Abstract

We present WiBi, an approach to the automatic creation of a bitaxonomy for Wikipedia, that is, an integrated taxonomy of Wikipage pages and categories. We leverage the information available in either one of the taxonomies to reinforce the creation of the other taxonomy. Our experiments show higher quality and coverage than state-of-the-art resources like DBpedia, YAGO, MENTA, WikiNet and WikiTaxonomy. WiBi is available at http://wibitaxonomy.org.

1 Introduction

Knowledge has unquestionably become a key component of current intelligent systems in many fields of Artificial Intelligence. The creation and use of machine-readable knowledge has not only entailed researchers (Mitchell, 2005; Mirkin et al., 2009; Poon et al., 2010) developing huge, broad-coverage knowledge bases (Hovy et al., 2013; Suchanek and Weikum, 2013), but it has also hit big industry players such as Google (Singhal, 2012) and IBM (Ferrucci, 2012), which are moving fast towards large-scale knowledge-oriented systems.

The creation of very large knowledge bases has been made possible by the availability of collaboratively-curated online resources such as Wikipedia and Wiktionary. These resources are increasingly becoming enriched with new content in many languages and, although they are only partially structured, they provide a great deal of valuable knowledge which can be harvested and transformed into structured form (Medelyan et al., 2009; Hovy et al., 2013). Prominent examples include DBpedia (Bizer et al., 2009), BabelNet (Navigli and Ponzetto, 2012), YAGO (Hoffart et al., 2013) and WikiNet (Nastase and Strube, 2013). The types of semantic relation in these resources range from domain-specific, as in Freebase (Bollacker et al., 2008), to unspecified relations, as in BabelNet. However, unlike the case with smaller manually-curated resources such as WordNet (Fellbaum, 1998), in many large automatically-created resources the taxonomical information is either missing, mixed across resources, e.g., linking Wikipedia categories to WordNet synsets as in YAGO, or coarse-grained, as in DBpedia whose hypernyms link to a small upper taxonomy.

Current approaches in the literature have mostly focused on the extraction of taxonomies from the network of Wikipedia categories. WikiTaxonomy (Ponzetto and Strube, 2007), the first approach of this kind, is based on the use of heuristics to determine whether is-a relations hold between a category and its subcategories. Subsequent approaches have also exploited heuristics, but have extended them to any kind of semantic relation expressed in the category names (Nastase and Strube, 2013). But while the aforementioned attempts provide structure for categories that supply meta-information for Wikipedia pages, surprisingly little attention has been paid to the acquisition of a full-fledged taxonomy for Wikipedia pages themselves. For instance, Ruiz-Casado et al. (2005) provide a general vector-based method which, however, is incapable of linking pages which do not have a WordNet counterpart. Higher coverage is provided by de Melo and Weikum (2010) thanks to the use of a set of effective heuristics, however, the approach also draws on WordNet and sense frequency information.

In this paper we address the task of taxonomizing Wikipedia in a way that is fully independent of other existing resources such as WordNet. We present WiBi, a novel approach to the creation of a Wikipedia bitaxonomy, that is, a taxonomy of Wikipedia pages aligned to a taxonomy of categories. At the core of our approach lies the idea that the information at the page and category

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 945–955,
Baltimore, Maryland, USA, June 23-25 2014.

level are mutually beneficial for inducing a wide-coverage and fine-grained integrated taxonomy.

2 WiBi: A Wikipedia Bitaxonomy

We induce a Wikipedia bitaxonomy, i.e., a taxonomy of pages and categories, in 3 phases:

1. **Creation of the initial page taxonomy:** we first create a taxonomy for the Wikipedia pages by parsing textual definitions, extracting the hypernym(s) and disambiguating them according to the page inventory.
2. **Creation of the bitaxonomy:** we leverage the hypernyms in the page taxonomy, together with their links to the corresponding categories, so as to induce a taxonomy over Wikipedia categories in an iterative way. At each iteration, the links in the page taxonomy are used to identify category hypernyms and, conversely, the new category hypernyms are used to identify more page hypernyms.
3. **Refinement of the category taxonomy:** finally we employ structural heuristics to overcome inherent problems affecting categories.

The output of our three-phase approach is a bitaxonomy of millions of pages and hundreds of thousands of categories for the English Wikipedia.

3 Phase 1: Inducing the Page Taxonomy

The goal of the first phase is to induce a taxonomy of Wikipedia pages. Let P be the set of all the pages and let $T_P = (P, E)$ be the page taxonomy directed graph whose nodes are pages and whose edge set E is initially empty ($E := \emptyset$). For each $p \in P$ our aim is to identify the most suitable generalization $p_h \in P$ so that we can create the edge (p, p_h) and add it to E. For instance, given the page APPLE, which represents the fruit meaning of *apple*, we want to determine that its hypernym is FRUIT and add the hypernym edge connecting the two pages (i.e., $E := E \cup \{(\text{APPLE}, \text{FRUIT})\}$). To do this, we perform a syntactic step, in which the hypernyms are extracted from the page's textual definition, and a semantic step, in which the extracted hypernyms are disambiguated according to the Wikipedia inventory.

3.1 Syntactic step: hypernym extraction

In the syntactic step, for each page $p \in P$, we extract zero, one or more hypernym lemmas, that is, we output potentially ambiguous hypernyms for the page. The first assumption, which follows

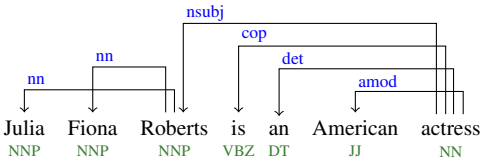

Figure 1: A dependency tree example with copula.

the Wikipedia guidelines and is validated in the literature (Navigli and Velardi, 2010; Navigli and Ponzetto, 2012), is that the first sentence of each Wikipedia page p provides a textual definition for the concept represented by p. The second assumption we build upon is the idea that a lexical taxonomy can be obtained by extracting hypernyms from textual definitions. This idea dates back to the early 1970s (Calzolari et al., 1973), with later developments in the 1980s (Amsler, 1981; Calzolari, 1982) and the 1990s (Ide and Véronis, 1993).

To extract hypernym lemmas, we draw on the notion of copula, that is, the relation between the complement of a copular verb and the copular verb itself. Therefore, we apply the Stanford parser (Klein and Manning, 2003) to the definition of a page in order to extract all the dependency relations of the sentence. For example, given the definition of the page JULIA ROBERTS, i.e., "Julia Fiona Roberts is an American actress.", the Stanford parser outputs the set of dependencies shown in Figure 1. The noun involved in the copula relation is *actress* and thus it is taken as the page's hypernym lemma. However, the extracted hypernym is sometimes overgeneral (*one*, *kind*, *type*, etc.). For instance, given the definition of the page APOLLO, "Apollo is one of the most important and complex of the Olympian deities in ancient Greek and Roman religion [...].", the only copula relation extracted is between *is* and *one*. To cope with this problem we use a list of stopwords.[1]When such a term is extracted as hypernym, we replace it with the rightmost noun of the first following noun sequence (e.g., *deity* in the above example). If the resulting lemma is again a stopword we repeat the procedure, until a valid hypernym or no appropriate hypernym can be found. Finally, to capture multiple hypernyms, we iteratively follow the *conj_and* and *conj_or* relations starting from the initially extracted hypernym. For example, consider the definition of ARISTOTLE: "Aristotle was a Greek philosopher and polymath, a student of Plato and teacher of Alexander the Great." Initially, the *philosopher* hypernym is selected thanks to the copula relation, then, fol-

[1]E.g., *species*, *genus*, *one*, etc. Full list available online.

lowing the conjunction relations, also *polymath*, *student* and *teacher* are extracted as hypernyms. While more sophisticated approaches like Word-Class Lattices could be applied (Navigli and Velardi, 2010), we found that, in practice, our hypernym extraction approach provides higher coverage, which is critical in our case.

3.2 Semantic step: hypernym disambiguation

Since our aim is to connect pairs of pages via hypernym relations, our second step consists of disambiguating the obtained hypernym lemmas of page p by associating the most suitable page with each hypernym. Following previous work (Ruiz-Casado et al., 2005; Navigli and Ponzetto, 2012), as the inventory for a given lemma we consider the set of pages whose main title is the lemma itself, except for the sense specification in parenthesis. For instance, given *fruit* as the hypernym for APPLE we would like to link APPLE to FRUIT as opposed to, e.g., FRUIT (BAND) or FRUIT (ALBUM).

3.2.1 Hypernym linkers

To disambiguate hypernym lemmas, we exploit the structural features of Wikipedia through a pipeline of hypernym linkers $\mathcal{L} = \{L_i\}$, applied in cascade order (cf. Section 3.3.1). We start with the set of page-hypernym pairs $H = \{(p, h)\}$ as obtained from the syntactic step. The successful application of a linker to a pair $(p, h) \in H$ yields a page p_h as the most suitable sense of h, resulting in setting $isa(p, h) = p_h$. At step i, the i-th linker $L_i \in \mathcal{L}$ is applied to H and all the hypernyms which the linker could disambiguate are removed from H. This prevents lower-precision linkers from overriding decisions taken by more accurate ones.

We now describe the hypernym linkers. In what follows we denote with $p \xrightarrow{h} p_h$ the fact that the definition of a Wikipedia page p contains an occurrence of h linked to page p_h. Note that p_h is not necessarily a sense of h.

Crowdsourced linker If $p \xrightarrow{h} p_h$, i.e., the hypernym h is found to have been manually linked to p_h in p by Wikipedians, we assign $isa(p, h) = p_h$. For example, because *capital* was linked in the BRUSSELS page definition to CAPITAL CITY, we set isa(BRUSSELS, *capital*) = CAPITAL CITY.

Category linker Given the set $W \subset P$ of Wikipedia pages which have at least one category in common with p, we select the majority sense of h, if there is one, as hyperlinked across all the definitions of pages in W:

$$isa(p, h) = \arg\max_{p_h} \sum_{p' \in W} 1(p' \xrightarrow{h} p_h)$$

where $1(p' \xrightarrow{h} p_h)$ is the characteristic function which equals 1 if h is linked to p_h in page p', 0 otherwise. For example, the linker sets isa(EGGPLANT, *plant*) = PLANT because most of the pages associated with TROPICAL FRUIT, a category of EGGPLANT, contain in their definitions the term *plant* linked to the PLANT page.

Multiword linker If $p \xrightarrow{m} p_h$ and m is a multiword expression containing the lemma h as one of its words, set $isa(p, h) = p_h$. For example, we set isa(PROTEIN, *compound*) = CHEMICAL COMPOUND, as *chemical compound* is linked to CHEMICAL COMPOUND in the definition of PROTEIN.

Monosemous linker If h is monosemous in Wikipedia (i.e., there is only a single page p_h for that lemma), link it to its only sense by setting $isa(p, h) = p_h$. For example, we extract the hypernym *businessperson* from the definition of MERCHANT and, as it is unambiguous, we link it to BUSINESSPERSON.

Distributional linker Finally, we provide a distributional approach to hypernym disambiguation. We represent the textual definition of page p as a distributional vector $\vec{v}_p$ whose components are all the English lemmas in Wikipedia. The value of each component is the occurrence count of the corresponding content word in the definition of p.

The goal of this approach is to find the best link for hypernym h of p among the pages h is linked to, across the whole set of definitions in Wikipedia. Formally, for each p_h such that h is linked to p_h in some definition, we define the set of pages $P(p_h)$ whose definitions contain a link to p_h, i.e., $P(p_h) = \{p' \in P | p' \xrightarrow{h} p_h\}$. We then build a distributional vector $\vec{v}_{p'}$ for each $p' \in P(p_h)$ as explained above and create an aggregate vector $\vec{v}_{p_h} = \sum_{p'} \vec{v}_{p'}$. Finally, we determine the similarity of p to each p_h by calculating the dot product between the two vectors $sim(p, p_h) = \vec{v}_p \cdot \vec{v}_{p_h}$. If $sim(p, p_h) > 0$ for any p_h we perform the following association:

$$isa(p, h) = \arg\max_{p_h} sim(p, p_h)$$

For example, thanks to this linker we set isa(VACUUM CLEANER, *device*) = MACHINE.

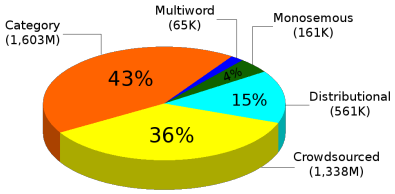

Figure 2: Distribution of linked hypernyms.

3.3 Page Taxonomy Evaluation

Statistics We applied the above linkers to the October 2012 English Wikipedia dump. Out of the 3,829,058 total pages, 4,270,232 hypernym lemmas were extracted in the syntactic step for 3,697,113 pages (covering more than 96% of the total). Due to illformed definitions, though, it was not always possible to extract the hypernym lemma: for example, 6 APRIL 2010 BAGHDAD BOMBINGS is defined as "A series of bomb explosions destroyed several buildings in Baghdad", which only implicitly provides the hypernym.

The semantic step disambiguated 3,718,612 hypernyms for 3,294,562 Wikipedia pages, i.e., covering more than 86% of the English pages with at least one disambiguated hypernym. Figure 2 plots the number and distribution of hypernyms disambiguated by our hypernym linkers.

Taxonomy quality To evaluate the quality of our page taxonomy we randomly sampled 1,000 Wikipedia pages. For each page we provided: i) a list of suitable hypernym lemmas for the page, mainly selected from its definition; ii) for each lemma the correct hypernym page(s). We calculated precision as the average ratio of correct hypernym lemmas (senses) to the total number of lemmas (senses) returned for all the pages in the dataset, recall as the number of correct lemmas (senses) over the total number of lemmas (senses) in the dataset, and coverage as the fraction of pages for which at least one lemma (sense) was returned, independently of its correctness. Results, both at lemma- and sense-level, are reported in Table 1. Not only does our taxonomy show high precision and recall in extracting ambiguous hypernyms, it also disambiguates more than 3/4 of the hypernyms with high precision.

3.3.1 Hypernym linker order

The optimal order of application of the above linkers is the same as that presented in Section 3.2.1. It was established by selecting the combination, among all possible permutations, which maximized precision on a tuning set of 100 randomly sampled pages, disjoint from our page dataset.

	Prec.	Rec.	Cov.
Lemma	94.83	90.20	98.50
Sense	82.77	75.10	89.20

Table 1: Page taxonomy performance.

4 Phase 2: Inducing the Bitaxonomy

The page taxonomy built in Section 3 will serve as a stable, pivotal input to the second phase, the aim of which is to build our bitaxonomy, that is, a taxonomy of pages and categories. Our key idea is that the generalization-specialization information available in each of the two taxonomies is mutually beneficial. We implement this idea by exploiting one taxonomy to update the other, and vice versa, in an iterative way, until a fixed point is reached. The final output of this phase is, on the one hand, a page taxonomy augmented with additional hypernymy relations and, on the other hand, a category taxonomy which is built from scratch.

4.1 Initialization

Our bitaxonomy $B = \{T_P, T_C\}$ is a pair consisting of the page taxonomy $T_P = (P, E)$, as obtained in Section 3, and the category taxonomy $T_C = (C, \emptyset)$, which initially contains all the categories as nodes but does not include any hypernym edge between category nodes. In the following we describe the core algorithm of our approach, which iteratively and mutually populates and refines the edge sets $E(T_P)$ and $E(T_C)$.

4.2 The Bitaxonomy Algorithm

Preliminaries Before proceeding, we define some basic concepts that will turn out to be useful for presenting our algorithm. We denote by $super_T(t)$ the set of all ancestors of a node t in the taxonomy T (be it T_P or T_C). We further define a verification function $t \rightsquigarrow_T t'$ which, in the case of T_C, returns true if there is a path in the Wikipedia category network between t and t', false otherwise, and, in the case of T_P, returns true if t' is a sense, i.e., a page, of a hypernym h of t (that is, $(t, h) \in H$, cf. Section 3.2.1). For instance, SPORTSMEN $\rightsquigarrow_{T_C}$ MEN BY OCCUPATION holds for categories because the former is a sub-category of the latter in Wikipedia, and RADIOHEAD $\rightsquigarrow_{T_P}$ BAND (MUSIC) for pages, because *band* is a hypernym extracted from the textual definition of RADIOHEAD and BAND (MUSIC) is a sense of *band* in Wikipedia. Note that, while the *super* function returns information that we have already learned, i.e., it is in T_P and T_C, the $\rightsquigarrow$ operator

holds just for candidate is-a relations, as it uses knowledge from Wikipedia itself which is potentially incorrect. For instance, SPORTSMEN $\rightsquigarrow_{T_C}$ MEN'S SPORTS in the Wikipedia category network, and RADIOHEAD $\rightsquigarrow_{T_P}$ BAND (RADIO) between the two Wikipedia pages, both hold according to our definition of $\rightsquigarrow$, while connecting the wrong hypernym candidates. At the core of our algorithm, explained below, is the mutual leveraging of the *super* function from one of the two taxonomies (pages or categories) to decide about which candidates (for which a $\rightsquigarrow$ relation holds) in the other taxonomy are real hypernyms.

Finally, we define the projection operator π, such that $\pi(c)$, $c \in C$, is the set of pages categorized with c, and $\pi(p)$, $p \in P$, is the set of categories associated with page p in Wikipedia. For instance, the pages which belong to the category OLYMPIC SPORTS are given by π(OLYMPIC SPORTS) = {BASEBALL, BOXING, ..., TRIATHLON}. Vice versa, π(TRIATHLON) = {MULTISPORTS, OLYMPIC SPORTS, ..., OPEN WATER SWIMMING}. The projection operator π enables us to jump from one taxonomy to the other and expresses the mutual membership relation between pages and categories.

Algorithm We now describe in detail the bitaxonomy algorithm, whose pseudocode is given in Algorithm 1. The algorithm takes as input the two taxonomies, initialized as described in Section 4.1. Starting from the category taxonomy (line 1), the algorithm updates the two taxonomies in turn, until convergence is reached, i.e., no more edges can be added to any side of the bitaxonomy. Let T be the current taxonomy considered at a given moment and T' its dual taxonomy. The algorithm proceeds by selecting a node $t \in V(T)$ for which no hypernym edge (t, t_h) could be found up until that moment (line 3), and then tries to infer such a relation by drawing on the dual taxonomy T' (lines 5-12). This is the core of the bitaxonomy algorithm, in which hypernymy knowledge is transferred from one taxonomy to the other. By applying the projection operator π to t, the algorithm considers those nodes t' aligned to t in the dual taxonomy (line 5) and obtains their hypernyms t'_h using the $super_{T'}$ function (line 6). The nodes reached in T' act as a clue for discovering the suitable hypernyms for the starting node $t \in V(T)$. To perform the discovery, the algorithm projects each such hypernym node $t'_h \in S$ and increments the count of each projection $t_h \in \pi(t'_h)$ (line 8). Finally, the node $\hat{t}_h \in V(T)$ with maximum count, and such that $t \rightsquigarrow_T \hat{t}_h$ holds, if one exists, is promoted as hypernym of t and a new hypernym edge $(t, \hat{t}_h)$ is added to $E(T)$ (line 12). Finally, the role of the two taxonomies is swapped and the process is repeated until no more change is possible.

Algorithm 1 The Bitaxonomy Algorithm

Input: T_P, T_C
1: $T := T_C, T' := T_P$
2: **repeat**
3: **for all** $t \in V(T)$ s.t. $\nexists(t, t_h) \in E(T)$ **do**
4: **reset** *count*
5: **for all** $t' \in \pi(t)$ **do**
6: $S := super_{T'}(t')$
7: **for all** $t'_h \in S$ **do**
8: **for all** $t_h \in \pi(t'_h)$ **do** $count(t_h)$++ **end for**
9: **end for**
10: **end for**
11: $\hat{t}_h := \arg\max_{t_h:\, t \rightsquigarrow_T t_h} count(t_h)$
12: **if** $count(\hat{t}_h) > 0$ **then** $E(T) := E(T) \cup \{(t, \hat{t}_h)\}$
13: **end for**
14: **swap** T and T'
15: **until** convergence
16: **return** $\{T, T'\}$

Example Let us illustrate the algorithm by way of an example. Assume we are in the first iteration ($T = T_C$) and consider the Wikipedia category t = OLYMPICS (line 3) and its super-categories {MULTI-SPORT EVENTS, SPORT AND POLITICS, INTERNATIONAL SPORTS COMPETITIONS}. This category has 27 pages associated with it (line 5), 23 of which provide a hypernym page in T_P (line 6): e.g., PARALYMPIC GAMES, associated with the category OLYMPICS, is a MULTI-SPORT EVENT and is therefore contained in S. By considering and counting the categories of each page in S (lines 7-8), we end up counting the category MULTI-SPORT EVENTS four times and other categories, such as AWARDS and SWIMSUITS, once. As MULTI-SPORT EVENTS has the highest count and is connected to OLYMPICS by a path in the Wikipedia category network (line 11), the hypernym edge (OLYMPICS, MULTI-SPORT EVENTS) is added to T_C (line 12).

