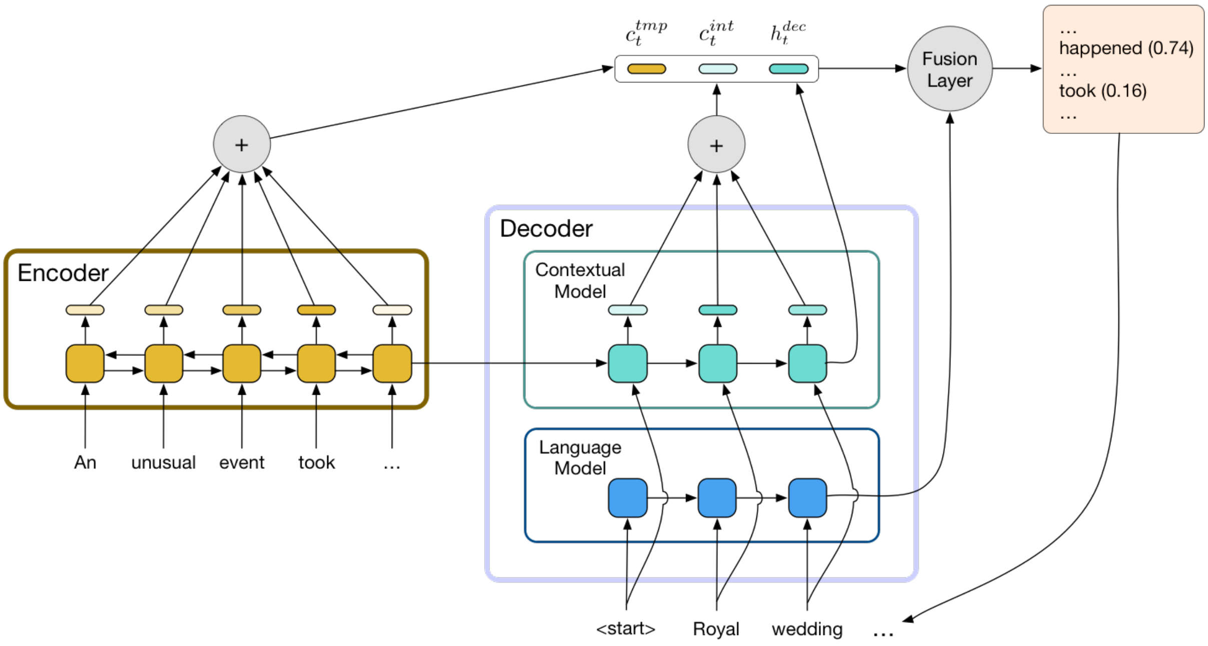

Figure 1: The network architecture with the decoder factorized into separate contextual and language models. The reference vector, composed of context vectors c_t^{tmp}, c_t^{int}, and the hidden state of the contextual model h_t^{dec}, is fused with the hidden state of the language model and then used to compute the distribution over the output vocabulary.

output word should be generated by the selecting from the output vocabulary as opposed to from the source document. We compute $p(z_t)$, the probability that the decoder generates from the output vocabulary, as

$$\begin{aligned} r_t &= [h_t^{\text{dec}}; c_t^{\text{tmp}}; c_t^{\text{int}}] \in \mathbb{R}^{3d^{\text{hid}}} && (8) \\ p(z_t) &= \text{sigmoid}(W^z r_t + b^z) \in \mathbb{R} && (9) \end{aligned}$$

The probability of selecting the word y_t from a fixed vocabulary at time step t is defined as

$$p^{\text{gen}}(y_t) = \text{softmax}\left(W^{\text{gen}} r_t + b^{\text{gen}}\right) \tag{10}$$

We set $p^{\text{cp}}(y_t)$, the probability of copying the word y_t from the source document, to the temporal attention distribution α_t^{tmp}. The joint probability of using the generator and generating the word y_t at time step t, $p(z_t, y_t)$, is then

$$p(z_t, y_t) = p(y_t \mid z_t) p(z_t) \tag{11}$$

the likelihood of which is

$$\begin{aligned} &\log p(z_t, y_t) = \log p(y_t \mid z_t) + \log p(z_t) \\ &= z_t \log p^{\text{gen}}(y_t) + (1 - z_t) \log p^{\text{cp}}(y_t) \\ &\quad + z_t \log p(z_t) + (1 - z_t) \log\left(1 - p\left(z_t\right)\right) \\ &= z_t \left(\log p^{\text{gen}}(y_t) + \log p(z_t)\right) \\ &\quad + (1 - z_t)\left(\log p^{\text{cp}}(y_t) + \log\left(1 - p\left(z_t\right)\right)\right) \end{aligned} \tag{12}$$

The objective function combines maximum likelihood estimation with policy learning. Let m denote the length of the ground-truth summary, The maximum likelihood loss L^{ml} is computed as

$$L^{\text{ml}} = -\sum_{t=1}^{m} \log p(z_t, y_t) \tag{13}$$

Policy learning uses ROUGE-L as its reward function and a self-critical baseline using the greedy decoding policy (Rennie et al., 2016). Let y^{sam} denote the summary obtained by sampling from the current policy p, y^{gre} and z^{gre} the summary and generator choice obtained by greedily choosing from $p(z_t, y_t)$, $R(y)$ the ROUGE-L score of the summary y, and Θ the model parameters. The policy learning loss is

$$\begin{aligned} \hat{R} &= R\left(y^{\mathrm{sam}}\right) - R\left(y^{\mathrm{gre}}\right) & (14) \\ L^{\mathrm{pg}} &= -\mathbb{E}_{\substack{z^{\mathrm{sam}} \sim p(z), \\ y^{\mathrm{sam}} \sim p(y|z)}} [\hat{R}] & (15) \end{aligned}$$

where we use greedy predictions by the model according to eq. (13) as a baseline for variance reduction. The policy gradient, as per Schulman et al. (2015), is

$$\nabla_{\Theta} L^{\mathrm{pg}} \approx -\hat{R} \sum_{t=1}^{m} \nabla_{\Theta} \log p\left(z_t^{\mathrm{sam}}, y_t^{\mathrm{sam}}\right) \quad (16)$$

The final loss is a mixture between the maximum likelihood loss and the policy learning loss, weighted by a hyperparameter γ.

$$L = (1-\gamma) L^{\mathrm{ml}} + \gamma L^{\mathrm{pg}} \quad (17)$$

2.2 Language Model Fusion

The decoder is an essential component of the base model. Given the source document and the previously generated summary tokens, the decoder both extracts relevant parts of the source document through the pointer network as well as composes paraphrases from the fixed vocabulary. We decouple these two responsibilities by augmenting the decoder with an external language model. The language model assumes responsibility of generating from the fixed vocabulary, and allows the decoder to focus on attention and extraction. This decomposition has the added benefit of easily incorporating external knowledge about fluency or domain specific styles via pre-training the language model on a large scale text corpora.

The architecture of our language model is based on Merity et al. (2018). We use a 3-layer unidirectional LSTM with weight-dropped LSTM units.

Let e_t denote the embedding of the word generated during time step t. The hidden state of the language model at the l-th layer is

$$h_{l,t}^{\mathrm{lm}} = \mathrm{LSTM}_3^{\mathrm{lm}}\left(e_{t-1}, h_{l,t-1}^{\mathrm{lm}}\right) \quad (18)$$

At each time step t, we combine the hidden state of the last language model LSTM layer, $h_{3,t}^{\mathrm{lm}}$, with r_t defined in eq. (8) in a fashion similar to Sriram et al. (2017). Let $\odot$ denote element-wise multiplication. We use a gating function whose output g_t filters the content of the language model hidden state.

$$\begin{aligned} f_t &= \mathrm{sigmoid}\left(W^{\mathrm{lm}}[r_t; h_{3,t}^{\mathrm{lm}}] + b^{\mathrm{lm}}\right) & (19) \\ g_t &= W^{\mathrm{fuse}}([r_t; g_t \odot h_{3,t}^{\mathrm{lm}}]) + b^{\mathrm{fuse}} & (20) \\ h_t^{\mathrm{fuse}} &= \mathrm{ReLU}\left(g_t\right) & (21) \end{aligned}$$

We then replace the output distribution of the language model $p^{\mathrm{gen}}\left(y_t\right)$ in eq. 10 with

$$p^{\mathrm{gen}}\left(y_t\right) = \mathrm{softmax}\left(W^{\mathrm{gen}} h_t^{\mathrm{fuse}} + b^{\mathrm{gen}}\right) \quad (22)$$

2.3 Abstractive Reward

In order to produce an abstractive summary, the model cannot exclusively copy from the source document. In particular, the model needs to parse large chunks of the source document and create concise summaries using phrases not in the source document. To encourage this behavior, we propose a novelty metric that promotes the generation of novel words.

We define a *novel* phrase in the summary as one that is not in the source document. Let $\mathrm{ng}\left(x, n\right)$ denote the function that computes the set of unique n-grams in a document x, x^{gen} the generated summary, x^{src} the source document, and $\|s\|$ the number of words in s. The unnormalized novelty metric N is defined as the fraction of unique n-grams in the summary that are novel.

$$N\left(x^{\mathrm{gen}}, n\right) = \frac{\left\|\mathrm{ng}\left(x^{\mathrm{gen}}, n\right) - \mathrm{ng}\left(x^{\mathrm{src}}, n\right)\right\|}{\left\|\mathrm{ng}\left(x^{\mathrm{gen}}, n\right)\right\|} \quad (23)$$

To prevent the model for receiving high novelty rewards by outputting very short summaries, we normalize the metric by the length ratio of the generated and ground-truth summaries. Let x^{gt} denote the ground-truth summary. We define the novelty metric as

$$R^{\mathrm{nov}}\left(x^{\mathrm{gen}}, n\right) = N\left(x^{\mathrm{gen}}, n\right) \frac{\|x^{\mathrm{gen}}\|}{\|x^{\mathrm{gt}}\|} \quad (24)$$

We incorporate the novelty metric as a reward into the policy gradient objective in eq. (15), alongside the original ROUGE-L metric. In doing so, we encourage the model to generate summaries that both overlap with human written ground-truth summaries as well as incorporate novel words not in the source document:

$$R(y) = \lambda^{\text{rou}} R^{\text{rou}}(y^{\text{sam}}) + \lambda^{\text{nov}} R^{\text{nov}}(y^{\text{sam}}) \quad (25)$$

where λ^{rou} and λ^{nov} are hyperparameters that control the weighting of each reward.

3 Experiments

3.1 Datasets

We train our model on the CNN/Daily Mail dataset (Hermann et al., 2015; Nallapati et al., 2016). Previous works on abstractive summarization either use an anonymized version of this dataset or the original article and summary texts. Due to these different formats, it is difficult to compare the overall ROUGE scores and performance between each version. In order to compare against previous results, we train and evaluate on both versions of this dataset. For the anonymized version, we follow the pre-processing steps described in Nallapati et al. (2016), and the pre-processing steps of See et al. (2017) for the the full-text version.

We use named entities and the source document to supervise the model regarding when to use the pointer and when to use the generator (e.g. z_t in eq. (13). Namely, during training, we teach the model to point from the source document if the word in the ground-truth summary is a named entity, an out-of-vocabulary word, or a numerical value that is in the source document. We obtain the list of named entities from Hermann et al. (2015).

3.2 Language Models

For each dataset version, we train a language model consisting of a 400-dimensional word embedding layer and a 3-layer LSTM with each layer having a hidden size of 800 dimensions, except the last input layer which has an output size of 400. The final decoding layer shares weights with the embedding layer (Inan et al., 2017; Press and Wolf, 2016). We also use DropConnect (Wan et al., 2013) in the hidden-to-hidden connections, as well as the non-monotonically triggered asynchronous gradient descent optimizer from Merity et al. (2018).

We train this language model on the CNN/Daily Mail ground-truth summaries only, following the same training, validation, and test splits as our main experiments.

3.3 Training details

The two LSTMs of our bidirectional encoder are 200-dimensional, and out decoder LSTM is 400-dimensional. We restrict the input vocabulary for the embedding matrix to 150,000 tokens, and the output decoding layer to 50,000 tokens. We limit the size of input articles to the first 400 tokens, and the summaries to 100 tokens. We use scheduled sampling (Bengio et al., 2015) with a probability of 0.25 when calculating the maximum-likelihood training loss. We also set $n = 3$ when computing our novelty reward $R^{nov}(x_{gen}, n)$. For our final training loss using reinforcement learning, we set $\gamma = 0.9984$, $\lambda^{rou} = 0.9$, and $\lambda^{nov} = 0.1$. Finally, we use the trigram repetition avoidance heuristic defined by Paulus et al. (2017) during beam search decoding to ensure that the model does not output twice the same trigram in a given summary, reducing the amount of repetitions.

3.4 Novelty baseline

We also create a novelty baseline by taking the outputs of our base model, without RL training and without the language model, and inserting random words not present in the article after each summary token with a probability $r = 0.0005$. This baseline will intuitively have a higher percentage of novel n-grams than our base model outputs while being very similar to these original outputs, hence keeping the ROUGE score difference relatively small.

4 Results

4.1 Quantitative analysis

We obtain a validation and test perplexity of 65.80 and 66.61 respectively on the anonymized dataset, and 81.13 and 82.98 on the full-text dataset with the language models described in Section 3.2.

The ROUGE scores and novelty scores of our final summarization model on both versions of the CNN/Daily Mail dataset are shown in Table 2. We report the ROUGE-1, ROUGE-2, and ROUGE-L F-scores as well as the percentage of novel n-grams, marked NN-n, in the generated summaries, with n from 1 to 4. Results are omitted in cases where they have not been made available by previous authors. We also include the novel n-gram scores for the ground-truth summaries as a comparison to indicate the level of abstraction of human written summaries.

Model	**R-1**	**R-2**	**R-L**	**NN-1**	**NN-2**	**NN-3**	**NN-4**

ML+RL ROUGE+Novel, with LM (ours)	40.19	17.38	**37.52**	**3.25**	**17.21**	**30.46**	**39.47**

Table 2: Comparison of ROUGE (R-) and novel n-gram (NN-) test results for our model and other abstractive summarization models on the CNN/Daily Mail dataset.

Even though our model outputs significantly fewer novel n-grams than human written summaries, it has a much higher percentage of novel n-grams than all the previous abstractive approaches. It also achieves state-of-the-art ROUGE-L performance on both dataset versions, and obtains ROUGE-1 and ROUGE-2 scores close to state-of-the-art results.

4.2 Ablation study

In order to evaluate the relative impact of each of our individual contributions, we run ablation studies comparing our model ablations against each other and against the novelty baseline. The results of these different models on the validation set of the anonymized CNN/Daily Mail dataset are shown in Table 3. Results show that our base model trained with the maximum-likelihood loss only and using the language model in the decoder (ML, with LM) has higher ROUGE scores, novel unigrams, and novel bigrams scores than our base model without the language model (ML). ML with LM also beats the novelty baseline for these metrics. When training these models with reinforcement learning using the ROUGE reward (ML+RL ROUGE and ML+RL ROUGE with LM), the model with language model obtains higher ROUGE-1 and ROUGE-2 scores. However, it also loses its novel unigrams and bigrams advantage. Finally, using the mixed ROUGE and novelty rewards (ML+RL ROUGE+Novel) produces both higher ROUGE scores and more novel unigrams with the language model than without it. This indicates that the combination of the language model in the decoder and the novelty reward during training makes our model produce more novel unigrams while maintaining high ROUGE scores.

4.3 ROUGE vs novelty trade-off

In order to understand the correlation between ROUGE and novel n-gram scores across different architectures, and to find the model type that gives the best trade-off between each of these metrics, we plot the ROUGE-1 and novel unigram scores for the five best iterations of each model type on the anonymized dataset, as well as the ROUGE-2 and novel bigram scores on a separate plot. We also include the novelty baseline described in Section 4.2 for values of r between 0.005 and 0.035. For each model type, we indicate the Pareto frontier by a line plot (Ben-Tal, 1980), illustrating which models of a given type give the best combination of ROUGE and novelty scores. These plots are shown in Figure 2.

These plots show that there exist an inverse correlation between ROUGE and novelty scores in all model types, illustrating the challenge of choosing a model that performs well in both. Given that, our final model (ML+RL ROUGE+Novel, with LM) provides the best trade-off of ROUGE-1 scores compared to novel unigrams, indicated by the higher Pareto frontier in the first plot. Similarly, our final model gives one of the best trade-offs of ROUGE-2 scores to novel bigrams, even though the same model without LM produces more novel

Model	R-1	R-2	R-L	NN-1	NN-2	NN-3	NN-4

bigrams with a lower ROUGE-2 score.

4.4 Qualitative evaluation

In order to ensure the quality of our model outputs, we ask 5 human evaluators to rate 100 randomly selected full-text test summaries, giving them two scores from 1 to 10 respectively for readability and relevance given the original article. We also include the full-text test outputs from See et al. (2017) and Liu et al. (2018) for comparison. Evaluators are shown different summaries corresponding to the same article side by side without being told which models have generated them. The mean score and confidence interval at 95% for each model and each evaluation criterion are reported in Table 4. These results show that our model matches the relevance score of See et al. (2017) and Liu et al. (2018), but is slightly inferior to them in terms of readability.

5 Related work

Text summarization. Existing summarization approaches are usually either extractive or abstractive. In extractive summarization, the model selects passages from the input document and combines them to form a shorter summary, sometimes with a post-processing step to ensure final coherence of the output (Neto et al., 2002; Dorr et al., 2003; Filippova and Altun, 2013; Colmenares et al., 2015; Nallapati et al., 2017). While extractive models are usually robust and produce coherent summaries, they cannot create concise summaries that paraphrase the source document using new phrases.

Abstractive summarization allows the model to paraphrase the source document and create concise summaries with phrases not in the source document. The state-of-the-art abstractive summarization models are based on sequence-to-sequence models with attention (Bahdanau et al., 2015). Extensions to this model include a self-attention mechanism (Paulus et al., 2017) and an article coverage vector (See et al., 2017) to prevent repeated phrases in the output summary. Different training procedures have also been used improve the ROUGE score (Paulus et al., 2017) or textual

Model	Readability	Relevance

entailment (Pasunuru and Bansal, 2018) with reinforcement learning; as well as generative adversarial networks to generate more natural summaries (Liu et al., 2018).

Several datasets have been used to train and evaluate summarization models. The Gigaword (Graff and Cieri, 2003) and some DUC datasets (Over et al., 2007) have been used for headline generation models (Rush et al., 2015; Nallapati et al., 2016), where the generated summary is shorter than 75 characters. However, generating longer summaries is a more challenging task, especially for abstractive models. Nallapati et al. (2016) have proposed using the CNN/Daily Mail dataset (Hermann et al., 2015) to train models for generating longer, multi-sentence summaries up to 100 words. The New York Times dataset (Sandhaus, 2008) has also been used as a benchmark for the generation of long summaries (Durrett et al., 2016; Paulus et al., 2017).

Training strategies for sequential models. The common approach to training models for sequence generation is maximum likelihood estimation with teacher forcing. At each time step, the model is given the previous ground-truth output and predicts the current output. The sequence objective is the accumulation of cross entropy losses from each time step.

Despite its popularity, this approach for sequence generation is suboptimal due to exposure bias (Huszar, 2015) and loss-evaluation mismatch (Wiseman and Rush, 2016). Goyal et al. (2016) propose one way to reduce exposure bias by explicitly forcing the hidden representations of the model to be similar during training and inference. Bengio et al. (2015) and Wiseman and Rush (2016) propose an alternate method that exposes the network to the test dynamics during training. Reinforcement learning methods (Sutton and Barto, 1998), such as policy learning (Sutton et al., 1999), mitigate the mismatch between the optimization objective and the evaluation metrics by directly optimizing evaluation metrics. This approach has led to consistent improvements in domains such as image captioning (Zhang et al., 2017) and abstractive text summarization (Paulus et al., 2017).

A recent approach to training sequential models utilizes generative adversarial networks to improving the human perceived quality of generated outputs (Fedus et al., 2018; Guimaraes et al., 2017; Liu et al., 2018). Such models use an additional discriminator network that distinguishes between natural and generated output to guide the generative model towards outputs akin to human-written text.

6 Conclusions

We introduced a new abstractive summarization model which uses an external language model in the decoder, as well as a new reinforcement learning reward to encourage summary abstraction. Experiments on the CNN/Daily Mail dataset show that our model generates summaries that are much more abstractive that previous approaches, while maintaining high ROUGE scores close to or above the state of the art. Future work could be done on closing the gap to match human levels of abstraction, which is still very far ahead from our model in terms of novel n-grams. Including mechanisms to promote paraphrase generation in the summary generator could be an interesting direction.

hal@cs.umd.edu

Abstract

We carry out experiments with deep learning models of summarization across the domains of news, personal stories, meetings, and medical articles in order to understand how content selection is performed. We find that many sophisticated features of state of the art extractive summarizers do not improve performance over simpler models. These results suggest that it is easier to create a summarizer for a new domain than previous work suggests and bring into question the benefit of deep learning models for summarization for those domains that do have massive datasets (i.e., news). At the same time, they suggest important questions for new research in summarization; namely, new forms of sentence representations or external knowledge sources are needed that are better suited to the sumarization task.

1 Introduction

Content selection is a central component in many natural language generation tasks, where, given a generation goal, the system must determine which information should be expressed in the output text (Gatt and Krahmer, 2018). In summarization, content selection is usually accomplished through sentence (and, occasionally, phrase) extraction. Despite being a key component of both extractive and abstractive summarization systems, it is is not well understood how deep learning models perform content selection with only word and sentence embedding based features as input. Non-neural network approaches often use frequency and information theoretic measures as proxies for content salience (Hong and Nenkova, 2014), but these are not explicitly used in most neural network summarization systems.

In this paper, we seek to better understand how deep learning models of summarization perform content selection across multiple domains (§ 4): news, personal stories, meetings, and medical articles (for which we collect a new corpus).[1] We analyze several recent sentence extractive neural network architectures, specifically considering the design choices for sentence encoders (§ 3.1) and sentence extractors (§ 3.2). We compare Recurrent Neural Network (RNN) and Convolutional Neural Network (CNN) based sentence representations to the simpler approach of word embedding averaging to understand the gains derived from more sophisticated architectures. We also question the necessity of auto-regressive sentence extraction (i.e. using previous predictions to inform future predictions), which previous approaches have used (§ 2), and propose two alternative models that extract sentences independently.

Our main results (§ 5) reveal:

1. Sentence position bias dominates the learning signal for news summarization, though not for other domains.[2] Summary quality for news is only slightly degraded when content words are omitted from sentence embeddings.
2. Word embedding averaging is as good or better than either RNNs or CNNs for sentence embedding across all domains.
3. Pre-trained word embeddings are as good, or better than, learned embeddings in five of six datasets.
4. Non auto-regressive sentence extraction performs as good or better than auto-regressive extraction in all domains.

Taken together, these and other results in the paper suggest that we are over-estimating the abil-

ity of deep learning models to learn robust and meaningful content features for summarization. In one sense, this might lessen the burden of applying neural network models of content to other domains; one really just needs in-domain word embeddings. However, if we want to learn something other than where the start of the article is, we will need to design other means of sentence representation, and possibly external knowledge representations, better suited to the summarization task.

2 Related Work

The introduction of the CNN-DailyMail corpus by Hermann et al. (2015) allowed for the application of large-scale training of deep learning models for summarization. Cheng and Lapata (2016) developed a sentence extractive model that uses a word level CNN to encode sentences and a sentence level sequence-to-sequence model to predict which sentences to include in the summary. Subsequently, Nallapati et al. (2017) proposed a different model using word-level bidirectional RNNs along with a sentence level bidirectional RNN for predicting which sentences should be extracted. Their sentence extractor creates representations of the whole document and computes separate scores for salience, novelty, and location. These works represent the state-of-the-art for deep learning-based extractive summarization and we analyze them further in this paper.

Other recent neural network approaches include, Yasunaga et al. (2017), who learn a graph-convolutional network (GCN) for multi-document summarization. They do not closely examine the choice of sentence encoder, which is one of the focuses of the present paper; rather, they study the best choice of graph structure for the GCN, which is orthogonal to this work.

Non-neural network learning-based approaches have also been applied to summarization. Typically they involve learning n-gram feature weights in linear models along with other non-lexical word or structural features (Berg-Kirkpatrick et al., 2011; Sipos et al., 2012; Durrett et al., 2016). In this paper, we study representation learning in neural networks that can capture more complex word level feature interactions and whose dense representations are more compatible with current practices in NLP.

The previously mentioned works have focused on news summarization. To further understand the content selection process, we also explore other domains of summarization. In particular, we explore personal narrative summarization based on stories shared on Reddit (Ouyang et al., 2017), workplace meeting summarization (Carletta et al., 2005), and medical journal article summarization (Mishra et al., 2014).

While most work on these summarization tasks often exploit domain-specific features (e.g. speaker identification in meeting summarization (Galley, 2006; Gillick et al., 2009)), we purposefully avoid such features in this work in order to understand the extent to which deep learning models can perform content selection using only surface lexical features. Summarization of academic literature (including medical journals), has long been a research topic in NLP (Kupiec et al., 1995; Elhadad et al., 2005), but most approaches have explored facet-based summarization (Jaidka et al., 2017), which is not the focus of our work.

3 Methods

The goal of extractive text summarization is to select a subset of a document's text to use as a summary, i.e. a short gist or excerpt of the central content. Typically, we impose a budget on the length of the summary in either words or bytes. In this work, we focus on *sentence* extractive summarization, where the basic unit of extraction is a sentence and impose a word limit as the budget.

We model the sentence extraction task as a sequence tagging problem, following (Conroy and O'Leary, 2001). Specifically, given a document containing n sentences $s_1, \ldots, s_n$ we generate a summary by predicting a corresponding label sequence $y_1, \ldots, y_n \in \{0, 1\}^n$, where $y_i = 1$ indicates the i-th sentence is to be included in the summary. Each sentence is itself a sequence of word embeddings $s_i = w_1^{(i)}, \ldots, w_{|s_i|}^{(i)}$ where $|s_i|$ is the length of the sentence in words. The word budget $c \in \mathbb{N}$ enforces a constraint that the total summary word length $\sum_{i=1}^{n} y_i \cdot |s_i| \leq c$.

For a typical deep learning model of extractive summarization there are two main design decisions: *a)* the choice of *sentence encoder* which maps each sentence s_i to an embedding h_i, and *b)* the choice of *sentence extractor* which maps a sequence of sentence embeddings $h = h_1, \ldots, h_n$ to a sequence of extraction decisions $y = y_1, \ldots, y_n$.

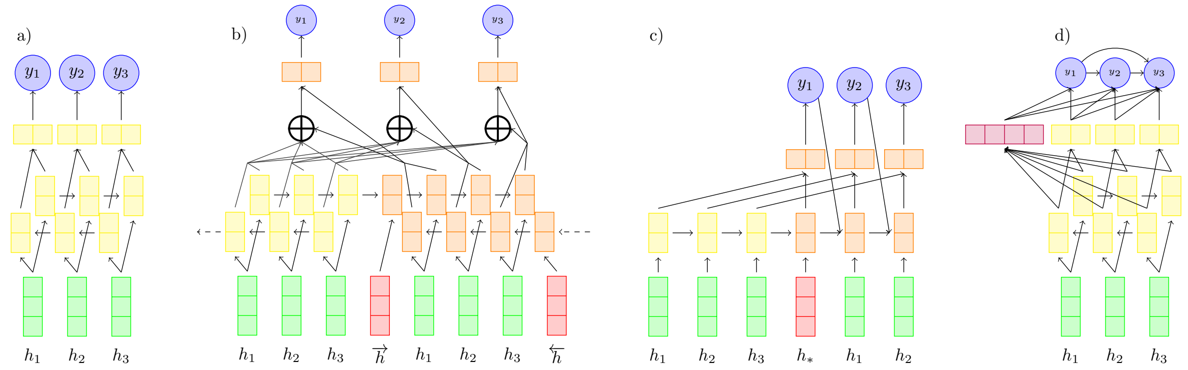

Figure 1: Sentence extractor architectures: a) RNN, b) Seq2Seq, c) Cheng & Lapata, and d) SummaRunner. The $\bigoplus$ indicates attention. Green blocks repesent sentence encoder output and red blocks indicates learned "begin decoding" embeddings. Vertically stacked yellow and orange boxes indicate extractor encoder and decoder hidden states respectively. Horizontal orange and yellow blocks indicate multi-layer perceptrons. The purple blocks represent the document and summary state in the SummaRunner extractor.

3.1 Sentence Encoders

We experiment with three architectures for mapping sequences of word embeddings to a fixed length vector: averaging, RNNs, and CNNs. Hyperparameter settings and implementation details can be found in Appendix A.

Averaging Encoder Under the averaging encoder, a sentence embedding h is simply the average of its word embeddings, i.e. $h = \frac{1}{|s|}\sum_{i=1}^{|s|} w_i$.

RNN Encoder When using the *RNN* sentence encoder, a sentence embedding is the concatenation of the final output states of a forward and backward RNN over the sentence's word embeddings. We use a Gated Recurrent Unit (GRU) for the RNN cell (Chung et al., 2014).

CNN Encoder The *CNN* sentence encoder uses a series of convolutional feature maps to encode each sentence. This encoder is similar to the convolutional architecture of Kim (2014) used for text classification tasks and performs a series of "one-dimensional" convolutions over word embeddings. The final sentence embedding h is a concatenation of all the convolutional filter outputs after max pooling over time.

3.2 Sentence Extractors

Sentence extractors take sentence embeddings $h_{1:n}$ and produce an extract $y_{1:n}$. The sentence extractor is essentially a discriminative classifier $p(y_{1:n}|h_{1:n})$. Previous neural network approaches to sentence extraction have assumed an auto-regressive model, leading to a semi-Markovian factorization of the extractor probabilities $p(y_{1:n}|h) = \prod_{i=1}^{n} p(y_i|y_{<i}, h)$, where each prediction y_i is dependent on *all* previous y_j for all $j < i$. We compare two such models proposed by Cheng and Lapata (2016) and Nallapati et al. (2017). A simpler approach that does not allow interaction among the $y_{1:n}$ is to model $p(y_{1:n}|h) = \prod_{i=1}^{n} p(y_i|h)$, which we explore in two proposed extractor models that we refer to as the RNN and Seq2Seq extractors. Implementation details for all extractors are in Appendix B.

Previously Proposed Sentence Extractors We consider two recent state-of-the-art extractors.

The first, proposed by Cheng and Lapata (2016), is built around a sequence-to-sequence model. First, each sentence embedding[3] is fed into an encoder side RNN, with the final encoder state passed to the first step of the decoder RNN. On the decoder side, the same sentence embeddings are fed as input to the decoder and decoder outputs are used to predict each y_i. The decoder input is weighted by the previous extraction probability, inducing the dependence of y_i on $y_{<i}$. See Figure 1.c for a graphical layout of the extractor.

Nallapati et al. (2017) proposed a sentence extractor, which we refer to as the SummaRunner Extractor, that factorizes the extraction probability into contributions from different sources. First, a bidirectional RNN is run over the sentence em-

---

[3] Cheng and Lapata (2016) used an CNN sentence encoder with this extractor architecture; in this work we pair the Cheng & Lapata extractor with several different encoders.

beddings[4] and the output is concatenated. A representation of the whole document is made by averaging the RNN output. A summary representation is also constructed by taking the sum of the previous RNN outputs weighted by their extraction probabilities. Extraction predictions are made using the RNN output at the i-th step, the document representation, and i-th version of the summary representation, along with factors for sentence location in the document. The use of the iteratively constructed summary representation creates a dependence of y_i on all $y_{<i}$. See Figure 1.d for a graphical layout.

Proposed Sentence Extractors We propose two sentence extractor models that make a stronger conditional independence assumption $p(y|h) = \prod_{i=1}^{n} p(y_i|h)$, essentially making independent predictions conditioned on h.

RNN Extractor Our first proposed model is a very simple bidirectional RNN based tagging model. As in the RNN sentence encoder we use a GRU cell. The forward and backward outputs of each sentence are passed through a multi-layer perceptron with a logsitic sigmoid output to predict the probability of extracting each sentence. See Figure 1.a for a graphical layout.

Seq2Seq Extractor One shortcoming of the RNN extractor is that long range information from one end of the document may not easily be able to affect extraction probabilities of sentences at the other end. Our second proposed model, the Seq2Seq extractor mitigates this problem with an attention mechanism commonly used for neural machine translation (Bahdanau et al., 2014) and abstractive summarization (See et al., 2017). The sentence embeddings are first encoded by a bidirectional GRU. A separate decoder GRU transforms each sentence into a query vector which attends to the encoder output. The attention weighted encoder output and the decoder GRU output are concatenated and fed into a multi-layer perceptron to compute the extraction probability. See Figure 1.b for a graphical layout.

4 Datasets

We perform our experiments across six corpora from varying domains to understand how different biases within each domain can affect content selection. The corpora come from the news domain (CNN-DailyMail, New York Times, DUC), personal narratives domain (Reddit), workplace meetings (AMI), and medical journal articles (PubMed). See Table 1 for dataset statistics.

Dataset	Train	Valid	Test	Refs
CNN/DM	287,113	13,368	11,490	1
NYT	44,382	5,523	6,495	1.93
DUC	516	91	657	2
Reddit	404	24	48	2
AMI	98	19	20	1
PubMed	21,250	1,250	2,500	1

Table 1: Sizes of the training, validation, test splits for each dataset and the average number of test set human reference summaries per document.

CNN-DailyMail We use the preprocessing and training, validation, and test splits of See et al. (2017). This corpus is a mix of news on different topics including politics, sports, and entertainment.

New York Times The New York Times (NYT) corpus (Sandhaus, 2008) contains two types of abstracts for a subset of its articles. The first summary is an archival abstract and the second is a shorter online teaser meant to entice a viewer of the webpage to click to read more. From this collection, we take all articles that have a concatenated summary length of at least 100 words. We create training, validation, and test splits by partitioning on dates; we use the year 2005 as the validation data, with training and test partitions including documents before and after 2005 respectively.

DUC We use the single document summarization data from the 2001 and 2002 Document Understanding Conferences (DUC) (Over and Liggett, 2002). We split the 2001 data into training and validation splits and reserve the 2002 data for testing.

AMI The AMI corpus (Carletta et al., 2005) is a collection of real and staged office meetings annotated with text transcriptions, along with abstractive summaries. We use the prescribed splits.

---

[4] Nallapati et al. (2017) use an RNN sentence encoder with this extractor architecture; in this work we pair the SummaRunner extractor with different encoders.

Table 2: METEOR (M) and ROUGE-2 recall (R-2) results across all extractor/encoder pairs. Results that are statistically indistinguishable from the best system are shown in bold face.

Reddit Ouyang et al. (2017) collected a corpus of personal stories shared on Reddit[5] along with multiple extractive and abstractive summaries. We randomly split this data using roughly three and five percent of the data validation and test respectively.

PubMed We created a corpus of 25,000 randomly sampled medical journal articles from the PubMed Open Access Subset[6]. We only included articles if they were at least 1000 words long and had an abstract of at least 50 words in length. We used the article abstracts as the ground truth human summaries.

4.1 Ground Truth Extract Summaries

Since we do not typically have ground truth extract summaries from which to create the labels y_i, we construct gold label sequences by greedily optimizing ROUGE-1, using the algorithm in Appendix C. We choose to optimize for ROUGE-1 rather than ROUGE-2 similarly to other optimization based approaches to summarization (Sipos et al., 2012; Durrett et al., 2016) which found this to be the easier target to learn.

5 Experiments

We evaluate summary quality using ROUGE-2 recall (Lin, 2004); ROUGE-1 and ROUGE-LCS trend similarity in our experiments. We use target word lengths of 100 words for news, and 75, 290, and 200 for Reddit, AMI, and PubMed respectively. We also evaluate using METEOR (Denkowski and Lavie, 2014).[7] Summaries are generated by extracting the top ranked sentences by model probability $p(y_i = 1|y_{<i}, h)$, stopping when the word budget is met or exceeded. We estimate statistical significance by averaging each document level score over the five random initializations. We then test the difference between the best system on each dataset and all other systems using the approximate randomization test (Riezler and Maxwell, 2005) with the Bonferroni correction for multiple comparisons, testing for significance at the 0.05 level.

5.1 Training

We train all models to minimize the weighted negative log-likelihood

$$\mathcal{L} = -\sum_{\substack{s,y \in \mathcal{D} \\ h=\text{enc}(s)}} \sum_{i=1}^{n} \omega(y_i) \log p\left(y_i | y_{<i}, h\right)$$

---

[5] `www.reddit.com`

[6] `https://www.ncbi.nlm.nih.gov/pmc/tools/openftlist/`

[7] We use the default settings for METEOR and use remove stopwords and no stemming options for ROUGE, keeping defaults for all other parameters.

Table 4: ROUGE-2 recall after removing nouns, verbs, adjectives/adverbs, and function words. Ablations are performed using the averaging sentence encoder and the RNN extractor. Bold indicates best performing system. † indicates significant difference with the non-ablated system. Difference in score from *all words* shown in parenthesis.

over the training data $\mathcal{D}$ using stochastic gradient descent with the ADAM optimizer (Kingma and Ba, 2014). $\omega(0) = 1$ and $\omega(1) = N_0/N_1$ where N_y is the number of training examples with label y. We trained for a maximum of 50 epochs and the best model was selected with early stopping on the validation set according to ROUGE-2. Each epoch constitutes a full pass through the dataset. The average stopping epoch was: CNN-DailyMail, 16.2; NYT, 21.36; DUC, 37.11; Reddit, 36.59; AMI, 19.58; PubMed, 19.84. All experiments were repeated with five random initializations. Unless specified, word embeddings were initialized using pretrained GloVe embeddings (Pennington et al., 2014) and we did not update them during training. Unknown words were mapped to a zero embedding. See Appendix D for more optimization and training details.

5.2 Baselines

Lead As a baseline we include the lead summary, i.e. taking the first x words of the document as summary, where x is the target summary length for each dataset (see the first paragraph of § 5). While incredibly simple, this method is still a competitive baseline for single document summarization, especially on newswire.

Oracle To measure the performance ceiling, we show the ROUGE/METEOR scores using the extractive summary which results from greedily optimizing ROUGE-1. I.e., if we had clairvoyant knowledge of the human reference summary, the oracle system achieves the (approximate) maximum possible ROUGE scores. See Appendix C for a detailed description of the oracle algorithm.

5.3 Results

The results of our main experiment comparing the different extractors/encoders are shown in Table 2. Overall, we find no major advantage when using the CNN and RNN sentence encoders over the averaging encoder. The best performing encoder/extractor pair either uses the averaging encoder (five out of six datasets) or the differences are not statistically significant.

When looking at extractors, the Seq2Seq extractor is either part of the best performing system (three out of six datasets) or is not statistically distinguishable from the best extractor.

Overall, on the news and medical journal domains, the differences are quite small with the dif-

Table 6: Example output of Seq2Seq extractor (left) and Cheng & Lapata Extractor (right). This is a typical example, where only one sentence is different between the two (shown in bold).

ferences between worst and best systems on the CNN/DM dataset spanning only .56 of a ROUGE point. While there is more performance variability in the Reddit and AMI data, there is less distinction among systems: no differences are significant on Reddit and every extractor has at least one configuration that is indistinguishable from the best system on the AMI corpus. This is probably due to the small test size of these datasets.

Word Embedding Learning Given that learning a sentence encoder (averaging has no learned parameters) does not yield significant improvement, it is natural to consider whether learning word embeddings is also necessary. In Table 3 we compare the performance of different extractors using the averaging encoder, when the word embeddings are held fixed or learned during training. In both cases, word embeddings are initialized with GloVe embeddings trained on a combination of Gigaword and Wikipedia. When learning embeddings, words occurring fewer than three times in the training data are mapped to an unknown token (with learned embedding).

In all but one case, fixed embeddings are as good or better than the learned embeddings. This is a somewhat surprising finding on the CNN/DM data since it is reasonably large, and learning embeddings should give the models more flexibility to identify important word features.[8] This suggests that we cannot extract much generalizable learning signal from the content other than what is already present from initialization. Even on PubMed, where the language is quite different from the news/Wikipedia articles the GloVe embeddings were trained on, learning leads to significantly worse results.

POS Tag Ablation It is also not well explored what word features are being used by the encoders. To understand which classes of words were most important we ran an ablation study, selectively removing nouns, verbs (including participles and auxiliaries), adjectives & adverbs, and function words (adpositions, determiners, conjunctions). All datasets were automatically tagged using the spaCy part-of-speech (POS) tagger[9]. The embeddings of removed words were replaced with a zero vector, preserving the order and position of the non-ablated words in the sentence. Ablations were performed on training, validation, and test partitions, using the RNN extractor with averaging encoder. Table 4 shows the results of the POS tag ablation experiments. While removing any word class from the representation generally hurts performance (with statistical significance), on the news domains, the absolute values of the

---

[8] The AMI corpus is an exception here where learning *does* lead to small performance boosts, however, only in the Seq2Seq extractor is this diference significant; it is quite possible that this is an artifact of the very small test set size.

[9] https://github.com/explosion/spaCy

differences are quite small (.18 on CNN/DM, .41 on NYT, .3 on DUC) suggesting that the model's predictions are not overly dependent on any particular word types. On the non-news datasets, the ablations have a larger effect (max differences are 1.89 on Reddit, 2.56 on AMI, and 1.3 on PubMed). Removing nouns leads to the largest drop on AMI and PubMed. Removing adjectives and adverbs leads to the largest drop on Reddit, suggesting the intensifiers and descriptive words are useful for identifying important content in personal narratives. Curiously, removing the function word POS class yields a significant improvement on DUC 2002 and AMI.

Document Shuffling Sentence position is a well known and powerful feature for news summarization (Hong and Nenkova, 2014), owing to the intentional lead bias in the news article writing[10]; it also explains the difficulty in beating the lead baseline for single-document summarization (Nenkova, 2005; Brandow et al., 1999). In examining the generated summaries, we found most of the selected sentences in the news domain came from the lead paragraph of the document. This is despite the fact that there is a long tail of sentence extractions from later in the document in the ground truth extract summaries (31%, 28.3%, and 11.4% of DUC, CNN/DM, and NYT training extract labels come from the second half of the document). Because this lead bias is so strong, it is questionable whether the models are learning to identify important content or just find the start of the document. We conduct a sentence order experiment where each document's sentences are randomly shuffled during training. We then evaluate each model performance on the unshuffled test data, comparing to the model trained on unshuffled data; if the models trained on shuffled data drop in performance, then this indicates the lead bias is the relevant factor.

Table 5 shows the results of the shuffling experiments. The news domains and PubMed suffer a significant drop in performance when the document order is shuffled. By comparison, there is no significant difference between the shuffled and in-order models on the Reddit domain, and shuffling actually improves performance on AMI. This suggest that position is being learned by the models in the news/journal article domain even when the model has no explicit position features, and that this feature is more important than either content or function words.

6 Discussion

Learning content selection for summarization in the news domain is severely inhibited by the lead bias. The summaries generated by all systems described here–the prior work and our proposed simplified models–are highly similar to each other and to the lead baseline. The Cheng & Lapata and Seq2Seq extractors (using the averaging encoder) share 87.8% of output sentences on average on the CNN/DM data, with similar numbers for the other news domains (see Table 6 for a typical example). Also on CNN/DM, 58% of the Seq2Seq selected sentences also occur in the lead summary, with similar numbers for DUC, NYT, and Reddit. Shuffling reduces lead overlap to 35.2% but the overall system performance drops significantly; the models are not able to identify important information without position.

The relative robustness of the news domain to part of speech ablation also suggests that models are mostly learning to recognize the stylistic features unique to the beginning of the article, and not the content. Additionally, the drop in performance when learning word embeddings on the news domain suggests that word embeddings alone do not provide very generalizable content features compared to recognizing the lead.

The picture is rosier for non-news summarization where part of speech ablation leads to larger performance differences and shuffling either does not inhibit content selection significantly or leads to modest gains. Learning better word-level representations on these domains will likely require much larger corpora, something which might remain unlikely for personal stories and meetings.

The lack of distinction among sentence encoders is interesting because it echoes findings in the generic sentence embedding literature where word embedding averaging is frustratingly difficult to outperform (Iyyer et al., 2015; Wieting et al., 2015; Arora et al., 2016; Wieting and Gimpel, 2017). The inability to learn useful sentence representations is also borne out in the SummaRunner model, where there are explicit similarity computations between document or summary representations and sentence embeddings; these computations do not seem to add much to the per-

---

[10] `https://en.wikipedia.org/wiki/Inverted_pyramid_(journalism)`

formance as the Cheng & Lapata and Seq2Seq models which lack these features generally perform as well or better. Furthermore, the Cheng & Lapata and SummaRunner extractors both construct a history of previous selection decisions to inform future choices but this does not seem to significantly improve performance over the Seq2Seq extractor (which does not). This suggests that we need to rethink or find novel forms of sentence representation for the summarization task.

A manual examination of the outputs revealed some interesting failure modes, although in general it was hard to discern clear patterns of behaviour other than lead bias. On the news domain, the models consistently learned to ignore quoted material in the lead, as often the quotes provide color to the story but are unlikely to be included in the summary (e.g. *"It was like somebody slugging a punching bag."*). This behavior was most likely triggered by the presence of quotes, as the quote attributions, which were often tokenized as separate sentences, would subsequently be included in the summary despite also not containing much information (e.g. *Gil Clark of the National Hurricane Center said Thursday*).

7 Conclusion

We have presented an empirical study of deep learning based content selection algorithms for summarization. Our findings suggest such models face stark limitations on their ability to learn robust features for this task and that more work is needed on sentence representation for summarization.

Improved Semantic-Aware Network Embedding with Fine-Grained Word Alignment

Dinghan Shen, Xinyuan Zhang, Ricardo Henao, Lawrence Carin

Abstract

Network embeddings, which learn low-dimensional representations for each vertex in a large-scale network, have received considerable attention in recent years. For a wide range of applications, vertices in a network are typically accompanied by rich textual information such as user profiles, paper abstracts, *etc*. We propose to incorporate semantic features into network embeddings by matching important words between text sequences for all pairs of vertices. We introduce a *word-by-word* alignment framework that measures the compatibility of embeddings between word pairs, and then adaptively accumulates these alignment features with a simple yet effective aggregation function. In experiments, we evaluate the proposed framework on three real-world benchmarks for downstream tasks, including link prediction and multi-label vertex classification. Results demonstrate that our model outperforms state-of-the-art network embedding methods by a large margin.

1 Introduction

Networks are ubiquitous, with prominent examples including social networks (*e.g.*, Facebook, Twitter) or citation networks of research papers (*e.g.*, arXiv). When analyzing data from these real-world networks, traditional methods often represent vertices (nodes) as one-hot representations (containing the connectivity information of each vertex with respect to all other vertices), usually suffering from issues related to the inherent sparsity of large-scale networks. This results in models that are not able to fully capture the relationships between vertices of the network (Perozzi et al., 2014; Tu et al., 2016). Alternatively, network embedding (*i.e.*, network representation learning) has been considered, representing each vertex of a network with a *low-dimensional vector* that preserves information on its similarity relative to other vertices. This approach has attracted considerable attention in recent years (Tang and Liu, 2009; Perozzi et al., 2014; Tang et al., 2015; Grover and Leskovec, 2016; Wang et al., 2016; Chen et al., 2016; Wang et al., 2017a; Zhang et al., 2018).

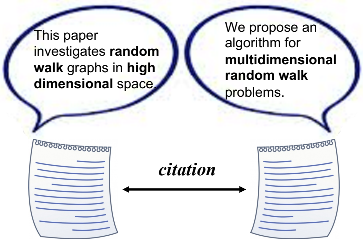

Figure 1: Example of the text information (abstracts) associated to two papers in a citation network. Key words for matching are highlighted.

Traditional network embedding approaches focus primarily on learning representations of vertices that preserve local structure, as well as internal structural properties of the network. For instance, Isomap (Tenenbaum et al., 2000), LINE (Tang et al., 2015), and Grarep (Cao et al., 2015) were proposed to preserve first-, second-, and higher-order proximity between nodes, respectively. DeepWalk (Perozzi et al., 2014), which learns vertex representations from random-walk sequences, similarly, only takes into account structural information of the network. However, in real-world networks, vertices usually contain rich textual information (*e.g.*, user profiles in Facebook, paper abstracts in arXiv, user-generated content on Twitter, *etc*.), which may be leveraged effectively for learning more informative embeddings.

To address this opportunity, Yang et al. (2015) proposed text-associated DeepWalk, to incorporate textual information into the vectorial representations of vertices (embeddings). Sun et al. (2016) employed deep recurrent neural networks to integrate the information from vertex-

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1829–1838
Brussels, Belgium, October 31 - November 4, 2018.

associated text into network representations. Further, Tu et al. (2017) proposed to more effectively model the semantic relationships between vertices using a mutual attention mechanism.

Although these methods have demonstrated performance gains over structure-only network embeddings, the relationship between text sequences for a pair of vertices is accounted for solely by comparing their sentence embeddings. However, as shown in Figure 1, to assess the similarity between two research papers, a more effective strategy would compare and align (via local-weighting) individual important words (keywords) within a pair of abstracts, while information from other words (*e.g.*, stop words) that tend to be less relevant can be effectively ignored (down-weighted). This alignment mechanism is difficult to accomplish in models where text sequences are first embedded into a common space and then compared in pairs (He and Lin, 2016; Parikh et al., 2016; Wang and Jiang, 2017; Wang et al., 2017b; Shen et al., 2018a).

We propose to learn a semantic-aware Network Embedding (NE) that incorporates word-level alignment features abstracted from text sequences associated with vertex pairs. Given a pair of sentences, our model first aligns each word within one sentence with keywords from the other sentence (adaptively up-weighted via an attention mechanism), producing a set of fine-grained matching vectors. These features are then accumulated via a simple but efficient aggregation function, obtaining the final representation for the sentence. As a result, the word-by-word alignment features (as illustrated in Figure 1) are explicitly and effectively captured by our model. Further, the learned network embeddings under our framework are adaptive to the specific (local) vertices that are considered, and thus are context-aware and especially suitable for downstream tasks, such as link prediction. Moreover, since the word-by-word matching procedure introduced here is highly parallelizable and does not require any complex encoding networks, such as Long Short-Term Memory (LSTM) or Convolutional Neural Networks (CNNs), our framework requires significantly less time for training, which is attractive for large-scale network applications.

We evaluate our approach on three real-world datasets spanning distinct network-embedding-based applications: link prediction, vertex classification and visualization. We show that the proposed word-by-word alignment mechanism efficiently incorporates textual information into the network embedding, and consistently exhibits superior performance relative to several competitive baselines. Analyses considering the extracted word-by-word pairs further validate the effectiveness of the proposed framework.

2 Proposed Methods

2.1 Problem Definition

A network (graph) is defined as $\boldsymbol{G} = \{\boldsymbol{V}, \boldsymbol{E}\}$, where $\boldsymbol{V}$ and $\boldsymbol{E}$ denote the set of N vertices (nodes) and edges, respectively, where elements of $\boldsymbol{E}$ are two-element subsets of $\boldsymbol{V}$. Here we only consider undirected networks, however, our approach (introduced below) can be readily extended to the directed case. We also define $\boldsymbol{W}$, the symmetric $\mathbb{R}^{N\times N}$ matrix whose elements, w_{ij}, denote the weights associated with edges in $\boldsymbol{V}$, and $\boldsymbol{T}$, the set of text sequences assigned to each vertex. Edges and weights contain the structural information of the network, while the text can be used to characterize the semantic properties of each vertex. Given network $\boldsymbol{G}$, with the *network embedding* we seek to encode each vertex into a low-dimensional vector $\boldsymbol{h}$ (with dimension much smaller than N), while preserving structural and semantic features of $\boldsymbol{G}$.

2.2 Framework Overview

To incorporate both structural and semantic information into the network embeddings, we specify two types of (latent) embeddings: (i) $\boldsymbol{h}_s$, the *structural embedding*; and (ii) $\boldsymbol{h}_t$, the *textual embedding*. Specifically, each vertex in $\boldsymbol{G}$ is encoded into a low-dimensional embedding $\boldsymbol{h} = [\boldsymbol{h}_s; \boldsymbol{h}_t]$. To learn these embeddings, we specify an objective that leverages the information from both $\boldsymbol{W}$ and $\boldsymbol{T}$, denoted as

$$\mathcal{L} = \sum_{\boldsymbol{e}\in\boldsymbol{E}} \mathcal{L}_{\text{struct}}(\boldsymbol{e}) + \mathcal{L}_{\text{text}}(\boldsymbol{e}) + \mathcal{L}_{\text{joint}}(\boldsymbol{e})\,, \quad (1)$$

where $\mathcal{L}_{\text{struct}}$, $\mathcal{L}_{\text{text}}$ and $\mathcal{L}_{\text{joint}}$ denote structure, text, and joint structure-text training losses, respectively. For a vertex pair $\{v_i, v_j\}$ weighted by w_{ij}, $\mathcal{L}_{\text{struct}}(v_i, v_j)$ in (1) is defined as (Tang et al., 2015)

$$\mathcal{L}_{\text{struct}}(v_i, v_j) = w_{ij} \log p(\boldsymbol{h}_s^i | \boldsymbol{h}_s^j)\,, \quad (2)$$

where $p(\boldsymbol{h}_s^i|\boldsymbol{h}_s^j)$ denotes the conditional probability between structural embeddings for vertices $\{v_i, v_j\}$. To leverage the textual information in $\boldsymbol{T}$, similar text-specific and joint structure-text training objectives are also defined

$$\mathcal{L}_{\text{text}}(v_i, v_j) = w_{ij}\alpha_1 \log p(\boldsymbol{h}_t^i|\boldsymbol{h}_t^j)\,, \tag{3}$$

$$\mathcal{L}_{\text{joint}}(v_i, v_j) = w_{ij}\alpha_2 \log p(\boldsymbol{h}_t^i|\boldsymbol{h}_s^j) \tag{4}$$

$$+\, w_{ij}\alpha_3 \log p(\boldsymbol{h}_s^i|\boldsymbol{h}_t^j)\,, \tag{5}$$

where $p(\boldsymbol{h}_t^i|\boldsymbol{h}_t^j)$ and $p(\boldsymbol{h}_t^i|\boldsymbol{h}_s^j)$ (or $p(\boldsymbol{h}_s^i|\boldsymbol{h}_t^j)$) denote the conditional probability for a pair of text embeddings and text embedding given structure embedding (or *vice versa*), respectively, for vertices $\{v_i, v_j\}$. Further, α_1, α_2 and α_3 are hyper-parameters that balance the impact of the different training-loss components. Note that structural embeddings, $\boldsymbol{h}_s$, are treated directly as parameters, while the text embeddings $\boldsymbol{h}_t$ are learned based on the text sequences associated with vertices.

For all conditional probability terms, we follow Tang et al. (2015) and consider the second-order proximity between vertex pairs. Thus, for vertices $\{v_i, v_j\}$, the probability of generating $\boldsymbol{h}_i$ conditioned on $\boldsymbol{h}_j$ may be written as

$$p(\boldsymbol{h}^i|\boldsymbol{h}^j) = \frac{\exp\left({\boldsymbol{h}^j}^T \boldsymbol{h}^i\right)}{\sum_{k=1}^{N} \exp\left({\boldsymbol{h}^j}^T \boldsymbol{h}^k\right)}\,. \tag{6}$$

Note that (6) can be applied to both structural and text embeddings in (2) and (3).

Inspired by Tu et al. (2017), we further assume that vertices in the network play different roles depending on the vertex with which they interact. Thus, for a given vertex, the text embedding, $\boldsymbol{h}_t$, is adaptive (specific) to the vertex it is being conditioned on. This type of context-aware textual embedding has demonstrated superior performance relative to context-free embeddings (Tu et al., 2017). In the following two sections, we describe our strategy for encoding the text sequence associated with an edge into its adaptive textual embedding, via word-by-context and word-by-word alignments.

2.3 Word-by-Context Alignment

We first introduce our base model, which re-weights the importance of individual words within a text sequence in the context of the edge being considered. Consider text sequences associated with two vertices connected by an edge, denoted $\boldsymbol{t}_a$ and $\boldsymbol{t}_b$ and contained in $\boldsymbol{T}$. Text sequences $\boldsymbol{t}_a$ and $\boldsymbol{t}_b$ are of lengths M_a and M_b, respectively, and are represented by $\mathbf{X}_a \in \mathbb{R}^{d\times M_a}$ and $\mathbf{X}_b \in \mathbb{R}^{d\times M_b}$, respectively, where d is the dimension of the word embedding. Further, $\boldsymbol{x}_a^{(i)}$ denotes the embedding of the i-th word in sequence $\boldsymbol{t}_a$.

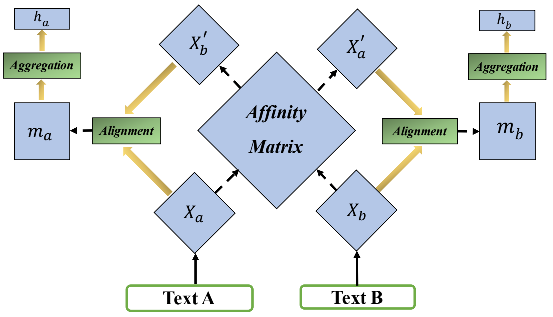

Figure 2: Schematic of the proposed *fine-grained word alignment module* for incorporating textual information into a network embedding. In this setup, word-by-word matching features are explicitly abstracted to infer the relationship between vertices.

Our goal is to encode text sequences $\boldsymbol{t}_a$ and $\boldsymbol{t}_b$ into *counterpart-aware* vectorial representations $\boldsymbol{h}_a$ and $\boldsymbol{h}_b$. Thus, while inferring the adaptive textual embedding for sentence $\boldsymbol{t}_a$, we propose re-weighting the importance of each word in $\boldsymbol{t}_a$ to explicitly account for its alignment with sentence $\boldsymbol{t}_b$. The weight α_i, corresponding to the i-th word in $\boldsymbol{t}_a$, is generated as:

$$\alpha_i = \frac{\exp(\tanh(\mathbf{W}_1 \boldsymbol{c}_b + \mathbf{W}_2 \boldsymbol{x}_a^{(i)}))}{\sum_{j=1}^{M_a} \exp(\tanh(\mathbf{W}_1 \boldsymbol{c}_b + \mathbf{W}_2 \boldsymbol{x}_a^{(j)}))}\,, \tag{7}$$

where $\mathbf{W}_1$ and $\mathbf{W}_2$ are model parameters and $\boldsymbol{c}_b = \sum_{i=1}^{M_b} \boldsymbol{x}_i^b$ is the context vector of sequence $\boldsymbol{t}_b$, obtained by simply averaging over all the word embeddings in the sequence, similar to fastText (Joulin et al., 2016). Further, the *word-by-context* embedding for sequence $\boldsymbol{t}_a$ is obtained by taking the weighted average over all word embeddings

$$\boldsymbol{h}_a = \textstyle\sum_{i=1}^{M_a} \alpha_i \boldsymbol{x}_a^{(i)}\,. \tag{8}$$

Intuitively, α_i may be understood as the relevance score between the ith word in $\boldsymbol{t}_a$ and sequence $\boldsymbol{t}_b$. Specifically, keywords within $\boldsymbol{t}_a$, in the context of $\boldsymbol{t}_b$, should be assigned larger weights, while less important words will be correspondingly down-weighted. Similarly, $\boldsymbol{h}_b$ is encoded as a weighted embedding using (7) and (8).

2.4 Fine-Grained Word-by-Word Alignment

With the alignment in the previous section, word-by-context matching features α_i are modeled; however, the *word-by-word* alignment information (*fine-grained*), which is key to characterize the relationship between two vertices (as discussed in the above), is not explicitly captured. So motivated, we further propose an architecture to explicitly abstract word-by-word alignment information from $\boldsymbol{t}_a$ and $\boldsymbol{t}_b$, to learn the relationship between the two vertices. This is inspired by the recent success of Relation Networks (RNs) for relational reasoning (Santoro et al., 2017).