5 Phase 3: Category taxonomy refinement

As the final phase, we refine and enrich the category taxonomy. The goal of this phase is to provide broader coverage to the category taxonomy T_C created as explained in Section 4. We apply three enrichment heuristics which add hypernyms to those categories c for which no hypernym could be found in phase 2, i.e., $\nexists c'$ s.t. $(c, c') \in E(T_C)$.

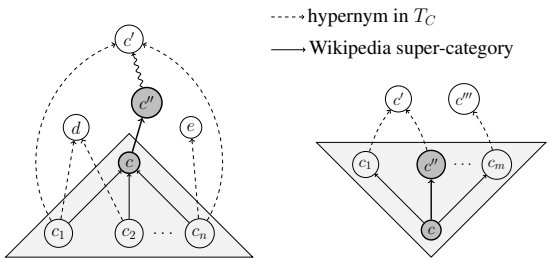
Single super-category As a first structural refinement, we automatically link an uncovered category c to c' if c' is the only direct super-category of c in Wikipedia.

Sub-categories We increase the hypernym coverage by exploiting the sub-categories of each uncovered category c (see Figure 3a). In detail, for each uncovered category c we consider the set $sub(c)$ of all the Wikipedia subcategories of c (nodes $c_1, c_2, \ldots, c_n$ in Figure 3a) and then let each category vote, according to its direct hypernym categories in T_C (the vote is as in Algorithm 1). Then we proceed in decreasing order of vote and select the highest-ranking category c' which is connected to c via a path in T_C, i.e., $c \rightsquigarrow_{T_C} c'$. We then pick up the direct ancestor c'' of c which lies in the path from c to c' and add the hypernym edge (c, c'') to $E(T_C)$. For example, consider the category FRENCH TELEVISION PEOPLE; since this category has no associated pages, in phase 2 no hypernym could be found. However, by applying the sub-categories heuristic, we discover that TELEVISION PEOPLE BY COUNTRY is the hypernym most voted by our target category's descendants, such as FRENCH TELEVISION ACTORS and FRENCH TELEVISION DIRECTORS. Since TELEVISION PEOPLE BY COUNTRY is at distance 1 in the Wikipedia category network from FRENCH TELEVISION PEOPLE, we add (FRENCH TELEVISION PEOPLE, TELEVISION PEOPLE BY COUNTRY) to $E(T_C)$.

Super-categories We then apply a similar heuristic involving super-categories (see Figure 3b). Given an uncovered category c, we consider its direct Wikipedia super-categories and let them vote, according to their hypernym categories in T_C. Then we proceed in decreasing order of vote and select the highest-ranking category c' which is connected to c in T_C, i.e., $c \rightsquigarrow_{T_C} c'$. We then pick up the direct ancestor c'' of c which lies in the path from c to c' and add the edge (c, c'') to $E(T_C)$.

5.1 Bitaxonomy Evaluation

Category taxonomy statistics We applied phases 2 and 3 to the output of phase 1, which was evaluated in Section 3.3. In Figure 4a we show the increase in category coverage at each iteration throughout the execution of the two phases (1SUP, SUB and SUPER correspond to the three above heuristics of phase 3). The final outcome is a category taxonomy which includes 594,917 hypernymy links between categories,



(a) Sub categ. heuristic. (b) Super categ. heuristic.

Figure 3: Heuristic patterns for the coverage refinement of the category taxonomy.

covering more than 96% of the 618,641 categories in the October 2012 English Wikipedia dump. The graph shows the steepest slope in the first iterations of phase 2, which converges around 400k categories at iteration 30, and a significant boost due to phase 3 producing another 175k hypernymy edges, with the super-category heuristic contributing most. 78.90% of the nodes in T_C belong to the same connected component. The average height of the biggest component of T_C is 23.26 edges and the maximum height is 49. We note that the average height of T_C is much greater than that of T_P, which reflects the category taxonomy distinguishing between very subtle classes, such as ALBUMS BY ARTISTS, ALBUMS BY RECORDING LOCATION, etc.

Category taxonomy quality To estimate the quality of the category taxonomy, we randomly sampled 1,000 categories and, for each of them, we manually associated the super-categories which were deemed to be appropriate hypernyms. Figure 4b shows the performance trend as the algorithm iteratively covers more and more categories. Phase 2 is particularly robust across iterations, as it leads to increased recall while retaining very high precision. As regards phase 3, the super-categories heuristic leads to only a slight precision decrease, while improving recall considerably. Overall, the final taxonomy T_C achieves 85.80% precision, 83.40% recall and 97.20% coverage on our dataset.

Page taxonomy improvement As a result of phase 2, 141,105 additional hypernymy links were also added to the page taxonomy, resulting in an overall 82.99% precision, 77.90% recall and 92.10% coverage, with a non-negligible 3% boost from phase 1 to phase 2 in terms of recall and coverage on our Wikipedia page dataset.

We also calculated some statistics for the resulting taxonomy obtained by aggregating the 3.8M

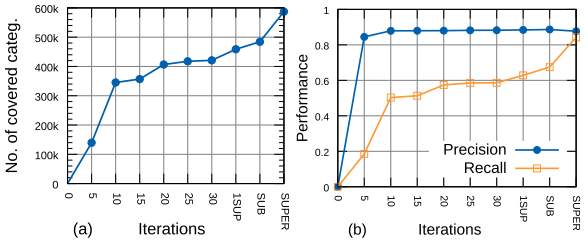


Figure 4: Category taxonomy evaluation.

hypernym links in a single directed graph. Overall, 99% of nodes belong to the same connected component, with a maximum height of 29 and an average height on the biggest component of 6.98.

6 Related Work

Although the extraction of taxonomies from machine-readable dictionaries was already being studied in the early 1970s (Calzolari et al., 1973), pioneering work on large amounts of data only appeared in the 1990s (Hearst, 1992; Ide and Véronis, 1993). Approaches based on handcrafted patterns and pattern matching techniques have been developed to provide a supertype for the extracted terms (Etzioni et al., 2004; Blohm, 2007; Kozareva and Hovy, 2010; Navigli and Velardi, 2010; Velardi et al., 2013, inter alia). However, these methods do not link terms to existing knowledge resources such as WordNet, whereas those that explicitly link do so by adding new leaves to the existing taxonomy instead of acquiring wide-coverage taxonomies from scratch (Pantel and Ravichandran, 2004; Snow et al., 2006).

The recent upsurge of interest in collaborative knowledge curation has enabled several approaches to large-scale taxonomy acquisition (Hovy et al., 2013). Most approaches initially focused on the Wikipedia category network, an entangled set of generalization-containment relations between Wikipedia categories, to extract the hypernymy taxonomy as a subset of the network. The first approach of this kind was WikiTaxonomy (Ponzetto and Strube, 2007; Ponzetto and Strube, 2011), based on simple, yet effective lightweight heuristics, totaling more than 100k is-a relations. Other approaches, such as YAGO (Suchanek et al., 2008; Hoffart et al., 2013), yield a taxonomical backbone by linking Wikipedia categories to WordNet. However, the categories are linked to the first, i.e., most frequent, sense of the category head in WordNet, involving only leaf categories in the linking.

Interest in taxonomizing Wikipedia pages, instead, developed with DBpedia (Auer et al., 2007), which pioneered the current stream of work aimed at extracting semi-structured information from Wikipedia templates and infoboxes. In DBpedia, entities are mapped to a coarse-grained ontology which is collaboratively maintained and contains only about 270 classes corresponding to popular named entity types, in contrast to our goal of structuring the full set of Wikipedia articles in a larger and finer-grained taxonomy.

A few notable efforts to reconcile the two sides of Wikipedia, i.e., pages and categories, have been put forward very recently: WikiNet (Nastase et al., 2010; Nastase and Strube, 2013) is a project which heuristically exploits different aspects of Wikipedia to obtain a multilingual concept network by deriving not only is-a relations, but also other types of relations. A second project, MENTA (de Melo and Weikum, 2010), creates one of the largest multilingual lexical knowledge bases by interconnecting more than 13M articles in 271 languages. In contrast to our work, hypernym extraction is supervised in that decisions are made on the basis of labelled training examples and requires a reconciliation step owing to the heterogeneous nature of the hypernyms, something that we only do for categories, due to their noisy network. While WikiNet and MENTA bring together the knowledge available both at the page and category level, like we do, they either achieve low precision and coverage of the taxonomical structure or exhibit overly general hypernyms, as we show in our experiments in the next section.

Our work differs from the others in at least three respects: first, in marked contrast to most other resources, but similarly to WikiNet and WikiTaxonomy, our resource is self-contained and does not depend on other resources such as WordNet; second, we address the taxonomization task on both sides, i.e., pages and categories, by providing an algorithm which mutually and iteratively transfers knowledge from one side of the bitaxonomy to the other; third, we provide a wide coverage bitaxonomy closer in structure and granularity to a manual WordNet-like taxonomy, in contrast, for example, to DBpedia's flat entity-focused hierarchy.[2]

[2]Note that all the competitors on categories have average height between 1 and 3.69 on their biggest component, while we have 23.26, while on pages their height is between 1.9 and 4.22, while ours is 6.98. Since WordNet's average height is 8.07 we deem WiBi to be the resource structurally closest to WordNet.

Dataset	System	Prec.	Rec.	Cov.

7 Comparative Evaluation

7.1 Experimental Setup

We compared our resource (WiBi) against the Wikipedia taxonomies of the major knowledge resources in the literature providing hypernym links, namely DBpedia, WikiNet, MENTA, WikiTaxonomy and YAGO (see Section 6). As datasets, we used our gold standards of 1,000 randomly-sampled pages (see Section 3.3) and categories (see Section 5.1). In order to ensure a level playing field, we detected those pages (categories) which do not exist in any of the above resources and removed them to ensure full coverage of the dataset across all resources. For each resource we calculated precision, by manually marking each hypernym returned for each page (category) as correct or not. As regards recall, we note that in two cases (i.e., DBpedia returning page supertypes from its upper taxonomy, YAGO linking categories to WordNet synsets) the generalizations are neither pages nor categories and that MENTA returns heterogeneous hypernyms as mixed sets of WordNet synsets, Wikipedia pages and categories. Given this heterogeneity, standard recall across resources could not be calculated. For this reason we calculated recall as described in Section 3.3.

7.2 Results

Wikipedia pages We first report the results of the knowledge resources which provide page hypernyms, i.e., we compare against WikiNet, DBpedia and MENTA. We use the original outputs from the three resources: the first two are based on dumps which are from the same year as the one used in WiBi (cf. Section 3.3), while MENTA is based on a dump dating back to 2010 (consisting of 3.25M pages and 565k categories). We decided to include the latter for comparison purposes, as it uses knowledge from 271 Wikipedias to build the final taxonomy. However, we recognize its performance might be relatively higher on a 2012 dump.

We show the results on our page hypernym dataset in Table 2 (top). As can be seen, WikiNet obtains the lowest precision, due to the high number of hypernyms provided, many of which are incorrect, with a recall between that of DBpedia and MENTA. WiBi outperforms all other resources with 84.11% precision, 79.40% recall and 92.57% coverage. MENTA seems to be the closest resource to ours, however, we remark that the hypernyms output by MENTA are very heterogeneous: 48% of answers are represented by a WordNet synset, 37% by Wikipedia categories and 15% are Wikipedia pages. In contrast to all other resources, WiBi outputs page hypernyms only.

Wikipedia categories We then compared all the knowledge resources which deal with categories, i.e., WikiTaxonomy, YAGO and MENTA. For the latter two, the above considerations about the 2012 dump hold, whereas we reimplemented WikiTaxonomy, which was based on a 2009 dump, to run it on the same dump as WiBi. We excluded WikiNet from our comparison because it turned out to have low coverage of categories (i.e., less than 1%).

We show the results on our category dataset in Table 2 (bottom). Despite other systems exhibiting higher precision, WiBi generally achieves higher recall, thanks also to its higher category coverage. YAGO obtains the lowest recall and coverage, because only leaf categories are considered. MENTA is the closest system to ours, obtaining slightly higher precision and recall. Notably, however, MENTA outputs the first WordNet sense of *entity* for 13.17% of all the given answers, which, despite being correct and accounted in precision and recall, is uninformative. Since a system which always outputs *entity* would maximise all the three measures, we also calculated the performance for MENTA when discarding *entity* as an answer; as Table 2 shows (bottom, MENTA$^{-\text{ENT}}$), recall drops to 71.95%. Further analysis, presented below, shows that the specificity of its hypernyms is considerably lower than that of WiBi.

7.3 Analysis of the results

To get further insight into our results we performed two additional analyses of the data. First, we estimated the level of specialization of the hypernyms in the different resources on our two datasets. The idea is that a hypernym should be

Dataset	System (X)	WiBi=X	WiBi>X	WiBi<X
Pages	WikiNet	33.38	34.94	31.68
	DBpedia	31.68	56.71	11.60
	MENTA	19.04	50.85	30.12
Categories	WikiTax	43.11	38.51	18.38
	YAGO	12.36	81.14	6.50
	MENTA	12.36	73.69	13.95

Table 3: Specificity comparison.

valid while at the same time being as specific as possible (e.g., SINGER should be preferred over PERSON). We therefore calculated a measure, which we called specificity, that computes the percentage of times a system outputs a more specific answer than another system. To do this, we annotated each hypernym returned by a system as follows: -1 if the answer was wrong, 0 if missing, $>$ 0 if correct; more specific answers were assigned higher scores. When comparing two systems, we select the respective most specific answers a_1, a_2 and say the first system is more specific than the latter whenever $score(a_1) > score(a_2)$. Table 3 shows the results for all the resources and for both the page and category taxonomies: WiBi consistently provides considerably more specific hypernyms than any other resource (middle column).

A second important aspect that we analyzed was the granularity of each taxonomy, determined by drawing each resource on a bidimensional plane with the number of distinct hypernyms on the x axis and the total number of hypernyms (i.e., edges) in the taxonomy on the y axis. Figures 5a and 5b show the position of each resource for the page and the category taxonomies, respectively. As can be seen, WiBi, as well as the page taxonomy of MENTA, is the resource with the best granularity, as not only does it attain high coverage, but it also provides a larger variety of classes as generalizations of pages and categories. Specifically, WiBi provides over 3M hypernym pages chosen from a range of 94k distinct hypernyms, while others exhibit a considerably smaller range of distinct hypernyms (e.g., DBpedia by design, but also WikiNet, with around 11k distinct page hypernyms). The large variety of classes provided by MENTA, however, is due to including more than 100k Wikipedia categories (among which, categories about *deaths* and *births* alone represent about 2% of the distinct hypernyms). As regards categories, while the number of distinct hypernyms of WiBi and WikiTaxonomy is approximately the same (around 130k), the total number of hypernyms (around 580k for both taxonomies) is distributed over half of the categories in WikiTaxonomy compared to WiBi, resulting in a double number of hypernyms per category, but lower coverage (cf. Table 2).

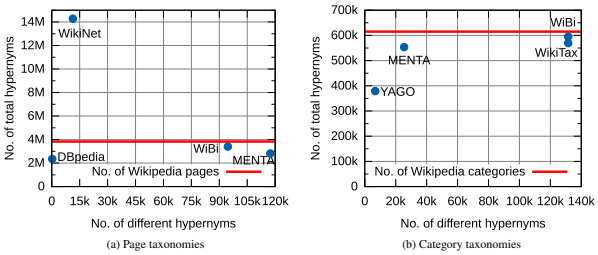

Figure 5: Hypernym granularity for the resources.

8 Conclusions

In this paper we have presented WiBi, an automatic 3-phase approach to the construction of a bitaxonomy for the English Wikipedia, i.e., a full-fledged, integrated page and category taxonomy: first, using a set of high-precision linkers, the page taxonomy is populated; next, a fixed point algorithm populates the category taxonomy while enriching the page taxonomy iteratively; finally, the category taxonomy undergoes structural refinements. Coverage, quality and granularity of the bitaxonomy are considerably higher than the taxonomy of state-of-the-art resources like DBpedia, YAGO, MENTA, WikiNet and WikiTaxonomy.

Our contributions are three-fold: i) we propose a unified, effective approach to the construction of a Wikipedia bitaxonomy, a richer structure than those produced in the literature; ii) our method for building the bitaxonomy is self-contained, thanks to its independence from external resources (like WordNet) and the virtual absence of supervision, making WiBi replicable on any new version of Wikipedia; iii) the taxonomy provides nearly full coverage of pages and categories, encompassing the entire encyclopedic knowledge in Wikipedia.

We will apply our video games with a purpose (Vannella et al., 2014) to validate WiBi. We also plan to integrate WiBi into BabelNet (Navigli and Ponzetto, 2012), so as to fully taxonomize it, and exploit its high quality for improving semantic predicates (Flati and Navigli, 2013).

Information Extraction over Structured Data: Question Answering with Freebase

Xuchen Yao [1] and **Benjamin Van Durme** [1,2]
[1]Center for Language and Speech Processing
[2]Human Language Technology Center of Excellence
Johns Hopkins University
Baltimore, MD, USA

Abstract

Answering natural language questions using the Freebase knowledge base has recently been explored as a platform for advancing the state of the art in open domain semantic parsing. Those efforts map questions to sophisticated meaning representations that are then attempted to be matched against viable answer candidates in the knowledge base. Here we show that relatively modest information extraction techniques, when paired with a web-scale corpus, can outperform these sophisticated approaches by roughly 34% relative gain.

1 Introduction

Question answering (QA) from a knowledge base (KB) has a long history within natural language processing, going back to the 1960s and 1970s, with systems such as `Baseball` (Green Jr et al., 1961) and `Lunar` (Woods, 1977). These systems were limited to closed-domains due to a lack of knowledge resources, computing power, and ability to robustly understand natural language. With the recent growth in KBs such as `DBPedia` (Auer et al., 2007), `Freebase` (Bollacker et al., 2008) and `Yago2` (Hoffart et al., 2011), it has become more practical to consider answering questions across wider domains, with commercial systems including `Google Now`, based on Google's `Knowledge Graph`, and `Facebook Graph Search`, based on social network connections.

The AI community has tended to approach this problem with a focus on first understanding the intent of the question, via shallow or deep forms of semantic parsing (c.f. §3 for a discussion). Typically questions are converted into some meaning representation (e.g., the lambda calculus), then mapped to database queries. Performance is thus bounded by the accuracy of the original semantic parsing, and the well-formedness of resultant database queries.[1]

The Information Extraction (IE) community approaches QA differently: first performing relatively coarse information retrieval as a way to triage the set of possible answer candidates, and only then attempting to perform deeper analysis.

Researchers in semantic parsing have recently explored QA over Freebase as a way of moving beyond closed domains such as GeoQuery (Tang and Mooney, 2001). While making semantic parsing more robust is a laudable goal, here we provide a more rigorous IE baseline against which those efforts should be compared: we show that "traditional" IE methodology can significantly outperform prior state-of-the-art as reported in the semantic parsing literature, with a relative gain of 34% F_1 as compared to Berant et al. (2013).

2 Approach

We will view a KB as an interlinked collection of "topics". When given a question about one or several topics, we can select a "view" of the KB concerning only involved topics, then inspect every related node within a few hops of relations to the topic node in order to extract the answer. We call such a view a *topic graph* and assume answers can be found within the graph. We aim to maximally automate the answer extraction process, by massively combining discriminative features for both the question and the topic graph. With a high performance learner we have found that a system with millions of features can be trained within hours, leading to intuitive, human interpretable features. For example, we learn that given a question concerning money, such as: what money is used in

[1]As an example, 50% of errors of the CCG-backed (Kwiatkowski et al., 2013) system were contributed by parsing or structural matching failure.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 956–966,
Baltimore, Maryland, USA, June 23-25 2014.

ukraine, the expected answer type is likely currency. We formalize this approach in §4.

One challenge for natural language querying against a KB is the relative informality of queries as compared to the grammar of a KB. For example, for the question: who cheated on celebrity A, answers can be retrieved via the Freebase relation celebrity.infidelity.participant, but the connection between the phrase cheated on and the formal KB relation is not explicit. To alleviate this problem, the best attempt so far is to map from ReVerb (Fader et al., 2011) predicate-argument triples to Freebase relation triples (Cai and Yates, 2013; Berant et al., 2013). Note that to boost precision, ReVerb has already pruned down less frequent or credible triples, yielding not as much coverage as its text source, ClueWeb. Here we instead directly mine relation mappings from ClueWeb and show that both direct relation mapping precision and indirect QA F_1 improve by a large margin. Details in §5.

Finally, we tested our system, jacana-freebase,[2] on a realistic dataset generously contributed by Berant et al. (2013), who collected thousands of commonly asked questions by crawling the Google Suggest service. Our method achieves state-of-the-art performance with F_1 at 42.0%, a 34% relative increase from the previous F_1 of 31.4%.