As illustrated in Figure 2, given two input embedding matrices $\mathbf{X}_a$ and $\mathbf{X}_b$, we first compute the affinity matrix $\mathbf{A} \in \mathbb{R}^{M_b \times M_a}$, whose elements represent the affinity scores corresponding to all word pairs between sequences $\boldsymbol{t}_a$ and $\boldsymbol{t}_b$

$$\mathbf{A} = \mathbf{X}_b^T \mathbf{X}_a \,. \qquad (9)$$

Subsequently, we compute the context-aware matrix for sequence $\boldsymbol{t}_b$ as

$$\mathbf{A}_b = \text{softmax}(\mathbf{A}) \,, \qquad \widetilde{\mathbf{X}}_b = \mathbf{X}_b \mathbf{A}_b \,, \qquad (10)$$

where the softmax$(\cdot)$ function is applied column-wise to $\mathbf{A}$, and thus $\mathbf{A}_b$ contains the attention weights (importance scores) across sequence $\boldsymbol{t}_b$ (columns), which account for each word in sequence $\boldsymbol{t}_a$ (rows). Thus, matrix $\widetilde{\mathbf{X}}_b \in \mathbb{R}^{d \times M_a}$ in (10) constitutes an attention-weighted embedding for $\mathbf{X}_b$. Specifically, the i-th column of $\widetilde{\mathbf{X}}_b$, denoted as $\widetilde{\boldsymbol{x}}_b^{(i)}$, can be understood as a weighted average over all the words in $\boldsymbol{t}_b$, where higher attention weights indicate better alignment (match) with the i-th word in $\boldsymbol{t}_a$.

To abstract the word-by-word alignments, we compare $\boldsymbol{x}_a^{(i)}$ with $\widetilde{\boldsymbol{x}}_b^{(i)}$, for $i = 1, 2, ..., M_a$, to obtain the corresponding matching vector

$$\boldsymbol{m}_a^{(i)} = f_{\text{align}}\left(\boldsymbol{x}_a^{(i)}, \widetilde{\boldsymbol{x}}_b^{(i)}\right) \,, \qquad (11)$$

where $f_{\text{align}}(\cdot)$ represents the alignment function. Inspired by the observation in Wang and Jiang (2017) that simple comparison/alignment functions based on element-wise operations exhibit excellent performance in matching text sequences, here we use a combination of element-wise subtraction and multiplication as

$$f_{\text{align}}(\boldsymbol{x}_a^{(i)}, \widetilde{\boldsymbol{x}}_a^{(i)}) = [\boldsymbol{x}_a^{(i)} - \widetilde{\boldsymbol{x}}_a^{(i)}; \boldsymbol{x}_a^{(i)} \odot \widetilde{\boldsymbol{x}}_a^{(i)}] \,,$$

where $\odot$ denotes the element-wise Hadamard product, then these two operations are concatenated to produce the matching vector $\boldsymbol{m}_a^{(i)}$. Note these operators may be used individually or combined as we will investigate in our experiments.

Subsequently, matching vectors from (11) are aggregated to produce the final textual embedding $\boldsymbol{h}_t^a$ for sequence $\boldsymbol{t}_a$ as

$$\boldsymbol{h}_t^a = f_{\text{aggregate}}\left(\boldsymbol{m}_a^{(1)}, \boldsymbol{m}_a^{(2)}, ..., \boldsymbol{m}_a^{(M_a)}\right) \,, \qquad (12)$$

where $f_{\text{aggregate}}$ denotes the aggregation function, which we specify as the max-pooling pooling operation. Notably, other commutative operators, such as summation or average pooling, can be otherwise employed. Although these aggregation functions are simple and invariant to the order of words in input sentences, they have been demonstrated to be highly effective in relational reasoning (Parikh et al., 2016; Santoro et al., 2017). To further explore this, in Section 5.3, we conduct an ablation study comparing different choices of alignment and aggregation functions.

The representation $\boldsymbol{h}_b$ can be obtained in a similar manner through (9), (10), (11) and (12), but replacing (9) with $\mathbf{A} = \mathbf{X}_a^T \mathbf{X}_b$ (its transpose). Note that this word-by-word alignment is more computationally involved than word-by-context; however, the former has substantially fewer parameters to learn, provided we no longer have to estimate the parameters in (7).

2.5 Training and Inference

For large-scale networks, computing and optimizing the conditional probabilities in (1) using (6) is computationally prohibitive, since it requires the summation over all vertices $\boldsymbol{V}$ in $\boldsymbol{G}$. To address this limitation, we leverage the negative sampling strategy introduced by Mikolov et al. (2013), *i.e.*, we perform computations by sampling a subset of negative edges. As a result, the conditional in (6) can be rewritten as:

$$p(\boldsymbol{h}^i | \boldsymbol{h}^j) = \log \sigma\left({\boldsymbol{h}^j}^T \boldsymbol{h}^i\right) + \sum_{i=1}^{K} \mathbb{E}_{\boldsymbol{h}^i \sim P(v)} \left[\log \sigma\left(-{\boldsymbol{h}^j}^T \boldsymbol{h}^i\right)\right] \,,$$

where $\sigma(x) = 1/(1 + \exp(-x))$ is the sigmoid function. Following Mikolov et al. (2013), we set the noise distribution $P(v) \propto d_v^{3/4}$, where d_v is the out-degree of vertex $v \in \boldsymbol{V}$. The number of negative samples K is treated as a hyperparameter. We use Adam (Kingma and Ba, 2014) to update the model parameters while minimizing the objective in (1).

3 Related Work

Network embedding methods can be divided into two categories: (*i*) methods that solely rely on the structure, *e.g.*, vertex information; and (*ii*) methods that leverage both the structure the network and the information associated with its vertices.

For the first type of models, DeepWalk (Perozzi et al., 2014) has been proposed to learn node representations by generating node contexts via truncated random walks; it is similar to the concept of Skip-Gram (Mikolov et al., 2013), originally introduced for learning word embeddings. LINE (Tang et al., 2015) proposed a principled objective to explicitly capture first-order and second-order proximity information from the vertices of a network. Further, Grover and Leskovec (2016) introduced a biased random walk procedure to generate the neighborhood for a vertex, which infers the node representations by maximizing the likelihood of preserving the local context information of vertices. However, these algorithms generally ignore rich heterogeneous information associated with vertices. Here, we focus on incorporating *textual information* into network embeddings.

To learn semantic-aware network embeddings, Text-Associated DeepWalk (TADW) (Yang et al., 2015) proposed to integrate textual features into network representations with matrix factorization, by leveraging the equivalence between DeepWalk and matrix factorization. CENE (Content-Enhanced Network Embedding) (Sun et al., 2016) used bidirectional recurrent neural networks to abstract the semantic information associated with vertices, which further demonstrated the advantages of employing textual information. To capture the interaction between sentences of vertex pairs, Tu et al. (2017) further proposed Context-Aware Network Embedding (CANE), that employs a mutual attention mechanism to adaptively account for the textual information from neighboring vertices. Despite showing improvement over structure-only models, these semantic-aware methods cannot capture word-level alignment information, which is important for inferring the relationship between node pairs, as previously discussed. In this work, we introduce a Word-Alignment-based Network Embedding (WANE) framework, which aligns and aggregates word-by-word matching features in an explicit manner, to obtain more informative network representations.

4 Experimental Setup

Datasets We investigate the effectiveness of the proposed WANE model on two standard network-embedding-based tasks, *i.e.*, link prediction and multi-label vertex classification. The following three real-world datasets are employed for quantitative evaluation: (*i*) *Cora*, a standard paper citation network that contains 2,277 machine learning papers (vertices) grouped into 7 categories and connected by 5,214 citations (edges) (*ii*) *HepTh*, another citation network of 1,038 papers with abstract information and 1,990 citations; (*iii*) *Zhihu*, a network of 10,000 active users from Zhihu, the largest Q&A website in China, where 43,894 vertices and descriptions of the Q&A topics are available. The average lengths of the text in the three datasets are 90, 54, and 190, respectively. To make direct comparison with existing work, we employed the same preprocessing procedure[1] of Tu et al. (2017).

Training Details For fair comparison with CANE (Tu et al., 2017), we set the dimension of network embedding for our model to 200. The number of negative samples K is selected from $\{1, 3, 5\}$ according to performance on the validation set. We set the batch size as 128, and the model is trained using Adam (Kingma and Ba, 2014), with a learning rate of 1×10^{-3} for all parameters. Dropout regularization is employed on the word embedding layer, with rate selected from $\{0.5, 0.7, 0.9\}$, also on the validation set. Our code will be released to encourage future research.

Baselines To evaluate the effectiveness of our framework, we consider several strong baseline methods for comparisons, which can be categorized into two types: (*i*) models that only exploit *structural* information: MMB (Airoldi et al., 2008), DeepWalk (Perozzi et al., 2014), LINE (Tang et al., 2015), and node2vec (Grover and Leskovec, 2016). (*ii*) Models that take both *structural* and *textual* information into account: Naive combination (which simply concatenates the structure-based embedding with CNN-based text embeddings, as explored in (Tu et al., 2017), TADW (Yang et al., 2015), CENE (Sun et al.,

2016), and CANE (Tu et al., 2017). It is worth noting that unlike all these baselines, WANE explicitly captures word-by-word interactions between text sequence pairs.

Evaluation Metrics We employ AUC (Hanley and McNeil, 1982) as the evaluation metric for link prediction, which measures the probability that vertices within an existing edge, randomly sampled from the test set, are more similar than those from a random pair of non-existing vertices, in terms of the inner product between their corresponding embeddings.

For multi-label vertex classification and to ensure fair comparison, we follow Yang et al. (2015) and employ a linear SVM on top of the learned network representations, and evaluate classification accuracy with different training ratios (varying from 10% to 50%). The experiments for each setting are repeated 10 times and the average test accuracy is reported.

5 Experimental Results

We experiment with three variants for our WANE model: (*i*) WANE: where the word embeddings of each text sequence are simply average to obtain the sentence representations, similar to (Joulin et al., 2016; Shen et al., 2018c). (*ii*) WANE-*wc*: where the textual embeddings are inferred with word-by-context alignment. (*iii*) WANE-*ww*: where the word-by-word alignment mechanism is leveraged to capture word-by-word matching features between available sequence pairs.

5.1 Link Prediction

Table 1 presents link prediction results for all models on Cora dataset, where different ratios of edges are used for training. It can be observed that when only a small number of edges are available, *e.g.*, 15%, the performances of structure-only methods is much worse than semantic-aware models that have taken textual information into consideration The perfromance gap tends to be smaller when a larger proportion of edges are employed for training. This highlights the importance of incorporating associated text sequences into network embeddings, especially in the case of representing a relatively sparse network. More importantly, the proposed WANE-*ww* model consistently outperforms other semantic-aware NE models by a substantial margin, indicating that our model better abstracts word-by-word alignment features from the text sequences available, thus yields more informative network representations.

Further, WANE-*ww* also outperforms WANE or WANE-*wc* on a wide range of edge training pro-

portions. This suggests that: (*i*) adaptively assigning different weights to each word within a text sequence (according to its paired sequence) tends to be a better strategy than treating each word equally (as in WANE). (*ii*) Solely considering the context-by-word alignment features (as in WANE-*wc*) is not as efficient as abstracting word-by-word matching information from text sequences. We observe the same trend and the superiority of our WANE-*ww* models on the other two datasets, HepTh and Zhihu datasets, as shown in Table 2 and 3, respectively.

5.2 Multi-label Vertex Classification

We further evaluate the effectiveness of proposed framework on vertex classification tasks with the Cora dataset. Similar to Tu et al. (2017), we generate the global embedding for each vertex by taking the average over its *context-aware* embeddings with all other connected vertices. As shown in Figure 3(c), semantic-aware NE methods (including naive combination, TADW, CENE, CANE) exhibit higher test accuracies than semantic-agnostic models, demonstrating the advantages of incorporating textual information. Moreover, WANE-*ww* consistently outperforms other competitive semantic-aware models on a wide range of labeled proportions, suggesting that explicitly capturing word-by-word alignment features is not only useful for vertex-pair-based tasks, such as link prediction, but also results in better global embeddings which are required for vertex classification tasks. These observations further demonstrate that WANE-*ww* is an effective and robust framework to extract informative network representations.

Semi-supervised classification We further consider the case where the training ratio is less than 10%, and evaluate the learned network embedding with a semi-supervised classifier. Following Yang et al. (2015), we employ a Transductive SVM (TSVM) classifier with a linear kernel (Joachims, 1998) for fairness. As illustrated in Table 4, the proposed WANE-*ww* model exhibits superior performances in most cases. This may be due to the fact that WANE-*ww* extracts information from the vertices and text sequences jointly, thus the obtained vertex embeddings are less noisy and perform more consistently with relatively small training ratios (Yang et al., 2015).

5.3 Ablation Study

Motivated by the observation in Wang and Jiang (2017) that the advantages of different functions to match two vectors vary from task to task, we further explore the choice of alignment and aggregation functions in our WANE-*ww* model. To match the word pairs between two sequences, we experimented with three types of operations: *sub-*

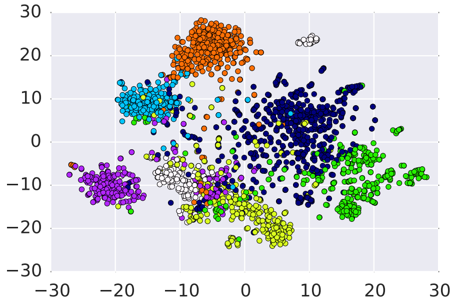

Figure 4: *t*-SNE visualization of the learned network embeddings on the Cora dataset.

traction, *multiplication*, and *Sub & Multi* (the concatenation of both approaches). As shown in Figure 3(a) and 3(b), element-wise *subtraction* tends to be the most effective operation performance-wise on both Cora and Zhihu datasets, and performs comparably to *Sub & Multi* on the HepTh dataset. This finding is consistent with the results in Wang and Jiang (2017), where they found that simple comparison functions based on *element-wise* operations work very well on matching text sequences.

In terms of the aggregation functions, we compare (one-layer) *CNN*, *mean-pooling*, and *max-pooling* operations to accumulate the matching vectors. As shown in Figure 3(b), *max-pooling* has the best empirical results on all three datasets. This may be attributed to the fact that the *max-pooling* operation is better at selecting important word-by-word alignment features, among all matching vectors available, to infer the relationship between vertices.

5.4 Qualitative Analysis

Embedding visualization To visualize the learned network representations, we further employ *t*-SNE to map the low-dimensional vectors of the vertices to a 2-D embedding space. We use the *Cora* dataset because there are labels associated with each vertex and WANE-*ww* to obtain the network embeddings.

As shown in Figure 4 where each point indicates one paper (vertex), and the color of each point indicates the *category* it belongs to, the embeddings of the same label are indeed very close in the 2-D plot, while those with different labels are relatively farther from each other. Note that the model is not trained with any label information, indicating that WANE-*ww* has extracted meaningful patterns from the text and vertex information available.

Baseline Models	1%	3%	7%	10%
Text Only	33.0	43.0	57.1	62.8
Naive Combination	67.4	70.6	75.1	77.4
TADW	72.1	77.0	79.1	81.3
CENE	**73.8**	79.1	81.5	84.5
CANE	72.6	78.2	80.4	83.4
WANE-*ww* (ours)	73.4	**79.6**	**82.7**	**85.1**

Table 4: *Semi-supervised* vertex classification results on the *Cora* dataset.

Case study The proposed word-by-word alignment mechanism can be used to highlight the most informative words (and the corresponding matching features) wrt the relationship between vertices. We visualize the norm of matching vector obtained in (11) in Figure 5 for the Cora dataset. It can be observed that matched key words, *e.g.*, 'MCMC', 'convergence', between the text sequences are indeed assigned higher values in the matching vectors. These words would be selected preferentially by the final *max-pooling* aggregation operation. This indicates that WANE-*ww* is able to abstract important word-by-word alignment features from paired text sequences.

6 Conclusions

We have presented a novel framework to incorporate the semantic information from vertex-associated text sequences into network embeddings. An *align-aggregate* framework is introduced, which first aligns a sentence pair by capturing the word-by-word matching features, and then adaptively aggregating these word-level alignment information with an efficient *max-pooling* function. The semantic features abstracted are further encoded, along with the structural information, into a shared space to obtain the final network embedding. Compelling experimental results on several tasks demonstrated the advantages of our approach. In future work, we aim to leverage abundant unlabeled text data to abstract more informative sentence representations (Dai and Le, 2015; Zhang et al., 2017; Shen et al., 2017; Tang and de Sa, 2018) . Another interesting direction is to learn *binary* and compact network embedding, which could be more efficient in terms of both computation and memory, relative to its continuous counterpart (Shen et al., 2018b).

Abstract

Convolutional neural networks (CNNs) have recently emerged as a popular building block for natural language processing (NLP). Despite their success, most existing CNN models employed in NLP share the same learned (and static) set of filters for all input sentences. In this paper, we consider an approach of using a small *meta network* to learn context-aware convolutional filters for text processing. The role of meta network is to abstract the contextual information of a sentence or document into a set of *input-aware* filters. We further generalize this framework to model sentence pairs, where a *bidirectional* filter generation mechanism is introduced to encapsulate co-dependent sentence representations. In our benchmarks on four different tasks, including ontology classification, sentiment analysis, answer sentence selection, and paraphrase identification, our proposed model, a modified CNN with context-aware filters, consistently outperforms the standard CNN and attention-based CNN baselines. By visualizing the learned *context-aware* filters, we further validate and rationalize the effectiveness of proposed framework.

1 Introduction

In the last few years, convolutional neural networks (CNNs) have demonstrated remarkable progress in various natural language processing applications (Collobert et al., 2011), including sentence/document classification (Kim, 2014; Zhang et al., 2015; Wang et al., 2018), text sequence matching (Hu et al., 2014; Yin et al., 2016; Shen et al., 2017), generic text representations (Gan et al., 2016; Tang et al., 2018), language modeling (Dauphin et al., 2017), machine translation (Gehring et al., 2017) and abstractive sentence summarization (Gehring et al., 2017). CNNs are typically applied to tasks where feature extraction and a corresponding supervised task are approached jointly (LeCun et al., 1998). As an encoder network for text, CNNs typically convolve a set of filters, of window size n, with an input-sentence embedding matrix obtained via *word2vec* (Mikolov et al., 2013) or Glove (Pennington et al., 2014). Different filter sizes n may be used within the same model, exploiting meaningful semantic features from different n-gram fragments.

The learned weights of CNN filters, in most cases, are assumed to be fixed regardless of the input text. As a result, the rich contextual information inherent in natural language sequences may not be fully captured. As demonstrated in Cohen and Singer (1999), the context of a word tends to greatly influence its contribution to the final supervised tasks. This observation is consistent with the following intuition: when reading different *types* of documents, *e.g.*, academic papers or newspaper articles, people tend to adopt distinct strategies for better and more effective understanding, leveraging the fact that the same words or phrases may have different meaning or imply different things, depending on context.

Several research efforts have sought to incorporate *contextual information* into CNNs to adaptively extract text representations. One common strategy is the *attention mechanism*, which is typically employed on top of a CNN (or Long Short-Term Memory (LSTM)) layer to guide the extraction of semantic features. For the embedding of a single sentence, Lin et al. (2017) proposed a self-attentive model that attends to different parts of a sentence and combines them into multiple vector representations. However, their model needs considerably more parameters to achieve performance gains over traditional CNNs. To match sentence pairs, Yin et al. (2016) introduced an attention-based CNN model, which re-weights the convolution inputs or outputs, to extract interdepen-

Brussels, Belgium, October 31 - November 4, 2018.

dent sentence representations. Wang et al. (2016); Wang and Jiang (2017) explore a *compare and aggregate* framework to directly capture the word-by-word matching between two paired sentences. However, these approaches suffer from the problem of high matching complexity, since a similarity matrix between pairwise words needs to be computed, and thus it is computationally inefficient or even prohibitive when applied to long sentences (Mou et al., 2016).

In this paper, we propose a generic approach to learn *context-aware* convolutional filters for natural language understanding. In contrast to traditional CNNs, the convolution operation in our framework does not have a fixed set of filters, and thus provides the network with stronger modeling flexibility and capacity. Specifically, we introduce a *meta network* to generate a set of context-aware filters, conditioned on specific input sentences; these filters are adaptively applied to either the same (Section 3.2) or different (Section 3.3) text sequences. In this manner, the learned filters vary from sentence to sentence and allow for more fine-grained feature abstraction.

Moreover, since the generated filters in our framework can adapt to different conditional information available (labels or paired sentences), they can be naturally generalized to model sentence pairs. In this regard, we propose a novel *bidirectional* filter generation mechanism to allow interactions between sentence pairs while constructing *context-aware* representations.

We investigate the effectiveness of our Adaptive Context-sensitive CNN (ACNN) framework on several text processing tasks: ontology classification, sentiment analysis, answer sentence selection and paraphrase identification. We show that the proposed methods consistently outperforms the standard CNN and attention-based CNN baselines. Our work provides a new perspective on how to incorporate contextual information into text representations, which can be combined with more sophisticated structures to achieve even better performance in the future.

2 Related Work

Learning deep text representations has attracted much attention recently, since they can potentially benefit a wide range of NLP applications (Collobert et al., 2011; Kim, 2014; Wang et al., 2017a; Shen et al., 2018a; Tang and de Sa, 2018; Zhang et al., 2018). CNNs have been extensively investigated as the encoder networks of natural language. Our work is in line with previous efforts on improving the adaptivity and flexibility of convolutional neural networks (Jeon and Kim, 2017; De Brabandere et al., 2016). Jeon and Kim (2017) proposed to enhance the transformation modeling capacity of CNNs by adaptively learning the filter shapes through backpropagation. De Brabandere et al. (2016) introduced an architecture to generate the future frames conditioned on given image(s), by adapting the CNN filter weights to the motion within previous video frames. Although CNNs have been widely adopted in a large number of NLP applications, improving the adaptivity of vanilla CNN modules has been considerably less studied. To the best of our knowledge, the work reported in this paper is the first attempt to develop more flexible and adjustable CNN architecture for modeling sentences.

Our use of a meta network to generate parameters for another network is directly inspired by the recent success of hypernetworks for text-generation tasks (Ha et al., 2017), and dynamic parameter-prediction for video-frame generation (De Brabandere et al., 2016). In contrast to these works that focus on generation problems, our model is based on context-aware CNN filters and is aimed at abstracting more informative and predictive sentence features. Most similar to our work, Liu et al. (2017) designed a meta network to generate compositional functions over tree-structured neural networks for encapsulating sentence features. However, their model is only suitable for encoding individual sentences, while our framework can be readily generalized to capture the interactions between sentence pairs. Moreover, our framework is based on CNN models, which is advantageous due to fewer parameters and highly parallelizable computations relative to sequential-based models.

3 Model

3.1 Basic CNN for text representations

The CNN architectures in (Kim, 2014; Collobert et al., 2011) are typically utilized for extracting sentence representations, by a composition of a convolutional layer and a *max-pooling* operation over all resulting feature maps. Let the words of a sentence of length T (padded where necessary) be x_1, x_2, ... , x_T. The sentence can be represented as a matrix $\boldsymbol{X} \in \mathbb{R}^{d \times T}$, where each column represents a d-dimensional embedding of the corresponding word.

In the convolutional layer, a set of filters with weights $\boldsymbol{W} \in \mathbb{R}^{K \times h \times d}$ is convolved with every window of h words within the sentence, *i.e.*, $\{x_{1:h}, x_{2:h+1}, \dots, x_{T-h+1:T}\}$, where K is the number of output feature maps (and filters). In this manner, feature maps $\boldsymbol{p}$ for these h-gram text fragments are generated as:

$$\boldsymbol{p}_i = f(\boldsymbol{W} \times x_{i:i+h-1} + b) \qquad (1)$$

where $i = 1, 2, ..., T - h + 1$ and $\times$ denotes the convolution operator at the ith shift location. Parameter $b \in \mathbb{R}^K$ is the bias term and $f(\cdot)$ is a non-linear function, implemented as a rectified linear unit (ReLU) in our experiments. The output feature maps of the convolutional layer, *i.e.*, $\boldsymbol{p} \in \mathbb{R}^{K \times (T-h+1)}$ are then passed to the pooling layer, which takes the maximum value in every row of $\boldsymbol{p}$, forming a K-dimensional vector, $\boldsymbol{z}$. This operation attempts to keep the most salient feature detected by every filter and discard the information from less fundamental text fragments. Moreover, the *max-over-time* nature of the pooling operation (Collobert et al., 2011) guarantees that the size of the obtained representation is independent of the sentence length.

Note that in basic CNN sentence encoders, filter weights are the same for different inputs, which may be suboptimal for feature extraction (De Brabandere et al., 2016), especially in the case where conditional information is available.

3.2 Learning context-sensitive filters

The proposed architecture to learn context-sensitive filters is composed of two principal modules: (*i*) a filter generation module, which produces a set of filters conditioned on the input sentence; and (*ii*) an adaptive convolution module, which applies the generated filters to an input sentence (this sentence may be either the same as or different from the first input, as discussed further in Section 3.3). The two modules are jointly differentiable, and the overall architecture can be trained in an end-to-end manner. Since the generated filters are sample-specific, our ACNN feature extractor for text tends to have stronger predictive power than a basic CNN encoder. The general ACNN framework is shown schematically in Figure 1.

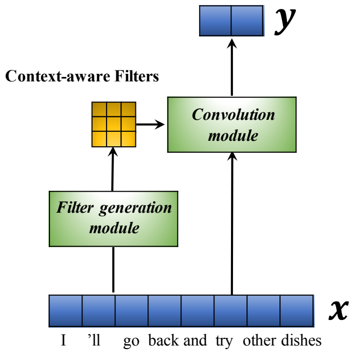

Figure 1: The general ACNN framework. Notably, the input sentences to filter generating module and convolution module could be different (see Section 3.3).

Filter generation module Instead of utilizing fixed filter weights $\boldsymbol{W}$ for different inputs (as (1)), our model generates a set of filters conditioned on the input sentence $\boldsymbol{X}$. Given an input $\boldsymbol{X}$, the filter-generation module can be implemented, in principle, as any deep (differentiable) architecture. However, in order to handle input sentences of variable length common in natural language, we design a generic filter generation module to produce filters with a predefined size.

First, the input $\boldsymbol{X}$ is encapsulated into a fixed-length vector (code) $\boldsymbol{z}$ with the dimension of l, via a basic CNN model, where one convolutional layer is employed along with the pooling operation (as described in Section 3.1). On top of this hidden representation $\boldsymbol{z}$, a deconvolutional layer, which performs transposed operations of convolutions (Radford et al., 2016), is further applied to produce a unique set of filters for $\boldsymbol{X}$ (as illustrated in Figure 1):

$$\boldsymbol{z} = \mathrm{CNN}(\boldsymbol{X}; \boldsymbol{\theta}_e), \qquad (2)$$

$$\boldsymbol{f} = \mathrm{DCNN}(\boldsymbol{z}; \boldsymbol{\theta}_d)\,, \qquad (3)$$

where $\boldsymbol{\theta}_e$ and $\boldsymbol{\theta}_d$ are the learned parameters in each layer of the filter-generating module, respectively. Specifically, we convolve $\boldsymbol{z}$ with a filter of size (f_s, l, k_x, k_y), where f_s is the number of generated filters and the kernel size is (k_x, k_y). The output will be a tensor of shape (f_s, k_x, k_y). Since the dimension of hidden representation $\boldsymbol{z}$ is independent of input-sentence length, this framework guarantees that the generated filters are of the same shape and size for every sentence. Intuitively, the encoding part of filter generation module abstracts the information from sentence $\boldsymbol{X}$ into $\boldsymbol{z}$. Based on this representation, the deconvolutional up-sampling layer determines a set of fixed-size, fine-grained filters $\boldsymbol{f}$ for the specific input.

Adaptive convolution module The adaptive convolution module takes as inputs the generated filters $\boldsymbol{f}$ and an input sentence. This sentence and the input to the filter-generation module may be identical (as in Figure 1) or different (as in Figure 2). With the sample-specific filters, the input sentence is adaptively encoded, again, via a basic CNN architecture as in Section 3.1, *i.e.*, one convolutional and one pooling layer. Notably, there are no additional parameters in the adaptive convolution module (no bias term is employed).

Our ACNN framework can be seen as a generalization of the basic CNN, which can be represented as an ACNN by setting the outputs of the filter-generation module to a constant, regardless of the contextual information from input sentence(s). Because of the learning-to-learn (Thrun and Pratt, 2012) nature of the proposed ACNN framework, it tends to have greater representational power than the basic CNN.

3.3 Extension to text sequence matching

Considering the ability of our ACNN framework to generate context-aware filters, it can be naturally generalized to the task of text sequence matching. In this section, we will describe the proposed Adaptive Question Answering (AdaQA) model in the context of answer sentence selection task. Note that the corresponding model can be readily adapted to other sentence matching problems as well (see Section 5.2).

Given a factual question q (associated with a list of candidate answers $\{a_1, a_2, \dots, a_m\}$ and their corresponding labels $\boldsymbol{y} = \{y_1, y_2, \dots, y_m\}$), the goal of the model is to identify the correct answers from the set of candidates. For $i = 1, 2, \dots, m$, if a_i correctly answers q, then $y_i = 1$, and otherwise $y_i = 0$. Therefore, the task can be cast as a classification problem where, given an unlabeled question-answer pair (q_i, a_i), we seek to predict the judgement y_i.

Conventionally, a question q and an answer a are independently encoded by two basic CNNs to fixed-length vector representations, denoted $\boldsymbol{h}_q$ and $\boldsymbol{h}_a$, respectively. They are then directly employed to predict the judgement $\boldsymbol{y}$. This strategy could be suboptimal, since no communication (information sharing) occurs between the question-answer pair until the top prediction layer. Intuitively, while the model is inferring the representation for a question, if the meaning of the answer is taken into account, those features that are relevant for final prediction are more likely to be extracted. So motivated, we propose an adaptive CNN-based question-answer (AdaQA) model for this problem. The AdaQA model can be divided into three modules: filter generation, adaptive convolution, and matching modules, as depicted schematically in Figure 2. Assume there is a question-answer pair to be matched, represented by word-embedding matrices, *i.e.* $\boldsymbol{Q} \in \mathbb{R}^{T_q \times d}$ and $\boldsymbol{A} \in \mathbb{R}^{T_a \times d}$, where d is the embedding dimension and T_q and T_a are respective sentence lengths. First, they are passed to two filter-generation modules, to produce two sets of filters that encapsulate features of the corresponding input sentences. Similar to the setup in Section 3.2, we also employ a two-step process to produce the filters. For a question $\boldsymbol{Q}$, the generating process is:

$$\boldsymbol{z}_q = \text{CNN}(\boldsymbol{Q}; \boldsymbol{\theta}_e^q), \tag{4}$$

$$\boldsymbol{f}_q = \text{DCNN}(\boldsymbol{z}_q; \boldsymbol{\theta}_d^q) \tag{5}$$

where CNN and DCNN denote the basic CNN unit and deconvolution layer, respectively, as discussed in Section 2.1. Parameters $\boldsymbol{\theta}_e^q$ and $\boldsymbol{\theta}_d^q$ are to be learned. The same process can be utilized to produce encodings $\boldsymbol{z}_a$ and filters $\boldsymbol{f}_a$ for the answer input, $\boldsymbol{A}$, with parameters $\boldsymbol{\theta}_e^a$ and $\boldsymbol{\theta}_d^a$, respectively.