3 Background

QA from a KB faces two prominent challenges: model and data. The model challenge involves finding the best meaning representation for the question, converting it into a query and executing the query on the KB. Most work approaches this via the bridge of various intermediate representations, including combinatory categorial grammar (Zettlemoyer and Collins, 2005, 2007, 2009; Kwiatkowski et al., 2010, 2011, 2013), synchronous context-free grammars (Wong and Mooney, 2007), dependency trees (Liang et al., 2011; Berant et al., 2013), string kernels (Kate and Mooney, 2006; Chen and Mooney, 2011), and tree transducers (Jones et al., 2012). These works successfully showed their effectiveness in QA, despite the fact that most of them require hand-labeled logic annotations. More recent research started to minimize this direct supervision by using latent meaning representations (Berant et al., 2013; Kwiatkowski et al., 2013) or distant supervision (Krishnamurthy and Mitchell, 2012).

We instead attack the problem of QA from a KB from an IE perspective: we learn directly the pattern of QA pairs, represented by the dependency parse of questions and the Freebase structure of answer candidates, without the use of intermediate, general purpose meaning representations.

The data challenge is more formally framed as ontology or (textual) schema matching (Hobbs, 1985; Rahm and Bernstein, 2001; Euzenat and Shvaiko, 2007): matching structure of two ontologies/databases or (in extension) mapping between KB relations and NL text. In terms of the latter, Cai and Yates (2013) and Berant et al. (2013) applied pattern matching and relation intersection between Freebase relations and predicate-argument triples from the ReVerb OpenIE system (Fader et al., 2011). Kwiatkowski et al. (2013) expanded their CCG lexicon with Wiktionary word tags towards more domain independence. Fader et al. (2013) learned question paraphrases from aligning multiple questions with the same answers generated by WikiAnswers. The key factor to their success is to have a huge text source. Our work pushes the data challenge to the limit by mining directly from ClueWeb, a 5TB collection of web data.

Finally, the KB community has developed other means for QA without semantic parsing (Lopez et al., 2005; Frank et al., 2007; Unger et al., 2012; Yahya et al., 2012; Shekarpour et al., 2013). Most of these work executed SPARQL queries on interlinked data represented by RDF (Resource Description Framework) triples, or simply performed triple matching. Heuristics and manual templates were also commonly used (Chu-Carroll et al., 2012). We propose instead to learn discriminative features from the data with shallow question analysis. The final system captures intuitive patterns of QA pairs automatically.

4 Graph Features

Our model is inspired by an intuition on how everyday people search for answers. If you asked someone: what is the name of justin bieber brother,[3] and gave them access to Freebase, that person might first determine that the question

[2] https://code.google.com/p/jacana

[3] All examples used in this paper come from the training data crawled from Google Suggest. They are lowercased and some contain typos.

is about Justin Bieber (or his brother), go to Justin Bieber's Freebase page, and search for his brother's name. Unfortunately Freebase does not contain an exact relation called brother, but instead sibling. Thus further inference (i.e., brother $\leftrightarrow$ male sibling) has to be made. In the following we describe how we represent this process.

4.1 Question Graph

In answering our example query a person might take into consideration multiple constraints. With regards to the question, we know we are looking for the name of a person based on the following:

- the dependency relation nsubj(what, name) and prep_of(name, brother) indicates that the question seeks the information of a name;[4]
- the dependency relation prep_of(name, brother) indicates that the name is about a brother (but we do not know whether it is a person name yet);
- the dependency relation nn(brother, bieber) and the facts that, (i) Bieber is a person and (ii) a person's brother should also be a person, indicate that the name is about a person.

This motivates the design of dependency-based features. We show one example in Figure 1(a), left side. The following linguistic information is of interest:

- question word (*qword*), such as what/who/how many. We use a list of 9 common qwords. [5]
- question focus (*qfocus*), a cue of expected answer types, such as name/money/time. We keep our analysis simple and do not use a question classifier, but simply extract the noun dependent of qword as qfocus.
- question verb (*qverb*), such as is/play/take, extracted from the main verb of the question. Question verbs are also good hints of answer types. For instance, play is likely to be followed by an instrument, a movie or a sports team.
- question topic (*qtopic*). The topic of the question helps us find relevant Freebase pages. We simply apply a named entity recognizer to find the question topic. Note that there can be more than one topic in the question.

Then we convert the dependency parse into a more generic question graph, in the following steps:

1. if a node was tagged with a question feature, then replace this node with its question feature, e.g., what $\rightarrow$ qword=what;
2. (special case) if a qtopic node was tagged as a named entity, then replace this node with its its named entity form, e.g., bieber $\rightarrow$ qtopic=person;
3. drop any leaf node that is a determiner, preposition or punctuation.

The converted graph is shown in Figure 1(a), right side. We call this a *question feature graph*, with every node and relation a potential feature for this question. Then features are extracted in the following form: with s the source and t the target node, for every edge $e(s,t)$ in the graph, extract s, t, $s \mid t$ and $s \mid e \mid t$ as features. For the edge, prep_of(qfocus=name, brother), this would mean the following features: qfocus=name, brother, qfocus=name|brother, and qfocus=name|prep_of|brother.

We show with examples why these features make sense later in §6 Table 6. Furthermore, the reason that we have kept some lexical features, such as brother, is that we hope to learn from training a high correlation between brother and some Freebase relations and properties (such as sibling and male) if we do not possess an external resource to help us identify such a correlation.

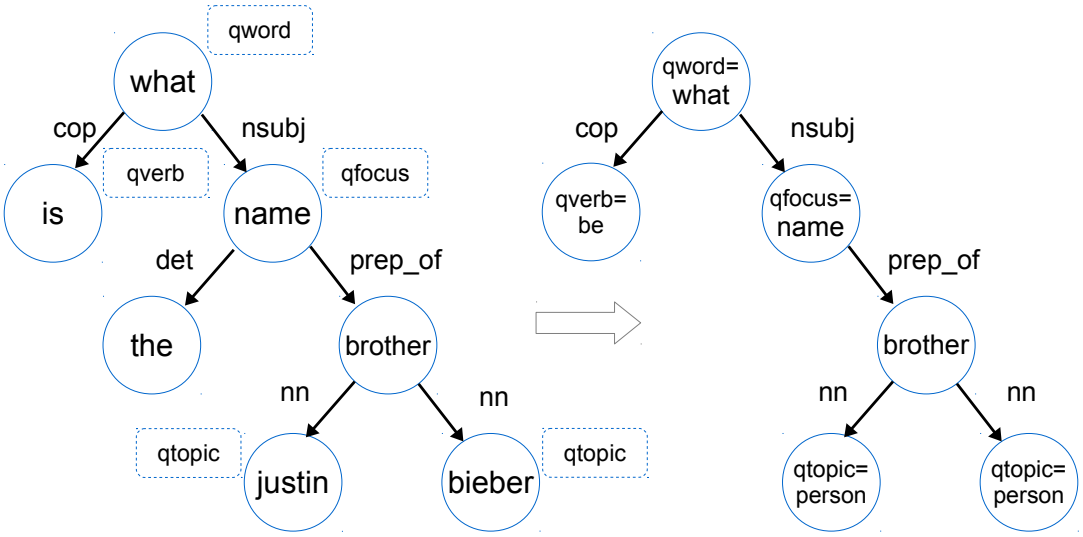
4.2 Freebase Topic Graph

Given a topic, we selectively roll out the Freebase graph by choosing those nodes within a few hops of relationship to the *topic node*, and form a *topic graph*. Besides incoming and/or outgoing relationships, nodes also have *properties*: a string that describes the attribute of a node, for instance, node type, gender or height (for a person). One major difference between relations and properties is that both arguments of a relation are nodes, while only one argument of a property is a node, the other a string. Arguments of relations are usually interconnected, e.g., London can be the place_of_birth for Justin Bieber, or capital_of the UK. Arguments of properties are attributes that are only "attached" to certain nodes and have no outgoing edges. Figure 1(b) shows an example.

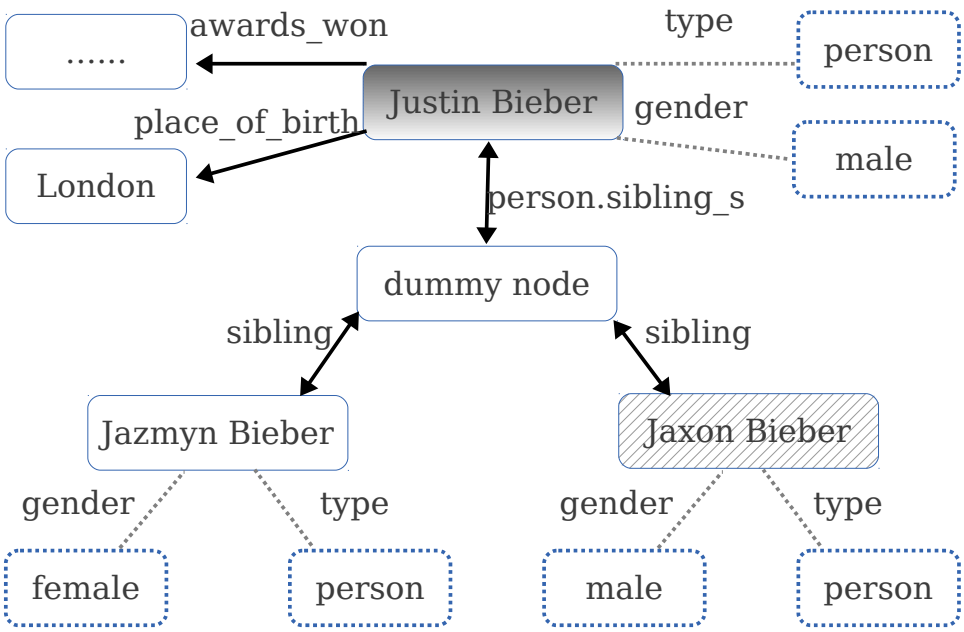
Both relationship and property of a node are important to identifying the answer. They connect the nodes with the question and describe some unique characteristics. For instance, without the properties type:person and gender:male,

[4] We use the Stanford collapsed dependency form.

[5] who, when, what, where, how, which, why, whom, whose.



(a) Dependence parse with annotated question features in dashed boxes (left) and converted feature graph (right) with only relevant and general information about the original question kept. Note that the left is a real but incorrect parse.



(b) A view of Freebase graph on the Justin Bieber topic with nodes in solid boxes and properties in dashed boxes. The hatching node, Jaxon Bieber, is the answer. Freebase uses a dummy parent node for a list of nodes with the same relation.

Figure 1: Dependency parse and excerpted Freebase topic graph on the question what is the name of justin bieber brother.

we would not have known the node Jaxon Bieber represents a male person. These properties, along with the sibling relationship to the topic node, are important cues for answering the question. Thus for the Freebase graph, we use relations (with directions) and properties as features for each node.

Additionally, we have analyzed how Freebase relations map back to the question. Some of the mapping can be simply detected as paraphrasing or lexical overlap. For example, the person.parents relationship helps answering questions about parenthood. However, most Freebase relations are framed in a way that is not commonly addressed in natural language questions. For instance, for common celebrity gossip questions like who cheated on celebrity A, it is hard for a system to find the Freebase relation celebrity.infidelity.participant as the target relation if it had not observed this pattern in training.

Thus assuming there is an alignment model that is able to tell how likely one relation maps to the original question, we add extra alignment-based features for the incoming and outgoing relation of each node. Specifically, for each relation rel in a topic graph, we compute $P(rel \mid question)$ to rank the relations. Finally the ranking (e.g., top 1/2/5/10/100 and beyond) of each relation is used as features instead of a pure probability. We describe such an alignment model in § 5.

4.3 Feature Production

We combine question features and Freebase features (per node) by doing a pairwise concatenation. In this way we hope to capture the association between question patterns and answer nodes. For instance, in a loglinear model setting, we expect to learn a high feature weight for features like:

qfocus=money|node_type=currency

and a very low weight for:

qfocus=money|node_type=person.

This combination greatly enlarges the total number of features, but owing to progress in large-scale machine learning such feature spaces are less of a concern than they once were (concrete numbers in § 6 Model Tuning).

5 Relation Mapping

In this section we describe a "translation" table between Freebase relations and NL words was built.

5.1 Formula

The objective is to find the most likely relation a question prompts. For instance, for the question who is the father of King George VI, the most likely relation we look for is people.person.parents. To put it more formally, given a question Q of a word vector $\mathbf{w}$, we want to find out the relation R that maximizes the probability $P(R \mid Q)$.

More interestingly, for the question who is the father of the Periodic Table, the actual relation that encodes its original meaning is law.invention.inventor, rather than people.person.parents. This simple example points out that *every* part of the question could change what the question inquires eventually. Thus we need to count for *each* word w in Q. Due to the bias and incompleteness of any data source, we approximate the true probability of P with $\tilde{P}$ under our specific model. For the simplicity of computation, we assume conditional independence between words and apply Naive Bayes:

$$\begin{aligned}\tilde{P}(R \mid Q) &\propto \tilde{P}(Q \mid R)\tilde{P}(R) \\ &\approx \tilde{P}(\mathbf{w} \mid R)\tilde{P}(R) \\ &\approx \prod_w \tilde{P}(w \mid R)\tilde{P}(R)\end{aligned}$$

where $\tilde{P}(R)$ is the prior probability of a relation R and $\tilde{P}(w \mid R)$ is the conditional probability of word w given R.

It is possible that we do not observe a certain relation R when computing the above equation. In this case we back off to the "sub-relations": a relation R is a concatenation of a series of sub-relations $R = \mathbf{r} = r_1.r_2.r_3.\ldots$. For instance, the sub-relations of people.person.parents are people, person, and parents. Again, we assume conditional independence between sub-relations and apply Naive Bayes:

$$\begin{aligned}\tilde{P}_{\text{backoff}}(R \mid Q) &\approx \tilde{P}(\mathbf{r} \mid Q) \\ &\approx \prod_r \tilde{P}(r \mid Q) \\ &\propto \prod_r \tilde{P}(Q \mid r)\tilde{P}(r) \\ &\approx \prod_r \prod_w \tilde{P}(w \mid r)\tilde{P}(r)\end{aligned}$$

One other reason that we estimated $\tilde{P}(w \mid r)$ and $\tilde{P}(r)$ for sub-relations is that Freebase relations share some common structures in between them. For instance, both people.person.parents and fictional_universe.fictional_character.parents

indicate the parent relationship but the latter is much less commonly annotated. We hope that the shared sub-relation, parents, can help better estimate for the less annotated. Note that the backoff model would have a much smaller value than the original, due to double multiplication $\prod_r \prod_w$. In practice we normalize it by the sub-relations size to keep it at the same scale with $\tilde{P}(R \mid Q)$.

Finally, to estimate the prior and conditional probability, we need a massive data collection.

5.2 Steps

The ClueWeb09[6] dataset is a collection of 1 billion webpages (5TB compressed in raw HTML) in 10 languages by Carnegie Mellon University in 2009. FACC1, the Freebase Annotation of the ClueWeb Corpus version 1 (Gabrilovich et al., 2013), contains index and offset of Freebase entities within the English portion of ClueWeb. Out of all 500 million English documents, 340 million were automatically annotated with at least one entity, with an average of 15 entity mentions per document. The precision and recall of annotation were estimated at $80-85\%$ and $70-85\%$ (Orr et al., 2013).

Given these two resources, for each binary Freebase relation, we can find a collection of sentences each of which contains both of its arguments, then simply learn how words in these sentences are associated with this relation, i.e., $\tilde{P}(w \mid R)$ and $\tilde{P}(w \mid r)$. By counting how many times each relation R was annotated, we can estimate $\tilde{P}(R)$ and $\tilde{P}(r)$. The learning task can be framed in the following short steps:

1. We split each HTML document by sentences (Kiss and Strunk, 2006) using NLTK (Bird and Loper, 2004) and extracted those with at least two Freebase entities which has at least one direct established relation according to Freebase.
2. The extraction formed two parallel corpora, one with "relation - sentence" pairs (for estimating $\tilde{P}(w \mid R)$ and $\tilde{P}(R)$) and the other with "subrelations - sentence" pairs (for $\tilde{P}(w \mid r)$ and $\tilde{P}(r)$). Each corpus has 1.2 billion pairs.
3. The tricky part was to align these 1.2 billion pairs. Since the relations on one side of these pairs are not *natural* sentences, we ran the most simple IBM alignment Model 1 (Brown et al., 1993) to estimate the translation probability with GIZA++ (Och and Ney, 2003). To speed up, the 1.2 billion pairs were split into 100 even chunks. We ran 5 iterations of EM on each one and finally aligned the 1.2 billion pairs from both directions. To symmetrize the alignment, common MT heuristics INTERSECTION, UNION, GROW-DIAG-FINAL, and GROW-DIAG-FINAL-AND (Koehn, 2010) were separately applied and evaluated later.
4. Treating the aligned pairs as *observation*, the co-occurrence matrix between aligning relations and words was computed. There were 10,484 relations and sub-relations in all, and we kept the top 20,000 words.
5. From the co-occurrence matrix we computed $\tilde{P}(w \mid R)$, $\tilde{P}(R)$, $\tilde{P}(w \mid r)$ and $\tilde{P}(r)$.

[6] http://lemurproject.org/clueweb09/

$\mathbf{0}$	$\leq \mathbf{10}$	$\leq \mathbf{10^2}$	$\leq \mathbf{10^3}$	$\leq \mathbf{10^4}$	$> \mathbf{10^4}$
7.0%	0.7%	1.2%	0.4%	1.3%	89.5%

Table 1: Percentage of answer relations (the incoming relation connected to the answer node) with respect to how many sentences we learned this relation from in CluewebMapping. For instance, the first column says there are 7% of answer relations for which we cannot find a mapping (so we had to use the backoff probability estimation); the last column says there are 89.5% of answer relations that we were able to learn the mapping between this relation and text based on more than 10 thousand relation-sentence pairs. The total number of answer relations is 7886.

Hand-checking the learned probabilities shows both success, failure and some bias. For instance, for the film.actor.film relation (mapping from film names to actor names), the top words given by $\tilde{P}(w \mid R)$ are won, star, among, show. For the film.film.directed_by relation, some important stop words that could indicate this relation, such as by and with, rank directly after director and direct. However, due to significant popular interest in certain news categories, and the resultant catering by websites to those information desires, then for example we also learned a heavily correlated connection between Jennifer Aniston and celebrity.infidelity.victim, and between some other you-know-who names and celebrity.infidelity.participant.

We next formally evaluate how the learned mapping help predict relations from words.

5.3 Evaluation

Both ClueWeb and its Freebase annotation has a bias. Thus we were firstly interested in the coverage of mined relation mappings. As a comparison, we used a dataset of relation mapping contributed by Berant et al. (2013) and Lin et al. (2012). The idea is very similar: they intersected Freebase relations with predicates in (arg1, predicate, arg2) triples extracted from `ReVerb` to learn the mapping between Freebase relations and triple predicates. Note the scale difference: although `ReVerb` was also extracted from ClueWeb09, there were only 15 million triples to intersect with the relations, while we had 1.2 billion alignment pairs. We call this dataset **ReverbMapping** and ours **CluewebMapping**.

The evaluation dataset, WEBQUESTIONS, was also contributed by Berant et al. (2013). It contains 3778 training and 2032 test questions collected from the Google Suggest service. All questions were annotated with answers from Freebase. Some questions have more than one answer, such as what to see near sedona arizona?.

We evaluated on the training set in two aspects: coverage and prediction performance. We define *answer node* as the node that is the answer and *answer relation* as the relation from the answer node to its direct parent. Then we computed how much and how well the answer relation was triggered by ReverbMapping and CluewebMapping. Thus for the question, who is the father of King George VI, we ask two questions: does the mapping, 1. (coverage) contain the answer relation people.person.parents? 2. (precision) predict the answer relation from the question?

Table 1 shows the coverage of CluewebMapping, which covers 93.0% of all answer relations. Among them, we were able to learn the rule mapping using more than 10 thousand relation-sentence pairs for *each* of the 89.5% of all answer relations. In contrast, ReverbMapping covers 89.7% of the answer relations.

Next we evaluated the prediction performance, using the evaluation metrics of information retrieval. For each question, we extracted all relations in its corresponding topic graph, and ranked each relation with whether it is the answer relation. For instance, for the previous example question, we want to rank the relation people.person.parents as number 1. We computed standard MAP (Mean Average Precision) and MRR (Mean Reciprocal Rank), shown in Table 2(a). As a simple baseline, "word overlap" counts the overlap between relations and the question. CluewebMapping ranks each relation by $\tilde{P}(R \mid Q)$. ReverbMapping does the same, except that we took a uniform distribution on $\tilde{P}(w \mid R)$ and $\tilde{P}(R)$ since the contributed dataset did not include co-occurrence counts to estimate these probabilities.[7] Note that the median rank from CluewebMapping is only 12, indicating that half of all answer relations are ranked in the top 12.