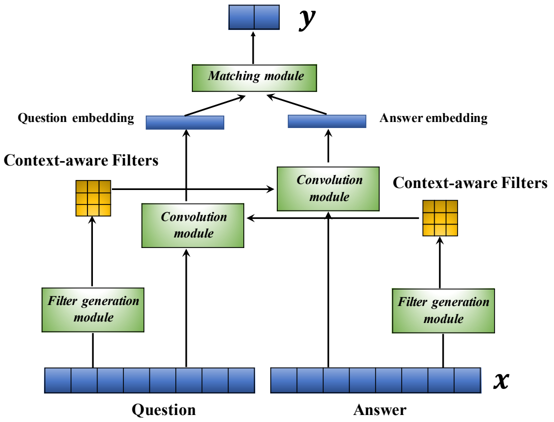

Figure 2: Schematic description of Adaptive Question Answering (AdaQA) model.

The two sets of filter weights are then passed to adaptive convolution modules, along with $\boldsymbol{Q}$ and $\boldsymbol{A}$, to obtain the extracted question and answer embeddings. That is, the question embedding is convolved with the filters produced by the answer and *vise versa* (ψ_q and ψ_a are the bias terms to be learned). The key idea is to abstract information from the answer (or question) that is pertinent to the corresponding question (or answer).

Compared to a Siamese CNN architecture (Bromley et al., 1994), our model selectively encapsulates the most important features for judgement prediction, removing less vital information. We then employ the question and answer representations $\boldsymbol{h}_q \in \mathbb{R}^{n_h}$, $\boldsymbol{h}_a \in \mathbb{R}^{n_h}$ as inputs to the matching module (where n_h is the dimension of question/answer embeddings). Following Mou et al. (2016), the matching function is defined as:

$$\boldsymbol{t} = [\boldsymbol{h}_q; \boldsymbol{h}_a; \boldsymbol{h}_q - \boldsymbol{h}_a; \boldsymbol{h}_q \odot \boldsymbol{h}_a] \tag{6}$$

$$p(\boldsymbol{y} = 1|\boldsymbol{h}_q, \boldsymbol{h}_a) = \text{MLP}(\boldsymbol{t}; \boldsymbol{\eta}') \tag{7}$$

where $-$ and $\odot$ denote an element-wise subtraction and element-wise product, respectively. $[\boldsymbol{h}_a; \boldsymbol{h}_b]$ indicates that $\boldsymbol{h}_a$ and $\boldsymbol{h}_b$ are stacked as column vectors. The resulting matching vector $\boldsymbol{t} \in \mathbb{R}^{4n_h}$ is then sent through an MLP layer (with sigmoid activation function and parameters $\boldsymbol{\eta}'$ to be learned) to model the desired conditional distribution $p(y_i = 1|\boldsymbol{h}_q, \boldsymbol{h}_a)$.

Notably, we share the weights of filter generating networks for both the question and answer, so that the model adaptivity for answer selection can be improved without an excessive increase in the number of parameters. All three modules in AdaQA model are jointly trained end-to-end. Note that the AdaQA model proposed can be readily adapted to other sentence matching tasks, such as paraphrase identification (see Section 5.2).

3.4 Connections to attention mechanism

The adaptive *context-aware* filter generation mechanism proposed here bears close resemblance to attention mechanism (Yin et al., 2016; Bahdanau et al., 2015; Xiong et al., 2017) widely adopted in the NLP community, in the sense that both methods intend to incorporate rich *contextual information* into text representations. However, attention is typically operated on top of the hidden units preprocessed by CNN or LSTM layers, and assigns different weights to each unit according to a *context vector*. By contrast, in our *context-aware* filter generation mechanism, the contextual information is inherently encoded into the convolutional filters, which directly interact with the input sentence during the convolution encoding operation. Notably, according to our experiments, the proposed filter generation module can be readily combined with (standard) attention mechanisms to further enhance the modeling expressiveness of CNN encoder.

4 Experimental Setup

Datasets We investigate the effectiveness of the proposed ACNN framework on both document classification and text sequence matching tasks. Specifically, we consider two large-scale document classification datasets: Yelp Reviews Polarity, and DBPedia ontology datasets (Zhang et al., 2015). For Yelp reviews, we seek to predict a binary label (positive or negative) regarding one review about a restaurant. DBpedia is extracted from Wikipedia by crowd-sourcing and is categorized into 14 non-overlapping ontology classes, including *Company*, *Athlete*, *Natural Place*, *etc*. We sample 15% of the training data as the validation set, to select hyperparameters for our models and perform early stopping. For sentence matching, we evaluate the AdaQA model on two datasets for open-domain question answering: WikiQA (Yang et al., 2015) and SelQA (Jurczyk et al., 2016). Given a question, the task is to rank the corresponding candidate answers, which, in the case of WikiQA, are sentences extracted from the summary section of a related Wikipedia article. To facilitate comparison with existing results (Yin et al., 2016; Yang et al., 2015; Shen et al., 2018b), we truncate the candidate answers to a maximum length of 40 tokens for all experiments on the WikiQA dataset. We also consider the task of paraphrase identification with the Quora Question Pairs dataset, with the same data splits as in (Wang et al., 2017b). A summary of all datasets is presented in Table 1.

Training Details For the document classification experiments, we randomly initialize the word embeddings uniformly within $[-0.001, 0.001]$ and update them during training. For the generated filters, we set the window size as $h = 5$, with $K = 100$ feature maps (the dimension of z is set as 100). For direct comparison, we employ the same filter shape/size settings as in our basic CNN implementation. A one-layer architecture is utilized for both the CNN baseline and the ACNN model, since we did not observe significant performance gains with a multilayer architecture. The minibatch size is set as 128, and a dropout rate of 0.2 is utilized on the embedding layer. We observed that a larger dropout rate (*e.g.*, 0.5) will hurt performance on document classifications and make training significantly slower.

For the sentence matching tasks, we initialized the word embeddings with 50-dimensional Glove (Pennington et al., 2014) word vectors pretrained from Wikipedia 2014 and Gigaword 5 (Pennington et al., 2014) for all model variants. As for the filters, we set the window size as $h = 5$, with $K = 300$ feature maps. As described in Section 3.3, the vector $\boldsymbol{t}$, output from the matching module, is fed to the prediction layer, implemented as a one-layer MLP followed by the sigmoid function. We use Adam (Kingma and Ba, 2014) to train the models, with a learning rate of 3×10^{-4}. Dropout (Srivastava et al., 2014), with a rate of 0.5, is employed on the word embedding layer. The hyperparameters are selected by choosing the best model on the validation set. All models are implemented with TensorFlow (Abadi et al., 2016) and are trained using one NVIDIA GeForce GTX TITAN X GPU with 12GB memory.

Baselines For document classification, we consider several baseline models: (i) ngrams (Zhang et al., 2015), a bag-of-means method based on TFIDF representations built by choosing the 500,000 most frequent n-grams (up to 5-grams) from the training set and use their corresponding counts as features; (ii) small/large word CNN (Zhang et al., 2015): 6 layer word-based convolutional networks, with 256/1024 features at each layer, denoted as small/large, respectively; (iii) deep CNN (Conneau et al., 2016): deep convolutional neural networks with 9/17/29 layers. To evaluate the effectiveness of proposed AdaQA model, we compare it with several CNN-based sequence matching baselines, including Vanilla CNN (Jurczyk et al., 2016; Santos et al., 2017), attentive pooling networks (dos Santos et al., 2016), and ABCNN (Yin et al., 2016) (where an attention mechanism is employed over the two sentence representations).

Evaluation Metrics For document categorization and paraphrase identification tasks, we employ the percentage of correct predictions on the test set to evaluate and compare different models.

Model	Yelp P.	DBpedia
CNN-based Baseline Models		
ngrams*	4.36	1.37
ngrams TFIDF*	4.56	1.31

M-ACNN	**3.89**	**1.07**

Table 2: Test error rates on document classification tasks (in percentages). S-*model* indicates that the *model* has one single convolutional filter, while M-*model* indicates that the *model* has multiple convolutional filters. Results marked with $*$ are reported by (Zhang et al., 2015), † are reported by (Conneau et al., 2016), and ‡ are reported by (Lin et al., 2017).

For the answer sentence selection task, mean average precision (MAP) and mean reciprocal rank (MRR) are utilized as the corresponding evaluation metrics.

5 Experimental Results

5.1 Document Classification

To explicitly explore whether our ACNN model can leverage the input-aware filter weights for better sentence representation, we perform a comparison between the basic CNN and ACNN models with only a *single* filter, which are denoted as S-CNN, S-ACNN, respectively (this setting may not yield best overall performance, since only a single filter is used, but it allows us to isolate the impact of adaptivity). As illustrated in Table 2, S-ACNN significantly outperforms S-CNN on both datasets, demonstrating the advantage of the filter-generation module in our ACNN framework. As a result, with only one convolutional filter and thus very limited modeling capacity, our S-ACNN model tends to be much more expressive than the basic CNN model, due to the flexibility of applying different filters to different sentences.

We further experiment on both ACNN and CNN models with *multiple* filters. The corresponding document categorization accuracies are presented in Table 2. Although we only use one convolution layer for our ACNN model, it already outperforms other CNN baseline methods with much deeper architectures. Moreover, our method ex-

hibits higher accuracy than n-grams, which is a very strong baseline as shown in (Zhang et al., 2015). We attribute the superior performance of the ACNN framework to its stronger (adaptive) feature-extraction ability. Moreover, our M-ACNN also achieves slightly better performance than self-attentive sentence embeddings proposed in Lin et al. (2017), which requires significant more parameters than our method.

Effect of number of filters To further demonstrate that the performance gains in document categorization experiments originates from the improved adaptivity of our ACNN framework, we implement the basic CNN model with different numbers of filter sizes, ranging from 1 to 1000. As illustrated in Figure 3(a), when the filter size is larger than 100, the test accuracy of the standard CNN model does not show any noticeable improvement with more filters. More importantly, even with a filter size of 1000, the classification accuracy of the CNN is worse than that of the ACNN model with the filter number restricted to 100. Given these observations, we believe that the boosted categorization accuracy does come from the improved flexibility and thus better feature extraction of our ACNN framework.

5.2 Answer Sentence Selection

To elucidate the role of different parts (modules) in our AdaQA model, we implement several model variants for comparison: (*i*) a "vanilla" CNN model that independently encodes two sentence representations for matching; (*ii*) a self-adaptive ACNN-based model where the question/answer sentence generates adaptive filters only to convolve with the input itself; (*iii*) a one-way ACNN model where only the answer sentence representation is extracted with adaptive filters, which are generated conditioned on the question; (*iv*) a two-way AdaQA model as described in Section 2.4, where both sentences are adaptively encoded, with filters generated conditioned on the other sequence; (*v*) considering that the proposed filter generation mechanism is complementary to the attention layer typically employed in sequence matching tasks (see Section 3.4), we experiment with another model variant that combines the proposed *context-aware* filter generation mechanism with the multi-perspective attention layer introduced in (Wang et al., 2017b).

Tables 3 and 4 show experimental results of our models on WikiQA and SelQA datasets, along with other state-of-the-art methods. Note that the self-adaptive ACNN model variant, which generates filters only for the input itself (without any interactions before the top matching module), slightly outperforms the vanilla CNN Siamese model. Combined with the results in document categorization experiments, we believe that our ACNN framework, in its simplest form, can be utilized as a powerful feature extractor for transforming natural language sentences into fixed-length vectors. More importantly, our two-way AdaQA model exhibits superior results compared with the one-way variant as well as other CNN-based baseline models on the WikiQA dataset. This observation indicates that the *bidirectional* filter generation mechanism is strongly associated with the performance gains. While combined with the multi-perspective attention layers, adopted after the ACNN encoding layer, our two-way AdaQA model achieves even better performance. This suggests that the proposed strategy is complemen-

Table 5: Results on the Quora Question Pairs dataset.

tary, in terms of the incorporation of rich contextual information, to the standard attention mechanism. The same trend is also observed on the SelQA dataset (as shown in Table 4), which is a much larger dataset than WikiQA.

Notably, our model yields significantly better results than an attentive pooling network and ABCNN (attention-based CNN) baselines. We attribute the improvement to two potential advantages of our AdaQA model: (*i*) for the two previous baseline methods, the interaction between question and answer takes place either before or after convolution. However, in our AdaQA model, the communication between two sentences is inherent in the convolution operation, and thus can provide the abstracted features with more flexibility; (*ii*) the *bidirectional* filter generation mechanism in our AdaQA model generates co-dependent representations for the question and candidate answer, which could enable the model to recover from initial local maxima corresponding to incorrect predictions (Xiong et al., 2017).

Paragraph Identification Considering that the proposed AdaQA model can be readily generalized to other text sequence matching problems, we further evaluate the proposed framework on the paraphrase identification task with the Quora question pairs dataset. To ensure a fair comparison, we employ the same data splits as in (Wang et al., 2017b). As illustrated in Table 5, our two-way AdaQA model again exhibits superior performances compared with basic CNN models (as reported in (Wang et al., 2017b)).

5.3 Discussion

Reasoning ability To associate the improved answer sentence selection results with the reasoning capabilities of our AdaQA model, we further categorize the questions in the WikiQA test set into 5 types containing: 'What', 'Where', 'How', 'When' or 'Who'. We then calculate the MAP scores of the basic CNN and our AdaQA model on different question types. Similar to the findings in (Miao et al., 2016), we observe that the 'How' question is the hardest to answer, with the lowest MAP scores. However, our AdaQA model improves most over the basic CNN on the 'How' type question, see Figure 3(b). Further comparing our results with NASM in (Miao et al., 2016), our AdaQA model (with a MAP score of 0.579) outperforms their reported 'How' question MAP scores (0.524) by a large margin, indicating that the adaptive convolutional filter-generation mechanism improves the model's ability to read and reason over natural language sentences.

Filter visualization To better understand what information has been encoded into our *context-aware* filters, we visualize one of the filters for sentences within the test set (on the DBpedia dataset) with t-SNE. The corresponding results are shown in Figure 3(c). It can be observed that the filters for documents with the same label (ontology) are grouped into clusters, indicating that for different types of document, ACNN has leveraged distinct convolutional filters for better feature extraction.

6 Conclusions

We presented a *context-aware* convolutional filter-generation mechanism, introducing a meta network to adaptively produce a set of input-aware filters. In this manner, the filter weights vary from sample to sample, providing the CNN encoder network with more modeling flexibility and capacity.

This framework is further generalized to model question-answer sentence pairs, leveraging a two-way feature abstraction process. We evaluate our models on several document-categorization and sentence matching benchmarks, and they consistently outperform the standard CNN and attention-based CNN baselines, demonstrating the effectiveness of our framework.

Deep Relevance Ranking Using Enhanced Document-Query Interactions

Ryan McDonald[1,2], **Georgios-Ioannis Brokos**[1] and **Ion Androutsopoulos**[1]

[1]Dept. of Informatics, Athens University of Economics and Business, Greece
[2]Google AI

Abstract

We explore several new models for document relevance ranking, building upon the Deep Relevance Matching Model (DRMM) of Guo et al. (2016). Unlike DRMM, which uses context-insensitive encodings of terms and query-document term interactions, we inject rich context-sensitive encodings throughout our models, inspired by PACRR's (Hui et al., 2017) convolutional n-gram matching features, but extended in several ways including multiple views of query and document inputs. We test our models on datasets from the BIOASQ question answering challenge (Tsatsaronis et al., 2015) and TREC ROBUST 2004 (Voorhees, 2005), showing they outperform BM25-based baselines, DRMM, and PACRR.

1 Introduction

Document relevance ranking, also known as *ad-hoc retrieval* (Harman, 2005), is the task of ranking documents from a large collection using the query and the text of each document only. This contrasts with standard information retrieval (IR) systems that rely on text-based signals in conjunction with network structure (Page et al., 1999; Kleinberg, 1999) and/or user feedback (Joachims, 2002). Text-based ranking is particularly important when (i) click-logs do not exist or are small, and (ii) the network structure of the collection is non-existent or not informative for query-focused relevance. Examples include various domains in digital libraries, e.g., patents (Azzopardi et al., 2010) or scientific literature (Wu et al., 2015; Tsatsaronis et al., 2015); enterprise search (Hawking, 2004); and personal search (Chirita et al., 2005).

We investigate new deep learning architectures for document relevance ranking, focusing on *term-based interaction models*, where query terms (*q-terms* for brevity) are scored relative to a document's terms (*d-terms*) and their scores are aggregated to produce a relevance score for the document. Specifically, we use the Deep Relevance Matching Model (DRMM) of Guo et al. (2016) (Fig. 1), which was shown to outperform strong IR baselines and other recent deep learning methods. DRMM uses pre-trained word embeddings for q-terms and d-terms, and cosine similarity histograms (outputs of ⊗ in Fig. 1), each capturing the similarity of a q-term to all the d-terms of a particular document. The histograms are fed to an MLP (dense layers of Fig. 1) that produces the (document-aware) score of each q-term. Each q-term score is then weighted using a gating mechanism (topmost box nodes in Fig. 1) that examines properties of the q-term to assess its importance for ranking (e.g., common words are less important). The sum of the weighted q-term scores is the relevance score of the document. This ignores entirely the contexts where the terms occur, in contrast to recent *position-aware* models such as PACRR (Hui et al., 2017) or those based on recurrent representations (Palangi et al., 2016).

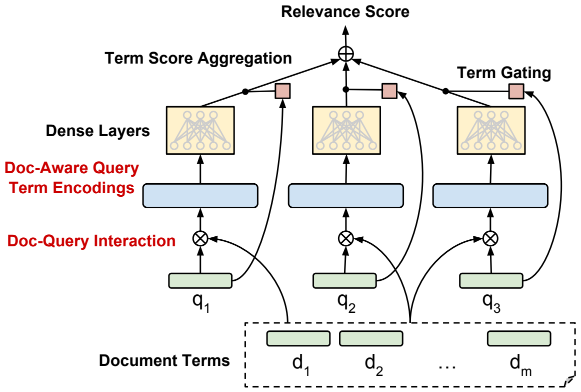

Figure 1: Illustration of DRMM (Guo et al., 2016) for a query of three terms and a document of m terms.

In order to enrich DRMM with context-sensitive representations, we need to change fundamentally how q-terms are scored. This is because rich

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1849–1860
Brussels, Belgium, October 31 - November 4, 2018.

context-sensitive representations – such as input term encodings based on RNNs or CNNs – require end-to-end training and histogram construction is not differentiable. To account for this we investigate novel query-document interaction mechanisms that are differentiable and show empirically that they are effective ways to enable end-to-end training of context-sensitive DRMM models. This is the primary contribution of this paper.

Overall, we explore several extensions to DRMM, including: PACRR-like convolutional n-gram matching features (§3.1); context-sensitive term encodings (§3.2); query-focused attention-based document representations (§3.3); pooling to reward denser term matches and turn rich term representations into fixed-width vectors (§3.4); multiple views of terms, e.g., context sensitive, insensitive, exact matches (§3.5).

We test our models on data from the BIOASQ biomedical question answering challenge (Tsatsaronis et al., 2015) and TREC ROBUST 2004 (Voorhees, 2005), showing that they outperform strong BM25-based baselines (Robertson and Zaragoza, 2009), DRMM, and PACRR.[1]

2 Related Work

Document ranking has been studied since the dawn of IR; classic term-weighting schemes were designed for this problem (Sparck Jones, 1988; Robertson and Sparck Jones, 1988). With the advent of statistical NLP and statistical IR, probabilistic language and topic modeling were explored (Zhai and Lafferty, 2001; Wei and Croft, 2006), followed recently by deep learning IR methods (Lu and Li, 2013; Hu et al., 2014; Palangi et al., 2016; Guo et al., 2016; Hui et al., 2017).

Most document relevance ranking methods fall within two categories: representation-based, e.g., Palangi et al. (2016), or interaction-based, e.g., Lu and Li (2013). In the former, representations of the query and document are generated independently. Interaction between the two only happens at the final stage, where a score is generated indicating relevance. End-to-end learning and backpropagation through the network tie the two representations together. In the interaction-based paradigm, explicit encodings between pairs of queries and documents are induced. This allows direct modeling of exact- or near-matching terms (e.g., synonyms), which is crucial for relevance ranking. Indeed, Guo et al. (2016) showed that the interaction-based DRMM outperforms previous representation-based methods. On the other hand, interaction-based models are less efficient, since one cannot index a document representation independently of the query. This is less important, though, when relevance ranking methods rerank the top documents returned by a conventional IR engine, which is the scenario we consider here.

One set of our experiments ranks biomedical texts. Several methods have been proposed for the BIOASQ challenge (Tsatsaronis et al., 2015), mostly based on traditional IR techniques. The most related work is of Mohan et al. (2017), who use a deep learning architecture. Unlike our work, they focus on user click data as a supervised signal, and they use context-insensitive representations of document-query interactions. The other dataset we experiment with, TREC ROBUST 2004 (Voorhees, 2005), has been used extensively to evaluate traditional and deep learning IR methods.

Document relevance ranking is also related to other NLP tasks. Passage scoring for question answering (Surdeanu et al., 2008) ranks passages by their relevance to the question; several deep networks have been proposed, e.g., Tan et al. (2015). Short-text matching/ranking is also related and has seen recent deep learning solutions (Lu and Li, 2013; Hu et al., 2014; Severyn and Moschitti, 2015). In document relevance ranking, though, documents are typically much longer than queries, which makes methods from other tasks that consider pairs of short texts not directly applicable.

Our starting point is DRMM, to which we add richer representations inspired by PACRR. Hence, we first discuss DRMM and PACRR further.

2.1 DRMM

We have already presented an overview of DRMM. For gating (topmost box nodes of Fig. 1), Guo et al. (2016) use a linear self-attention:

$$g_i = \text{softmax}\Big(w_g^T\, \phi_g(q_i); q_1, \dots, q_n\Big)$$

where $\phi_g(q_i)$ is the embedding $e(q_i)$ of the i-th q-term, or its IDF, $\text{idf}(q_i)$, and w_g is a weights vector. Gating aims to weight the (document-aware) score of each q-term (outputs of dense layers in Fig. 1) based on the importance of the term. We found that $\phi_g(q_i) = [e(q_i); \text{idf}(q_i)]$, where ';' is concatenation, was optimal for all DRMM-based models.

---

[1] The code and data of our experiments, including word embeddings, are available at `https://github.com/nlpaueb/deep-relevance-ranking`.

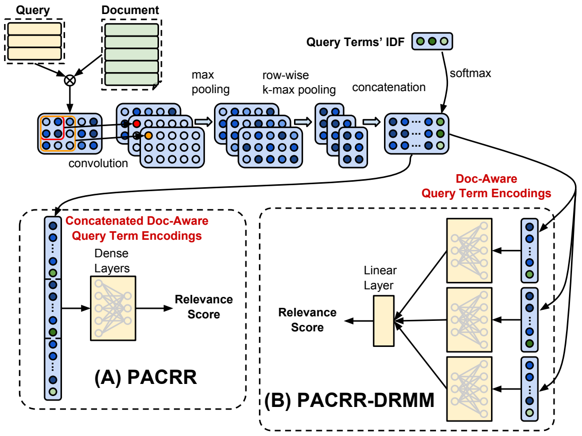

Figure 2: PACRR (Hui et al., 2017) and PACRR-DRMM.

The crux of the original DRMM are the bucketed cosine similarity histograms (outputs of $\otimes$ nodes in Fig. 1), each capturing the similarity of a q-term to all the d-terms. In each histogram, each bucket counts the number of d-terms whose cosine similarity to the q-term is within a particular range. Consider a document with three terms, with cosine similarities, s, to a particular q-term q_i 0.5, 0.1, -0.3, respectively. If we used two buckets $-1 \leq s < 0$ and $0 \leq s \leq 1$, then the input to the dense layers for q_i would be $\langle 1, 2 \rangle$. The fixed number of buckets leads to a fixed-dimension input for the dense layers and makes the model agnostic to different document and query lengths – one of DRMM's main strengths. The main disadvantage is that bucketed similarities are independent of the contexts where terms occur. A q-term 'regulated' will have a perfect match with a d-term 'regulated', even if the former is 'up regulated' and the latter is 'down regulated' in context. Also, there is no reward for term matches that preserve word order, or multiple matches within a small window.

2.2 PACRR

In PACRR (Hui et al., 2017), a query-document term similarity matrix *sim* is computed (Fig. 2A). Each cell (i, j) of *sim* contains the cosine similarity between the embeddings of a q-term q_i and a d-term d_j. To keep the dimensions $l_q \times l_d$ of *sim* fixed across queries and documents of varying lengths, queries are padded to the maximum number of q-terms l_q, and only the first l_d terms per document are retained.[2] Then, convolutions (Fig. 2A) of different kernel sizes $n \times n$ ($n = 2, \ldots, l_g$) are applied to *sim* to capture n-gram query-document similarities. For each size $n \times n$, multiple kernels (filters) are used. Max pooling is then applied along the dimension of the filters (max value of all filters), followed by row-wise k-max pooling to capture the strongest k signals between each q-term and all the d-terms. The resulting matrices are concatenated into a single matrix where each row is a document-aware q-term encoding; the IDF of the q-term is also appended, normalized by applying a softmax across the IDFs of all the q-terms. Following Hui et al. (2018), we concatenate the rows of the resulting matrix into a single vector, which is passed to an MLP (Fig. 2A, dense layers) that produces a query-document relevance score.[3]

The primary advantage of PACRR over DRMM is that it models context via the n-gram convolutions, i.e., denser n-gram matches and matches preserving word order are encoded. However, this context-sensitivity is weak, as the convolutions operate over the similarity matrix, not directly on terms or even term embeddings. Also, unlike DRMM, PACRR requires padding and hyperparameters for maximum number of q-terms (l_q) and d-terms (l_d), since the convolutional and dense layers operate over fixed-size matrices and vectors. On the other hand, PACRR is end-to-end trainable – though Hui et al. (2017) use fixed pre-trained embeddings – unlike DRMM where the bucketed histograms are not differentiable.

3 New Relevance Ranking Models

3.1 PACRR-DRMM

In a DRMM-like version of PACRR, instead of using an MLP (dense layers, Fig. 2A) to score the *concatenation* of all the (document-aware) q-term encodings, the MLP *independently* scores each q-term encoding (the same MLP for all q-terms, Fig. 2B); the resulting scores are aggregated via a linear layer. This version, PACRR-DRMM, performs better than PACRR, using the same number of hidden layers in the MLPs. Likely this is due to the fewer parameters of its MLP, which is shared across the q-term representations and operates on shorter input vectors. Indeed, in early experiments PACRR-DRMM was less prone to over-fitting.

In PACRR-DRMM, the scores of the q-terms (outputs of dense layers, Fig. 2B) are not weighted by a gating mechanism, unlike DRMM (Fig. 1). Nevertheless, the IDFs of the q-terms, which are appended to the q-term encodings (Fig. 2B), are a

---

[2] We use PACRR-*firstk*, which Hui et al. (2017) recommend when documents fit in memory, as in our experiments.

[3] Hui et al. (2017) used an additional LSTM, which was later replaced by the final concatanation (Hui et al., 2018).

form of term-gating (shortcut passing on information about the terms, here their IDFs, to upper layers) applied before scoring the q-terms. By contrast, in DRMM (Fig. 1) term-gating is applied after q-term scoring, and operates on $[e(q_i); \text{idf}(q_i)]$.

3.2 Context-sensitive Term Encodings

In their original incarnations, DRMM and PACRR use pre-trained word embeddings that are insensitive to the context of a particular query or document where a term occurs. This contrasts with the plethora of systems that use context-sensitive word encodings (for each particular occurrence of a word) in virtually all NLP tasks (Bahdanau et al., 2014; Plank et al., 2016; Lample et al., 2016). In general, this is achieved via RNNs, e.g., LSTMs (Gers et al., 2000), or CNNs (Bai et al., 2018).

In the IR literature, context-sensitivity is typically viewed through two lenses: term proximity (Büttcher et al., 2006) and term dependency (Metzler and Croft, 2005). The former assumes that the context around a term match is also relevant, whereas the latter aims to capture when multiple terms (e.g., an n-gram) must be matched together. An advantage of neural network architectures like RNNs and CNNs is that they can capture both.

In the models below (§§3.3–3.4), an encoder produces the *context-sensitive encoding* of each q-term or d-term from the pre-trained embeddings. To compute this we use a standard BILSTM encoding scheme and set the context-sentence encoding as the concatenation of the last layer's hidden states of the forward and backward LSTMs at each position. As is common for CNNs and even recent RNN term encodings (Peters et al., 2018), we use the original term embedding $e(t_i)$ as a residual and combine it with the BILSTM encodings. Specifically, if $\overrightarrow{h}(t_i)$ and $\overleftarrow{h}(t_i)$ are the last layer's hidden states of the left-to-right and right-to-left LSTMs for term t_i, respectively, then we set the context-sensitive term encoding as:

$$c(t_i) = [\overrightarrow{h}(t_i) + e(t_i); \overleftarrow{h}(t_i) + e(t_i)] \quad (1)$$

Since we are adding the original term embedding to each LSTM hidden state, we require the dimensionality of the hidden layers to be equal to that of the original embedding. Other methods were tried, including passing all representations through an MLP, but these had no effect on performance.

This is an orthogonal way to incorporate context into the model relative to PACRR. PACRR creates a query-document similarity matrix and computes n-gram convolutions over the matrix. Here we incorporate context directly into the term encodings; hence similarities in this space are already context-sensitive. One way to view this difference is the point at which context enters the model – directly during term encoding (Eq. 1) or after term similarity scores have been computed (PACRR, Fig. 2).

3.3 ABEL-DRMM

Using the context-sensitive q-term and d-term encodings of §3.2 (Eq. 1), our next extension to DRMM is to create *document-aware* q-term encodings that go beyond bucketed histograms of cosine similarities, the stage in Fig. 1 indicated by $\otimes$. We focus on differentiable encodings to facilitate end-to-end training from inputs to relevance scores.