Table 2(b) further shows the percentage of answer relations with respect to their ranking. CluewebMapping successfully ranked 19% of answer relations as top 1. A sample of these includes person.place_of_birth, location.containedby, country.currency_used, regular_tv_appearance.actor, etc. These percentage numbers are good clue for feature design: for instance, we may be confident in a relation if it is ranked top 5 or 10 by CluewebMapping.

To conclude, we found that CluewebMapping provides satisfying coverage on the 3778 training questions: only 7% were missing, despite the biased nature of web data. Also, CluewebMapping gives reasonably good precision on its prediction, despite the noisy nature of web data. We move on to fully evaluate the final QA F_1.

6 Experiments

We evaluate the final F_1 in this section. The system of comparison is that of Berant et al. (2013).

Data We re-used WEBQUESTIONS, a dataset collected by Berant et al. (2013). It contains 5810 questions crawled from the Google Suggest service, with answers annotated on Amazon Mechanical Turk. All questions contain at least one answer from Freebase. This dataset has been split by $65\%/35\%$ into TRAIN-ALL and TEST. We further randomly divided TRAIN-ALL by $80\%/20\%$ to a smaller TRAIN and development set DEV. Note that our DEV set is different from that of Berant et al. (2013), but the final result on TEST is directly comparable. Results are reported in terms of macro F_1 with partial credit (following Berant et al. (2013)) if a predicted answer list does not have a perfect match with all gold answers, as a

[7] The way we used ReverbMapping was not how Berant et al. (2013) originally used it: they employed a discriminative log-linear model to judge relations and that might yield better performance. As a fair comparison, ranking of CluewebMapping under uniform distribution is also included in Table 2(a).

	Median Rank	MAP	MRR
word overlap	471	0.0380	0.0590
ReverbMapping	60	0.0691	0.0829
CluewebMapping	12	0.2074	0.2900
with uniform dist.	61	0.0544	0.0561

(a) Ranking on answer relations. Best result on CluewebMapping was under the GROW-DIAG-FINAL-AND heuristics (row 3) when symmetrizing alignment from both directions. The last row shows ranking of CluewebMapping under uniform distribution (assuming counting on words and relations is not known).

	1	≤ 5	≤ 10	≤ 50	≤ 100	> 100
w. o.	3.5	4.7	2.5	3.9	4.1	81.3
R.M.	2.6	9.1	8.6	26.0	13.0	40.7
C.M.	19.0	19.9	8.9	22.3	7.5	22.4

(b) Percentage of answer relations w.r.t. ranking number (header). w.o.: word overlap; R.M.: ReverbMapping; C.M.: CluewebMapping.

Table 2: Evaluation on answer relation ranking prediction on 3778 training questions.

lot of questions in WEBQUESTIONS contain more than one answer.

Search With an Information Retrieval (IR) front-end, we need to locate the exact Freebase topic node a question is about. For this purpose we used the Freebase Search API (Freebase, 2013a).All named entities [8] in a question were sent to this API, which returned a ranked list of relevant topics. We also evaluated how well the search API served the IR purpose. WEBQUESTIONS not only has answers annotated, but also which Freebase topic nodes the answers come from. Thus we evaluated the ranking of retrieval with the gold standard annotation on TRAIN-ALL, shown in Table 3. The top 2 results of the Search API contain gold standard topics for more than 90% of the questions and the top 10 results contain more than 95%. We took this as a "good enough" IR front-end and used it on TEST.

Once a topic is obtained we query the Freebase Topic API (Freebase, 2013b) to retrieve all relevant information, resulting in a topic graph. The API returns almost identical information as displayed via a web browser to a user viewing this topic. Given that turkers annotated answers based on the topic page via a browser, this supports the assumption that the same answer would be located in the topic graph, which is then passed to the QA engine for feature extraction and classification.

[8] When no named entities are detected, we fall back to noun phrases.

top	1	2	3	5	10
#	3263	3456	3532	3574	3604
%	86.4	91.5	93.5	94.6	95.4

Table 3: Evaluation on the Freebase Search API: how many questions' top n retrieved results contain the gold standard topic. Total number of questions is 3778 (size of TRAIN-ALL). There were only 5 questions with no retrieved results.

	P	R	F_1
basic	57.3	30.1	39.5
+ word overlap	56.0	31.4	40.2
+ CluewebMapping	59.9	35.4	44.5
+both	59.0	35.4	44.3

Table 4: F_1 on DEV with different feature settings.

Model Tuning We treat QA on Freebase as a binary classification task: for each node in the topic graph, we extract features and judge whether it is the answer node. Every question was processed by the Stanford CoreNLP suite with the caseless model. Then the question features (§4.1) and node features (§4.2) were combined (§4.3) for each node. The learning problem is challenging: for about 3000 questions in TRAIN, there are 3 million nodes (1000 nodes per topic graph), and 7 million feature types. We employed a high-performance machine learning tool, `Classias` (Okazaki, 2009). Training usually took around 4 hours. We experimented with various discriminative learners on DEV, including logistic regression, perceptron and SVM, and found L1 regularized logistic regression to give the best result. The L1 regularization encourages sparse features by driving feature weights towards zero, which was ideal for the over-generated feature space. After training, we had around 30 thousand features with non-zero weights, a 200 fold reduction from the original features.

Also, we did an ablation test on DEV about how additional features on the mapping between Freebase relations and the original questions help, with three feature settings: 1) "basic" features include feature productions read off from the feature graph (Figure 1); 2) "+ word overlap" adds additional features on whether sub-relations have overlap with the question; and 3) "+ CluewebMapping" adds the ranking of relation prediction given the question according to CluewebMapping. Table 4 shows that the additional CluewebMapping

	P	R	F_1
Gold Retrieval	45.4	52.2	48.6
Freebase Search API	38.8	45.8	42.0
Berant et al. (2013)	-	-	31.4

Table 5: F_1 on TEST with Gold Retrieval and Freebase Search API as the IR front end. Berant et al. (2013) actually reported *accuracy* on this dataset. However, since their system predicted answers for almost every question (p.c.), it is roughly that precision=recall=F_1=accuracy for them.

features improved overall F_1 by 5%, a 13% relative improvement: a remarkable gain given that the model already learned a strong correlation between question types and answer types (explained more in discussion and Table 6 later).

Finally, the ratio of positive vs. negative examples affect final F_1: the more positive examples, the lower the precision and the higher the recall. Under the original setting, this ratio was about $1:275$. This produced precision around 60% and recall around 35% (c.f. Table 4). To optimize for F_1, we down-sampled the negative examples to 20%, i.e., a new ratio of $1:55$. This boosted the final F_1 on DEV to 48%. We report the final TEST result under this down-sampled training. In practice the precision/recall balance can be adjusted by the positive/negative ratio.

Test Results Table 5 gives the final F_1 on TEST. "Gold Retrieval" always ranked the correct topic node top 1, a perfect IR front-end assumption. In a more realistic scenario, we had already evaluated that the Freebase Search API returned the correct topic node 95% of the time in its top 10 results (c.f. Table 3), thus we also tested on the top 10 results returned by the Search API. To keep things simple, we did not perform answer voting, but simply extracted answers from the first (ranked by the Search API) topic node with predicted answer(s) found. The final F_1 of 42.0% gives a relative improvement over previous best result (Berant et al., 2013) of 31.4% by one third.

One question of interest is whether our system, aided by the massive web data, can be fairly compared to the semantic parsing approaches (note that Berant et al. (2013) also used ClueWeb indirectly through `ReVerb`). Thus we took out the word overlapping and CluewebMapping based features, and the new F_1 on TEST was 36.9%.

The other question of interest is that whether our system has acquired some level of "machine intelligence": how much does it know what the question inquires? We discuss it below through feature and error analysis.

wgt.	feature
5.56	qfocus=money|type=Currency
5.35	qverb=die|type=Cause_Of_Death
5.11	qword=when|type=datetime
4.56	qverb=border|rel=location.adjoins
3.90	qword=why|incoming_relation_rank=top_3
2.94	qverb=go|qtopic=location|type=Tourist_attraction
-3.94	qtopic=location|rel=location.imports_exports.date
-2.93	qtopic=person|rel=education.end_date

Table 6: A sample of the top 50 most positive/negative features. Features are production between question and node features (c.f. Figure 1).

Discussion The combination between questions and Freebase nodes captures some real gist of QA pattern typing, shown in Table 6 with sampled features and weights. Our system learned, for instance, when the question asks for geographic adjacency information (qverb=border), the correct answer relation to look for is location.adjoins. Detailed comparison with the output from Berant et al. (2013) is a work in progress and will be presented in a follow-up report.

7 Conclusion

We proposed an automatic method for Question Answering from structured data source (Freebase). Our approach associates question features with answer patterns described by Freebase and has achieved state-of-the-art results on a balanced and realistic QA corpus. To compensate for the problem of domain mismatch or overfitting, we exploited ClueWeb, mined mappings between KB relations and natural language text, and showed that it helped both relation prediction and answer extraction. Our method employs relatively lightweight machinery but has good performance. We hope that this result establishes a new baseline against which semantic parsing researchers can measure their progress towards deeper language understanding and answering of human questions.

Acknowledgments We thank the Allen Institute for Artificial Intelligence for funding this work. We are also grateful to Jonathan Berant, Tom Kwiatkowski, Qingqing Cai, Adam Lopez, Chris Callison-Burch and Peter Clark for helpful discussion and to the reviewers for insightful comments.

Abstract

A typical knowledge-based question answering (KB-QA) system faces two challenges: one is to transform natural language questions into their meaning representations (MRs); the other is to retrieve answers from knowledge bases (KBs) using generated MRs. Unlike previous methods which treat them in a cascaded manner, we present a translation-based approach to solve these two tasks in one unified framework. We translate questions to answers based on CYK parsing. Answers as translations of the span covered by each CYK cell are obtained by a question translation method, which first generates formal triple queries as MRs for the span based on question patterns and relation expressions, and then retrieves answers from a given KB based on triple queries generated. A linear model is defined over derivations, and minimum error rate training is used to tune feature weights based on a set of question-answer pairs. Compared to a KB-QA system using a state-of-the-art semantic parser, our method achieves better results.

1 Introduction

Knowledge-based question answering (KB-QA) computes answers to natural language (NL) questions based on existing knowledge bases (KBs). Most previous systems tackle this task in a cascaded manner: First, the input question is transformed into its meaning representation (MR) by an independent semantic parser (Zettlemoyer and Collins, 2005; Mooney, 2007; Artzi and Zettlemoyer, 2011; Liang et al., 2011; Cai and Yates, 2013; Poon, 2013; Artzi et al., 2013; Kwiatkowski et al., 2013; Berant et al., 2013); Then, the answers are retrieved from existing KBs using generated MRs as queries.

Unlike existing KB-QA systems which treat semantic parsing and answer retrieval as two cascaded tasks, this paper presents a unified framework that can integrate semantic parsing into the question answering procedure directly. Borrowing ideas from machine translation (MT), we treat the QA task as a translation procedure. Like MT, CYK parsing is used to parse each input question, and answers of the span covered by each CYK cell are considered the translations of that cell; unlike MT, which uses offline-generated translation tables to translate source phrases into target translations, a semantic parsing-based question translation method is used to translate each span into its answers on-the-fly, based on question patterns and relation expressions. The final answers can be obtained from the root cell. Derivations generated during such a translation procedure are modeled by a linear model, and minimum error rate training (MERT) (Och, 2003) is used to tune feature weights based on a set of question-answer pairs.

Figure 1 shows an example: the question *director of movie starred by Tom Hanks* is translated to one of its answers *Robert Zemeckis* by three main steps: (i) translate *director of* to *director of*; (ii) translate *movie starred by Tom Hanks* to one of its answers *Forrest Gump*; (iii) translate *director of Forrest Gump* to a final answer *Robert Zemeckis*. Note that the updated question covered by Cell[0, 6] is obtained by combining the answers to question spans covered by Cell[0, 1] and Cell[2, 6].

The contributions of this work are two-fold: (1) We propose a translation-based KB-QA method that integrates semantic parsing and QA in one unified framework. The benefit of our method is that we don't need to explicitly generate complete semantic structures for input questions. Be-

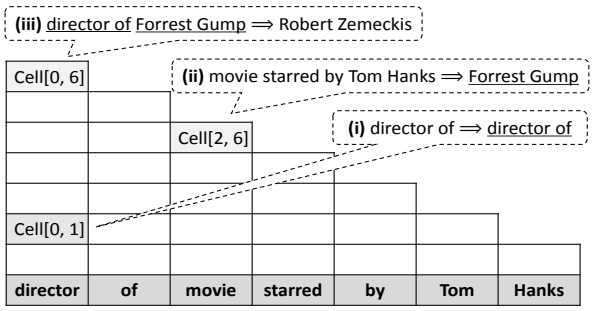

Figure 1: Translation-based KB-QA example

sides which, answers generated during the translation procedure help significantly with search space pruning. (2) We propose a robust method to transform single-relation questions into formal triple queries as their MRs, which trades off between transformation accuracy and recall using question patterns and relation expressions respectively.

2 Translation-Based KB-QA

2.1 Overview

Formally, given a knowledge base $\mathcal{KB}$ and an N-L question $\mathcal{Q}$, our KB-QA method generates a set of formal triples-answer pairs $\{\langle \mathcal{D}, \mathcal{A} \rangle\}$ as derivations, which are scored and ranked by the distribution $P(\langle \mathcal{D}, \mathcal{A} \rangle | \mathcal{KB}, \mathcal{Q})$ defined as follows:

$$\frac{exp\{\sum_{i=1}^{M} \lambda_i \cdot h_i(\langle \mathcal{D}, \mathcal{A} \rangle, \mathcal{KB}, \mathcal{Q})\}}{\sum_{\langle \mathcal{D}', \mathcal{A}' \rangle \in \mathcal{H}(\mathcal{Q})} exp\{\sum_{i=1}^{M} \lambda_i \cdot h_i(\langle \mathcal{D}', \mathcal{A}' \rangle, \mathcal{KB}, \mathcal{Q})\}}$$

- $\mathcal{KB}$ denotes a knowledge base[1] that stores a set of assertions. Each assertion $t \in \mathcal{KB}$ is in the form of $\{e_{sbj}^{ID}, p, e_{obj}^{ID}\}$, where p denotes a predicate, e_{sbj}^{ID} and e_{obj}^{ID} denote the subject and object entities of t, with unique IDs[2].

- $\mathcal{H}(\mathcal{Q})$ denotes the search space $\{\langle \mathcal{D}, \mathcal{A} \rangle\}$. $\mathcal{D}$ is composed of a set of *ordered* formal triples $\{t_1, ..., t_n\}$. Each triple $t = \{e_{sbj}, p, e_{obj}\}_i^j \in \mathcal{D}$ denotes an assertion in $\mathcal{KB}$, where i and j denotes the beginning and end indexes of the question span from which t is transformed. The order of triples in $\mathcal{D}$ denotes the order of translation steps from $\mathcal{Q}$ to $\mathcal{A}$. E.g., $\langle$*director of, Null, director of*$\rangle_0^1$, $\langle$*Tom Hanks, Film.Actor.Film, Forrest Gump*$\rangle_2^6$ and $\langle$*Forrest Gump, Film.Film.Director, Robert Zemeckis*$\rangle_0^6$ are three ordered formal triples corresponding to the three translation steps in Figure 1. We define the task of transforming question spans into formal triples as *question translation*. $\mathcal{A}$ denotes one final answer of $\mathcal{Q}$.

- $h_i(\cdot)$ denotes the i^{th} feature function.

- λ_i denotes the feature weight of $h_i(\cdot)$.

According to the above description, our KB-QA method can be decomposed into four tasks as: (1) search space generation for $\mathcal{H}(\mathcal{Q})$; (2) question translation for transforming question spans into their corresponding formal triples; (3) feature design for $h_i(\cdot)$; and (4) feature weight tuning for $\{\lambda_i\}$. We present details of these four tasks in the following subsections one-by-one.

2.2 Search Space Generation

We first present our translation-based KB-QA method in Algorithm 1, which is used to generate $\mathcal{H}(\mathcal{Q})$ for each input NL question $\mathcal{Q}$.

Algorithm 1: Translation-based KB-QA

```
for l = 1 to |Q| do
    for all i, j s.t. j − i = l do
        H(Q_i^j) = ∅;
        T = QTrans(Q_i^j, KB);
        foreach formal triple t ∈ T do
            create a new derivation d;
            d.A = t.e_obj;
            d.D = {t};
            update the model score of d;
            insert d to H(Q_i^j);
        end
    end
end
for l = 1 to |Q| do
    for all i, j s.t. j − i = l do
        for all m s.t. i ≤ m < j do
            for d_l ∈ H(Q_i^m) and d_r ∈ H(Q_{m+1}^j) do
                Q_update = d_l.A + d_r.A;
                T = QTrans(Q_update, KB);
                foreach formal triple t ∈ T do
                    create a new derivation d;
                    d.A = t.e_obj;
                    d.D = d_l.D ⋃ d_r.D ⋃ {t};
                    update the model score of d;
                    insert d to H(Q_i^j);
                end
            end
        end
    end
end
return H(Q).
```

[1] We use a large scale knowledge base in this paper, which contains 2.3B entities, 5.5K predicates, and 18B assertions. A 16-machine cluster is used to host and serve the whole data.

[2] Each KB entity has a unique ID. For the sake of convenience, we omit the ID information in the rest of the paper.

The first half (from Line 1 to Line 13) generates a formal triple set T for each unary span $\mathcal{Q}_i^j \in \mathcal{Q}$, using the question translation method $QTrans(\mathcal{Q}_i^j, \mathcal{KB})$ (Line 4), which takes $\mathcal{Q}_i^j$ as the input. Each triple $t \in T$ returned is in the form of $\{e_{sbj}, p, e_{obj}\}$, where e_{sbj}'s mention occurs in $\mathcal{Q}_i^j$, p is a predicate that denotes the meaning expressed by the context of e_{sbj} in $\mathcal{Q}_i^j$, e_{obj} is an answer of $\mathcal{Q}_i^j$ based on e_{sbj}, p and $\mathcal{KB}$. We describe the implementation detail of $QTrans(\cdot)$ in Section 2.3.

The second half (from Line 14 to Line 31) first updates the content of each bigger span $\mathcal{Q}_i^j$ by concatenating the answers to its any two consecutive smaller spans covered by $\mathcal{Q}_i^j$ (Line 18). Then, $QTrans(\mathcal{Q}_i^j, \mathcal{KB})$ is called to generate triples for the updated span (Line 19). The above operations are equivalent to answering a simplified question, which is obtained by replacing the answerable spans in the original question with their corresponding answers. The search space $\mathcal{H}(\mathcal{Q})$ for the entire question $\mathcal{Q}$ is returned at last (Line 31).

2.3 Question Translation

The purpose of question translation is to translate a span $\mathcal{Q}$ to a set of formal triples T. Each triple $t \in T$ is in the form of $\{e_{sbj}, p, e_{obj}\}$, where e_{sbj}'s mention[3] occurs in $\mathcal{Q}$, p is a predicate that denotes the meaning expressed by the context of e_{sbj} in $\mathcal{Q}$, e_{obj} is an answer to $\mathcal{Q}$ retrieved from $\mathcal{KB}$ using a triple query $q = \{e_{sbj}, p, ?\}$. Note that if no predicate p or answer e_{obj} can be generated, $\{\mathcal{Q}, Null, \mathcal{Q}\}$ will be returned as a special triple, which sets e_{obj} to be $\mathcal{Q}$ itself, and p to be $Null$. This makes sure the un-answerable spans can be passed on to the higher-level operations.

Question translation assumes each span $\mathcal{Q}$ is a *single-relation question* (Fader et al., 2013). Such assumption simplifies the efforts of semantic parsing to the minimum question units, while leaving the capability of handling multiple-relation questions (Figure 1 gives one such example) to the outer CYK-parsing based translation procedure. Two question translation methods are presented in the rest of this subsection, which are based on question patterns and relation expressions respectively.

2.3.1 Question Pattern-based Translation

A question pattern $\mathcal{QP}$ includes a pattern string $\mathcal{QP}_{pattern}$, which is composed of words and a slot symbol $[Slot]$, and a KB predicate $\mathcal{QP}_{predicate}$, which denotes the meaning expressed by the context words in $\mathcal{QP}_{pattern}$.

Algorithm 2: $\mathcal{QP}$-based Question Translation

```
1  T = ∅;
2  foreach entity mention e_Q ∈ Q do
3      Q_pattern = replace e_Q in Q with [Slot];
4      foreach question pattern QP do
5          if Q_pattern == QP_pattern then
6              E = Disambiguate(e_Q, QP_predicate);
7              foreach e ∈ E do
8                  create a new triple query q;
9                  q = {e, QP_predicate, ?};
10                 {A_i} = AnswerRetrieve(q, KB);
11                 foreach A ∈ {A_i} do
12                     create a new formal triple t;
13                     t = {q.e_sbj, q.p, A};
14                     t.score = 1.0;
15                     insert t to T;
16                 end
17             end
18         end
19     end
20 end
21 return T.
```

Algorithm 2 shows how to generate formal triples for a span $\mathcal{Q}$ based on question patterns ($\mathcal{QP}$-based question translation). For each entity mention $e_{\mathcal{Q}} \in \mathcal{Q}$, we replace it with $[Slot]$ and obtain a pattern string $\mathcal{Q}_{pattern}$ (Line 3). If $\mathcal{Q}_{pattern}$ can match one $\mathcal{QP}_{pattern}$, then we construct a triple query q (Line 9) using $\mathcal{QP}_{predicate}$ as its predicate and one of the KB entities returned by $Disambiguate(e_{\mathcal{Q}}, \mathcal{QP}_{predicate})$ as its subject entity (Line 6). Here, the objective of $Disambiguate(e_{\mathcal{Q}}, \mathcal{QP}_{predicate})$ is to output a set of disambiguated KB entities $\mathcal{E}$ in $\mathcal{KB}$. The name of each entity returned equals the input entity mention $e_{\mathcal{Q}}$ and occurs in some assertions where $\mathcal{QP}_{predicate}$ are the predicates. The underlying idea is to use the context (predicate) information to help entity disambiguation. The answers of q are returned by $AnswerRetrieve(q, \mathcal{KB})$ based on q and $\mathcal{KB}$ (Line 10), each of which is used to construct a formal triple and added to T for $\mathcal{Q}$ (from Line 11 to Line 16). Figure 2 gives an example.

Question patterns are collected as follows: First, *5W* queries, which begin with What, Where, Who, When, or Which, are selected from a large scale query log of a commercial search engine; Then, a cleaned entity dictionary is used to annotate each query by replacing all entity mentions it contains with the symbol $[Slot]$. Only high-frequent query patterns which contain one $[Slot]$ are maintained;

[3]For simplicity, a cleaned entity dictionary dumped from the entire $\mathcal{KB}$ is used to detect entity mentions in $\mathcal{Q}$.

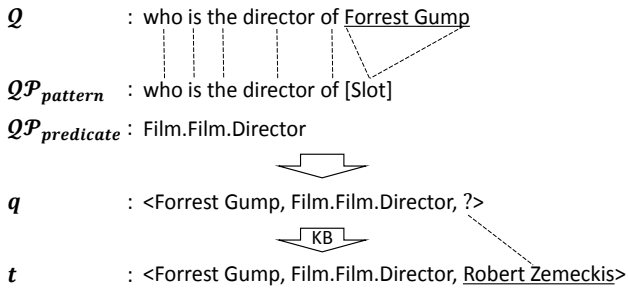

Figure 2: $\mathcal{QP}$-based question translation example

Lastly, annotators try to manually label the most-frequent 50,000 query patterns with their corresponding predicates, and 4,764 question patterns with single labeled predicates are obtained.

From experiments (Table 3 in Section 4.3) we can see that, question pattern based question translation can achieve high end-to-end accuracy. But as human efforts are needed in the mining procedure, this method cannot be extended to large scale very easily. Besides, different users often type the questions with the same meaning in different NL expressions. For example, although the question *Forrest Gump was directed by which moviemaker* means the same as the question $\mathcal{Q}$ in Figure 2, no question pattern can cover it. We need to find an alternative way to alleviate such coverage issue.

2.3.2 Relation Expression-based Translation

Aiming to alleviate the coverage issue occurring in $\mathcal{QP}$-based method, an alternative relation expression ($\mathcal{RE}$) -based method is proposed, and will be used when the $\mathcal{QP}$-based method fails.

We define $\mathcal{RE}_p$ as a relation expression set for a given KB predicate $p \in \mathcal{KB}$. Each relation expression $\mathcal{RE} \in \mathcal{RE}_p$ includes an expression string $\mathcal{RE}_{expression}$, which must contain at least one content word, and a weight $\mathcal{RE}_{weight}$, which denotes the confidence that $\mathcal{RE}_{expression}$ can represent p's meaning in NL. For example, *is the director of* is one relation expression string for the predicate *Film.Film.Director*, which means it is usually used to express this relation (predicate) in NL.

Algorithm 3 shows how to generate triples for a question $\mathcal{Q}$ based on relation expressions. For each possible entity mention $e_{\mathcal{Q}} \in \mathcal{Q}$ and a KB predicate $p \in \mathcal{KB}$ that is related to a KB entity e whose name equals $e_{\mathcal{Q}}$, $Sim(e_{\mathcal{Q}}, \mathcal{Q}, \mathcal{RE}_p)$ is computed (Line 5) based on the similarity between question context and $\mathcal{RE}_p$, which measures how likely $\mathcal{Q}$ can be transformed into a triple query

Algorithm 3: $\mathcal{RE}$-based Question Translation

```
1  T = ∅;
2  foreach entity mention e_Q ∈ Q do
3      foreach e ∈ KB s.t. e.name==e_Q do
4          foreach predicate p ∈ KB related to e do
5              score = Sim(e_Q, Q, RE_p);
6              if score > 0 then
7                  create a new triple query q;
8                  q = {e, p, ?};
9                  {A_i} = AnswerRetrieve(q, KB);
10                 foreach A ∈ {A_i} do
11                     create a new formal triple t;
12                     t = {q.e_sbj, q.p, A};
13                     t.score = score;
14                     insert t to T;
15                 end
16             end
17         end
18     end
19 end
20 sort T based on the score of each t ∈ T;
21 return T.
```

$q = \{e, p, ?\}$. If this score is larger than 0, which means there are overlaps between $\mathcal{Q}$'s context and $\mathcal{RE}_p$, then q will be used as the triple query of $\mathcal{Q}$, and a set of formal triples will be generated based on q and $\mathcal{KB}$ (from Line 7 to Line 15). The computation of $Sim(e_{\mathcal{Q}}, \mathcal{Q}, \mathcal{RE}_p)$ is defined as follows:

$$\sum_{n} \frac{1}{|\mathcal{Q}| - n + 1} \cdot \{ \sum_{\omega_n \in \mathcal{Q}, \omega_n \bigcap e_{\mathcal{Q}} = \phi} P(\omega_n | \mathcal{RE}_p) \}$$

where n is the n-gram order which ranges from 1 to 5, ω_n is an n-gram occurring in $\mathcal{Q}$ without overlapping with $e_{\mathcal{Q}}$ and containing at least one content word, $P(\omega_n|\mathcal{RE}_p)$ is the posterior probability which is computed by:

$$P(\omega_n|\mathcal{RE}_p) = \frac{Count(\omega_n, \mathcal{RE}_p)}{\sum_{\omega'_n \in \mathcal{RE}_p} Count(\omega'_n, \mathcal{RE}_p)}$$

$Count(\omega, \mathcal{RE}_p)$ denotes the weighted sum of times that ω occurs in $\mathcal{RE}_p$:

$$Count(\omega, \mathcal{RE}_p) = \sum_{\mathcal{RE} \in \mathcal{RE}_p} \{\#_{\omega}(\mathcal{RE}) \cdot \mathcal{RE}_{weight}\}$$

where $\#_{\omega}(\mathcal{RE})$ denotes the number of times that ω occurs in $\mathcal{RE}_{expression}$, and $\mathcal{RE}_{weight}$ is decided by the relation expression extraction component.

Figure 3 gives an example, where n-grams with rectangles are the ones that occur in both $\mathcal{Q}$'s context and the relation expression set of a given predicate $p = Film.Film.Director$. Unlike the $\mathcal{QP}$-based method which needs a perfect match, the

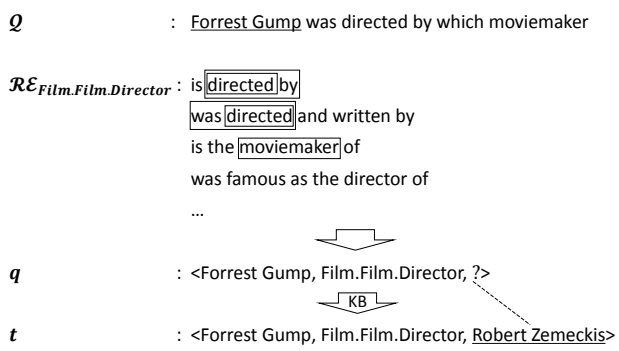

Figure 3: $\mathcal{RE}$-based question translation example

$\mathcal{RE}$-based method allows fuzzy matching between $\mathcal{Q}$ and $\mathcal{RE}_p$, and records this (Line 13) in generated triples, which is used as features later.

Relation expressions are mined as follows: Given a set of KB assertions with an identical predicate p, we first extract all sentences from English Wiki pages[4], each of which contains at least one pair of entities occurring in one assertion. Then, we extract the shortest path between paired entities in the dependency tree of each sentence as an $\mathcal{RE}$ candidate for the given predicate. The intuition is that any sentence containing such entity pairs occur in an assertion is likely to express the predicate of that assertion in some way. Last, all relation expressions extracted are filtered by heuristic rules, i.e., the frequency must be larger than 4, the length must be shorter than 10, and then weighted by the pattern scoring methods proposed in (Gerber and Ngomo, 2011; Gerber and Ngomo, 2012). For each predicate, we only keep the relation expressions whose pattern scores are larger than a pre-defined threshold. Figure 4 gives one relation expression extraction example. The statistics and overall quality of the relation expressions are listed in Section 4.1.

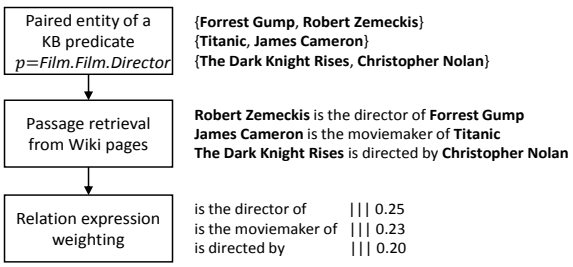

Figure 4: $\mathcal{RE}$ extraction example

[4]http://en.wikipedia.org/wiki/Wikipedia:Database_download

2.3.3 Question Decomposition

Sometimes, a question may provide multiple constraints to its answers. *movie starred by Tom Hanks in 1994* is one such question. All the films as the answers of this question should satisfy the following two constraints: (1) starred *by Tom Hanks*; and (2) released *in 1994*. It is easy to see that such questions cannot be translated to single triples.

We propose a dependency tree-based method to handle such multiple-constraint questions by (i) decomposing the original question into a set of *sub-questions* using syntax-based patterns; and (ii) intersecting the answers of all sub-questions as the final answers of the original question. Note, question decomposition only operates on the original question and question spans covered by complete dependency subtrees. Four syntax-based patterns (Figure 5) are used for question decomposition. If a question matches any one of these patterns, then sub-questions are generated by collecting the paths between n_0 and each $n_i(i > 0)$ in the pattern, where each n denotes a complete subtree with a noun, number, or question word as its root node, the symbol $*$ above $prep^*$ denotes this preposition can be skipped in matching. For the question mentioned at the beginning, its two sub-questions generated are *movie starred by Tom Hanks* and *movie starred in 1994*, as its dependency form matches pattern (a). Similar ideas are used in IBM Watson (Kalyanpur et al., 2012) as well.

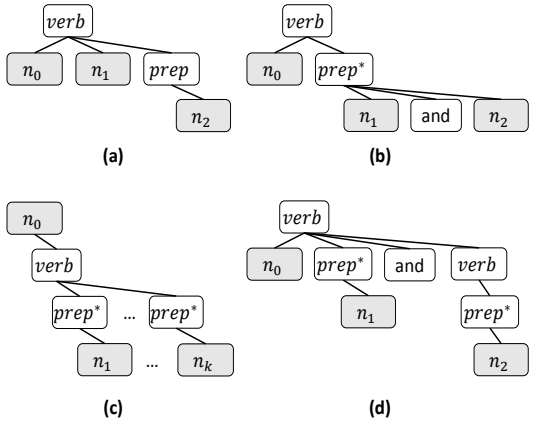

Figure 5: Four syntax-based patterns for question decomposition

As dependency parsing is not perfect, we generate single triples for such questions without considering constraints as well, and add them to the search space for competition. $h_{syntax\_constraint}(\cdot)$

is used to boost triples that are converted from sub-questions generated by question decomposition. The more constraints an answer satisfies, the better. Obviously, current patterns used can't cover all cases but most-common ones. We leave a more general pattern mining method for future work.

2.4 Feature Design

The objective of our KB-QA system is to seek the derivation $\langle \hat{\mathcal{D}}, \hat{\mathcal{A}} \rangle$ that maximizes the probability $P(\langle \mathcal{D}, \mathcal{A} \rangle | \mathcal{KB}, \mathcal{Q})$ described in Section 2.1 as:

$$\begin{aligned} \langle \hat{\mathcal{D}}, \hat{\mathcal{A}} \rangle &= \underset{\langle \mathcal{D}, \mathcal{A} \rangle \in \mathcal{H}(\mathcal{Q})}{argmax} P(\langle \mathcal{D}, \mathcal{A} \rangle | \mathcal{KB}, \mathcal{Q}) \\ &= \underset{\langle \mathcal{D}, \mathcal{A} \rangle \in \mathcal{H}(\mathcal{Q})}{argmax} \sum_{i=1}^{M} \lambda_i \cdot h_i(\langle \mathcal{D}, \mathcal{A} \rangle, \mathcal{KB}, \mathcal{Q}) \end{aligned}$$

We now introduce the feature sets $\{h_i(\cdot)\}$ that are used in the above linear model:

- $h_{question\_word}(\cdot)$, which counts the number of original question words occurring in $\mathcal{A}$. It penalizes those partially answered questions.
- $h_{span}(\cdot)$, which counts the number of spans in $\mathcal{Q}$ that are converted to formal triples. It controls the granularity of the spans used in question translation.
- $h_{syntax\_subtree}(\cdot)$, which counts the number of spans in $\mathcal{Q}$ that are (1) converted to formal triples, whose predicates are not $Null$, and (2) covered by complete dependency subtrees at the same time. The underlying intuition is that, dependency subtrees of $\mathcal{Q}$ should be treated as units for question translation.
- $h_{syntax\_constraint}(\cdot)$, which counts the number of triples in $\mathcal{D}$ that are converted from sub-questions generated by the question decomposition component.
- $h_{triple}(\cdot)$, which counts the number of triples in $\mathcal{D}$, whose predicates are not $Null$.
- $h_{triple_{weight}}(\cdot)$, which sums the scores of all triples $\{t_i\}$ in $\mathcal{D}$ as $\sum_{t_i \in \mathcal{D}} t_i.score$.
- $h_{\mathcal{QP}_{count}}(\cdot)$, which counts the number of triples in $\mathcal{D}$ that are generated by $\mathcal{QP}$-based question translation method.
- $h_{\mathcal{RE}_{count}}(\cdot)$, which counts the number of triples in $\mathcal{D}$ that are generated by $\mathcal{RE}$-based question translation method.
- $h_{staticrank_{sbj}}(\cdot)$, which sums the static rank scores of all subject entities in $\mathcal{D}$'s triple set as $\sum_{t_i \in \mathcal{D}} t_i.e_{sbj}.static\_rank$.
- $h_{staticrank_{obj}}(\cdot)$, which sums the static rank scores of all object entities in $\mathcal{D}$'s triple set as $\sum_{t_i \in \mathcal{D}} t_i.e_{obj}.static\_rank$.
- $h_{confidence_{obj}}(\cdot)$, which sums the confidence scores of all object entities in $\mathcal{D}$'s triple set as $\sum_{t \in \mathcal{D}} t.e_{obj}.confidence$.

For each assertion $\{e_{sbj}, p, e_{obj}\}$ stored in $\mathcal{KB}$, $e_{sbj}.static\_rank$ and $e_{obj}.static\_rank$ denote the static rank scores[5] for e_{sbj} and e_{obj} respectively; $e_{obj}.confidence\_rank$ represents the probability $p(e_{obj}|e_{sbj}, p)$. These three scores are used as features to rank answers generated in QA procedure.

2.5 Feature Weight Tuning

Given a set of question-answer pairs $\{\mathcal{Q}_i, \mathcal{A}_i^{ref}\}$ as the development (dev) set, we use the minimum error rate training (MERT) (Och, 2003) algorithm to tune the feature weights λ_i^M in our proposed model. The training criterion is to seek the feature weights that can minimize the accumulated errors of the top-1 answer of questions in the dev set:

$$\hat{\lambda}_1^M = \underset{\lambda_1^M}{argmin} \sum_{i=1}^{N} Err(\mathcal{A}_i^{ref}, \hat{\mathcal{A}}_i; \lambda_1^M)$$

N is the number of questions in the dev set, $\mathcal{A}_i^{ref}$ is the correct answers as references of the i^{th} question in the dev set, $\hat{\mathcal{A}}_i$ is the top-1 answer candidate of the i^{th} question in the dev set based on feature weights λ_1^M, $Err(\cdot)$ is the error function which is defined as:

$$Err(\mathcal{A}_i^{ref}, \hat{\mathcal{A}}_i; \lambda_1^M) = 1 - \delta(\mathcal{A}_i^{ref}, \hat{\mathcal{A}}_i)$$

where $\delta(\mathcal{A}_i^{ref}, \hat{\mathcal{A}}_i)$ is an indicator function which equals 1 when $\hat{\mathcal{A}}_i$ is included in the reference set $\mathcal{A}_i^{ref}$, and 0 otherwise.

3 Comparison with Previous Work

Our work intersects with two research directions: semantic parsing and question answering.

Some previous works on semantic parsing (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Wong and Mooney, 2006; Zettlemoyer and Collins, 2007; Wong and Mooney,

[5]The static rank score of an entity represents a general indicator of the overall quality of that entity.

2007; Kwiatkowski et al., 2010; Kwiatkowski et al., 2011) require manually annotated logical forms as supervision, and are hard to extend resulting parsers from limited domains, such as GEO, JOBS and ATIS, to open domains. Recent works (Clarke and Lapata, 2010; Liang et al., 2013) have alleviated such issues using question-answer pairs as weak supervision, but still with the shortcoming of using limited lexical triggers to link NL phrases to predicates. Poon (2013) has proposed an unsupervised method by adopting grounded-learning to leverage the database for indirect supervision. But transformation from NL questions to MRs heavily depends on dependency parsing results. Besides, the KB used (ATIS) is limited as well. Kwiatkowski et al. (2013) use Wiktionary and a limited manual lexicon to map POS tags to a set of predefined CCG lexical categories, which aims to reduce the need for learning lexicon from training data. But it still needs human efforts to define lexical categories, which usually can not cover all the semantic phenomena.

Berant et al. (2013) have not only enlarged the KB used for Freebase (Google, 2013), but also used a bigger lexicon trigger set extracted by the open IE method (Lin et al., 2012) for NL phrases to predicates linking. In comparison, our method has further advantages: (1) Question answering and semantic parsing are performed in an joint way under a unified framework; (2) A robust method is proposed to map NL questions to their formal triple queries, which trades off the mapping quality by using question patterns and relation expressions in a cascaded way; and (3) We use domain independent feature set which allowing us to use a relatively small number of question-answer pairs to tune model parameters.

Fader et al. (2013) map questions to formal (triple) queries over a large scale, open-domain database of facts extracted from a raw corpus by ReVerb (Fader et al., 2011). Compared to their work, our method gains an improvement in two aspects: (1) Instead of using facts extracted using the open IE method, we leverage a large scale, high-quality knowledge base; (2) We can handle multiple-relation questions, instead of single-relation queries only, based on our translation based KB-QA framework.

Espana-Bonet and Comas (2012) have proposed an MT-based method for factoid QA. But MT in there work means to translate questions into n-best translations, which are used for finding similar sentences in the document collection that probably contain answers. Echihabi and Marcu (2003) have developed a noisy-channel model for QA, which explains how a sentence containing an answer to a given question can be rewritten into that question through a sequence of stochastic operations. Compared to the above two MT-motivated QA work, our method uses MT methodology to translate questions to answers directly.

4 Experiment

4.1 Data Sets

Following Berant et al. (2013), we use the same subset of WEBQUESTIONS (3,778 questions) as the development set (Dev) for weight tuning in MERT, and use the other part of WEBQUESTIONS (2,032 questions) as the test set (Test). Table 1 shows the statistics of this data set.

Data Set	# Questions	# Words
WEBQUESTIONS	5,810	6.7

Table 1: Statistics of evaluation set. # Questions is the number of questions in a data set, # Words is the averaged word count of a question.

Table 2 shows the statistics of question patterns and relation expressions used in our KB-QA system. As all question patterns are collected with human involvement as we discussed in Section 2.3.1, the quality is very high (98%). We also sample 1,000 instances from the whole relation expression set and manually label their quality. The accuracy is around 89%. These two resources can cover 566 head predicates in our KB.