Figure 3 shows the sub-network that computes the document-aware encoding of a q-term q_i in the new model, given a document $d = \langle d_1, \ldots, d_m \rangle$ of m d-terms. We first compute a dot-product[4] attention score $a_{i,j}$ for each d_j relative to q_i:

$$a_{i,j} = \text{softmax}\Big(c(q_i)^T\, c(d_j); d_1, \ldots, d_m\Big) \quad (2)$$

where $c(t)$ is the context-sensitive encoding of t (Eq. 1). We then sum the context-sensitive encodings of the d-terms, weighted by their attention scores, to produce an attention-based representation d_{q_i} of document d from the viewpoint of q_i:

$$d_{q_i} = \sum_j a_{i,j}\; c(d_j) \quad (3)$$

The Hadamard product (element-wise multiplication, $\odot$) between the (L2-normalized) document representation d_{q_i} and the q-term encoding $c(q_i)$ is then computed and used as the fixed-dimension document-aware encoding $\phi_H(q_i)$ of q_i (Fig. 3):

$$\phi_H(q_i) = \frac{d_{q_i}}{||d_{q_i}||} \odot \frac{c(q_i)}{||c(q_i)||} \quad (4)$$

The $\otimes$ nodes and lower parts of the DRMM network of Fig. 1 are now replaced by (multiple copies of) the sub-network of Fig. 3 (one copy per q-term), with the $\odot$ nodes replacing the $\otimes$ nodes. We call the resulting model Attention-Based ELement-wise DRMM (ABEL-DRMM).

Intuitively, if the document contains one or more terms d_j that are similar to q_i, the attention

---

[4] Dot-products have a larger range than other similarity functions, encouraging low entropy attention distributions.

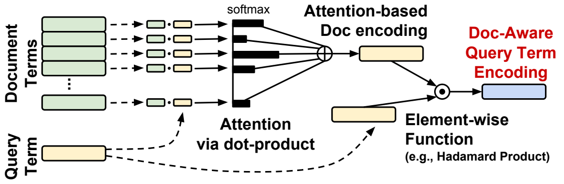

Figure 3: ABEL-DRMM sub-net. From context-aware q-term and d-term encodings (Eq. 1), it generates fixed-dimension *document-aware q-term encodings* to be used in DRMM (Fig. 1, replacing ⊗ nodes).

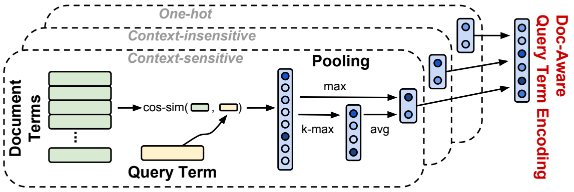

Figure 4: POSIT-DRMM with multiple views (+MV). Three two-dimensional document-aware q-term encodings, one from each view, are produced, concatenated, and used in DRMM (Fig. 1, replacing ⊗ nodes).

mechanism will have emphasized mostly those terms and, hence, d_{q_i} will be similar to $c(q_i)$, otherwise not. This similarity could have been measured by the cosine similarity between d_{q_i} and $c(q_i)$, but the cosine similarity assigns the same weight to all the dimensions, i.e., to all the (L2 normalized) element-wise products in $\phi_H(q_i)$, which cosine similarity just sums. By using the Hadamard product, we pass on to the upper layers of DRMM (the dense layers of Fig. 1), which score each q-term with respect to the document, all the (normalized) element-wise products of $\phi_H(q_i)$, allowing the upper layers to learn which element-wise products (or combinations of them) are important when matching a q-term to the document.

Other element-wise functions can also be used to compare d_{q_i} to $c(q_i)$, instead of the Hadamard product (Eq. 4). For example, a vector containing the squared terms of the Euclidean distance between d_{q_i} and $c(q_i)$ could be used instead of $\phi_H(q_i)$. This change had no effect on ABEL-DRMM's performance on development data. We also tried using $[d_{q_i}; c(q_i)]$ instead of $\phi_H(q_i)$, but performance on development data deteriorated.

ABEL-DRMM is agnostic to document length, like DRMM. ABEL-DRMM, however, is trainable end-to-end, unlike the original DRMM. Still, both models do not reward higher density matches.

3.4 POSIT-DRMM

Ideally, we want models to reward both the maximum match between a q-term and a document, but also the average match (between several q-terms and the document) to reward documents that have a higher density of matches. The document-aware q-term scoring of ABEL-DRMM does not account for this, as the attention summation hides whether a single or multiple terms were matched with high similarity. We also want models to be end-to-end trainable, like ABEL-DRMM.

Figure 4 (context-sensitive box) outlines a simple network that produces document-aware q-term encodings, replacing the ABEL-DRMM sub-network of Fig. 3 in the DRMM framework. We call the resulting model POoled SImilariTy DRMM (POSIT-DRMM). As in ABEL-DRMM, we compute an attention score $a_{i,j}$ for each d_j relative to q_i, now using cosine similarity (cf. Eq. 2):

$$a_{i,j} = \frac{c(q_i)^T c(d_j)}{||c(q_i)||\ ||c(d_j)||} \tag{5}$$

However, we do not use the $a_{i,j}$ scores to compute a weighted average of the encodings of the d-terms (cf. Eq. 3), which is also why there is no softmax in $a_{i,j}$ above (cf. Eq. 2).[5] Instead, we concatenate the attention scores of the m d-terms:

$$a_i = \langle a_{i,1}, \dots, a_{i,j}, \dots, a_{i,m} \rangle^T$$

and we apply two pooling steps on a_i to create a 2-dimensional document-aware encoding $\phi_P(q_i)$ of the q-term q_i (Fig. 4). First max-pooling, which returns the single best match of q_i in the document. Then average pooling over a k-max-pooled version of a_i, which represents the average similarity for the top k matching terms:

$$\phi_P(q_i) = \Big\langle \max(a_i), \text{avg}\Big(\text{k-max}(a_i)\Big) \Big\rangle^T$$

POSIT-DRMM has many fewer parameters than the other models. The input to the upper q-term scoring dense layers of the DRMM framwork (Fig. 1) for ABEL-DRMM has the same dimensionality as pre-trained term embeddings, on the order of hundreds. By contrast, the input dimensionality here is 2. Hence, POSIT-DRMM does not require deep dense layers, but uses a single layer (depth 1). More information on hyperparameters is provided in Appendix A (supplementary material).

POSIT-DRMM is closely related to PACRR (and PACRR-DRMM). Like POSIT-DRMM, PACRR first

---

[5] The $a_{i,j}$s still need to be normalized for input to the upper layers, but they do not need to be positive summing to 1. This is why we use cosine similarity in Eq. 5 instead of dot-products combined with softmax of Eq. 2.

computes cosine similarities between all q-terms and d-terms (Fig. 2). It then applies n-gram convolutions to the similarity matrix to inject context-awareness, and then pooling to create document-aware q-term representations. Instead, POSIT-DRMM relies on the fact that the term encodings are now already context sensitive (Eq. 1) and thus skips the n-gram convolutions. Again, this is a choice of when context is injected – during term encoding or after computing similarity scores.

Mohan et al.'s work (2017) is related in the sense that for each q-term, document-aware encodings are built over the best matching (Euclidean distance) d-term. But again, term encodings are context-insensitive pre-trained word embeddings and the model is not trained end-to-end.

3.5 Multiple Views of Terms (+MV)

An extension to ABEL-DRMM and POSIT-DRMM (or any deep model) is to use multiple views of terms. The basic POSIT-DRMM produces a two-dimensional document-aware encoding of each q-term (Fig. 4, context-sensitive box) viewing the terms as their context-sensitive encodings (Eq. 1). Another two-dimensional document-aware q-term encoding can be produced by viewing the terms directly as their pre-trained embeddings without converting them to context-sensitive encodings (Fig. 4, context-insensitive box). A third view uses one-hot vector representations of terms, which allows exact term matches to be modeled, as opposed to near matches in embedding space. Concatenating the outputs of the 3 views, we obtain 6-dimensional document-aware q-term encodings, leading to a model dubbed POSIT-DRMM+MV. An example of this multi-view document-aware query term representation is given in Fig. 5 for a query-document pair from BIOASQ's development data.

The multi-view extension of ABEL-DRMM (ABEL-DRMM+MV) is very similar, i.e., it uses context-sensitive term encodings, pre-trained term embeddings, and one-hot term encodings in its three views. The resulting three document-aware q-term embeddings can be summed or concatenated, though we found the former more effective.

3.6 Alternative Network Structures

The new models (§§3.1–3.5) were selected by experimenting on development data. Many other extensions were considered, but not ultimately used as they were not beneficial empirically, including deeper and wider RNNs or CNN encoders (Bai et al., 2018); combining document-aware encodings from all models; different attention mechanisms, e.g., multi-head (Vaswani et al., 2017).

Pointer Networks (Vinyals et al., 2015) use the attention scores directly to select an input component. POSIT-DRMM does this via max and average pooling, not argmax. We implemented Pointer Networks – argmax over ABEL-DRMM attention to select the best d-term encoding – but empirically this was similar to ABEL-DRMM. Other architectures considered in the literature include the K-NRM model of Xiong et al. (2017). This is similar to both ABEL-DRMM and POSIT-DRMM in that it can be viewed as an end-to-end version of DRMM. However, it uses kernels over the query-document interaction matrix to produce features per q-term.

The work of Pang et al. (2017) is highly related and investigates many different structures, specifically aimed at incorporating context-sensitivity. However, unlike our work, Pang et al. first extract contexts (n-grams) of documents that match q-terms. Multiple interaction matrices are then constructed for the entire query relative to each of these contexts. These document contexts may match one or more q-terms allowing the model to incorporate term proximity. These interaction matrices can also be constructed using exact string match similar to POSIT-DRMM+MV.

4 Experiments

We experiment with ad-hoc retrieval datasets with hundreds of thousands or millions of documents. As deep learning models are computationally expensive, we first run a traditional IR system[6] using the BM25 score (Robertson and Zaragoza, 2009) and then re-rank the top N returned documents.

4.1 Methods Compared

All systems use an extension proposed by Severyn and Moschitti (2015), where the relevance score is combined via a linear model with a set of *extra features*. We use four extra features: z-score normalized BM25 score; percentage of q-terms with exact match in the document (regular and IDF weighted); and percentage of q-term bigrams matched in the document. The latter three features were taken from Mohan et al. (2017).

In addition to the models of §§2.1, 2.2, 3.1–3.5, we used the following baselines: Standard Okapi

---

[6] We used Galago (`http://www.lemurproject.org/galago.php`, v.3.10). We removed stop words and applied Krovetz's stemmer (Krovetz, 1993).

BM25 (**BM25**); and BM25 re-ranked with a linear model over the four extra features (**BM25+extra**). These IR baselines are very strong and most recently proposed deep learning models do *not* beat them.[7] DRMM and PACRR are also strong baselines and have shown superior performance over other deep learning models on a variety of data (Guo et al., 2016; Hui et al., 2017).[8]

All hyperparameters were tuned on development data and are available in Appendix A. All models were trained using Adam (Kingma and Ba, 2014) with batches containing a randomly sampled negative example per positive example[9] and a pair-wise loss. As the datasets contain only documents marked as relevant, negative examples were sampled from the top N documents (returned by BM25) that had not been marked as relevant.

We evaluated the models using the TREC ad-hoc retrieval evaluation script[10] focusing on MAP, Precision@20 and nDCG@20 (Manning et al., 2008). We trained each model five times with different random seeds and report the mean and standard deviation for each metric on test data; in each run, the model selected had the highest MAP on the development data. We also report results for an **oracle**, which re-ranks the N documents returned by BM25 placing all human-annotated relevant documents at the top. To test for statistical significance between two systems, we employed two-tailed stratified shuffling (Smucker et al., 2007; Dror et al., 2018) using the model with the highest development MAP over the five runs per method.

4.2 BioASQ Experiments

Our first experiment used the dataset of the document ranking task of BIOASQ (Tsatsaronis et al., 2015), years 1–5.[11] It contains 2,251 English biomedical questions, each formulated by a biomedical expert, who searched (via PubMed[12]) for, and annotated relevant documents. Not all relevant documents were necessarily annotated, but the data includes additional expert relevance judgments made during the official evaluation.[13]

The document collection consists of approx. 28M 'articles' (titles and abstracts only) from the 'MEDLINE/PubMed Baseline 2018' collection.[14] We discarded the approx. 10M articles that contained only titles, since very few of these were annotated as relevant. For the remaining 18M articles, a document was the concatenation of each title and abstract. Consult Appendix B for further statistics of the dataset. Word embeddings were pre-trained by applying word2vec (Mikolov et al., 2013) (see Appendix A for hyper-parameters) to the 28M 'articles' of the MEDLINE/PubMed collection. IDF values were computed over the 18M articles that contained both titles and abstracts.

The 1,751 queries of years 1–4 were used for training, the first 100 queries of year 5 (batch 1) for development, and the remaining 400 queries of year 5 (batches 2–5) as test set. We set $N = 100$, since even using only the top 100 documents of BM25, the oracle scores are high. PubMed articles published after 2015 for the training set, and after 2016 for the development and test sets, were removed from the top N (and replaced by lower ranked documents up to N), as these were not available at the time of the human annotation.

Table 1 reports results on the BIOASQ test set, averaged over five runs as well as the single best run (by development MAP) with statistical significance. The enhanced models of this paper perform better than BM25 (even with extra features), PACRR, and DRMM. There is hardly any difference between PACRR and DRMM, but our combination of the two (PACRR-DRMM) surpasses them both on average, though the difference is statistically significant ($p < 0.05$) only when comparing to PACRR. Models that use context-sensitive term encodings (ABEL-DRMM, POSIT-DRMM) outperform other models, even PACRR-style models that incorporate context at later stages in the network. This is true both on average and by statistical significance over the best run. The best model on average is POSIT-DRMM+MV, though it is not significantly different than POSIT-DRMM.

4.3 TREC Robust 2004 Experiments

Our primary experiments were on the BIOASQ dataset as it has one of the largest sets of queries

---

[7] See, for example, Table 2 of Guo et al. (2016).

[8] For PACRR/PACRR-DRMM, we used/modified the code released by Hui et al. (2017, 2018). We use our own implementation of DRMM, which performs roughly the same as Guo et al. (2016), though the results are not directly comparable due to different random partitions of the data.

[9] We limit positive examples to be in the top N documents.

Table 2: Performance on TREC ROBUST test data. Statistically significant ($p < 0.05$) difference from BM25^1; BM25+extra^2; PACRR^3; DRMM^4; PACRR-DRMM^5; ABEL-DRMM^6; ABEL-DRMM+MV^7.

(with manually constructed relevance judgments) and document collections, making it a particularly realistic dataset. However, in order to ground our models in past work we also ran experiments on TREC ROBUST 2004 (Voorhees, 2005), which is a common benchmark. It contains 250 queries[15] and 528K documents. As this dataset is quite small, we used a 5-fold cross-validation. In each fold, approx. $\frac{3}{5}$ of the queries were used for training, $\frac{1}{5}$ for development, and $\frac{1}{5}$ for testing. We applied word2vec to the 528K documents to obtain pre-trained embeddings. IDF values were computed over the same corpus. Here we used $N = 1000$, as the oracle scores for $N = 100$ were low.

Table 2 shows the TREC ROBUST results, which largely mirror those of BIOASQ. POSIT-DRMM+MV is still the best model, though again not significantly different than POSIT-DRMM. Furthermore, ABEL-DRMM and POSIT-DRMM are clearly better than the deep learning baselines,[16] but unlike BIOASQ, there is no statistically significant difference between PACRR-DRMM and the two deep learning baselines. Even though the scores are quite close (particularly MAP) both ABEL-DRMM and POSIT-DRMM are statistically different from PACRR-DRMM, which was not the case for BIOASQ. ABEL-DRMM+MV is significantly different than ABEL-DRMM on the best run for MAP and nDCG@20, unlike BIOASQ where there was no statistically significant difference between the two methods. However, on average over 5 runs, the systems show little difference.

5 Discussion

An interesting question is how well the deep models do without the extra features. For BIOASQ, the best model's (POSIT-DRMM+MV) MAP score drops from 48.1 to 46.2 on the development set, which is higher than the BM25 baseline (43.7), but on-par with BM25+EXTRA (46.0). We should

---

[15] We used the 'title' fields of the queries.

[16] The results we report for our implementation of DRMM are slightly different than those of Guo et al. (2016). There are a number of reasons for why this might be the case: there is no standard split of the data; non-standard preprocessing of the documents; the original DRMM paper reranks the top documents returned by Query Likelihood and not BM25.

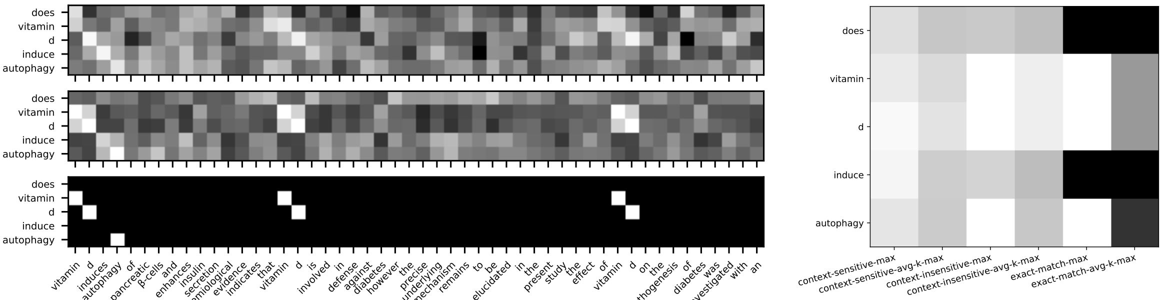

Figure 5: Left: Cosine similarities (POSIT-DRMM attention) of query and document terms, with context-sensitive, context-insensitive, and exact match views of the terms (top to bottom). Document truncated to 50 words. White is stronger. Right: Corresponding POSIT-DRMM+MV 6-dimensional document-aware query term encodings.

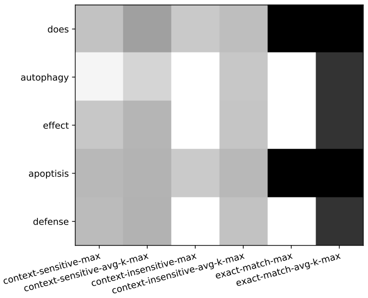

Figure 6: POSIT-DRMM+MV 6-dimensional document-aware q-term encodings for 'Does autophagy induce apoptosis defense?' and the same document as Fig. 5.

note, however, that on this set, the DRMM baseline without the extra features (which include BM25) is actually lower than BM25 (MAP 42.5), though it is obviously adding a useful signal, since DRMM with the extra features performs better (46.5).

We also tested the contribution of context-sensitive term encodings (Eq. 1). Without them, i.e., using directly the pre-trained embeddings, MAP on BIOASQ development data dropped from 47.6 to 46.3, and from 48.1 to 47.0 for ABEL-DRMM and POSIT-DRMM, respectively.

Fig. 5 shows the cosine similarities (attention scores, Eq. 5) between q-terms and d-terms, using term encodings of the three views (Fig. 4), for a query "Does Vitamin D induce autophagy?" and a relevant document from the BIOASQ development data. POSIT-DRMM indeed marks this as relevant. In the similarities of the context-insensitive view (middle left box) we see multiple matches around 'vitamin d' and 'induce autophagy'. The former is an exact match (white squares in lower left box) and the latter a soft match. The context-sensitive view (upper left box) smooths things out and one can see a straight diagonal white line matching 'vitamin d induce autophagy'. The right box of Fig. 5 shows the 6 components (Fig. 4) of the document-aware q-term encodings. Although some terms are not matched exactly, the context sensitive max and average pooled components (two left-most columns) are high for all q-terms. Interestingly, 'induce' and 'induces' are not an exact match (leading to black cells for 'induce' in the two right-most columns) and the corresponding context-insensitive component of (third cell from left) is low. However, the two components of the context-sensitive view (two left-most cells of 'induce') are high, esp. the max-pooling component (left-most).Finally, 'vitamin d' has multiple matches leading to a high average k-max pooled value, which indicates that the importance of that phrase in the document.

Fig. 6 shows the 6 components of the document-aware q-term encodings for another query and the same document, which is now irrelevant. In the max pooling columns of the exact match and context-insensitive view (columns 3, 5), the values look quite similar to those of Fig. 5. However, POSIT-DRMM scores this query-document pair low for two reasons. First, in the average-k-max pooling columns (columns 2, 4, 6) we get lower values than Fig. 5, indicating that there is less support for this pair in terms of density. Second, the context sensitive values (columns 1, 2) are much worse, indicating that even though many exact matches exist, in context, the meaning is not the same.

We conclude by noting there is still quite a large gap between the current best models and the oracle re-ranking scores. Thus, there is head room for improvements through more data or better models.

Acknowledgements

We thank the reviewers for their constructive feedback that greatly improved this work. Oscar Täckström gave thorough input on an early draft of this work. Finally, AUEB's NLP group provided many suggestions over the course of the work.

Learning Neural Representation for CLIR with Adversarial Framework

Bo Li, Ping Cheng

Abstract

The existing studies in cross-language information retrieval (CLIR) mostly rely on general text representation models (e.g., vector space model or latent semantic analysis). These models are not optimized for the target retrieval task. In this paper, we follow the success of neural representation in natural language processing (NLP) and develop a novel text representation model based on adversarial learning, which seeks a task-specific embedding space for CLIR. Adversarial learning is implemented as an interplay between the generator process and the discriminator process. In order to adapt adversarial learning to CLIR, we design three constraints to direct representation learning, which are (1) a matching constraint capturing essential characteristics of cross-language ranking, (2) a translation constraint bridging language gaps, and (3) an adversarial constraint forcing both language and source invariant to be reached more efficiently and effectively. Through the joint exploitation of these constraints in an adversarial manner, the underlying cross-language semantics relevant to retrieval tasks are better preserved in the embedding space. Standard CLIR experiments show that our model significantly outperforms state-of-the-art continuous space models and approaches the strong machine translation and monolingual baselines.

1 Introduction

Text representation is a crucial problem in most natural language processing (NLP) and information retrieval (IR) tasks. In monolingual IR, early research works mostly use vector space models for query-document semantic matching (Salton et al., 1975), which suffer from the problem of *synonymy* and *polysemy*. In order to bridge the lexical gaps, latent semantic models such as latent semantic analysis (LSA) (Deerwester et al., 1990) have been proposed to abstract away from surface text forms to approximate semantics. More recently, text representation learned with neural networks is attracting increasing attention of the IR community (Mitra and Craswell, 2017) and positive results have been reported on various evaluation data sets (Fan et al., 2018).

Compared to the prosperity in monolingual IR, there have been less advancements in CLIR where documents are written in a language different from that of queries. In addition to document ranking, CLIR models need to cross the language barriers, which makes the task intuitively more difficult than monolingual IR. Traditional approaches reduce CLIR to its monolingual counterpart via performing some way of translation on queries or/and documents. The typical translation process is performed with either off-the-shelf machine translation (MT) systems or multilingual dictionaries (Nie, 2010). However, MT based approaches are far from being a suitable solution for solving CLIR problems (refer to detailed analysis in (Zhou et al., 2012)). Dictionary-based approaches suffer from the same problem of lexical gaps as in the monolingual case (Gupta et al., 2017). An efficient cross-language representation is in need for CLIR, which is expected to be able to cross both the language and lexical gaps.

The most intuitive idea one can have so as to represent text in cross-language settings is to extend those models in monolingual environment. For instance, we note studies such as the extension of LSA in (Littman et al., 1998), the extension of principle component analysis (PCA) in (Platt et al., 2010), the extension of autoencoder model in (Chandar et al., 2014), and the extension of word2vec (Mikolov et al., 2013) in (Vulić and Moens, 2015). These approaches construct cross-language and semantic-rich representation of text, which can be applied to CLIR directly. However, all the models listed here aim to learn general text

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1861–1870
Brussels, Belgium, October 31 - November 4, 2018.

representation where the objective is to capture term proximity rather than relevance that is essential for retrieval task (Zamani and Croft, 2017). A recent work (Gupta et al., 2017) tries to learn task-specific representation for CLIR. However, their model only captures ranking signals in monolingual settings, which does not necessarily generalize well in CLIR.

In this paper, we propose to learn task-specific text representation for CLIR via a novel adversarial learning framework. Following the convention in generative adversarial networks (GAN) (Goodfellow et al., 2014), our representation learning model is realized as an interplay between two processes, an embedding generator (G) and an adversarial discriminator (D), conducted as a min-max game. With the GAN framework, we design three constraints to direct the representation learning process. CLIR is essentially a ranking problem and we develop a matching constraint to make sure that documents can be ranked in the right order given a query in another language. The matching constraint considers both cross-language and monolingual pairwise ranking signals, which is superior to previous studies (e.g., (Gupta et al., 2017)) only considering monolingual matching signals. Meanwhile, a translation constraint is imposed on the latent representation to bridge the language gaps. These two constraints direct the encoding networks to generate a language-invariant and task-specific representation in the embedding space. Lastly, an adversarial constraint is proposed to force both language and source invariant to be reached more efficiently and effectively. Through the joint exploitation of these constraints in an adversarial manner, the embedding space being optimal for CLIR will then result through the convergence of this process. Comprehensive CLIR experiments reveal that our model is superior to state-of-the-art continuous space models and approaches the machine translation and monolingual baselines.

2 Related work

Text representation has been a long-standing research question in IR. Classic methods such as vector space model are not able to deal with lexical gaps between queries and documents, resulting in inferior retrieval performance. Latent semantic approaches such as LSA (Deerwester et al., 1990) and latent dirichlet allocation (LDA) (Blei et al., 2003) abstract away from surface text forms to alleviate sparsity and approximate semantics. More recently, learning based approaches with neural networks have gained great success in NLP (Baroni et al., 2014) and started to attract increasing interests of the IR community. In terms of word level embedding, word2vec (Mikolov et al., 2013) and Glove (Pennington et al., 2014) are two models that have been cited frequently in recent literature. These two models provide semantic-rich representations to bridge lexical gaps between queries and documents, which have been used broadly in neural IR studies (Ganguly et al., 2015; Zheng and Callan, 2015; Zamani and Croft, 2016).

The above studies deal with monolingual text representation, which are related to the cross-language models presented below. As for CLIR, typical approaches reduce CLIR to its monolingual counterparts via performing some way of translation. Machine translation systems such as Google translator[1] have been widely used to translate queries or documents, which serve as a default and convenient translation option in CLIR. It is however far from being a suitable solution for solving CLIR problems (a detailed analysis can be found in (Zhou et al., 2012)). An alternative solution is to rely on multilingual dictionaries to perform lexicon-level translation, which is mostly in combination with either language modeling strategy (Kraaij et al., 2003) or query structuring framework (Pirkola, 1998). However, dictionary-based methods still suffer from the lexical gap problem which reduces their performance in CLIR.

In fact, researchers have extended the models in monolingual settings and developed continuous space models for cross-language tasks to capture rich semantics. These cross-language extensions can be applied to CLIR directly. For instance, Littman et al. (1998) extend LSA to its cross-language version CL-LSA by concatenating document-term matrix of parallel data which acts as dual-language documents to be learned by LSA. Such a methodology leads to a dual-language semantic space in which terms from both languages are represented. Vinokourov et al. (2002) use parallel data to find most likely correlations between projected vectors based on canonical component analysis technique. The OPCA model (Platt et al., 2010) starts with the basic model

---

[1] https://translate.google.com

PCA that is then made discriminative by encouraging comparable document pairs to have similar vector representation. Compared to CL-LSA, OPCA avoids the use of artificial concatenated documents. More recently, neural models have been employed to learn cross-language representations. For instance, autoencoder is extended to a bilingual version BAE in (Chandar et al., 2014) which learns vectorial word representations from aligned sentences. Yih et al. (2011) develop S2Net to learn a projection matrix to map the corresponding term vectors into a latent space where similar documents are close. S2Net is implemented with Siamese neural network framework. Vulić and Moens (2015) first merge two documents from the aligned document pair in a comparable corpus and then train word2vec on the pseudo-bilingual document to obtain cross-language embeddings. The above approaches learn general text representation that captures term proximity rather than relevance which is important for retrieval task (Zamani and Croft, 2017). A recent work (Gupta et al., 2017) tries to learn task-specific embeddings for CLIR. However, it learns ranking signals by preserving pairwise ranking in monolingual settings prior to a transfer learning process to another language, which does not necessarily generalize well in CLIR.

One can find from above analysis that, most existing approaches, either based on neural networks or not, learn general embeddings irrelevant to CLIR. We argue that task-specific embeddings are superior, a fact that is inspired by monolingual IR studies and that will actually be validated by CLIR experiments in this paper. To this end, we will learn cross-language and task-specific embeddings for CLIR via a novel text representation model based on adversarial learning (Goodfellow et al., 2014).

3 Representation learning framework

We will present in this section a neural representation learning framework for CLIR. As discussed before, the framework is realized based on adversarial learning as an interplay between the generator process and the discriminator process. We will develop three constraints, namely a matching constraint, a translation constraint and an adversarial constraint, to direct the learning of cross-language and target-specific text embeddings. For ease of presentation, let us assume in CLIR we have a source language query q_s and a target language document d_t. The translation of q_s in the target language is q_t. The learning framework is illustrated in figure 1, which consists of an adversarial network NN_{adv}, three dimension adaptation networks NN_{dim} and three encoding networks respectively for q_t, d_t and q_s.

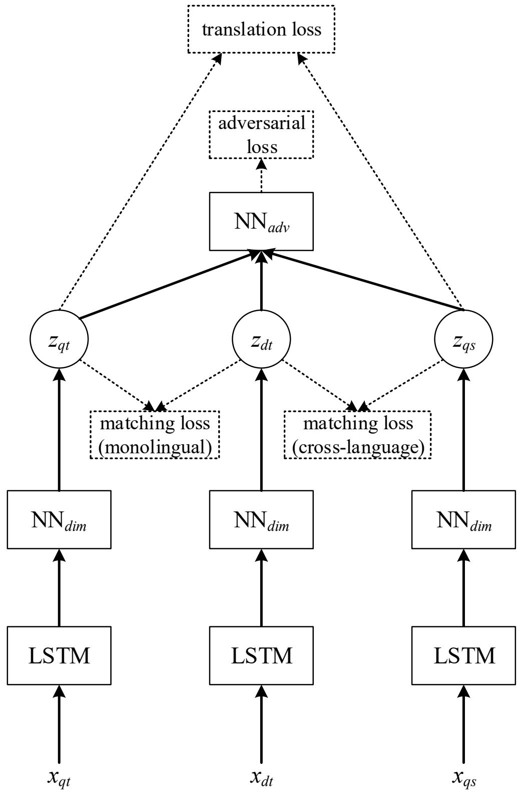

Figure 1: Text representation learning model for CLIR with adversarial framework.