	# Entries	Accuracy
Question Patterns	4,764	98%
Relation Expressions	133,445	89%

Table 2: Statistics of question patterns and relation expressions.

4.2 KB-QA Systems

Since Berant et al. (2013) is one of the latest work which has reported QA results based on a large scale, general domain knowledge base (Freebase), we consider their evaluation result on WEBQUESTIONS as our baseline.

Our KB-QA system generates the k-best derivations for each question span, where k is set to 20.

The answers with the highest model scores are considered the best answers for evaluation. For evaluation, we follow Berant et al. (2013) to allow partial credit and score an answer using the F1 measure, comparing the predicted set of entities to the annotated set of entities.

One difference between these two systems is the KB used. Since Freebase is completely contained by our KB, we disallow all entities which are not included by Freebase. By doing so, our KB provides the same knowledge as Freebase does, which means we do not gain any extra advantage by using a larger KB. But we still allow ourselves to use the static rank scores and confidence scores of entities as features, as we described in Section 2.4.

4.3 Evaluation Results

We first show the overall evaluation results of our KB-QA system and compare them with baseline's results on Dev and Test. Note that we do not re-implement the baseline system, but just list their evaluation numbers reported in the paper. Comparison results are listed in Table 3.

	Dev (Accuracy)	Test (Accuracy)
Baseline	32.9%	31.4%
Our Method	42.5% **(+9.6%)**	37.5% **(+6.1%)**

Table 3: Accuracy on evaluation sets. $Accuracy$ is defined as the number of correctly answered questions divided by the total number of questions.

Table 3 shows our KB-QA method outperforms baseline on both Dev and Test. We think the potential reasons of this improvement include:

- Different methods are used to map NL *phrases* to KB predicates. Berant et al. (2013) have used a lexicon extracted from a subset of ReVerb triples (Lin et al., 2012), which is similar to the relation expression set used in question translation. But as our relation expressions are extracted by an in-house extractor, we can record their extraction-related statistics as extra information, and use them as features to measure the mapping quality. Besides, as a portion of entities in our KB are extracted from Wiki, we know the one-to-one correspondence between such entities and Wiki pages, and use this information in relation expression extraction for entity disambiguation. A lower disambiguation error rate results in better relation expressions.
- Question patterns are used to map NL *context* to KB predicates. Context can be either continuous or discontinues phrases. Although the size of this set is limited, they can actually cover head questions/queries[6] very well. The underlying intuition of using patterns is that those high-frequent questions/queries should and can be treated and solved in the QA task, by involving human effort at a relative small price but with very impressive accuracy.

In order to figure out the impacts of question patterns and relation expressions, another experiment (Table 4) is designed to evaluate their independent influences, where $\mathcal{QP}_{only}$ and $\mathcal{RE}_{only}$ denote the results of KB-QA systems which only allow question patterns and relation expressions in question translation respectively.

Settings	Test (Accuracy)	Test (Precision)
$\mathcal{QP}_{only}$	11.8%	97.5%
$\mathcal{RE}_{only}$	32.5%	73.2%

Table 4: Impacts of question patterns and relation expressions. $Precision$ is defined as the number of correctly answered questions divided by the number of questions with non-empty answers generated by our KB-QA system.

From Table 4 we can see that the accuracy of $\mathcal{RE}_{only}$ on Test (32.5%) is slightly better than baseline's result (31.4%). We think this improvement comes from two aspects: (1) The quality of the relation expressions is better than the quality of the lexicon entries used in the baseline; and (2) We use the extraction-related statistics of relation expressions as features, which brings more information to measure the confidence of mapping between NL phrases and KB predicates, and makes the model to be more flexible. Meanwhile, $\mathcal{QP}_{only}$ perform worse (11.8%) than $\mathcal{RE}_{only}$, due to coverage issue. But by comparing the precisions of these two settings, we find $\mathcal{QP}_{only}$ (97.5%) outperforms $\mathcal{RE}_{only}$ (73.2%) significantly, due to its high quality. This means how to extract high-quality question patterns is worth to be studied for the question answering task.

As the performance of our KB-QA system relies heavily on the k-best beam approximation, we evaluate the impact of the beam size and list the comparison results in Figure 6. We can see that as

[6]Head questions/queries mean the questions/queries with high frequency and clear patterns.

we increase k incrementally, the accuracy increase at the same time. However, a larger k (e.g. 200) cannot bring significant improvements comparing to a smaller one (e.g., 20), but using a large k has a tremendous impact on system efficiency. So we choose $k = 20$ as the optimal value in above experiments, which trades off between accuracy and efficiency.

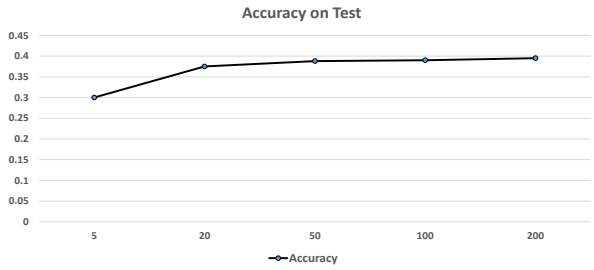

Figure 6: Impacts of beam size on accuracy.

Actually, the size of our system's search space is much smaller than the one of the semantic parser used in the baseline.This is due to the fact that, if triple queries generated by the question translation component cannot derive any answer from KB, we will discard such triple queries directly during the QA procedure. We can see that using a small k can achieve better results than baseline, where the beam size is set to be 200.

4.4 Error Analysis

4.4.1 Entity Detection

Since named entity recognizers trained on Penn TreeBank usually perform poorly on web queries, We instead use a simple string-match method to detect entity mentions in the question using a cleaned entity dictionary dumped from our KB. One problem of doing so is the entity detection issue. For example, in the question *who was Esther's husband ?*, we cannot detect *Esther* as an entity, as it is just part of an entity name. We need an ad-hoc entity detection component to handle such issues, especially for a web scenario, where users often type entity names in their partial or abbreviation forms.

4.4.2 Predicate Mapping

Some questions lack sufficient evidences to detect predicates. *where is Byron Nelson 2012 ?* is an example. Since each relation expression must contain at least one content word, this question cannot match any relation expression. Except for *Byron Nelson* and *2012*, all the others are non-content words.

Besides, ambiguous entries contained in relation expression sets of different predicates can bring mapping errors as well. For the following question *who did Steve Spurrier play pro football for?* as an example, since the unigram *play* exists in both *Film.Film.Actor* and *American_Football.Player.Current_Team* 's relation expression sets, we made a wrong prediction, which led to wrong answers.

4.4.3 Specific Questions

Sometimes, we cannot give exact answers to superlative questions like *what is the first book Sherlock Holmes appeared in?*. For this example, we can give all book names where *Sherlock Holmes* appeared in, but we cannot rank them based on their publication date , as we cannot learn the alignment between the constraint word *first* occurred in the question and the predicate *Book.Written_Work.Date_Of_First_Publication* from training data automatically. Although we have followed some work (Poon, 2013; Liang et al., 2013) to handle such special linguistic phenomena by defining some specific operators, it is still hard to cover all unseen cases. We leave this to future work as an independent topic.

5 Conclusion and Future Work

This paper presents a translation-based KB-QA method that integrates semantic parsing and QA in one unified framework. Comparing to the baseline system using an independent semantic parser with state-of-the-art performance, we achieve better results on a general domain evaluation set.

Several directions can be further explored in the future: (i) We plan to design a method that can extract question patterns automatically, using existing labeled question patterns and KB as weak supervision. As we discussed in the experiment part, how to mine high-quality question patterns is worth further study for the QA task; (ii) We plan to integrate an ad-hoc NER into our KB-QA system to alleviate the entity detection issue; (iii) In fact, our proposed QA framework can be generalized to other intelligence besides knowledge bases as well. Any method that can generate answers to questions, such as the Web-based QA approach, can be integrated into this framework, by using them in the question translation component.

Discourse Complements Lexical Semantics for Non-factoid Answer Reranking

Abstract

We propose a robust answer reranking model for non-factoid questions that integrates lexical semantics with discourse information, driven by two representations of discourse: a shallow representation centered around discourse markers, and a deep one based on Rhetorical Structure Theory. We evaluate the proposed model on two corpora from different genres and domains: one from Yahoo! Answers and one from the biology domain, and two types of non-factoid questions: manner and reason. We experimentally demonstrate that the discourse structure of non-factoid answers provides information that is complementary to lexical semantic similarity between question and answer, improving performance up to 24% (relative) over a state-of-the-art model that exploits lexical semantic similarity alone. We further demonstrate excellent domain transfer of discourse information, suggesting these discourse features have general utility to non-factoid question answering.

1 Introduction

Driven by several international evaluations and workshops such as the Text REtrieval Conference (TREC)[1] and the Cross Language Evaluation Forum (CLEF),[2] the task of question answering (QA) has received considerable attention. However, most of this effort has focused on factoid questions rather than more complex non-factoid (NF) questions, such as manner, reason, or causation questions. Moreover, the vast majority of QA models explore only local linguistic structures, such as syntactic dependencies or semantic role frames, which are generally restricted to individual sentences. This is problematic for NF QA, where questions are answered not by atomic facts, but by larger cross-sentence conceptual structures that convey the desired answers. Thus, to answer NF questions, one needs a model of what these answer structures look like.

Driven by this observation, our main hypothesis is that the discourse structure of NF answers provides complementary information to state-of-the-art QA models that measure the similarity (either lexical and/or semantic) between question and answer. We propose a novel answer reranking (AR) model that combines lexical semantics (LS) with discourse information, driven by two representations of discourse: a shallow representation centered around discourse markers and surface text information, and a deep one based on the Rhetorical Structure Theory (RST) discourse framework (Mann and Thompson, 1988). To the best of our knowledge, this work is the first to systematically explore within- and cross-sentence structured discourse features for NF AR. The contributions of this work are:

1. We demonstrate that modeling discourse is greatly beneficial for NF AR for two types of NF questions, manner (*"how"*) and reason (*"why"*), across two large datasets from different genres and domains – one from the community question-answering (CQA) site of Yahoo! Answers[3], and one from a biology textbook. Our results show statistically significant improvements of up to 24% on top of state-of-the-art LS models (Yih et al., 2013).
2. We demonstrate that both shallow and deep discourse representations are useful, and, in general, their combination performs best.
3. We show that discourse-based QA models using inter-sentence features considerably out-

perform single-sentence models when answers span multiple sentences.

4. We demonstrate good domain transfer performance between these corpora, suggesting that answer discourse structures are largely independent of domain, and thus broadly applicable to NF QA.

2 Related Work

The body of work on factoid QA is too broad to be discussed here (see, e.g., the TREC workshops for an overview). However, in the context of LS, Yih et al. (2013) recently addressed the problem of answer sentence selection and demonstrated that LS models, including recurrent neural network language models (RNNLM), have a higher contribution to overall performance than exploiting syntactic analysis. We extend this work by showing that discourse models coupled with LS achieve the best performance for NF AR.

The related work on NF QA is considerably more scarce, but several trends are clear. First, most NF QA approaches tend to use multiple similarity models (information retrieval or alignment) as features in discriminative rerankers (Riezler et al., 2007; Higashinaka and Isozaki, 2008; Verberne et al., 2010; Surdeanu et al., 2011). Second, and more relevant to this work, all these approaches focus either on bag-of-word representations or linguistic structures that are restricted to single sentences (e.g., syntactic dependencies, semantic roles, or standalone discourse cue phrases).

Answering *how* questions using a single discourse marker, *by*, was previously explored by Prager et al. (2000), who searched for *by* followed by a present participle (e.g. *by *ing*) to elevate answer candidates in a ranking framework. Verberne et al. (2011) extracted 47 cue phrases such as *because* from a small collection of web documents, and used the cosine similarity between an answer candidate and a bag of words containing these cue phrases as a single feature in their reranking model for non-factoid *why* QA. Extending this, Oh et al. (2013) built a classifier to identify causal relations using a small set of cue phrases (e.g., *because* and *is caused by*). This classifier was then used to extract instances of causal relations in answer candidates, which were turned into features in a reranking model for Japanese *why* QA.

In terms of discourse parsing, Verberne et al. (2007) conducted an initial evaluation of the utility of RST structures to *why* QA by evaluating

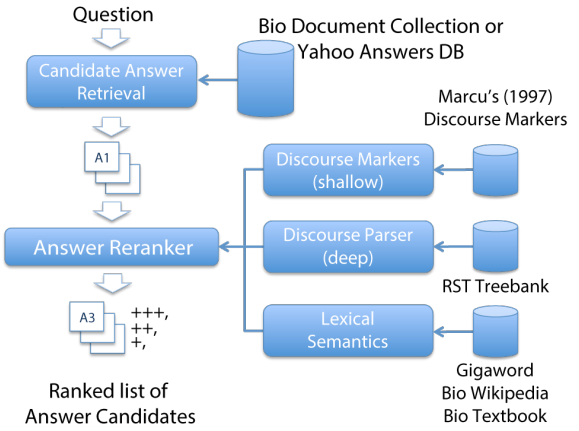

Figure 1: Architecture of the reranking framework for QA.

performance on a small sample of seven WSJ articles drawn from the RST Treebank (Carlson et al., 2003). They later concluded that while discourse parsing appears to be useful for QA, automated discourse parsing tools are required before this approach can be tested at scale (Verberne et al., 2010). Inspired by this previous work and recent work in discourse parsing (Feng and Hirst, 2012), our work is the first to systematically explore structured discourse features driven by several discourse representations, combine discourse with lexical semantic models, and evaluate these representations on thousands of questions using both in-domain and cross-domain experiments.

3 Approach

The proposed answer reranking component is embedded in the QA framework illustrated in Figure 1. This framework functions in two distinct scenarios, which use the same AR model, but differ in the way candidate answers are retrieved:

CQA: In this scenario, the task is defined as reranking all the user-posted answers for a particular question to boost the community-selected best answer to the top position. This is a commonly used setup in the CQA community (Wang et al., 2009).[4] Thus, for a given question, all its answers are fetched from the answer collection, and an initial ranking is constructed based on the cosine similarity between theirs and the question's lemma vector representations, with lemmas weighted using *tf.idf* (Ch. 6, (Manning et al., 2008)).

[4] Although most of these works use shallow textual features and focus mostly on meta data, e.g., number of votes for a particular answer. Here we use no meta data and rely solely on linguistic features.

Traditional QA: In this scenario answers are dynamically constructed from larger documents (Pasca, 2001). We use this setup to answer questions from a biology textbook, where each section is indexed as a standalone document, and each paragraph in a given document is considered as a candidate answer. We implemented the document indexing and retrieval stage using Lucene[5]. The candidate answers are scored using a linear interpolation of two cosine similarity scores: one between the entire parent document and question (to model global context), and a second between the answer candidate and question (for local context).[6] Because the number of answer candidates is typically large (e.g., equal to the number of paragraphs in the textbook), we return the N top candidates with the highest scores.

These answer candidates are then passed to the answer reranking component, the focus of this work. AR analyzes the candidates using more expensive techniques to extract discourse and LS features (detailed in §4), and these features are then used in concert with a learning framework to rerank the candidates and elevate correct answers to higher positions. For the learning framework, we used SVM^{rank}, a variant of Support Vector Machines for structured output adapted to ranking problems.[7] In addition to these features, each reranker also includes a single feature containing the score of each candidate, as computed by the above candidate retrieval (CR) component.[8]

4 Models and Features

We propose two separate discourse representation schemes – one shallow, centered around discourse markers, and one deep, based on RST.

4.1 Discourse Marker Model

The discourse marker model (DMM) extracts cross-sentence discourse structures centered around a discourse marker. This extraction process is illustrated in the top part of Figure 2. These structures are represented using three components: (1) A **discourse marker** from Daniel Marcu's list (see Appendix B in Marcu (1997)), that serves as a divisive boundary between sentences. Examples of these markers include *and, in, that, for, if, as, not, by,* and *but*; (2) **two marker arguments**, i.e., text segments before and after the marker, labeled to indicate if they are related to the question text or not; and (3) **a sentence range** around the marker, which defines the length of these segments (e.g., ± 2 sentences). For example, a marker feature may take the form of: `QSEG BY OTHER SR2`, which means that the the marker *by* has been detected in an answer candidate. Further, the text preceeding *by* matches text from the question (and is therefore labeled `QSEG`), while the text after *by* differs considerably from the question text, and is labeled `OTHER`. In this particular example, the scope of this similarity matching occurs over a span of ± 2 sentences around the marker.

Note that our marker arguments are akin to EDUs in RST, but, in this shallow representation, they are simply constructed around discourse markers and bound by an arbitrary sentence range.

Argument Labels: We label marker arguments based on their similarity to question content. If text before or after a marker out to a given sentence range matches the entire text of the question (with a cosine similarity score larger than a threshold), that argument takes on the label `QSEG`, or `OTHER` otherwise. In this way the features are only partially lexicalized with the discourse markers. Argument labels indicate only if lemmas from the question were found in a discourse structure present in an answer candidate, and do not speak to the specific lemmas that were found. We show in §5 that these lightly lexicalized features perform well in domain and transfer between domains. We explore other argument labeling strategies in §5.7.

Feature Values: Our reranking framework uses real-valued features. The values of the discourse features are the mean of the similarity scores (e.g., cosine similarity using *tf.idf* weighting) of the two marker arguments and the corresponding question. For example, the value of the `QSEG BY QSEG SR1` feature in Figure 2 is the average of the cosine similarities of the question text with the answer texts before/after *by* out to a distance of one sentence before/after the marker.

It is important to note that these discourse features are more expressive than features based on discourse markers alone (Higashinaka and Isozaki, 2008; Verberne et al., 2010). First,

[5] `http://lucene.apache.org`

[6] We empirically observed that this combination of scores performs better than using solely the cosine similarity between the answer and question.

[7] `http://www.cs.cornell.edu/people/tj/svm_light/svm_rank.html`

[8] Including these scores as features in the reranker model is a common strategy that ensures that the reranker takes advantage of the analysis already performed by the CR model.

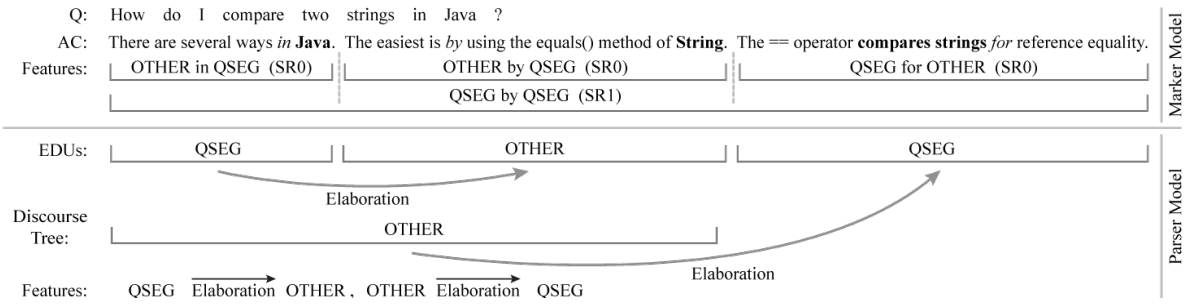

Figure 2: **Top:** Example feature generation for the discourse marker model, for one question (Q) and one answer candidate (AC). Answer candidates are searched for discourse markers (*italic*) and question word matches (**bold**), which are used to generate features both within-sentence (SR0), and ± 1 sentence (SR1). The actual DMM exhaustively generates features for all markers and all sentence ranges. Here we show just a few for brevity. **Bottom:** Example feature generation for the discourse parser model using the output of an actual discourse parser. The DPM creates one feature for each individual discourse relation.

the argument sequences used here capture cross-sentence discourse structures. Second, these features model the intensity of the match between the text surrounding the discourse structure and the question text using both the assigned argument labels and the feature values.

4.2 Discourse Parser Model

The discourse parser model (DPM) is based on the RST discourse framework (Mann and Thompson, 1988). In RST, the text is segmented into a sequence of non-overlapping fragments called elementary discourse units (EDUs), and binary discourse relations recursively connect neighboring units. Most relations are *hypotactic*, where one of the units in the relation (the *nucleus*) is considered more important than the other (the *satellite*). A few relations are *paratactic*, where both participants have equal importance. In the bottom part of Figure 2, we show hypotactic relations as directed arrows, from the nucleus to the satellite. In this work, we construct the RST discourse trees using the parser of Feng and Hirst (2012).

Relying on a proper discourse framework facilitates the modeling of the numerous implicit relations that are not driven by discourse markers (see Ch. 21 in Jurafsky and Martin (2009)). However, this also introduces noise because discourse analysis is a complex task and discourse parsers are not perfect. To mitigate this, we used a simple feature generation strategy, which creates one feature for each individual discourse relation by concatenating the relation type with the labels of the discourse units participating in it. To this end, for every relation, we extract the entire text dominated by each of its arguments, and we generate labels for the two participants in the relation using the same strategy as the DMM (based on the similarity with the question content). Similar to the DMM, these features take real values obtained by averaging the cosine similarity of the arguments with the question content.[9] Fig. 2 shows several such features, created around two RST `Elaboration` relations, indicating that the latter sentences expand on the information at the beginning of the answer. Other common relations include `Attribution`, `Contrast`, `Background`, and `Evaluation`.

4.3 Lexical Semantics Model

Inspired by the work of Yih et al. (2013), we include lexical semantics in our reranking model. Several of their proposed models rely on proprietary data; here we focus on LS models that rely on open-source data and frameworks. In particular, we use the recurrent neural network language model (RNNLM) of Mikolov et al. (2013; 2010). Like any language model, a RNNLM estimates the probability of observing a word given the preceding context, but, in this process, it learns word embeddings into a latent, conceptual space with a fixed number of dimensions. Consequently, related words tend to have vectors that are close to each other in this space.

We derive two LS measures from these vectors, which are then are included as features in the reranker. The first is a measure of the overall LS similarity of the question and answer can-

[9] We investigated more complex features, e.g., by exploring depths of two and three in the discourse tree, and also models that relied on tree kernels over these trees, but none improved upon this simple representation. This suggests that, in the domains explored here, there is a degree of noise introduced by the discourse parser, and the simple features proposed here are the best strategy to avoid overfitting on it.

didate, which is computed as the cosine similarity between the two composite vectors of the question and the answer candidate. These composite vectors are assembled by summing the vectors for individual question (or answer candidate) words, and re-normalizing this composite vector to unit length. Both this overall similarity score, as well as the average pairwise cosine similarity between each word in the question and answer candidate, serve as features.

5 Experiments

5.1 Data

To test the utility of our approach, we experimented with the two QA scenarios introduced in §3 using the following two datasets:

Yahoo! Answers Corpus (YA): Yahoo! Answers[10] is an open domain community-generated QA site, with questions and answers that span formal and precise to informal and ambiguous language. Due to the speed limitations of the discourse parser, we randomly drew 10,000 QA pairs from the corpus of *how* questions described by Surdeanu et al. (2011) using their filtering criteria, with the additional criterion that answers had to contain at least four community-generated answers, one of which was voted as the top answer. The number of answers to each question ranged from 4 to over 50, with the average 9.[11]

Biology Textbook Corpus (Bio): This corpus focuses on the domain of cellular biology, and consists of 185 *how* and 193 *why* questions handcrafted by a domain expert. Each question has one or more gold answers identified in Campbell's Biology (Reece et al., 2011), a popular undergraduate text. The entire biology text (at paragraph granularity) serves as the possible set of answers. Note that while our system retrieves answers at paragraph granularity, the expert was not constrained in any way during the annotation process, so gold answers might be smaller than a paragraph or span multiple paragraphs. This complicates evaluation metrics on this dataset (see §5.3).

[10] `http://answers.yahoo.com`

[11] Note that our experimental setup, i.e., reranking all the answers provided for each question, is different from that of Surdeanu et al. For each question, they retrieved candidate answers from all answers voted as best for some question in the collection. The setup in this paper, commonly used in the CQA community (Wang et al., 2009), is more relevant here because it includes both high and low quality answers.

For the YA CQA corpora, 50% of QA pairs were used for training, 25% for development, and 25% for test. Because of the small size of the Bio corpus, it was evaluated using 5-fold cross-validation, with three folds for training, one for development, and one for test.

The following additional resources were used:

Discourse Markers: A set of 75 high-frequency[12] single-word discourse markers were extracted from Marcu's (1997) list of cue phrases, and used for feature generation in DMM. These discourse markers are extremely common in the answer corpora – for example, the YA corpus contains an average of 7 markers per answer.

Discourse Trees: We generated all discourse trees using the parser of Feng and Hirst (2012). For YA, we parsed entire answers. For Bio, we parsed individual paragraphs. Note that, because these domains are considerably different from the RST Treebank, the parser fails to produce a tree on a large number of answer candidates: 6.2% for YA, and 41.1% for Bio. In these situations, we constructed artificial discourse trees using a right-attachment heuristic and a single relation label `X`.

Lexical Semantics: We trained two different RNNLMs for this work. First, for the YA experiments we trained an open-domain RNNLM using the entire Gigaword corpus of approximately 4G words.[13] For the Bio experiments, we trained a domain specific RNNLM over a concatenation of the textbook and a subset of Wikipedia specific to biology. The latter was created by extracting: (a) pages matching a word/phrase in a glossary of biology (derived from the textbook); plus (b) pages hyperlinked from (a) that are also tagged as being in a small set of (hand-selected) biology-related categories. The combined dataset contains 7.7M words. For all RNNLMs we used 200-dimensional vectors.

5.2 Hyper Parameter Tuning

The following hyper parameters were tuned using grid search to maximize P@1 on each development partition: (a) the segment matching thresholds that determine the minimum cosine similarity between an answer segment and a question for the segment to be labeled `QSEG`; and (b)

[12] We selected all cue phrases with more than 100 occurrences in the Brown corpus.

Table 1: Overall results across three datasets. The improvements in each section are computed relative to their respective baseline (CR or CR + LS). Bold font indicates the best score in a given column. * indicates that a score is significantly better ($p < 0.05$) than the score of the corresponding baseline. All significance tests were implemented using one-tailed non-parametric bootstrap resampling using 10,000 iterations.

SVM^{rank}'s regularization parameter C. For all experiments, the sentence range parameter (`SRx`) for DMM ranged from 0 (within sentence) to ± 3 sentences.[14]

5.3 Evaluation Metrics

For YA, we used the standard implementations for P@1 and mean reciprocal rank (MRR) (Manning et al., 2008). In the Bio corpus, because answer candidates are not guaranteed to match gold annotations exactly, these metrics do not immediately apply. We adapted them to this dataset by weighing each answer by its overlap with gold answers, where overlap is measured as the highest F1 score between the candidate and a gold answer. Thus, P@1 reduces to this F1 score for the top answer. For MRR, we used the rank of the candidate with the highest overlap score, weighed by the inverse of the rank. For example, if the best answer for a question appears at rank 2 with an F1 score of 0.3, the corresponding MRR score is $0.3/2$.

[14]This was only limited to reduce the combinatorial expansion of feature generation, and in principle could be set much broader.

5.4 Overall Results

Table 1 analyzes the performance of the proposed reranking model on the three datasets and against two baselines. The first baseline sorts the candidate answers in descending order of the scores produced by the candidate retrieval (CR) module. The second baseline (CR + LS) trains a reranking model without discourse, using just the CR and LS features. For YA, we include an additional baseline that selects an answer randomly. We list multiple versions of the proposed reranking model, broken down by the features used. For Bio, we retrieved the top 20 answer candidates in CR. At this setting, the oracle performance (i.e., the performance with perfect reranking of the 20 candidates) was 69.6% P@1 for Bio HOW, and 72.3% P@1 for Bio WHY. These relatively low oracle scores, which serve as a performance ceiling for our approach, highlight the difficulty of the task. For YA, we used all answers provided for each given question. For all experiments we used a linear SVM kernel.[15]

Examining Table 1, several trends are clear. Both discourse models significantly increase both P@1 and MRR performance over all baselines broadly across genre, domain, and question types. More specifically, DMM and DPM show similar performance benefits when used individually, but their combination generally outperforms the individual models, illustrating the fact that the two models capture related but different discourse information. This is a motivating result for discourse analysis, especially considering that the discourse parser was trained on a domain different from the corpora used here.

Lexical semantic features increase performance for all settings, but demonstrate far more utility to the open-domain YA corpus. This disparity is likely due to the difficulty in assembling LS training data at an appropriate level for the biology corpus, contrasted with the relative abundance of large scale open-domain lexical semantic resources. For the YA corpus, where lexical semantics showed the most benefit, simply adding

[15]The performance of all models can ultimately be increased by using more sophisticated learning frameworks, and considering more answer candidates in CR (for Bio). For example, SVMs with polynomial kernels of degree two showed approximately half a percent (absolute) performance gain over the linear kernel. However, this came at the expense of an experiment runtime about an order of magnitude larger. Experiments with more answer candidates in Bio showed similar trends to the results reported.

Q	How does myelination affect action potentials?
$A_{baseline}$	The major selective advantage of myelination is its space efficiency. A myelinated axon 20 microns in diameter has a conduction speed faster than that of a squid giant axon [...]. Furthermore, more than 2,000 of those myelinated axons can be packed into the space occupied by just one giant axon.
A_{rerank}	A nerve impulse travels [...] to the synaptic terminals by propagation of a series action potentials along the axon. The speed of conduction increases [...] with myelination. Action potentials in myelinated axons jump between the nodes of Ranvier, a process called saltatory conduction.

Table 2: An example question from the Biology corpus where the correct answer is elevated to the top position by the discourse model. $A_{baseline}$ is the top answer proposed by the CR + LS baseline, which is incorrect, whereas A_{rerank} is the correct answer boosted to the top after reranking. [...] indicates non-essential text that was removed for space.

Range	Bio HOW	Bio WHY	YA
CR + LS + DMM + DPM			
within-sentence	+0.8%	+8.4%	+13.1%
full model	+21.0%*	+23.9%*	+14.8%

Table 3: Relative P@1 performance increase over the CR + LS baseline for a model containing only intra-sentence features, compared to the full model.

LS features to the CR baseline increases baseline P@1 performance from 19.57 to 26.57, a +36% relative improvement. Most importantly, comparing lines 5 and 9 with their respective baselines (lines 2 and 6, respectively) indicates that LS is largely orthogonal to discourse. Line 5, the top-performing model with discourse but without LS outperforms the CR baseline by +5.24 absolute P@1 improvement. Similarly, line 9, the top-performing model that combines discourse with LS has a +5.69 absolute P@1 improvement over the CR + LS baseline. That this absolute performance increase is nearly identical indicates that LS features are complementary to and additive with the full discourse model. Indeed, an analysis of the questions improved by discourse vs. LS (line 5 vs. 6) showed that the intersection of the two sets is low (approximately a third of each set).

Finally, while the discourse models perform well for HOW or *manner* questions, performance on Bio WHY corpus suggests that *reason* questions are particularly amenable to discourse analysis. Relative improvements on WHY questions reach +38% (without LS) and +24% (with LS), with absolute performance on these non-factoid questions jumping from 28% to nearly 40% P@1.

Table 2 shows one example where discourse helps boost the correct answer to the top position. In this example, the correct answer contains multiple `Elaboration` relations that are both cross sentence (e.g., between the first two sentences) and intra-sentence (e.g., between the first part of the second sentence and the phrase "with myelination"). Model features associated with `Elaboration` relations are ranked highly by the learned model. In contrast, the answer preferred by the baseline contains mostly `Joint` relations, which "represent the lack of a rhetorical relation between the two nuclei" (Mann and Thompson, 1988) and have very small weights in the model.

5.5 Intra vs. Inter-sentence Features

To tease apart the relative contribution of discourse features that occur only within a single sentence versus features that span multiple sentences, we examined the performance of the full model when using only intra-sentence features, i.e., `SR0` features for DMM, and features based on discourse relations where both EDUs appear in the same sentence for DPM, versus the full intersentence models. The results are shown in Table 3.

For the Bio corpus where answer candidates consist of entire paragraphs of a biology text, overall performance is dominated by inter-sentence discourse features. Conversely, for YA, a large proportion of performance comes from features that span only a single sentence. This is caused by the fact that YA answers are far shorter and of variable grammatical quality, with 39% of answer candidates consisting of only a single sentence, and 57% containing two or fewer sentences. All in all, this experiment emphasizes that modeling both intra- and inter-sentence discourse (where available) is beneficial for non-factoid QA.

5.6 Domain Transfer

Because these discourse models appear to capture high-level information about answer structures, we hypothesize that the models should make use of many of the same discourse features, even when training on data from different domains. Table 4 shows that of the highest-weighted SVM features learned when training models for HOW questions on YA and Bio, many are shared (e.g., 56.5% of the features in the top half of both DPMs are shared), suggesting that a core set of discourse features may be of utility across domains.

To test the generality of these features, we performed a transfer study where the full model was trained and tuned on the open-domain YA corpus, then evaluated as is on Bio HOW. This is

Model	Top 10%	Top 25%	Top 50%
DMM	20.2%	33.2%	49.4%
DPM	22.2%	39.1%	56.5%

Table 4: Percentage of top features with the highest SVM weights that are shared between Bio HOW and YA models.

a somewhat radical setup, where the target corpus has both a different genre (formal text vs. CQA) and different domain (biology vs. open domain). These experiments were performed in several groups: both with and without LS features, as well as using either a single SVM or an ensemble model that linearly interpolates the predictions of two SVM classifiers (one each for DMM and DPM).[16] The results are summarized in Table 5.

The transferred models always outperform the baselines, but only the ensemble model's improvement is statistically significant. This confirms existing evidence that ensemble models perform better cross-domain because they overfit less (Domingos, 2012; Hastie et al., 2009). The ensemble model without LS (third line) has a nearly identical P@1 score as the equivalent in-domain model (line 13 in Table 1), while slightly surpassing in-domain MRR performance. To the best of our knowledge, this is one of the most striking demonstrations of domain transfer in answer ranking for non-factoid QA, and highlights the generality of these discourse features in identifying answer structures across domains and genres.

The results of the transferred models that include LS features are slightly lower, but still approach statistical significance for P@1 and are significant for MRR. We hypothesize that the limited transfer observed for models with LS compared to their counterparts without LS is due to the disparity in the size and utility of the biology LS training data compared to the open-domain LS resources. The open-domain YA model learns to place more weight on LS features, which are unable to provide the same utility in the biology domain.

5.7 Integrating Discourse and LS

So far, we have treated LS and discourse as distinct features in the reranking model, However, given that LS features greatly improve the CR baseline, we hypothesize that a natural extension

[16]The interpolation parameter was tuned on the YA development corpus. The in-domain performance of the ensemble model is similar to that of the single classifier in both YA and Bio HOW so we omit these results here for simplicity.

Model/Features	P@1	P@1 Impr.	MRR	MRR Impr.
Transfer: YA → Bio HOW				
CR Baseline	24.12		32.90	
CR + DMM + DPM	27.13	+13%	36.36†	+11%
(CR + DMM) ∪ (CR + DPM)	**30.10***	**+25%**	**39.62***	**+20%**
CR + LS Baseline	25.35		33.79	
CR + LS + DMM + DPM	25.79	+2%	35.58	+5%
(CR + LS + DMM) ∪ (CR + LS + DPM)	**29.54**†	**+17%**	**38.68***	**+15%**

Table 5: Transfer performance from YA to Bio HOW for single classifiers and ensembles (denoted with a ∪). † indicates approaching statistical significance with $p = 0.07$ or 0.06.

to the discourse models would be to make use of LS similarity (in addition to the traditional information retrieval similarity) to label discourse segments. For example, for the question *"How do cells replicate?"*, answer discourse segments containing LS associates of *cell* and *replicate*, e.g., *nucleus, membrane, genetic*, and *duplicate*, should be considered as related to the question (i.e., be labeled QSEG). We implemented two such models, denoted DMM$_{LS}$ and DPM$_{LS}$, by replacing the component that assigns argument labels with one that relies on LS. Specifically, as in §4.3, we compute the cosine similarity between the composite LS vectors of the question text and each marker argument (in DMM) or EDU (in DPM), and label the corresponding answer segment QSEG if this score is higher than a threshold, or OTHER otherwise. This way, the DMM and DPM features jointly capture discourse structures and semantic similarity between answer segments and question.

To test this, we use the YA corpus, which has the best-performing LS model. Because we are adding two new discourse models, we now tune four segment matching thresholds, one for each of the DMM, DPM, DMM$_{LS}$, and DPM$_{LS}$ models.[17] The results are shown in Table 6. These results demonstrate that incorporating LS in the discourse models further increases performance for all configurations, nearly doubling the relative performance benefits over models that do not integrate LS and discourse (compare with lines 6–9 of Table 1). For example, the last model in the table, which combines four discourse representations, improves P@1 by 24%, whereas the equivalent model without this integration (line 9 in Table 1) outperforms the baseline by only 15%.

[17]These hyperparameters were tuned on the development corpus, and were found to be stable over broad ranges.

Model Features	P@1	P@1 Impr.	MRR	MRR Impr.
CR + LS Baseline	26.57		49.31	
CR + LS + DMM + DMM_{LS}	32.41*	+22%	53.55*	+9%
CR + LS + DPM + DPM_{LS}	31.21*	+18%	52.50*	+7%
CR + LS + DMM + DPM + DMM_{LS} + DPM_{LS}	**32.93***	**+24%**	**53.91***	**+9%**

Table 6: YA results with integrated discourse and LS.

5.8 Error Analysis

We performed an error analysis of the full QA model (CR + LS + DMM + DPM) across the entire Bio corpus (lines 17 and 25 from Table 1). We chose the Bio setup for this analysis because it is more complex than the CQA one: here gold answers may have a granularity completely different from what the system choses as best answers (in our particular case, the QA system is currently limited to answers consisting of single paragraphs, whereas gold answers may be of any size).

Here, 94 of the 378 Bio HOW and WHY questions have improved answer scores, while 36 have reduced performance relative to the CR baseline. Of these 36 questions where answer scores decreased, nearly two thirds were directly related to the paragraph granularity of the candidate answer retrieval (see §5.1):

Same Subsection (50%): In these cases, the model selected an on-topic answer paragraph in the same subsection of the textbook as a gold answer. Often times this paragraph directly preceded or followed the gold answer.

Answer Window Size (14%): Here, both the CR and full model chose a paragraph containing a different gold answer. However, as discussed, gold answers may unevenly straddle paragraph boundaries, and the paragraph chosen by the model happened to have a somewhat lower overlap with its gold answer than the one chosen by the baseline.

Similar Topic (25%): The model chose a paragraph that had a similar topic to the question, but doesn't answer the question. These are challenging errors, often associated with short questions (e.g. *"How does HIV work?"*) that provide few keywords. In these cases, discourse features tend to dominate, and shift the focus towards answers that have many discourse structures deemed relevant. For example, for the above question, the model chose a paragraph containing many discourse structures positively correlated with high-quality answers, but which describes the origins of HIV instead of how the virus enters a cell.

Similar Words, Different Topic (8%): The model chose a paragraph that had many of the same words as the question, but is on a different topic. For example, for the question *"How are fossil fuels formed, and why do they contain so much energy?"*, the model selected an answer that mentions fossil fuels in a larger discussion of human ecological footprints. Here, the matching of both keywords and discourse structures shifted the answer towards a different, incorrect topic.

Finally, in one case (3%), the model identified an answer paragraph that contained a gold answer, but was missed by the domain expert annotator.

In summary, this analysis suggests that, for the majority of errors, the QA system selects an answer that is both topical and adjacent to a gold answer selected by the domain expert. This suggests that most errors are minor and are driven by current limitations of our answer boundary selection mechanism, rather than the inherent limitations of the discourse model.

6 Conclusions

This work focuses on two important aspects of answer reranking for non-factoid QA: similarity between question and answer content, and answer structure. While the former has been addressed with a variety of lexical-semantic models, the latter has received little attention. Here we show how to model answer structures using discourse and how to integrate the two aspects into a holistic framework. Empirically we show that modeling answer discourse structures is complementary to modeling lexical semantic similarity and that the best performance is obtained when they are tightly integrated. We evaluate the proposed approach on multiple genres and question types and obtain benefits of up to 24% relative improvement over a strong baseline that combines information retrieval and lexical semantics. We further demonstrate that answer discourse structures are largely independent of domain and transfer well, even between radically different datasets.

Abstract

We propose a supervised method of extracting event causalities like *conduct slash-and-burn agriculture→exacerbate desertification* from the web using semantic relation (between nouns), context, and association features. Experiments show that our method outperforms baselines that are based on state-of-the-art methods. We also propose methods of generating *future scenarios* like *conduct slash-and-burn agriculture→exacerbate desertification→increase Asian dust (from China)→asthma gets worse*. Experiments show that we can generate 50,000 scenarios with 68% precision. We also generated a scenario *deforestation continues→global warming worsens→sea temperatures rise→vibrio parahaemolyticus fouls (water)*, which is written in no document in our input web corpus crawled in 2007. But the vibrio risk due to global warming was observed in Baker-Austin et al. (2013). Thus, we "predicted" the future event sequence in a sense.

1 Introduction

The world can be seen as a network of causality where people, organizations, and other kinds of entities causally depend on each other. This network is so huge and complex that it is almost impossible for humans to exhaustively predict the consequences of a given event. Indeed, after the Great East Japan Earthquake in 2011, few expected that it would lead to an enormous trade deficit in Japan due to a sharp increase in energy imports. For effective decision making that carefully considers any form of future risks and chances, we need a system that helps humans do *scenario planning* (Schwartz, 1991), which is a decision-making scheme that examines possible future events and assesses their potential chances and risks. Our ultimate goal is to develop a system that supports scenario planning through generating possible future events using big data, which would contain what Donald Rumsfeld called "unknown unknowns"[1] (Torisawa et al., 2010).