3.1 Text representation networks

There have been various approaches one can use to encode sentences/documents into dense vectors. For instance, models based on convolutional neural networks (Kalchbrenner et al., 2014) and models based on recurrent neural networks (Liu et al., 2016) have been popular choices.

In order to map queries and documents into the embedding space, we make use of recurrent neural network with the long short-term memory (LSTM) architecture that can deal with vanishing and exploring gradient problems (Hochreiter and Schmidhuber, 1997). We present here derivation details of LSTM for clarification sake. The LSTM framework consists of several gates to control the cell state in the network. Firstly, a forget gate f (a sigmoid layer) functions according to:

$$f^\tau = \sigma(W_f \cdot [h^{\tau-1}, x^\tau] + b_f)$$

Then, an input gate i (a sigmoid layer) and a tanh layer work together as follows:

$$i^\tau = \sigma(W_i \cdot [h^{\tau-1}, x^\tau] + b_i)$$
$$\widetilde{C}^\tau = tanh(W_c \cdot [h^{\tau-1}, x^\tau] + b_c)$$

With the forget gate f, the input gate i and the new value $\widetilde{C}$, one can update the cell state C as:

$$C^\tau = f^\tau * C^{\tau-1} + i^\tau * \widetilde{C}^\tau$$

Lastly, an output gate o (a sigmoid layer) outputs:

$$o^\tau = \sigma(W_o \cdot [h^{\tau-1}, x^\tau] + b_o)$$
$$h^\tau = o^\tau * tanh(C^\tau)$$

In above equations, x^τ is the input at time step τ. h^τ and $h^{\tau-1}$ denote the hidden states at time steps τ and $\tau - 1$. All W and b are parameters. For brevity, we can write the update process as:

$$h^\tau = LSTM(h^{\tau-1}, x^\tau)$$

Given a text sequence $x = (x^1, x^2, \ldots, x^l)$, typical methods take the output h^l of LSTM at the last time step l as the concentrated representation of the whole sequence x (Sutskever et al., 2014). Since queries in IR tasks tend to be short and noisy, we make use of Bidirectional LSTM with pooling (Tan et al., 2015) to obtain a more effective text representation from all the hidden states $h^{1:l}$. The sequence x is fed from left to right into $LSTM_a$ and from right to left into $LSTM_b$. The new hidden state h^τ_{ab} at time step τ is obtained by concatenating the hidden states of $LSTM_a$ and $LSTM_b$ at their respective time step τ. Since max-pooling has been proven to be efficient in similar tasks (Tan et al., 2015), the latent representation z_x of x can be formulated as:

$$z_x = NN_{dim}(MaxPooling(h^{1:l}_{ab}))$$

where x can be q_s, q_t or d_t. NN_{dim} is designed to adapt the output dimension and to allow further flexibility for representation learning.

3.2 Matching constraint and Translation constraint

Document ranking is the central problem in both monolingual IR and CLIR tasks. CLIR differs itself from its monolingual counterpart in that the language gap needs to be crossed prior to the retrieval process. Since the choice of translation strategies (query, document or both) affects the design of other components in our model, we will discuss the translation constraint in section 3.2.1 prior to matching constraints in sections 3.2.2 and 3.2.3.

3.2.1 Translation constraint

The translation constraint is developed to minimize the differences between a pair of parallel texts, which serves as a basic requirement in the translation scenario. Such a constraint directs the learning of language-invariant text representation for CLIR. We follow the arguments in previous studies (Vilares et al., 2016) and choose to translate queries in our model, since it is computationally expensive to translate large-scale document collections in practice. In this paper, we directly employ Google translator to translate queries, which is a popular choice for machine translation that leads to state-of-the-art translation performance. The translation constraint is then imposed on the embedding vectors z_{q_s} and z_{q_t} of the queries q_s and q_t. The translation loss L_{tra} on a set QP of query pairs can be defined with the squared L2 norm, which is:

$$L_{tra} = \sum_{(q_s, q_t) \in QP} \|z_{q_s} - z_{q_t}\|_2^2$$

3.2.2 Cross-language matching constraint

The matching constraint captures essential characteristics of cross-language ranking. Following the practice in learning to rank (Liu, 2009), we model document ranking in the *pairwise* style where the relevance information is in the form of preferences between pairs of documents with respect to individual queries. In the model for CLIR, since we have matching signals from both monolingual text pairs and cross-language text pairs, the model can benefit from complementary knowledge from two resources. The monolingual pairwise matching constraint will be introduced in section 3.2.3.

Similar to neural models in monolingual settings (Huang et al., 2013), the cross-language pairwise matching constraint is placed on top of the embedding vectors of source language query and target language documents. In figure 1, let us assume x_{q_s} has a relevant document $x_{d_{t+}}$ and an irrelevant document $x_{d_{t-}}$ according to annotated text pairs. In training, the positive sample $x_{d_{t+}}$

for x_{q_s} can be chosen as the most relevant texts according to annotation, and the negative sample $x_{d_{t-}}$ is picked randomly from the data collection. The cross-language matching constraint encourages the hidden representation of $x_{d_{t+}}$ to be near to the hidden representation of x_{q_s} in the semantic-rich embedding space. Meanwhile, it asks the hidden representation of $x_{d_{t-}}$ to be far from that of x_{q_s}. We follow typical neural IR models and make use of cosine as the distance measure of hidden vectors. The probability that d_{t+} is ranked higher than d_{t-} given q_s can be derived as:

$$\hat{P}(q_s) = \sigma[\beta_c \cdot (\cos(z_{q_s}, z_{d_{t+}}) - \cos(z_{q_s}, z_{d_{t-}}))]$$

where σ is the sigmoid function with a hyper-parameter β_c controlling its shape. The cross-language matching loss L_{matc} on cross-language triplet set QD_c can be defined with cross-entropy loss as:

$$L_{matc} = \sum_{(q_s, d_{t+}, d_{t-}) \in QD_c} CE[P(q_s), \hat{P}(q_s)]$$

where CE denotes the cross-entropy operator between two distributions and $P(q_s)$ is the actual counterpart of $\hat{P}(q_s)$ estimated from annotation with a strategy similar to that in (Dehghani et al., 2017).

3.2.3 Monolingual matching constraint

The monolingual matching constraint L_{matm} can be built in a way similar to that of L_{matc}. L_{matm} is imposed on a set QD_m of monolingual triplet (q_t, d_{t+}, d_{t-}) as:

$$L_{matm} = \sum_{(q_t, d_{t+}, d_{t-}) \in QD_m} CE[P(q_t), \tilde{P}(q_t)]$$

where $P(q_t)$ is the actual counterpart of $\tilde{P}(q_t)$ estimated from annotation. $\tilde{P}(q_t)$ denotes the probability that d_{t+} is ranked higher than d_{t-} given q_t. It can be computed with the sigmoid function as:

$$\tilde{P}(q_t) = \sigma[\beta_m \cdot (\cos(z_{q_t}, z_{d_{t+}}) - \cos(z_{q_t}, z_{d_{t-}}))]$$

where β_m is a hyper-parameter.

3.2.4 Embedding generator constraint

Since our model is implemented with adversarial framework, we propose to model the representation generator G, which embodies the process of language-invariant and task-specific embedding of queries and documents into a latent subspace, under a combination of three constraints introduced above. The translation constraint aims to guarantee language invariant when translating queries. The cross-language matching constraint explicitly captures cross-language ranking signals from cross-language text pairs. The monolingual matching constraint takes monolingual ranking into account so as to complement the cross-language ranking signals.

Combing the three constraints above, we obtain a comprehensive constraint that should be obeyed by the embedding generator process. With the regularization term L_{reg} equaling to the sum of Frobenius norms of all weight matrices in the text embedding phase, we can write the embedding generator constraint L_G as:

$$L_G(\theta_G) = \gamma_1 \cdot L_{tra} + \gamma_2 \cdot L_{matc} + \gamma_3 \cdot L_{matm} + L_{reg}$$

where θ_G denotes the set of parameters in the generator networks, and γ_1, γ_2, γ_3 are hyper-parameters.

3.3 Adversarial constraint

We will introduce the adversarial constraint in this part. GAN (Goodfellow et al., 2014) simultaneously trains a generative model G and a disriminative model D in a competing way. G generates samples from a source of noise w that satisfies $w \sim P_n(w)$ and tries to capture the real data distribution P_r. D learns to distinguish between the generated samples from G and the true data sampled from P_r (in practice, from training data). The training procedure for G is to try its best to fool D. Let us assume that G generates samples satisfying the distribution P_g that is implicitly decided by $G(w)$. The GAN value function $V(G, D)$ on which D and G play the minmax game can be written as:

$$\begin{aligned} \min_G \max_D V(D, G) = & E_{x \sim P_r}[\log D(x)] \\ & + E_{x \sim P_g}[\log(1 - D(x))] \end{aligned} \quad (1)$$

Theoretical analysis has indicated that playing the minmax game as above amounts to minimizing the Jensen-Shannon divergence between P_g and P_r.

We follow the general idea of GAN and develop an adversarial component on top of the embedding space in figure 1. We note that GAN has been used in representation learning in a similar way as in (Bousmalis et al., 2016; Liu et al., 2017). In our model in figure 1, the adversarial component NN_{adv} acts as the discriminator D which tries its best to detect whether the embedding vector z is encoded from x_{q_t}, x_{d_t} or x_{q_s}. In this paper, NN_{adv} is implemented as a neural network with a softmax output layer. The output of NN_{adv} then corresponds to a probability distribution vector over the input sources. Let us denote the ground truth label of the current input z to NN_{adv} as l_z which indicates the source that z is encoded from. We can adjust equation 1 to our settings and obtain the adversarial loss L_{adv} on a query set Q_t and a document set D_t in the target language, as well as a query set Q_s in the source language, which can be written as:

$$L_{adv} = \min_{G} \max_{D} \sum_{x \in Q_t, D_t, Q_s} \log NN_{adv}(z_x) \circ l_{z_x}$$

where $\circ$ is the inner product operator.

3.4 Training procedure

Following the training convention of GAN (Goodfellow et al., 2014), the process of learning the language-invariant and task-specific text representation for CLIR should be conducted by jointly minimizing the generator constraint L_G and the adversarial loss L_{adv}, which leads us to the combined objective function L as:

$$L = L_G + L_{adv}$$

According to the rule of playing the minmax game in GAN, G tries its best to maximize the probability that D makes a mistake and D tries its best to distinguish between real data and generated data (in our case, various input sources). The theoretical requirement behind GAN that D is maintained near its optimal solution as long as G changes slowly enough motivates us to update the discriminator part k steps per update of the generator part in the iterative optimization process. Based on these discussions, the minmax optimization process can be derived as:

1. Optimize D when fixing G through: $\hat{\theta}_D = \arg\max_{\theta_D} L(\hat{\theta}_G, \theta_D)$
2. Optimize G when fixing D through: $\hat{\theta}_G = \arg\min_{\theta_G} L(\theta_G, \hat{\theta}_D)$

The optimization can be implemented with mini-batch gradient ascent (for θ_D) and descent (for θ_G).

4 Experiments and results

In this section, we conduct CLIR experiments so as to compare our text representation model with several other models.

4.1 Data sets

4.1.1 CLIR evaluation sets

To perform CLIR experiments, we rely on broadly used data sets released in the bilingual tasks of the cross-language evaluation forum (CLEF) [2]. We choose to use the data from the year 2000 to 2004. Table 1 lists the characteristics of the data set, which include number of documents (N_d), number of distinct words (N_w), the average document length (DL_{avg}) and the number of queries (N_q) in each task. We use source language queries in French (Fr), German (De) and Italian (It) to retrieve target language documents in English (En). Queries from year 2000 to 2002 are combined to a single task in table 1 since they have the same target set.

Table 1: CLIR dataset statistics (k = thousand).

Dataset	N_d	N_w	DL_{avg}	N_q
CLEF00-02	113k	173k	311	140
CLEF03	169k	233k	284	60
CLEF04	56k	120k	231	50

4.1.2 Training set

In order to train the representation learning model, we need to construct a data set consisting of annotated text pairs. We combine AOL queries (Pass et al., 2006) and a set of news titles downloaded from the news sites[3] to constitute training query set of diversity. Following the previous work (Gupta et al., 2017), we sample a balanced subset (1M) from such query set and use these queries to retrieve the data collection with BM25. For each training query, we take the top retrieved texts as positive samples, and the negative samples are selected randomly from the data collection. In addition to the pseudo-labeled text pairs of low quality, we combine the LETOR4.0 dataset (Qin and Liu, 2013) that is developed for evaluating learning to rank models. The LETOR4.0 dataset consists of relevance judgments of higher quality compared to

---

[2] http://www.clef-initiative.eu

[3] We fetch 2.8M web pages from several news websites such as ChinaDaily (www.chinadaily.com.cn) and XinhuaNews (www.xinhuanet.com).

pseudo-labeled data. The two data resources can complement each other in the training process.

In our experiments, the pseudo-labeled data is used to train the whole model and the LETOR dataset is employed to fine tune the parameters relevant to the source queries and target documents which are more important for the cross-language retrieval task.

4.2 Experimental settings

4.2.1 Experimental setup

The terms are initialized as the 512d word2vec vectors trained on Wikipedia dump corpus[4]. The term embeddings are fed into the LSTM model of which the hidden unit number is chosen from $\{64, 128, 256, 512\}$. The adversarial network NN_{adv} is as a three-layer feed-forward network with softmax on top of the last layer. NN_{dim} is implemented as a feed-forward network with layer dimension chosen from $\{32, 64, 128, 256\}$ and hidden layer number chosen from $\{1, 2\}$. The values of hyper-parameters γ_1, γ_2 and γ_3 are chosen from $\{0.01, 0.1, 1, 10, 100\}$. The learning rate is selected from $\{10^{-1}, 10^{-2}, 10^{-3}, 10^{-4}, 10^{-5}\}$. Those hyper-parameters are tuned on the validation set which is 20% of the training queries randomly selected.

For evaluation, we present results in terms of mean average precision (MAP). Statistically significant differences between various models are determined using the paired t-test with $p < 0.05$.

4.2.2 Baseline approaches

We make use of three categories of baselines for CLIR experiments.

1. Monolingual run (MON): a baseline with target language queries that are strictly parallel to source language queries.

2. Machine translation (MT): a baseline with target-language queries translated by machine translation system from source-language queries.

3. Cross-language text representation models: baselines that rely on continuous space models for cross-language text representation. We make use here of S2Net (Yih et al., 2011), BAE (Chandar et al., 2014), and XCNN (Gupta et al., 2017) for the CLIR task.

4.3 Results and analysis

4.3.1 Comparisons to state-of-the-art

Table 2 lists the experimental results on CLEF dataset for our model (the column OURS) and all baseline models. There are three data collections and three language pairs, amounting to nine cross-language retrieval tasks. Except the strong baselines MON and MT, our model shows the best overall performance among all CLIR strategies. Indeed, our model outperforms all continuous space baselines (i.e., S2Net, BAE and XCNN) with statistical significance in almost all cases. Our model decreases slightly from the strong MT baseline in most retrieval tasks with only one degradation being significant on 03(De-En). Furthermore, one can find that our model approaches the monolingual baseline very much in all retrieval tasks with all MAP ratios around or over 90%. In our experiments, we have not performed comparisons to CL-LSA (Littman et al., 1998) and its variant OPCA (Platt et al., 2010), because they have been consistently outperformed by other CLIR strategies with a large margin (Schauble and Sheridan, 1997; Nie, 2010; Vulić et al., 2011).

Among all continuous space baselines, the most recent model XCNN shows the best performance. XCNN always outperforms linear projection methods S2Net with significance. It also significantly outperforms the non-linear model BAE in all cases. This is coincident with previous conclusions in (Gupta et al., 2017) due to the fact that XCNN learns target-specific representation for CLIR but the other models do not. Our model also tries to learn task-specific representation for CLIR, which significantly outperforms XCNN in most cases according to the results in table 2. The reasons might be that (1) our method is modeled in a more effective adversarial learning framework. (2) we explicitly capture cross-language ranking signals in embedding generator in addition to monolingual ranking signals used in XCNN. (3) our model can jointly capture the translation knowledge and document ranking knowledge in a unified framework.

4.3.2 Variant of our model

Our model can be customized easily by altering the constraints to direct the representation learning process. Since the specificity of our model comes from the adversarial learning framework that has never been investigated in CLIR, we re-

move the constraint L_{adv} from the original model M and obtain the variant M_{adv}. In this case, M_{adv} can be optimized with standard mini-batch gradient descent approach, without playing the minmax game. We redo above CLIR experiments with the same settings as above and obtain the retrieval results of M_{adv} in table 3.

Table 3: Retrieval performance (MAP scores) of the variant M_{adv} on CLEF collections. $+$ or $-$ indicates that the improvements or degradations with respect to our original model M are statistically significant. The higher value in each row is marked in bold.

Data	Lang	M	M_{adv}
00-02	Fr-En	**0.424**	0.412^{-}
	De-En	**0.435**	0.418^{-}
	It-En	**0.426**	0.424
03	Fr-En	**0.456**	0.440^{-}
	De-En	**0.439**	0.435
	It-En	**0.467**	0.448^{-}
04	Fr-En	**0.470**	0.453^{-}
	De-En	**0.473**	0.465
	It-En	**0.481**	0.469

From the results one can find that when removing the adversarial component from the original model, M_{adv} decreases from the original model M in all retrieval tasks. The differences that are significant appear in 5 out of 9 retrieval tasks. The results demonstrate that learning generator and discriminator in a competing style within the adversarial learning framework leads to representation of higher quality, which eventually supports efficient CLIR. If we compare the variant M_{adv} with the XCNN model in table 2, we find that M_{adv} still performs better than XCNN in most cases. Such a comparison implicitly indicates that the joint exploitation of monolingual matching constraint, cross-language matching constraint and translation constraint in a single model is more efficient than using them separately as in the XCNN model.

5 Conclusions

In this paper, we propose a novel text representation approach for CLIR based on the adversarial learning framework. The learning framework is implemented as an interplay between an embedding generator process and an adversarial discriminator process, which leads to an optimal representation that is both language invariant and domain specific. The embedding generator is learned such that it explicitly considers both cross-language and monolingual pairwise ranking signals. In this way, it can ensure that the learned embeddings benefit from both sources and are directly optimized for CLIR. To the best of our knowledge, it is the first time adversarial learning has been applied to CLIR. Experiments on various language pairs in CLEF data collection show that our model is significantly better than other latent semantic models for CLIR. Indeed, our model approaches the performance of machine translation and monolingual baselines.

Abstract

Knowledge of the creation date of documents facilitates several tasks such as summarization, event extraction, temporally focused information extraction etc. Unfortunately, for most of the documents on the Web, the time-stamp metadata is either missing or can't be trusted. Thus, predicting creation time from document content itself is an important task. In this paper, we propose Attentive Deep Document Dater (AD3), an attention-based neural document dating system which utilizes both context and temporal information in documents in a flexible and principled manner. We perform extensive experimentation on multiple real-world datasets to demonstrate the effectiveness of AD3 over neural and non-neural baselines.

1 Introduction

Many natural language processing tasks require document creation time (DCT) information as a useful additional metadata. Tasks such as information retrieval (Li and Croft, 2003; Dakka et al., 2008), temporal scoping of events and facts (Allan et al., 1998; Talukdar et al., 2012b), document summarization (Wan, 2007) and analysis (de Jong et al., 2005a) require precise and validated creation time of the documents. Most of the documents obtained from the Web either contain DCT that cannot be trusted or contain no DCT information at all (Kanhabua and Nørvåg, 2008). Thus, predicting the time of these documents based on their content is an important task, often referred to as *Document Dating*.

A few generative approaches (de Jong et al., 2005b; Kanhabua and Nørvåg, 2008) as well as a discriminative model (Chambers, 2012) have been previously proposed for this task. Kotsakos et al. (2014) employs term-burstiness resulting in improved precision on this task.

Recently proposed NeuralDater (Vashishth et al., 2018) uses a graph convolution network (GCN) based approach for document dating, outperforming all previous models by a significant margin. NeuralDater extensively uses the syntactic and temporal graph structure present within the document itself. Motivated by NeuralDater, we explicitly develop two different methods: a) *Attentive Context Model*, and b) *Ordered Event Model*. The first component tries to accumulate knowledge across documents, whereas the latter uses the temporal structure of the document for predicting its DCT.

Motivated by the effectiveness of attention based models in different NLP tasks (Yang et al., 2016a; Bahdanau et al., 2014), we incorporate attention in our method in a principled fashion. We use attention not only to capture context but also for feature aggregation in the graph convolution network (Hamilton et al., 2017). Our contributions are as follows.

- We propose Attentive Deep Document Dater (AD3), the first attention-based neural model for time-stamping documents.
- We devise a novel method for label based attentive graph convolution over directed graphs and use it for the document dating task.
- Through extensive experiments on multiple real-world datasets, we demonstrate AD3's effectiveness over previously proposed methods.

AD3 source code and datasets used in the paper are available at https://github.com/malllabiisc/AD3

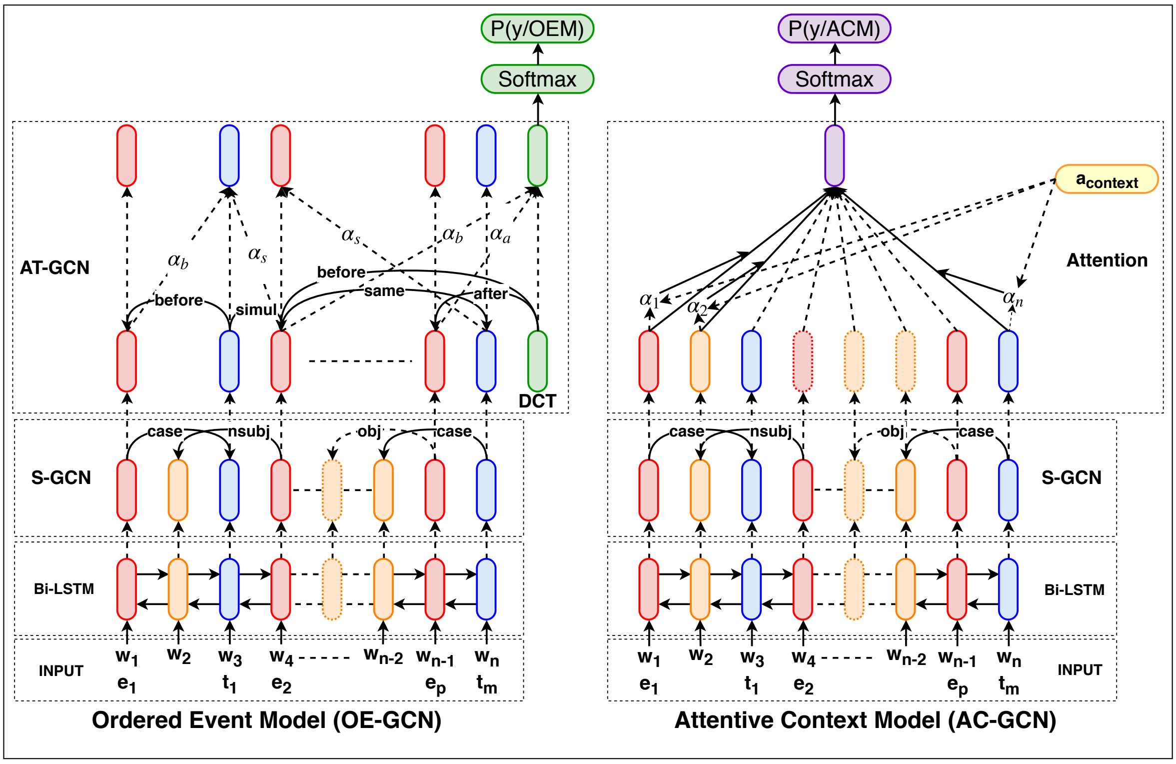

Figure 1: Two proposed models a) Ordered Event Model (left) and b) Attentive Context Model (right), where w_i are the words of a document (D), e_i are the words signifying events and t_i are the temporal tokens as detected in the document. Both models use Bi-LSTM and S-GCN (Syntactic-GCN, see Section 3.2.2) in the initial part of their pipeline. Ordered Event Model (OE-GCN) uses a label based attentive graph convolutional network for encoding the DCT, whereas Attentive Context Model (AC-GCN) uses a word attention based model to encode the document. $\alpha_i(\forall\, i \in [1, n])$ denotes attention over the words of document and α_a, α_b and α_s denote attention over nodes connected with edge labels *AFTER*, *BEFORE* and *SIMULTANEOUS*, respectively. OE-GCN provides the probability scores over the years given the encoded DCT, while AC-GCN provides the probability scores given the context of the document. Both the models are trained separately.

made for document time-stamping task include statistical language models proposed by de Jong et al. (2005b) and Kanhabua and Nørvåg (2008). (Chambers, 2012) use temporal and hand-crafted features extracted from documents to predict DCT. They propose two models, one of which learns the probabilistic constraints between year mentions and the actual creation time, whereas the other one is a discriminative model trained on hand-crafted features. Kotsakos et al. (2014) propose a term-burstiness (Lappas et al., 2009) based statistical method for the task. Vashishth et al. (2018) propose a deep learning based model which exploits the temporal and syntactic structure in documents using graph convolutional networks (GCN).

Event Ordering System: The task of extracting temporally rich events and time expressions and ordering between them is introduced in the TempEval challenge (UzZaman et al., 2013; Verhagen et al., 2010). Various approaches (McDowell et al., 2017; Mirza and Tonelli, 2016) made for solving the task use sieve-based architectures, where multiple classifiers are ranked according to their precision and their predictions are weighted accordingly resulting in a temporal graph structure. A method to extract temporal ordering among relational facts was proposed in (Talukdar et al., 2012a).

Graph Convolutional Network (GCN): GCN (Kipf and Welling, 2016) is the extension of convolutional networks over graphs. In different NLP tasks such as semantic-role labeling (Marcheggiani and Titov, 2017), neural machine translation (Bastings et al., 2017), and event detection (Nguyen and Grishman, 2018), GCNs have proved to be effective. We extensively use GCN for capturing both syntactic and temporal aspect of the document.

Attention Network: Attention networks have been well exploited for various tasks such as document classification (Yang et al., 2016b), question answering (Yang et al., 2016a), machine translation (Bahdanau et al., 2014; Vaswani et al., 2017). Recently, attention over graph structure has been shown to work well by Veličković et al. (2018). Taking motivation from them, we deploy an attentive convolutional network on temporal graph for the document dating problem.

3 Background: GCN & NeuralDater

The task of document dating can be modeled as a multi-class classification problem. Following prior work, we shall focus on DCT prediction at the year-granularity in this paper. In this section, we summarize the previous state-of-the-art model NeuralDater (Vashishth et al., 2018), before moving onto our method. An overview of graph convolutional network (GCN) (Kipf and Welling, 2016) is also necessary as it is used in NeuralDater as well as in our model.

3.1 Graph Convolutional Network

GCN for Undirected Graph: Consider an undirected graph, $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V}$ and $\mathcal{E}$ are the set of n vertices and set of edges respectively. Matrix $\mathcal{X} \in \mathbb{R}^{n \times m}$, whose rows are input representation of node u, where $x_u \in \mathbb{R}^m$, $\forall\ u \in \mathcal{V}$, is the input feature matrix. The output hidden representation $h_v \in \mathbb{R}^d$ of a node v after a single layer of graph convolution operation can be obtained by considering only the immediate neighbours of v, as formulated in (Kipf and Welling, 2016). In order to capture information at multi-hop distance, one can stack layers of GCN, one over another.

GCN for Directed Graph: Consider a labelled edge from node u to v with label $l(u, v)$, denoted collectively as $(u, v, l(u, v))$. Based on the assumption that information in a directed edge need not only propagate along its direction, Marcheggiani and Titov (2017) added opposite edges viz., for each $(u, v, l(u, v))$, $(v, u, l(u, v)^{-1})$ is added to the edge list. Self loops are also added for passing the current embedding information. When GCN is applied over this modified directed graph, the embedding of the node v after k^{th} layer will be,

$$h_v^{k+1} = f\left(\sum_{u \in \mathcal{N}(v)} \left(W^k_{l(u,v)} h^k_u + b^k_{l(u,v)}\right)\right).$$

We note that the parameters $W^k_{l(u,v)}$ and $b^k_{l(u,v)}$ in this case are edge label specific. h^k_u is the input to the k^{th} layer. Here, $\mathcal{N}(v)$ refers to the set of neighbours of v, according to the updated edge list and f is any non-linear activation function (e.g., ReLU: $f(x) = \max(0, x)$).

3.2 NeuralDater

In this sub-section, we provide a brief overview of the components of the NeuralDater (Vashishth et al., 2018). Given a document D with n tokens $w_1, w_2, \cdots w_n$, NeuralDater extracts a temporally rich embedding of the document in a principled way as explained below:

3.2.1 Context Embedding

Bi-directional LSTM is employed for embedding each word with its context. The GloVe representation of the words $X \in \mathbb{R}^{n \times k}$ is transformed to a context aware representation $H^{cntx} \in \mathbb{R}^{n \times k}$ to get the context embedding. This is essentially shown as the Bi-LSTM in Figure 1.

3.2.2 Syntactic Embedding

In this step, the context embeddings are further processed using GCN over the dependency parse tree of the sentences in the document, in order to capture long range connection among words. The syntactic dependency structure is extracted by Stanford CoreNLP's dependency parser (Manning et al., 2014). NeuralDater follows the same formulation of GCN for directed graph as described in Section 3.1, where additional edges are added to the graph to model the information flow. Again following (Marcheggiani and Titov, 2017), NeuralDater does not allocate separate weight matrices for different types of dependency edge labels, rather it considers only three type of edges: a) edges that exist originally, b) the reverse edges that are added explicitly, and c) self loops. The S-GCN portion of Figure 1 represents this component.

More formally, $H^{cntx} \in \mathbb{R}^{n \times k}$ is transformed to $H^{syn} \in \mathbb{R}^{n \times k_{syn}}$ by applying S-GCN.

3.2.3 Temporal Embedding

In this layer, NeuralDater exploits the Event-Time graph structure present in the document. CATENA (Mirza and Tonelli, 2016), current state-of-the-art temporal and causal relation extraction algorithm, produces the temporal graph from the event time annotation of the document. GCN applied over this Event-Time graph, namely T-GCN, chooses n_T number of tokens out of total n tokens from the document for further revision in their embeddings. Note that T is the total number of events and time mentions present in the document. A special node DCT is added to the graph and its embedding is jointly learned. Note that this layer learns both label and direction specific parameters.

3.2.4 Classifier

Finally, the DCT embedding concatenated with the average pooled syntactic embedding is fed to a softmax layer for classification. This whole procedure is trained jointly.

4 Attentive Deep Document Dater (AD3): Proposed Method

In this section, we describe Attentive Deep Document Dater (AD3), our proposed method. AD3 is inspired by NeuralDater, and shares many of its components. Just like in NeuralDater, AD3 also leverages two main types of signals from the document – syntactic and event-time – to predict the document's timestamp. However, there are crucial differences between the two systems. Firstly, instead of concatenating embeddings learned from these two sources as in NeuralDater, AD3 treats these two models completely separate and combines them at a later stage. Secondly, unlike NeuralDater, AD3 employs attention mechanisms in each of these two models. We call the resulting models Attentive Context Model (AC-GCN) and Ordered Event Model (OE-GCN). These two models are described in Section 4.1 and Section 4.2, respectively.

4.1 Attentive Context Model (AC-GCN)

Recent success of attention-based deep learning models for classification (Yang et al., 2016b), question answering (Yang et al., 2016a), and machine translation (Bahdanau et al., 2014) have motivated us to use attention during document dating. We extend the syntactic embedding model of NeuralDater (Section 3.2.2) by incorporating an attentive pooling layer. We call the resulting model AC-GCN. This model (right side in Figure 1) has two major components.

- **Context Embedding and Syntactic Embedding**: Following NeuralDater, we used Bi-LSTM and S-GCN to capture context and long-range syntactic dependencies in the document (Please refer to Section 3.2.1, Section 3.2.2 for brief description). The syntactic embedding, $H^{syn} \in \mathbb{R}^{n \times k_{syn}}$ is then fed to an Attention Network for further processing. Note that, k_{syn} is the dimension of the output of Syntactic-GCN and n is the number of tokens in the document.

- **Attentive Embedding**: In this layer, we learn the representation for the whole document through word level attention network. We learn a context vector, $u_s \in \mathbb{R}^s$ with respect to which we calculate attention for each token. Finally, we aggregate the token features with respect to their attention weights in order to represent the document. More formally, let $h_t^{syn} \in \mathbb{R}^{k_{syn}}$ be the syntactic representation of the t^{th} token in the document. We take non-linear projection of it in $\mathbb{R}^s$ with $W_s \in \mathbb{R}^{s \times k_{syn}}$. Attention weight α_t for t^{th} token is calculated with respect to the context vector u_t^T as follows.

$$u_t = \tanh(W_s h_t^{syn}),$$

$$\alpha_t = \frac{\exp(u_t^T u_s)}{\sum_t \exp(u_t^T u_s)}.$$

  Finally, the document representation for the AC-GCN is computed as shown below.

$$d_{\text{AC-GCN}} = \sum_t \alpha_t h_t^{syn}$$

  This representation is fed to a softmax layer for the final classification.

The final probability distribution over years predicted by the AC-GCN is given below.

$$\text{P}_{\text{AC-GCN}}(y|D) = \text{Softmax}(W \cdot d_{\text{AC-GCN}} + b).$$

4.2 Ordered Event Model (OE-GCN)

The OE-GCN model is shown on the left side of Figure 1. Just like in AC-GCN, context and syntactic embedding is also part of OE-GCN. The syntactic embedding is fed to the Attentive Graph Convolution Network (AT-GCN) where the graph is obtained from the time-event ordering algorithm CATENA (Mirza and Tonelli, 2016). We describe these components in detail below.

4.2.1 Temporal Graph

We use the same process used in NeuralDater (Vashishth et al., 2018) for procuring the Temporal Graph from the document. CATENA (Mirza and Tonelli, 2016) generates 9 different temporal links between events and time expressions present in the document. Following Vashishth et al. (2018), we choose 5 most frequent ones - AFTER, BEFORE, SIMULTANEOUS, INCLUDES, and IS INCLUDED – as labels. The temporal graph is constructed from the partial ordering between event verbs and time expressions.

Let $\mathcal{E}_T$ be the edge list of the Temporal Graph. Similar to (Marcheggiani and Titov, 2017; Vashishth et al., 2018), we also add reverse edges for each of the existing edge and self loops for passing current node information as explained in Section 3.1. The new edge list $\mathcal{E}_T^{'}$ is shown below.

$$\mathcal{E}_{\mathrm{T}}' = \mathcal{E}_{\mathrm{T}} \cup \{(j, i, l(i,j)^{-1}) \mid (i, j, l(i,j)) \in \mathcal{E}_{\mathrm{T}}\} \\ \cup \{(i, i, \text{self}) \mid i \in \mathcal{V})\}.$$

The reverse edges are added with reverse labels like AFTER^{-1}, BEFORE^{-1} etc . Finally, we get 10 labels for our temporal graph and we denote the set of edge labels by $\mathcal{L}$.

4.2.2 Attentive Graph Convolution (AT-GCN)

Since the temporal graph is automatically generated, it is likely to have incorrect edges. Ideally, we would like to minimize the influence of such noisy edges while computing temporal embedding. In order to suppress the noisy edges in the Temporal Graph and detect important edges for reasoning, we use attentive graph convolution (Hamilton et al., 2017) over the Event-Time graph. The attention mechanism learns the aggregation function jointly during training. Here, the main objective is to calculate the attention over the neighbouring nodes with respect to the current node for a given label. Then the embedding of the current node is updated by mixing neighbouring node embedding according to their attention scores. In this respect, we propose a label-specific attentive graph convolution over directed graphs.

Let us consider an edge in the temporal graph from node i to node j with type l, where $l \in \mathcal{L}$ and $\mathcal{L}$ is the label set. The label set $\mathcal{L}$ can be divided broadly into two coarse labels as done in Section 3.2.2. The attention weights are specific to only these two type of edges to reduce parameter and prevent overfitting. For illustration, if there exists an edge from node i to j then the edge types will be,

- $L(i,j) = \rightarrow$ if $(i,j,l(i,j)) \in \mathcal{E}_T^{'}$,
  i.e., if the edge is an original event-time edge.
- $L(i,j) = \leftarrow$ if $(i,j,l(i,j)^{-1}) \in \mathcal{E}_T^{'}$,
  i.e., if the edge is added later.

First, we take a linear projection ($W^{atten}_{L(i,j)} \in \mathbb{R}^{F \times k_{syn}}$) of both the nodes in $\mathbb{R}^F$ in order to map both of them in the same direction-specific space. The concatenated vector $[W^{atten}_{L(i,j)} \times h_i; W^{atten}_{L(i,j)} \times h_j]$, signifies the importance of the node j w.r.t. node i. A non linear transformation of this concatenation can be treated as the importance feature vector between i and j.

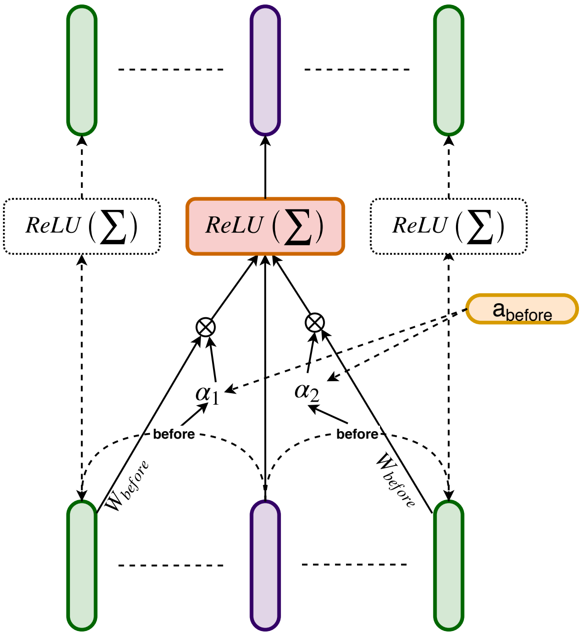

Figure 2: Attentive Graph Convolution (AT-GCN). In this layer, we learn attention weights for every edge based on label and direction. The attention weights are learnt using a context vector. The final representation of every node is a summation of weighted convolution over neighboring nodes based on labels.

$$e_{ij} = \tanh[W^{atten}_{L(i,j)} \times h_i; W^{atten}_{L(i,j)} \times h_j].$$

Now, we compute the attention weight of node j for node i with respect to a direction-specific context vector $a_{L(i,j)} \in \mathbb{R}^{2F}$, as follows.

$$\alpha_{ij}^{l(i,j)} = \frac{\exp\left(a^T_{L(i,j)} e_{ij}\right)}{\sum\limits_{k \in \mathcal{N}_i^{l(i,\cdot)}} \exp\left(a^T_{L(i,j)} e_{ik}\right)},$$

where, $\alpha_{ij}^{l(i,j)} = 0$ if node i and j is not connected through label l. $\mathcal{N}^{l(i,\cdot)}$ denotes the subset of the neighbourhood of node i with label l only. Please note that, although the linear transform weight ($W^{atten}_{L(i,j)} \in \mathbb{R}^{F \times k_{syn}}$) is specific to the coarse labels L, but for each finer label $l \in \mathcal{L}$ we get these convex weights of attentions. Figure 2 illustrates the above description w.r.t. edge type BEFORE.

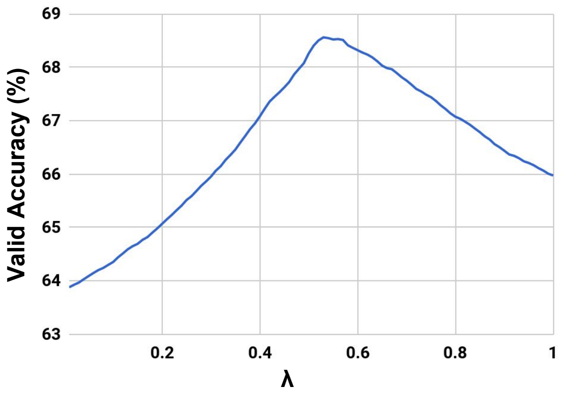

Figure 3: Variation of validation accuracy with λ (for APW dataset). We observe that AC-GCN and OE-GCN are both important for the task as we get optimal λ = 0.52.

Finally, the feature aggregation is done according to the attention weights. Prior to that, another label specific linear transformation is taken to perform the convolution operation. Then, the updated feature for node i is calculated as follows.

$$h_i^{k+1} = f\left(\sum_{l\in\mathcal{L}} \sum_{j\in\mathcal{N}_i^{l(i,\cdot)}} \alpha_{ij}^{l(i,j)} \left(W_{l(i,j)} h_j + b_{l(i,j)}\right)\right).$$

where, $\alpha_{ii} = 1$, $\mathcal{N}^{l(i,\cdot)}$ denotes the subset of the neighbourhood of node i with label l only. Note that, $\alpha_{ij}^{l(i,j)} = 0$ when $j \notin \mathcal{N}^{l(i,\cdot)}$. To illustrate formally, from Figure 2, we see that weight α_1 and α_2 is calculated specific to label type BEFORE and the neighbours which are connected through BEFORE is being multiplied with W_{before} prior to aggregation in the $ReLU$ block.

Now, after applying attentive graph convolution network, we only consider the representation of Document Creation Time (DCT), h_{DCT}, as the document representation itself. h_{DCT} is now passed through a fully connected layer prior to softmax. Prediction of the OE-GCN for the document D will be given as

$$\mathrm{P}_{\text{OE}-\text{GCN}}(y|D) = \text{Softmax}(W \cdot d_{\text{DCT}} + b).$$

4.3 AD3: Attentive Deep Document Dater

In this section, we propose an unified model by mixing both AC-GCN and OE-GCN. Even on validation data, we see that performance of both the models differ to a large extent. This significant difference (McNemar test p $<$ 0.000001) motivated the unification. We take convex combination of the output probabilities of the two models as shown below.

$$\mathrm{P}_{joint}(y|D) = \lambda \mathrm{P}_{\text{AC}-\text{GCN}}(y|D) + (1-\lambda)\mathrm{P}_{\text{OE}-\text{GCN}}(y|D).$$

Datasets	# Docs	Start Year	End Year
APW	675k	1995	2010
NYT	647k	1987	1996

Table 1: Details of datasets used. Please refer Section 5 for details.

The combination hyper-parameter λ is tuned on the validation data. We obtain the value of λ to be 0.52 (Figure 3) and 0.54 for APW and NYT datasets, respectively. This depicts that the two models are capturing significantly different aspects of documents, resulting in a substantial improvement in performance when combined.

5 Experimental Setup

Dataset: Experiments are carried out on the Associated Press Worldstream (APW) and New York Times (NYT) sections of the Gigaword corpus (Parker et al., 2011). We have used the same 8:1:1 split as Vashishth et al. (2018) for all the models. For quantitative details please refer to Table 1.

Evaluation Criteria: In accordance with prior work (Chambers, 2012; Kotsakos et al., 2014; Vashishth et al., 2018) the final task is to predict the publication year of the document. We give a brief description of the baselines below.

Baseline Methods:

- **MaxEnt-Joint** (Chambers, 2012): This method engineers several hand-crafted temporally influenced features to classify the document using MaxEnt Classifier.

- **BurstySimDater** (Kotsakos et al., 2014): This is a purely statistical method which uses lexical similarity and term burstiness (Lappas et al., 2009) for dating documents in arbitrary length time frame. For our experiments, we used a time frame length of 1 year.

- **NeuralDater** (Vashishth et al., 2018): This is the first deep neural network based approach for the document dating task. Details are provided in Section 3.2.

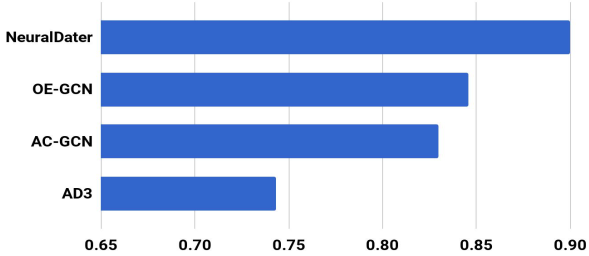

Figure 4: Mean absolute deviation (in years; lower is better) between a model's top prediction and the true year in the APW dataset. We find that all of our proposed methods outperform the previous state-of-the-art NeuralDater. Please refer to Section 6.1 for details.

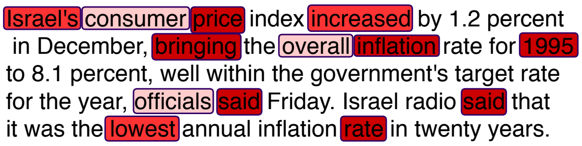
Method	APW	NYT
BurstySimDater	45.9	38.5
MaxEnt-Joint	52.5	42.5
NeuralDater	64.1	58.9
Attentive NeuralDater [6.2]	66.2	60.1
OE-GCN [4.2]	63.9	58.3
AC-GCN [4.1]	65.6	60.3
AD3 [4.3]	**68.2**	**62.2**

Table 2: Accuracy (%) of different methods on the APW and NYT datasets for the document dating problem (higher is better). The unified model significantly outperforms all previous models.



Israel's consumer price index increased by 1.2 percent
in December, bringing the overall inflation rate for 1995
to 8.1 percent, well within the government's target rate
for the year, officials said Friday. Israel radio said that
it was the lowest annual inflation rate in twenty years.

Figure 5: Visualization of the attention of AC-GCN. AC-GCN captures the intuitive tokens as seen in the figure. Darker shade implies higher attention. The correct DCT is 1996.

Method	Accuracy
T-GCN of NeuralDater	61.8
OE-GCN	**63.9**
S-GCN of NeuralDater	63.2
AC-GCN	**65.6**

Table 3: Accuracy (%) comparisons of component models with and without Attention. This results show the effectiveness of both word attention and Graph Attention for this task. Please see Section 6.2 for more details.

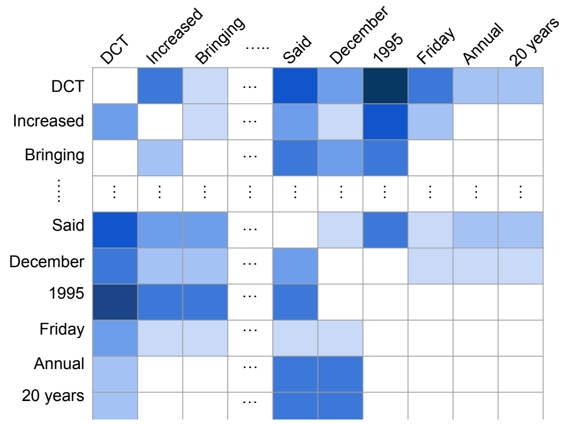


Figure 6: Visualization of the average edge attention of the temporal graph as learnt by OE-GCN for the document shown in Figure 5. Darker color implies higher attention. The correct DCT is 1996.

Hyperparameters: We use 300-dimensional GloVe embeddings and 128-dimensional hidden state for both GCNs and BiLSTM with 0.8 dropout. We use Adam (Kingma and Ba, 2014) with 0.001 learning rate for training. For OE-GCN we use 2-layers of AT-GCN. 1-layer of S-GCN is used for both the models.

6 Results

6.1 Performance Analysis

In this section, we compare the effectiveness of our method with that of prior work. The deep network based NeuralDater model in (Vashishth et al., 2018) outperforms previous feature engineered (Chambers, 2012) and statistical methods (Kotsakos et al., 2014) by a large margin. We observe a similar trend in our case. Compared to the state-of-the-art model NeuralDater, we gain, on an average, a 3.7% boost in accuracy on both the datasets (Table 2).

Among individual models, OE-GCN performs at par with NeuralDater, while AC-GCN outperforms it. The empirical results imply that AC-GCN by itself is effective for this task. The relatively worse performance of OE-GCN can be attributed to the fact that it only focuses on the Event-Time information and leaves out most of the contextual information. However, it captures various different ($p < 0.000001$, McNemar's test, 2-tailed) aspects of the document for classification, which motivated us to propose an ensemble of the two models. This explains the significant boost in performance of AD3 over NeuralDater as well as the individual models. It is worth mentioning that although AC-GCN and OE-GCN do not provide significant boosts in accuracy, their predictions have considerably lower mean-absolute-deviation as shown in Figure 4.

We concatenated the DCT embedding provided by OE-GCN with the document embedding provided by AC-GCN and trained in an end to end joint fashion like NeuralDater. We see that even with a similar training method, the Attentive NeuralDater model on an average, performs 1.6% better in terms of accuracy, once again proving the efficacy of attention based models over normal models.

6.2 Effectiveness of Attention

Attentive Graph Convolution (Section 4.2.2) proves to be effective for OE-GCN, giving a 2% accuracy improvement over non-attentive T-GCN of NeuralDater (Table 3). Similarly the efficacy of word level attention is also prominent from Table 3.

We have also analyzed our models by visualizing attentions over words and attention over graph nodes. Figure 5 shows that AC-GCN focuses on temporally informative words such as ”said” (for tense) or time mentions like “1995”, alongside important contextual words like “inflation”, “Israel” etc. For OE-GCN, from Figure 6 we observe that “DCT” and time-mention ‘1995’ grabs the highest attention. Attention between “DCT” and other event verbs indicating past tense are quite prominent, which helps the model to infer 1996 (which is correct) as the most likely time-stamp of the document. These analyses provide us with a good justification for the performance of our attentive models.

7 Discussion

Apart from empirical improvements over previous models, we also perform a qualitative analysis of the individual models. Figure 7 shows that the performance of AC-GCN improves with the length of documents, thus indicating that richer context leads to better model prediction. Figure 8 shows how the performance of OE-GCN improves with the number of event-time mentions in the document, thus further reinforcing our claim that more temporal information improves model performance.

Vashishth et al. (2018) reported that their model got confused by the presence of multiple misleading time mentions. AD3 overcomes this limitation using attentive graph convolution, which successfully filters out noisy time mentions as is evident from Figure 8.

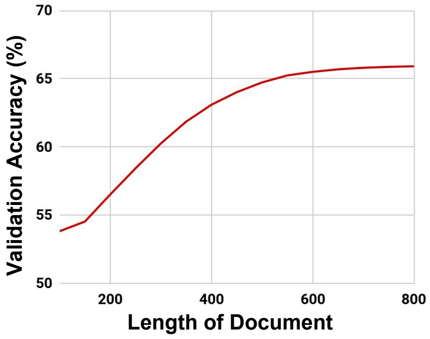

Figure 7: Variation of validation accuracy (%) with respect to length of documents (for APW dataset) for AC-GCN. Documents having more than 100 tokens are selected for this analysis. Please see Section 7.

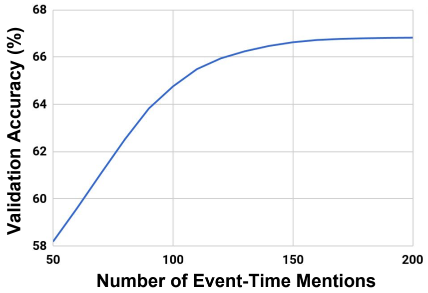

Figure 8: Variation of validation accuracy (%) with number of event-time mentions in documents (for APW dataset) for OE-GCN. Documents with more than 100 tokens are selected for this analysis. Please see Section 7.

8 Conclusion

We propose AD3, an ensemble model which exploits both syntactic and temporal information in a document explicitly to predict its creation time (DCT). To the best of our knowledge, this is the first application of attention based deep models for dating documents. Our experimental results demonstrate the effectiveness of our model over all previous models. We also visualize the attention weights to show that the model is able to choose what is important for the task and filter out noise inherent in language. As part of future work, we would like to incorporate external knowledge as a side information for improved time-stamping of documents.

Abstract

Cross-lingual or cross-domain correspondences play key roles in tasks ranging from machine translation to transfer learning. Recently, purely unsupervised methods operating on monolingual embeddings have become effective alignment tools. Current state-of-the-art methods, however, involve multiple steps, including heuristic post-hoc refinement strategies. In this paper, we cast the correspondence problem directly as an optimal transport (OT) problem, building on the idea that word embeddings arise from metric recovery algorithms. Indeed, we exploit the *Gromov-Wasserstein* distance that measures how similarities between pairs of words relate across languages. We show that our OT objective can be estimated efficiently, requires little or no tuning, and results in performance comparable with the state-of-the-art in various unsupervised word translation tasks.

1 Introduction

Many key linguistic tasks, within and across languages or domains, including machine translation, rely on learning cross-lingual correspondences between words or other semantic units. While the associated alignment problem could be solved with access to large amounts of parallel data, broader applicability relies on the ability to do so with largely mono-lingual data, from Part-of-Speech (POS) tagging (Zhang et al., 2016), dependency parsing (Guo et al., 2015), to machine translation (Lample et al., 2018). The key subtask of bilingual lexical induction, for example, while long standing as a problem (Fung, 1995; Rapp, 1995, 1999), has been actively pursued recently (Artetxe et al., 2016; Zhang et al., 2017a; Conneau et al., 2018).

Current methods for learning cross-domain correspondences at the word level rely on distributed representations of words, building on the observation that mono-lingual word embeddings exhibit similar geometric properties across languages Mikolov et al. (2013). While most early work assumed some, albeit minimal, amount of parallel data (Mikolov et al., 2013; Dinu et al., 2014; Zhang et al., 2016), recently fully-unsupervised methods have been shown to perform on par with their supervised counterparts (Conneau et al., 2018; Artetxe et al., 2018). While successful, the mappings arise from multiple steps of processing, requiring either careful initial guesses or post-mapping refinements, including mitigating the effect of frequent words on neighborhoods. The associated adversarial training schemes can also be challenging to tune properly (Artetxe et al., 2018).

In this paper, we propose a direct optimization approach to solving correspondences based on recent generalizations of optimal transport (OT). OT is a general mathematical toolbox used to evaluate correspondence-based distances and establish mappings between probability distributions, including discrete distributions such as point-sets. However, the nature of mono-lingual word embeddings renders the classic formulation of OT inapplicable to our setting. Indeed, word embeddings are estimated primarily in a relational manner to the extent that the algorithms are naturally interpreted as metric recovery methods (Hashimoto et al., 2016). In such settings, previous work has sought to bypass this lack of *registration* by jointly optimizing over a matching and an orthogonal mapping (Rangarajan et al., 1997; Zhang et al., 2017b). Due to the focus on distances rather than points, we instead adopt a relational OT formulation based on the Gromov-Wasserstein distance that measures how distances between pairs of words are mapped across languages. We show that the resulting mapping admits an efficient solution and requires little or no tuning.

In summary, we make the following contributions:

Proceedings of the 2018 Conference on Empirical Methods in Natural Language Processing, pages 1881–1890
Brussels, Belgium, October 31 - November 4, 2018.

- We propose the use of the Gromov-Wasserstein distance to learn correspondences between word embedding spaces in a fully-unsupervised manner, leading to a theoretically-motivated optimization problem that can be solved efficiently, robustly, in a single step, and requires no post-processing or heuristic adjustments.

- To scale up to large vocabularies we realize an extended mapping to words not part of the original optimization problem.

- We show that the proposed approach performs on par with state-of-the-art neural network based methods on benchmark word translation tasks, while requiring a fraction of the computational cost and/or hyper-parameter tuning.

2 Problem Formulation

In the unsupervised bilingual lexical induction problem we consider two languages with vocabularies V_x and V_y, represented by word embeddings $X = \{\mathbf{x}^{(i)}\}_{i=1}^{n}$ and $Y = \{\mathbf{y}^{(j)}\}_{j=1}^{m}$, respectively, where $\mathbf{x}^{(i)} \in \mathcal{X} \subset \mathbb{R}^{d_x}$ corresponds to $w_i^x \in V_x$ and $\mathbf{y}^{(j)} \in \mathcal{Y} \subset \mathbb{R}^{d_y}$ to $w_j^y \in V_y$. For simplicity, we let $m = n$ and $d_x = d_y$, although our methods carry over to the general case with little or no modifications. Our goal is to learn an alignment between these two sets of words without any parallel data, i.e., we learn to relate $\mathbf{x}^{(i)} \leftrightarrow \mathbf{y}^{(j)}$ with the implication that w_i^x translates to w_j^y.

As background, we begin by discussing the problem of learning an explicit map between embeddings in the supervised scenario. The associated training procedure will later be used for extending unsupervised alignments (Section 3.2).

2.1 Supervised Maps: Procrustes

In the supervised setting, we learn a map $T : \mathcal{X} \rightarrow \mathcal{Y}$ such that $T(\mathbf{x}^{(i)}) \approx \mathbf{y}^{(j)}$ whenever w_j^y is a translation of w_i^x. Let $\mathbf{X}$ and $\mathbf{Y}$ be the matrices whose columns are vectors $\mathbf{x}^{(i)}$ and $\mathbf{y}^{(j)}$, respectively. Then we can find T by solving

$$\min_{T \in \mathcal{F}} \|\mathbf{X} - T(\mathbf{Y})\|_F^2 \tag{1}$$

where $\|\cdot\|_F$ is the Frobenius norm $\|A\|_F = \sqrt{\sum_{i,j} |a_{ij}|^2}$. Naturally, both the difficulty of finding T and the quality of the resulting alignment depend on the choice of space $\mathcal{F}$. A classic approach constrains T to be orthonormal matrices, i.e., rotations and reflections, resulting in the orthogonal Procrustes problem

$$\min_{\mathbf{P} \in O(n)} \|\mathbf{X} - \mathbf{P}\mathbf{Y}\|_F^2 \tag{2}$$

where $O(n) = \{\mathbf{P} \in \mathbb{R}^{n \times n} \mid \mathbf{P}^\top\mathbf{P} = \mathbf{I}\}$. One key advantage of this formulation is that it has a closed-form solution in terms of a singular value decomposition (SVD), whereas for most other choices of constraint set $\mathcal{F}$ it does not. Given an SVD decomposition $\mathbf{U}\Sigma\mathbf{V}^\top$ of $\mathbf{X}\mathbf{Y}^\top$, the solution to problem (2) is $\mathbf{P}^* = \mathbf{U}\mathbf{V}^\top$ (Schönemann, 1966). Besides obvious computational advantage, constraining the mapping between spaces to be orthonormal is justified in the context of word embedding alignment because orthogonal maps preserve angles (and thus distances), which is often the only information used by downstream tasks (e.g., for nearest neighbor search) that rely on word embeddings. (Smith et al., 2017) further show that orthogonality is required for self-consistency of linear transformations between vector spaces.

Clearly, the Procrustes approach only solves the supervised version of the problem as it requires a known correspondence between the columns of $\mathbf{X}$ and $\mathbf{Y}$. Steps beyond this constraint include using small amounts of parallel data (Zhang et al., 2016) or an unsupervised technique as the initial step to generate pseudo-parallel data (Conneau et al., 2018) before solving for $\mathbf{P}$.

2.2 Unsupervised Maps: Optimal Transport

Optimal transport formalizes the problem of finding a minimum cost mapping between two point sets, viewed as discrete distributions. Specifically, we assume two empirical distributions over embeddings, e.g.,

$$\mu = \sum_{i=1}^{n} \mathbf{p}_i \delta_{\mathbf{x}^{(i)}}, \quad \nu = \sum_{j=1}^{m} \mathbf{q}_j \delta_{\mathbf{y}^{(i)}} \tag{3}$$

where $\mathbf{p}$ and $\mathbf{q}$ are vectors of probability weights associated with each point set. In our case, we usually consider uniform weights, e.g., $\mathbf{p}_i = 1/n$ and $\mathbf{q}_j = 1/m$, although if additional information were provided (such as in the form of word frequencies), those could be naturally incorporated via $\mathbf{p}$ and $\mathbf{q}$ (see discussion at the end of Section 3). We find a *transportation map* T realizing

$$\inf_T \left\{ \int_{\mathcal{X}} c(\mathbf{x}, T(\mathbf{x})) d\mu(\mathbf{x}) \mid T_{\#}\mu = \nu \right\}, \tag{4}$$

where the cost $c(\mathbf{x}, T(\mathbf{x}))$ is typically just $\|\mathbf{x} - T(\mathbf{x})\|$ and $T_{\#}\mu = \nu$ implies that the source points must exactly map to the targets. However, such a map need not exist in general and we instead follow a relaxed Kantorovich's formulation. In this case, the set of transportation plans is a polytope:

$$\Pi(\mathbf{p}, \mathbf{q}) = \{\Gamma \in \mathbb{R}_+^{n \times m} \mid \Gamma \mathbb{1}_n = \mathbf{p},\ \Gamma^\top \mathbb{1}_n = \mathbf{q}\}.$$

The cost function is given as a matrix $\mathbf{C} \in \mathbb{R}^{n \times m}$, e.g., $C_{ij} = \|\mathbf{x}^{(i)} - \mathbf{y}^{(j)}\|$. The total cost incurred by Γ is $\langle \Gamma, C \rangle := \sum_{ij} \Gamma_{ij} C_{ij}$. Thus, the discrete optimal transport (DOT) problem consists of finding a plan Γ that solves

$$\min_{\Gamma \in \Pi(\mathbf{p}, \mathbf{q})} \langle \Gamma, \mathbf{C} \rangle. \tag{5}$$

Problem (5) is a linear program, and thus can be solved exactly in $O(n^3 \log n)$ with interior point methods. However, regularizing the objective leads to more efficient optimization and often better empirical results. The most common such regularization, popularized by Cuturi (2013), involves adding an entropy penalization:

$$\min_{\Gamma \in \Pi(\mathbf{p}, \mathbf{q})} \langle \Gamma, \mathbf{C} \rangle - \lambda H(\Gamma). \tag{6}$$

The solution of this strictly convex optimization problem has the form $\Gamma^* = \operatorname{diag}(\mathbf{a}) \, \mathbf{K} \operatorname{diag}(\mathbf{b})$, with $\mathbf{K} = e^{-\frac{\mathbf{C}}{\lambda}}$ (element-wise), and can be obtained efficiently via the Sinkhorn-Knopp algorithm, a matrix-scaling procedure which iteratively computes:

$$\mathbf{a} \leftarrow \mathbf{p} \oslash \mathbf{K}\mathbf{b} \quad \text{and} \quad \mathbf{b} \leftarrow \mathbf{q} \oslash \mathbf{K}^\top \mathbf{a}, \tag{7}$$

where $\oslash$ denotes entry-wise division. The derivation of these updates is immediate from the form of Γ^* above, combined with the marginal constraints $\Gamma \mathbb{1}_n = \mathbf{p}$, $\Gamma^\top \mathbb{1}_n = \mathbf{q}$ (Peyré and Cuturi, 2018).

Although simple, efficient and theoretically-motivated, a direct application of discrete OT for unsupervised word translation is not appropriate. One reason is that the mono-lingual embeddings are estimated in a relative manner, leaving, e.g., an overall rotation unspecified. Such degrees of freedom can dramatically change the entries of the cost matrix $C_{ij} = \|\mathbf{x}^{(i)} - \mathbf{y}^{(j)}\|$ and the resulting transport map. One possible solution is to simultaneously learn an optimal coupling and an orthogonal transformation (Zhang et al., 2017b). The transport problem is then solved iteratively, using $C_{ij} = \|\mathbf{x}^{(i)} - \mathbf{P}\mathbf{y}^{(j)}\|$, where $\mathbf{P}$ is in turn chosen to minimize the transport cost (via Procrustes). While promising, the resulting iterative approach is sensitive to initialization, perhaps explaining why Zhang et al. (2017b) used an adversarially learned mapping as the initial step. The computational cost can also be prohibitive (Artetxe et al., 2018) though could be remedied with additional development.

We adopt a theoretically well-founded generalization of optimal transport for pairs of points (their distances), thus in line with how the embeddings are estimated in the first place. We explain the approach in detail in the next Section.

3 Transporting across unaligned spaces

In this section we introduce the Gromov-Wasserstein distance, describe an optimization algorithm for it, and discuss how to extend the approach to out-of-sample vectors.

3.1 The Gromov Wasserstein Distance

The classic optimal transport requires a distance between vectors *across* the two domains. Such a metric may not be available, for example, when the sample sets to be matched do not belong to the same metric space (e.g., different dimension). The Gromov-Wasserstein distance (Mémoli, 2011) generalizes optimal transport by comparing the metric spaces directly instead of samples across the spaces. In other words, this framework operates on distances between pairs of points calculated within each domain and measures how these distances compare to those in the other domain. Thus, it requires a weaker but easy to define notion of *distance between distances*, and operates on pairs of points, turning the problem from a linear to a quadratic one.

Formally, in its discrete version, this framework considers two measure spaces expressed in terms of within-domain similarity matrices $(\mathbf{C}, \mathbf{p})$ and $(\mathbf{C}', \mathbf{q})$ and a loss function defined between *similarity pairs*: $L : \mathbb{R} \times \mathbb{R} \to \mathbb{R}$, where $L(C_{ik}, C'_{jl})$ measures the discrepancy between the distances $d(\mathbf{x}^{(i)}, \mathbf{x}^{(k)})$ and $d'(\mathbf{y}^{(j)}, \mathbf{y}^{(l)})$. Typical choices for L are $L(a, b) = \frac{1}{2}(a - b)^2$ or $L(a, b) = \mathrm{KL}(a|b)$. In this framework, $L(C_{ik}, C'_{jl})$ can also be understood as the cost of "matching" i to j *and* k to l.

All the relevant values of $L(\cdot, \cdot)$ can be put in a 4-th order tensor $\mathbf{L} \in \mathbb{R}^{N_1 \times N_1 \times N_2 \times N_2}$, where $\mathbf{L}_{ijkl} = L(C_{ik}, C'_{jl})$. As before, we seek a cou-

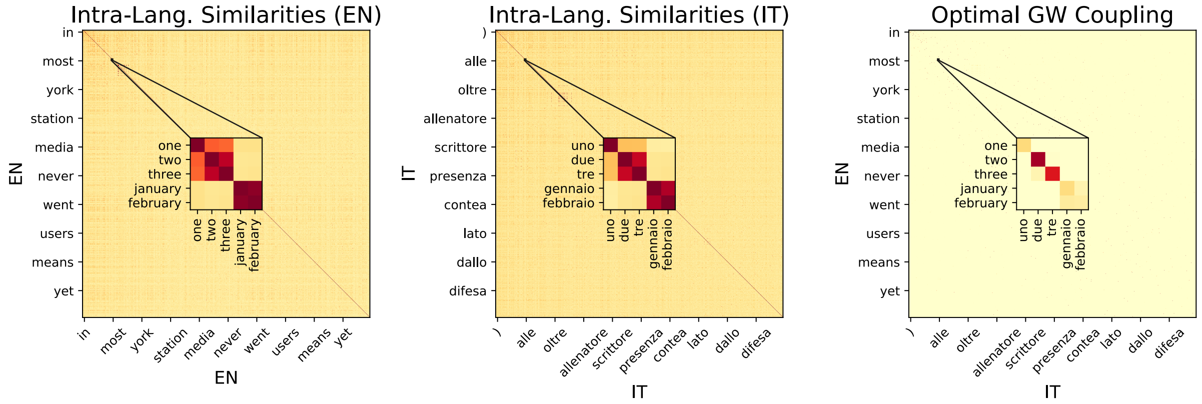

Figure 1: The Gromov-Wasserstein distance is well suited for the task of cross-lingual alignment because it relies on *relational* rather than *positional* similarities to infer correspondences across domains. Computing it requires two intra-domain similarity (or equivalently cost) matrices (**left** & **center**), and it produces an optimal coupling of source and target points with minimal discrepancy cost (**right**).

pling Γ specifying how much mass to transfer between each pair of points from the two spaces. The Gromov-Wasserstein problem is then defined as solving

$$\mathrm{GW}(\mathbf{C}, \mathbf{C}', \mathbf{p}, \mathbf{q}) = \min_{\Gamma \in \Pi(\mathbf{p},\mathbf{q})} \sum_{i,j,k,l} \mathbf{L}_{ijkl} \Gamma_{ij} \Gamma_{kl} \quad (8)$$

Compared to problem (5), this version is substantially harder since the objective is now not only non-linear, but non-convex too.[1] In addition, it requires operating on a fourth-order tensor, which would be prohibitive in most settings. Surprisingly, this problem can be optimized efficiently with first-order methods, whereby each iteration involves solving a traditional optimal transport problem (Peyré et al., 2016). Furthermore, for suitable choices of loss function L, Peyré et al. (2016) show that instead of the $O(N_1^2 N_2^2)$ complexity implied by naive fourth-order tensor product, this computation reduces to $O(N_1^2 N_2 + N1 N_2^2)$ cost. Their approach consists of solving (5) by projected gradient descent, which yields iterations that involve projecting onto $\Pi(\mathbf{p}, \mathbf{q})$ a pseudo-cost matrix of the form

$$\hat{\mathbf{C}}_\Gamma(\mathbf{C}, \mathbf{C}', \Gamma) = \mathbf{C}_{xy} - h_1(\mathbf{C}) \Gamma h_2(\mathbf{C}')^\top \quad (9)$$

where

$$\mathbf{C}_{xy} = f_1(\mathbf{C}) \mathbf{p} \mathbb{1}_m^\top + \mathbb{1}_n \mathbf{q}^\top f_2(\mathbf{C}')^\top$$

and f_1, f_2, h_2, h_2 are functions that depend on the loss L. We provide an explicit algorithm for the case $L = L_2$ at the end of this section.

Once we have solved (8), the optimal transport coupling Γ^* provides an explicit (soft) matching between source and target samples, which for the problem of interest can be interpreted as a probabilistic translation: for every pair of words $(w_{src}^{(i)}, w_{trg}^{(j)})$, Γ^*_{ij} provides a likelihood that these two words are translations of each other. This itself is enough to translate, and we show in the experiments section that Γ^* by itself, without any further post-processing, provides high-quality translations. This stands in sharp contrast to mapping-based methods, which rely on nearest-neighbor computation to infer translations, and thus become prone to hub-word effects which have to be mitigated with heuristic post-processing techniques such as Inverted Softmax (Smith et al., 2017) and Cross-Domain Similarity Scaling (CSLS) (Conneau et al., 2018). The transportation coupling Γ, being normalized *by construction*, requires no such artifacts.

The Gromov-Wasserstein problem (8) possesses various desirable theoretical properties, including the fact that for a suitable choice of the loss function it is indeed a distance:

Theorem 3.1 (Mémoli 2011)**.** *With the choice* $L = L_2$, $GW^{\frac{1}{2}}$ *is a distance on the space of metric measure spaces.*

Solving problem (8) therefore yields a fascinating accompanying notion: the *Gromov-Wasserstein distance between languages*, a measure of semantic discrepancy purely based on the relational characterization of their word embeddings. Owing to Theorem 3.1, such values can be

---

[1] In fact, the discrete (Monge-type) formulation of the problem is essentially an instance of the well-known (and NP-hard) quadratic assignment problem (QAP).

interpreted as distances, so that, e.g., the triangle inequality holds among them. In Section 4.4 we compare various languages in terms of their GW-distance.

Finally, we note that whenever word frequency counts are available, those would be used for $\mathbf{p}$ and $\mathbf{q}$. If they are not, but words are sorted according to occurrence (as they often are in popular off-the-shelf embedding formats), one can estimate rank-probabilities such as Zipf power laws, which are known to accurately model multiple languages (Piantadosi, 2014). In order to provide a fair comparison to previous work, throughout our experiments **we use uniform distributions** so as to avoid providing our method with additional information not available to others.

3.2 Scaling Up

While the pure Gromov-Wasserstein approach leads to high quality solutions, it is best suited to small-to-moderate vocabulary sizes,[2] since its optimization becomes prohibitive for very large problems. For such settings, we propose a two-step approach in which we first match a subset of the vocabulary via the optimal coupling, after which we learn an orthogonal mapping through a modified Procrustes problem. Formally, suppose we solve problem (8) for a reduced matrices $\mathbf{X}_{1:k}$ and $\mathbf{Y}_{i:k}$ consisting of the first columns k of $\mathbf{X}$ and $\mathbf{Y}$, respectively, and let Γ^* be the optimal coupling. We seek an orthogonal matrix that best recovers the barycentric mapping implied by Γ^*. Namely, we seek to find $\mathbf{P}$ which solves:

$$\min_{\mathbf{P}\in O(n)} \|\mathbf{X}\Gamma^* - \mathbf{P}\mathbf{Y}\|_2^2 \tag{10}$$

Just as problem (2), it is easy to show that this Procrustes-type problem has a closed form solution in terms of a singular value decomposition. Namely, the solution to (10) is $\mathbf{P}^* = \mathbf{U}\mathbf{V}^\top$, where $\mathbf{U}\Sigma\mathbf{V}^* = \mathbf{X}_{1:m}\Gamma^*\mathbf{Y}_{1:m}^\top$. After obtaining this projection, we can immediately map the rest of the embeddings via $\hat{\mathbf{y}}^{(j)} = \mathbf{P}^*\mathbf{y}^{(j)}$.

We point out that this two-step procedure resembles that of Conneau et al. (2018). Both ultimately produce an orthogonal mapping obtained by solving a Procrustes problems, but they differ in the way they produce pseudo-matches to allow for such second-step: while their approach relies on an adversarially-learned transformation, we use an explicit optimization problem.

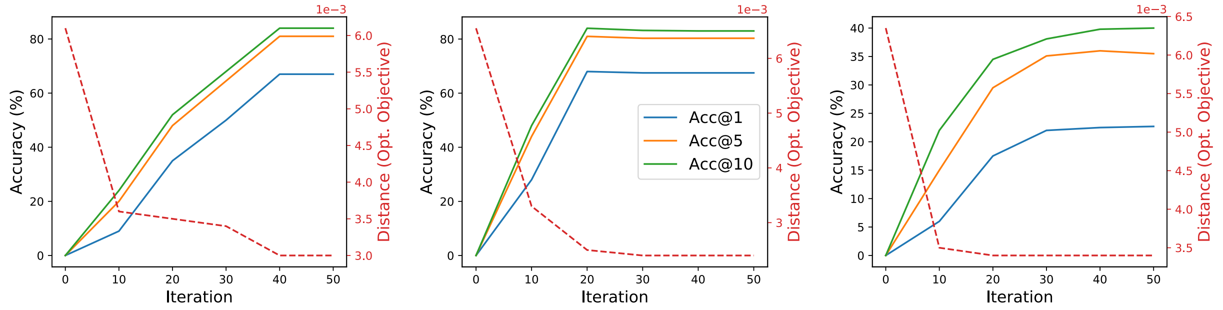
Algorithm 1 Gromov-Wasserstein Computation for Word Embedding Alignment

```
Input: Source and target embeddings $\mathbf{X}, \mathbf{Y}$. Regularization $\lambda$. Probability vectors $\mathbf{p}, \mathbf{q}$.
// Compute intra-language similarities
$\mathbf{C}_s \leftarrow \cos(\mathbf{X}, \mathbf{X}), \quad \mathbf{C}_t \leftarrow \cos(\mathbf{Y}, \mathbf{Y})$
$\mathbf{C}_{st} \leftarrow \mathbf{C}_s^2 \mathbf{p} \mathbb{1}_m^\top + \mathbb{1}_n \mathbf{q} (\mathbf{C}_t^2)^\top$
while not converged do
  // Compute pseudo-cost matrix (Eq. (9))
  $\hat{\mathbf{C}}_\Gamma \leftarrow \mathbf{C}_{st} - 2\mathbf{C}_s \Gamma \mathbf{C}_t^\top$
  // Sinkhorn iterations (Eq. (7))
  $\mathbf{a} \leftarrow \mathbb{1}, \quad \mathbf{K} \leftarrow \exp\{-\hat{\mathbf{C}}_\Gamma / \lambda\}$
  while not converged do
    $\mathbf{a} \leftarrow \mathbf{p} \oslash \mathbf{K}\mathbf{b}, \ \mathbf{b} \leftarrow \mathbf{q} \oslash \mathbf{K}^\top \mathbf{a}$
  end while
  $\Gamma \leftarrow \mathrm{diag}(\mathbf{a})\, \mathbf{K}\, \mathrm{diag}(\mathbf{b})$
end while
// Optional step: Learn explicit projection
$\mathbf{U}, \Sigma, \mathbf{V}^\top \leftarrow \mathrm{SVD}(\mathbf{X}\Gamma\mathbf{Y}^\top)$
$\mathbf{P} = \mathbf{U}\mathbf{V}^\top$
return $\Gamma, \mathbf{P}$
```

We end this section by discussing parameter and configuration choices. To leverage the fast algorithm of Peyré et al. (2016), we always use the L_2 distance as the loss function L between cost matrices. On the other hand, we observed throughout our experiments that the choice of cosine distance as the metric in both spaces consistently leads to better results, which agrees with common wisdom on computing distances between word embeddings. This leaves us with a single hyper-parameter to control: the entropy regularization term λ. By applying any sensible normalization on the cost matrices (e.g., dividing by the mean or median value), we are able to almost entirely eliminate sensitivity to that parameter. In practice, we use a simple scheme in all experiments: we first try the same fixed value ($\lambda = 5 \times 10^{-5}$), and if the regularization proves too small (by leading to floating point errors), we instead use $\lambda = 1 \times 10^{-4}$. We never had to go beyond these two values in all our experiments. We emphasize that at no point we use train (let alone test) supervision available with many datasets—model selection is done solely in terms of the unsupervised objective. Pseudocode for the full method (with $L = L_2$ and cosine similarity) is shown here as Algorithm 1.

---

[2] As shown in the experimental section, we are able to run problems of size in the order of $|V_s| \approx 10^5 \approx |V_t|$ on a single machine **without** relying on GPU computation.



(a) $\text{EN} \rightarrow \text{FR}$, 15K words, $\lambda = 5 \cdot 10^{-4}$ (b) $\text{EN} \rightarrow \text{FR}$, 15K words, $\lambda = 10^{-4}$ (c) $\text{EN} \rightarrow \text{RU}$, 15K words, $\lambda = 10^{-4}$

Figure 2: **Training dynamics for the Gromov-Wasserstein alignment problem**. The algorithm provably makes progress in each iteration, and the objective (red dashed line) closely follows the metric of interest (translation accuracy, not available during training). More related languages (e.g., EN →FR in 2b,2a) lead to faster optimization, while more distant pairs yield slower learning curves (EN →RU, 2c).

4 Experiments

Through this experimental evaluation we seek to: (i) understand the optimization dynamics of the proposed approach (§4.2), evaluate its performance on benchmark cross-lingual word embedding tasks (§4.3), and (iii) qualitatively investigate the notion of distance-between-languages it computes (§4.4). Rather than focusing solely on prediction accuracy, we seek to demonstrate that the proposed approach offers a fast, principled, and robust alternative to state-of-the-art multi-step methods, delivering comparable performance.

4.1 Evaluation Tasks and Methods

Datasets We evaluate our method on two standard benchmark tasks for cross-lingual embeddings. First, we consider the dataset of Conneau et al. (2018), which consists of word embeddings trained with FASTTEXT (Bojanowski et al., 2017) on Wikipedia and parallel dictionaries for 110 language pairs. Here, we focus on the language pairs for which they report results: English (EN) from/to Spanish (ES), French (FR), German (DE), Russian (RU) and simplified Chinese (ZH). We do not report results on Esperanto (EO) as dictionaries for that language were not provided with the original dataset release.

For our second set of experiments, we consider the—substantially harder[3]—dataset of (Dinu et al., 2014), which has been extensively compared against in previous work. It consists of embeddings and dictionaries in four pairs of languages; EN from/to ES, IT, DE, and FI (Finnish).

Methods To see how our fully-unsupervised method compares with methods that require (some) cross-lingual supervision, we follow (Conneau et al., 2018) and consider a simple but strong baseline consisting of solving a procrustes problem directly using the available cross-lingual embedding pairs. We refer to this method simply as PROCRUSTES. In addition, we compare against the fully-unsupervised methods of Zhang et al. (2017a), Artetxe et al. (2018) and Conneau et al. (2018).[4] As proposed by the latter, we use CSLS whenever nearest neighbor search is required, which has been shown to improve upon naive nearest-neighbor retrieval in multiple work.

4.2 Training Dynamics of G-W

As previously mentioned, our approach involves only two optimization choices, one of which is required only for very large settings. When running Algorithm 1 for the full set of embeddings is infeasible (due to memory limitations), one must decide what fraction of the embeddings to use during optimization. In our experiments, we use the largest possible size allowed by memory constraints, which was found to be $K = 20,000$ for the personal computer we used.

The other—more interesting—optimization choice involves the entropy regularization parameter λ used within the Sinkhorn iterations. Large regularization values lead to denser optimal coupling Γ^*, while less regularization leads to sparser solutions,[5] at the cost of a harder (more

---

[3] We discuss the difference in hardness of these two benchmark datasets in Section 4.3.

[4] Despite its relevance, we do not include the OT-based method of Zhang et al. (2017b) in the comparison because their implementation required use of proprietary software.

[5] In the limit $\lambda \rightarrow 0$, when $n = m$, the solution converges

			En-Es		En-Fr		En-De		En-It		En-Ru	
	Supervision	Time	→	←	→	←	→	←	→	←	→	←

G-W ($\lambda = 10^{-4}$)	None	70	78.3	79.5	79.3	78.3	69.6	66.9	75.3	74.1	26.1	35.4
G-W ($\lambda = 10^{-5}$)	None	37	**81.7**	80.4	81.3	78.9	71.9	**72.8**	**78.9**	75.2	45.1	43.7

Table 1: Performance (P@1) of unsupervised and minimally-supervised methods on the dataset of Conneau et al. (2018). The time columns shows the average runtime in minutes of an instance (i.e., one language pair) of the method in this task on the same quad-core **CPU** machine.

non-convex) optimization problem.

In Figure 2 we show the training dynamics of our method when learning correspondences between word embeddings from the dataset of Conneau et al. (2018). As expected, larger values of λ lead to smoother improvements with faster runtime-per-iteration, at a price of some drop in performance. In addition, we found that computing GW distances between closer languages (such as En and Fr) leads to faster convergence than for more distant ones (such as En and Ru, in Fig. 2c).

Worth emphasizing are three desirable optimization properties that set apart the Gromov-Wasserstein distance from other unsupervised alignment approaches, particularly adversarial-training ones: (i) the objective decreases monotonically (ii) its value closely follows the true metric of interest (translation, which naturally is not available during training) and (iii) there is no risk of degradation due to *overtraining*, as is the case for adversarial-based methods trained with stochastic gradient descent (Conneau et al., 2018).

4.3 Benchmark Results

We report the results on the dataset of Conneau et al. (2018) in Table 1. The strikingly high performance of all methods on this task belies the hardness of the general problem of unsupervised cross-lingual alignment. Indeed, as pointed out by Artetxe et al. (2018), the fastText embeddings provided in this task are trained on very large and highly comparable—across languages—corpora (Wikipedia), and focuses on closely related pairs of languages. Nevertheless, we carry out experiments here to have a broad evaluation of our approach in both *easier* and *harder* settings.

Next, we present results on the more challenging dataset of (Dinu et al., 2014) in Table 2. Here, we rely on the results reported by (Artetxe et al., 2018) since by the time of writing the present work their implementation was not available yet.

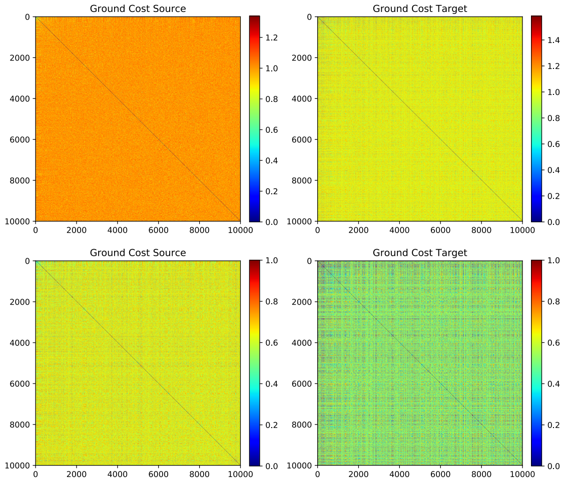

Figure 3: **Top**: Word embeddings trained on non-comparable corpora can lead to uneven distributions of pairwise distances as shown here for the En-Fi pair of (Dinu et al., 2014). **Bottom:** Normalizing the cost matrices leads to better optimization and improved performance.

Part of what makes this dataset hard is the wide discrepancy between word distance across languages, which translates into uneven distance matrices (Figure 3), and in turn leads to poor results for G-W. To account for this, previous work has relied on an initial whitening step on the embeddings. In our case, it suffices to normalize the pairwise similarity matrices to the same range to obtain substantially better results. While we have observed that careful choice of the regularization parameter λ can obviate the need for this step, we opt for the normalization approach since it allows us to optimize without having to tune λ.

We compare our method (with and without nor-

---

to a permutation matrix, which gives a hard-matching solution to the transportation problem (Peyré and Cuturi, 2018).

	En-It		En-De		En-Fi		En-Es	
	P@1	Time	P@1	Time	P@1	Time	P@1	Time
(Zhang et al., 2017a)†	0	46.6	0	46.0	0.07	44.9	0.07	43.0
(Conneau et al., 2018)†	45.40	46.1	47.27	45.4	1.62	44.4	36.20	45.3
(Artetxe et al., 2018)†	48.53	8.9	**48.47**	7.3	**33.50**	12.9	**37.60**	9.1
G-W	44.4	35.2	37.83	36.7	6.8	15.6	12.5	18.4
G-W + Normalize	**49.21**	36	46.5	33.2	18.3	42.1	**37.60**	38.2

Table 2: Results of unsupervised methods on the dataset of Dinu et al. (2014) with runtimes in minutes. Those marked with † are from (Artetxe et al., 2018). Note that their runtimes correspond to GPU computation, while ours are CPU-minutes, so the numbers are not directly comparable.

malization) against alternative approaches in Table 2. Note that we report the runtimes of Artetxe et al. (2018) as-is, which are obtained by running on a Titan XP GPU, while our runtimes are, as before, obtained purely by CPU computation.

4.4 Qualitative Results

As mentioned earlier, Theorem 3.1 implies that the optimal value of the Gromov-Wasserstein problem can be legitimately interpreted as a distance between languages, or more explicitly, between their word embedding spaces. This distributional notion of distance is completely determined by pair-wise geometric relations between these vectors. In Figure 4 we show the values $\mathrm{GW}(\mathbf{C}_s, \mathbf{C}_t, \mathbf{p}, \mathbf{q})$ computed on the fastText word embeddings of Conneau et al. (2018) corresponding to the most frequent 2000 words in each language.

Overall, these distances conform to our intuitions: the cluster of romance languages exhibits some of the shortest distances, while classical Chinese (Zh) has the overall largest discrepancy with all other languages. But somewhat surprisingly, Russian is relatively close to the romance languages in this metric. We conjecture that this could be due to Russian's rich morphology (a trait shared by romance languages but not English). Furthermore, both Russian and Spanish are pro-drop languages (Haspelmath, 2001) and share syntactic phenomena, such as dative subjects (Moore and Perlmutter, 2000; Melis et al., 2013) and differential object marking (Bossong, 1991), which might explain why Es is closest to Ru overall.

On the other hand, English appears remarkably isolated from all languages, equally distant from its germanic (De) and romance (Fr) cousins. Indeed, other aspects of the data (such as corpus size) might be underlying these observations.

	DE	EN	ES	FR	IT	RU	ZH

5 Related Work

Study of the problem of bilingual lexical induction goes back to Rapp (1995) and Fung (1995). While the literature on this topic is extensive, we focus here on recent fully-unsupervised and minimally-supervised approaches, and refer the reader to one of various existing surveys for a broader panorama (Upadhyay et al., 2016; Ruder et al., 2017).

Methods with coarse or limited parallel data. Most of these fall in one of two categories: methods that learn a mapping from one space to the other, e.g., as a least-squares objective (e.g., (Mikolov et al., 2013)) or via orthogonal transformations Zhang et al. (2016); Smith et al. (2017); Artetxe et al. (2016), and methods that find a common space on which to project both sets of embeddings (Faruqui and Dyer, 2014; Lu et al., 2015).

Fully Unsupervised methods. Conneau et al. (2018) and Zhang et al. (2017a) rely on adversarial training to produce an initial alignment between the spaces. The former use pseudo-matches derived from this initial alignment to solve a Procrustes (2) alignment problem. Our Gromov-Wasserstein framework can be thought of as providing an alternative to these adversarial training steps, albeit with a concise optimization formulation and producing explicit matches (via the optimal coupling) instead of depending on nearest neighbor search, as the adversarially-learnt mappings do.

Zhang et al. (2017b) also leverage optimal transport distances for the cross-lingual embedding task. However, to address the issue of non-alignment of embedding spaces, their approach follows the joint optimization of the transportation and procrustes problem as outlined in Section 2.2. This formulation makes an explicit modeling assumption (invariance to unitary transformations), and requires repeated solution of Procrustes problems during alternating minimization. Gromov-Wasserstein, on the other hand, is more flexible and makes no such assumption, since it directly deals with similarities rather than vectors. In the case where it is required, such an orthogonal mapping can be obtained by solving a single procrustes problem, as discussed in Section 3.2.

6 Discussion and future work

In this work we provided a direct optimization approach to cross-lingual word alignment. The Gromov-Wasserstein distance is well-suited for this task as it performs a relational comparison of word-vectors across languages rather than word-vectors directly. The resulting objective is concise, and can be optimized efficiently. The experimental results show that the resulting alignment framework is fast, stable and robust, yielding near state-of-the-art performance at a computational cost orders of magnitude lower than that of alternative fully unsupervised methods.

While directly solving Gromov-Wasserstein problems of reasonable size is feasible, scaling up to large vocabularies made it necessary to learn an explicit mapping via Procrustes. GPU computations or stochastic optimization could help avoid this secondary step.

Abstract

Deep learning has emerged as a versatile tool for a wide range of NLP tasks, due to its superior capacity in representation learning. But its applicability is limited by the reliance on annotated examples, which are difficult to produce at scale. Indirect supervision has emerged as a promising direction to address this bottleneck, either by introducing labeling functions to automatically generate noisy examples from unlabeled text, or by imposing constraints over interdependent label decisions. A plethora of methods have been proposed, each with respective strengths and limitations. Probabilistic logic offers a unifying language to represent indirect supervision, but end-to-end modeling with probabilistic logic is often infeasible due to intractable inference and learning. In this paper, we propose deep probabilistic logic (DPL) as a general framework for indirect supervision, by composing probabilistic logic with deep learning. DPL models label decisions as latent variables, represents prior knowledge on their relations using weighted first-order logical formulas, and alternates between learning a deep neural network for the end task and refining uncertain formula weights for indirect supervision, using variational EM. This framework subsumes prior indirect supervision methods as special cases, and enables novel combination via infusion of rich domain and linguistic knowledge. Experiments on biomedical machine reading demonstrate the promise of this approach.

1 Introduction