To this end, we propose a supervised method of extracting such event causality as *conduct slash-and-burn agriculture→exacerbate desertification* and use its output to generate *future scenarios* (*scenarios*), which are chains of causality that have been or might be observed in this world like *conduct slash-and-burn agriculture→exacerbate desertification→increase Asian dust (from China)→asthma gets worse*. Note that, in this paper, *A→B* denotes that *A* causes *B*, which means that "*if A happens, the probability of B increases*." Our notion of causality should be interpreted probabilistically rather than logically.

Our method extracts event causality based on three assumptions that are embodied as features of our classifier. First, we assume that two nouns (e.g. *slash-and-burn agriculture* and *desertification*) that take some specific binary semantic relations (e.g. *A* CAUSES *B*) tend to constitute event causality if combined with two predicates (e.g. *conduct* and *exacerbate*). Note that semantic relations are not restricted to those directly relevant to causality like *A* CAUSES *B* but can be those that might seem irrelevant to causality like *A* IS AN INGREDIENT FOR *B* (e.g. *plutonium* and *atomic bomb* as in *plutonium is stolen→atomic bomb is made*). Our underlying intuition is the observation that event causality tends to hold between two entities linked by semantic relations which roughly entail that one entity strongly affects the other. Such semantic relations can be expressed by (otherwise unintuitive) patterns like *A* IS AN INGREDIENT FOR *B*. As such, semantic relations like the MATERIAL relation can also be useful. (See Sec-

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 987–997,
Baltimore, Maryland, USA, June 23-25 2014.

tion 3.2.1 for a more intuitive explanation.)

Our second assumption is that there are grammatical contexts in which event causality is more likely to appear. We implement what we consider likely contexts for event causality as context features. For example, a likely context of event causality (underlined) would be: *CO2 levels rose, so climatic anomalies were observed*, while an unlikely context would be: *It remains uncertain whether if the recession is bottomed the declining birth rate is halted*. Useful context information includes the mood of the sentences (e.g., the uncertainty mood expressed by *uncertain* above), which is represented by lexical features (Section 3.2.2).

The last assumption embodied in our association features is that each word of the cause phrase must have a strong association (i.e., PMI, for example) with that of the effect phrase as *slash-and-burn agriculture* and *desertification* in the above example, as in Do et al. (2011).

Our method exploits these features on top of our base features such as nouns and predicates. Experiments using 600 million web pages (Akamine et al., 2010) show that our method outperforms baselines based on state-of-the-art methods (Do et al., 2011; Hashimoto et al., 2012) by more than 19% of average precision.

We require that event causality be *self-contained*, i.e., intelligible as causality without the sentences from which it was extracted. For example, *omit toothbrushing→get a cavity* is self-contained, but *omit toothbrushing→get a girlfriend* is not since this is not intelligible without a context: *He omitted toothbrushing every day and got a girlfriend who was a dental assistant of dental clinic he went to for his cavity*. This is important since future scenarios, which are generated by chaining event causality as described below, must be self-contained, unlike Hashimoto et al. (2012). To make event causality self-contained, we wrote guidelines for manually annotating training/development/test data. Annotators regarded as event causality only phrase pairs that were interpretable as event causality without contexts (i.e., self-contained). From the training data, our method seemed to successfully learn what self-contained event causality is.

Our scenario generation method generates scenarios by chaining extracted event causality; generating $A \rightarrow B \rightarrow C$ from $A \rightarrow B$ and $B \rightarrow C$. The challenge is that many acceptable scenarios are overlooked if we require the joint part of the chain (B above) to be an exact match. To increase the number of acceptable scenarios, our method identifies compatibility w.r.t causality between two phrases by a recently proposed semantic polarity, *excitation* (Hashimoto et al., 2012), which properly relaxes the chaining condition (Section 3.1 describes it). For example, our method can identify the compatibility between *sea temperatures are high* and *sea temperatures rise* to chain *global warming worsens→sea temperatures are high* and *sea temperatures rise→vibrio parahaemolyticus*[2] *fouls (water)*. Accordingly, we generated a scenario *deforestation continues→global warming worsens→sea temperatures rise→vibrio parahaemolyticus fouls (water)*, which is written in no document in our input web corpus that was crawled in 2007, but the vibrio risk due to global warming has actually been observed in the Baltic sea and reported in Baker-Austin et al. (2013). In a sense, we "predicted" the event sequence reported in 2013 by documents written in 2007. Our experiments also show that we generated 50,000 scenarios with 68% precision, which include *conduct terrorist operations→terrorist bombing occurs→cause fatalities and injuries→cause economic losses* and the above "*slash-and-burn agriculture*" scenario (Section 5.2). Neither is written in any document in our input corpus.

In this paper, our target language is Japanese. However, we believe that our ideas and methods are applicable to many languages. Examples are translated into English for ease of explanation. Supplementary notes of this paper are available at `http://khn.nict.go.jp/analysis/member/ch/acl2014-sup.pdf`.

2 Related Work

For **event causality extraction**, clues used by previous methods can roughly be categorized as lexico-syntactic patterns (Abe et al., 2008; Radinsky et al., 2012), words in context (Oh et al., 2013), associations among words (Torisawa, 2006; Riaz and Girju, 2010; Do et al., 2011), and predicate semantics (Hashimoto et al., 2012). Besides features similar to those described above, we propose semantic relation features[3] that include those that are not obviously related to causality. We show that such thorough exploitation of new and existing features leads to high performance.

[2] A bacterium in the sea causing food-poisoning.

[3] Radinsky et al. (2012) and Tanaka et al. (2012) used semantic relations to *generalize* acquired causality instances.

Other clues include shared arguments (Torisawa, 2006; Chambers and Jurafsky, 2008; Chambers and Jurafsky, 2009), which we ignore since we target event causality about two distinct entities.

To the best of our knowledge, **future scenario generation** is a new task, although previous works have addressed similar tasks (Radinsky et al., 2012; Radinsky and Horvitz, 2013). Neither involves chaining and restricts themselves to only one event causality step. Besides, the events they predict must be those for which similar events have previously been observed, and their method only applies to news domain.

Some of the scenarios we generated are written on no page in our input web corpus. Similarly, Tsuchida et al. (2011) generated semantic knowledge like causality that is written in no sentence. However, their method cannot combine more than two pieces of knowledge unlike ours, and their target knowledge consists of nouns, but ours consists of verb phrases, which are more informative.

Tanaka et al. (2013)'s web information analysis system provides a *what-happens-if QA* service, which is based on our scenario generation method.

3 Event Causality Extraction Method

This section describes our event causality extraction method. Section 3.1 describes how to extract event causality candidates, and Section 3.2 details our features. Section 3.3 shows how to rank event causality candidates.

3.1 Event Causality Candidate Extraction

We extract the event causality between two events represented by two phrases from single sentences that are dependency parsed.[4] We obtained sentences from 600 million web pages. Each phrase in the event causality must consist of a predicate with an argument position (*template*, hereafter) like *conduct X* and a noun like *slash-and-burn agriculture* that completes *X*. We also require the predicate of the cause phrase to syntactically depend on the effect phrase in the sentence from which the event causality was extracted; we guarantee this by verifying the dependencies of the original sentence. In Japanese, since the temporal order between events is usually determined by precedence in a sentence, we require the cause phrase to precede the effect phrase. For context feature extraction, the event causality candidates are accompanied by the original sentences from which they were extracted.

Excitation We only keep the event causality candidates each phrase of which consists of *excitation templates*, which have been shown to be effective for causality extraction (Hashimoto et al., 2012) and other semantic NLP tasks (Oh et al., 2013; Varga et al., 2013; Kloetzer et al., 2013a). Excitation is a semantic property of templates that classifies them into *excitatory*, *inhibitory*, and *neutral*. Excitatory templates such as *cause X* entail that the function, effect, purpose or role of their argument's referent is activated, enhanced, or manifested, while inhibitory templates such as *lower X* entail that it is deactivated or suppressed. Neutral ones like *proportional to X* belong to neither of them. We collectively call both excitatory and inhibitory templates excitation templates. We acquired 43,697 excitation templates by Hashimoto et al.'s method and the manual annotation of excitation template candidates.[5] We applied the excitation filter to all 272,025,401 event causality candidates from the web and 132,528,706 remained.

After applying additional filters (see Section A in the supplementary notes) including those based on a stop-word list and a causal connective list to remove unlikely event causality candidates that are not removed by the above filter, we finally acquired 2,451,254 event causality candidates.

3.2 Features for Event Causality Classifier

3.2.1 Semantic Relation Features

We hypothesize that two nouns with some particular semantic relations are more likely to constitute event causality. Below we describe the semantic relations that we believe are likely to constitute event causality.

CAUSATION is the causal relation between two entities and is expressed by binary patterns like *A* CAUSES *B*. *Deforestation* and *global warming* might complete the *A* and *B* slots. We manually collected 748 binary patterns for this relation. (See Section B in the supplementary notes for examples of our binary patterns.)

MATERIAL is the relation between a material and a product made of it (e.g. *plutonium* and

[4] We used a Japanese dependency parser called J.DepP (Yoshinaga and Kitsuregawa, 2009), available at `http://www.tkl.iis.u-tokyo.ac.jp/~ynaga/jdepp/`.

[5] Hashimoto et al.'s method constructs a network of templates based on their co-occurrence in web sentences with a small number of polarity-assigned seed templates and infers the polarity of all the templates in the network by a constraint solver based on the spin model (Takamura et al., 2005).

atomic bomb) and can be expressed by *A* IS MADE OF *B*. Its relation to event causality might seem unclear, but a material can be seen as a "cause" of a product. Indeed materials can participate in event causality with the help of such template pairs as *A is stolen→B is made* as in *plutonium is stolen→atomic bomb is made*. We manually collected 187 binary patterns for this relation.

NECESSITY's patterns include *A* IS NECESSARY FOR *B*, which can be filled with *verbal aptitude* and *ability to think*. Noun pairs with this relation can constitute event causality when combined with template pairs like *improve A→cultivate B*. We collected 257 patterns for this relation.

USE is the relation between means (or instruments) and the purpose for using them. *A* IS USED FOR *B* is a pattern of the relation, which can be filled with *e-mailer* and *exchanges of e-mail messages*. Note that means can be seen as "causing" or "realizing" the purpose of using the means in this relation, and actually event causality can be obtained by incorporating noun pairs of this relation into template pairs like *activate A→conduct B*. 2,178 patterns were collected for this relation.

PREVENTION is the relation expressed by patterns like *A* PREVENTS *B*, which can be filled with *toothbrushing* and *periodontal disease*. This relation is, so to speak, "negative CAUSATION" since the entity denoted by the noun completing the *A* slot makes the entity denoted by the *B* noun NOT realized. Such noun pairs mean event causality by substituting them into template pairs like *omit A→get B*. The number of patterns is 490.

The experiments in Section 5.1.1 show that not only CAUSATION and PREVENTION ("negative CAUSATION") but the other relations are also effective for event causality extraction.

In addition, we invented the EXCITATION relation that is expressed by binary patterns made of excitatory and inhibitory templates (Section 3.1). For instance, we make binary patterns *A* RISES *B* and *A* LOWERS *B* from excitatory template *rise X* and inhibitory template *lower X* respectively. The EXCITATION relation roughly means that *A* activates *B* (excitatory) or suppresses it (inhibitory). We simply add an additional argument position to each template in the 43,697 excitation templates to make binary patterns. We restricted the argument positions (represented by Japanese postpositions) of the *A* slot to either *ha* (topic marker), *ga* (nominative), or *de* (instrumental) and those of the *B* slot to either *ha*, *ga*, *de*, *wo* (accusative), or *ni* (dative), and obtained 55,881 patterns.

SR1: Binary pattern of our semantic relations that co-occurs with two nouns of an event causality candidate in our web corpus.

SR2: Semantic relation types (e.g CAUSATION and ENTAILMENT) of the binary pattern of SR1. EXCITATION is divided into six sub types based on the excitation polarity of the binary patterns, the argument positions, and the existence of causative markers. A CAUSATION pattern, *B* BY *A*, constitutes an independent relation called the BY relation.

Table 1: Semantic relation features.

Moreover, for broader coverage, we acquired binary patterns that entail or are entailed by one of the patterns of the above six semantic relations. Those patterns were acquired from our web corpus by Kloetzer et al. (2013b)'s method, which acquired 185 million entailment pairs with 80% precision from our web corpus and was used for contradiction acquisition (Kloetzer et al., 2013a). We acquired 335,837 patterns by this method. They are *class-dependent patterns*, which have semantic class restrictions on arguments. The semantic classes were obtained from our web corpus based on Kazama and Torisawa (2008). See De Saeger et al. (2009), De Saeger et al. (2011) and Kloetzer et al. (2013a) for more on our patterns. They collectively constitute the ENTAILMENT relation.

Table 1 shows our semantic relation features. To use them, we first make a database that records which noun pairs co-occur with each binary pattern. Then we check a noun pair (the nouns of the cause and effect phrases) for each event causality candidate, and give the candidate all the patterns in the database that co-occur with the noun pair.

3.2.2 Context Features

We believe that contexts exist where event causality candidates are more likely to appear, as described in Section 1. We developed features that capture the characteristics of likely contexts for Japanese event causality (See Section C in the supplementary notes). In a nutshell, they represent a connective (**C1** and **C2** in Section C), the distance between the elements of event causality candidate (**C3** and **C4**), words in context (**C5** to **C8**), the existence of adnominal modifier (**9** to **C10**), and the existence of additional arguments of cause and effect predicates (**C13** to **C20**), among others.

3.2.3 Association Features

These features measure the association strength between *slash-and-burn agriculture* and *deser-*

AC1: The CEA value, the sum of AC2, AC3, and AC4.
AC2: Do et al.'s S_{pp}. This is the association measure between predicates, which is the product of AC5, AC6 and AC7 below. They are calculated from the 132,528,706 event causality candidates in Section 3.1. We omit Do et al.'s $Dist$, which is a constant since we set our window size to one.
AC3: Do et al.'s S_{pa}. This is the association measure between arguments and predicates, which is the sum of AC8 and AC9. They are calculated from the 132,528,706 event causality candidates.
AC4: Do et al.'s S_{aa}, which is PMI between arguments. We obtained it in the same way as Filter 5 in the supplementary notes.
AC5: PMI between predicates.
AC6 / AC7: Do et al.'s max / IDF.
AC8: PMI between a cause noun and an effect predicate.
AC9: PMI between a cause predicate and an effect noun.

Table 2: CEA-based association features.

tification in *conduct slash-and-burn agriculture→exacerbate desertification* for instance and consist of CEA-, Wikipedia-, definition-, and web-based features. **CEA-based features** are based on the Cause Effect Association (CEA) measure of Do et al. (2011). It consists of association measures like PMI between arguments (nouns), between arguments and predicates, and between predicates (Table 2). Do et al. used it (along with discourse relations) to extract event causality. **Wikipedia-based features** are the co-occurrence counts and the PMI values between cause and effect nouns calculated using Wikipedia (as of 2013-Sep-19). We also checked whether an Wikipedia article whose title is a cause (effect) noun contains its effect (cause) noun, as detailed in Section D.1 in the supplementary notes. **Definition-based features**, as detailed in Section D.2 in the supplementary notes, resemble the Wikipedia-based features except that the information source is the definition sentences automatically acquired from our 600 million web pages using the method of Hashimoto et al. (2011). **Web-based features** provide association measures between nouns using various window sizes in the 600 million web pages. See Section D.3 for detail. Web-based association measures were obtained from the same database as **AC4** in Table 2.

3.2.4 Base Features

Base features represent the basic properties of event causality like nouns, templates, and their excitation polarities (See Section E in the supplementary notes). For **B3** and **B4**, 500 semantic classes were obtained from our web corpus using the method of Kazama and Torisawa (2008).

3.3 Event Causality Scoring

Using the above features, a classifier[6] classifies each event causality candidate into causality and non-causality. An event causality candidate is given a causality score $CScore$, which is the SVM score (distance from the hyperplane) that is normalized to $[0, 1]$ by the sigmoid function $\frac{1}{1+e^{-x}}$. Each event causality candidate may be given multiple original sentences, since a phrase pair can appear in multiple sentences, in which case it is given more than one SVM score. For such candidates, we give the largest score and keep only one original sentence that corresponds to the largest score.[7] Original sentences are also used for scenario generation, as described below.

4 Future Scenario Generation Method

Our future scenario generation method creates scenarios by chaining event causalities. A naive approach chains two phrase pairs by exact matching. However, this approach would overlook many acceptable scenarios as discussed in Section 1. For example, *global warming worsens→sea temperatures are high* and *sea temperatures rise→vibrio parahaemolyticus fouls (water)* can be chained to constitute an acceptable scenario, but the joint part is not the same string. Note that the two phrases are not simply paraphrases; temperatures may be rising but remain cold, or they may be decreasing even though they remain high.

What characterizes two phrases that can be the joint part of acceptable scenarios? Although we have no definite answer yet, we *name* it the *causal-compatibility* of two phrases and provide its preliminary characterization based on the excitation polarity. Remember that excitatory templates like *cause X* entail that *X*'s function or effect is activated, but inhibitory templates like *lower X* entail that it is suppressed (Section 3.1). Two phrases are *causally-compatible* if they mention the same entity (typically described by a noun) that is predicated by the templates of the *same excitation polarity*. Indeed, both *X rise* and *X are high* are excitatory and hence *sea temperatures are high* and *sea temperatures rise* are causally-compatible.[8]

[6] We used SVM^{light} with the polynominal kernel ($d = 2$), available at `http://svmlight.joachims.org`.

[7] Future work will exploit other original sentences, as suggested by an anonymous reviewer.

[8] Using other knowledge like verb entailment (Hashimoto et al., 2009) can be helpful too, which is further future work.

Scenarios (scs) generated by chaining causally-compatible phrase pairs are scored by $Score(sc)$, which embodies our assumption that an acceptable scenario consists of plausible event causality pairs:

$$Score(sc) = \prod_{cs \in CAUS(sc)} CScore(cs)$$

where $CAUS(sc)$ is a set of event causality pairs that constitutes sc and cs is a member of $CAUS(sc)$. $CScore(cs)$, which is cs's score, was described in Section 3.3.

Our method optionally applies the following two filters to scenarios for better precision: An **original sentence filter** removes a scenario if two event causality pairs that are chained in it are extracted from original sentences between which no word overlap exists other than words constituting causality pairs. In this case, the two event causality pairs tend to be about different topics and constitute an incoherent scenario. A **common argument filter** removes a scenario if a joint part consists of two templates that share no argument in our ⟨argument, template⟩ database, which is compiled from the syntactic dependency data between arguments and templates extracted from our web corpus. Such a scenario tends to be incoherent too.

5 Experiments

5.1 Event Causality Extraction

Next we describe our experiments on event causality extraction and show **(a)** that most of our features are effective and **(b)** that our method outperforms the baselines based on state-of-the-art methods (Do et al., 2011; Hashimoto et al., 2012). Our method achieved 70% precision at 13% recall; we can extract about 69,700 event causality pairs with 70% precision, as described below.

For the **test data**, we randomly sampled 23,650 examples of ⟨event causality candidate, original sentence⟩ among which 3,645 were positive from 2,451,254 event causality candidates extracted from our web corpus (Section 3.1). For the **development data**, we identically collected 11,711 examples among which 1,898 were positive. These datasets were annotated by three annotators (not the authors), who annotated the event causality candidates without looking at the original sentences. The final label was determined by majority vote. The **training data** were created by the annotators through our preliminary experiments and consists of 112,110 among which 9,657 were positive. The Kappa (Fleiss, 1971) of their judgments was 0.67 (substantial agreement (Landis and Koch, 1977)). These three datasets have no overlap in terms of phrase pairs. About nine man-months were required to prepare the data.

Method	Ave. prec. (%)

CAUSATION and PREVENTION	45.78
None (w/o Semantic relation features)	44.44

Table 4: Ablation tests on semantic relations.

Our evaluation is based on *average precision*;[9] we believe that it is important to *rank* the plausible event causality candidates higher.

5.1.1 Ablation Tests

We evaluated the features of our method by ablation tests. Table 3 shows the results of removing the semantic relation, the context, and the association features from our method. All the feature types are effective and contribute to the performance gain that was about 5% higher than the **Base features only**. **Proposed** achieved 70% precision at 13% recall. We then estimated that, with the precision rate, we can extract 69,700 event causality pairs from the 2,451,254 event causality candidates, among which the estimated number of positive examples is 377,794.

Next we examined whether the semantic relations that do not seem directly relevant to causality like MATERIAL are effective. Table 4 shows that the performance degraded (46.27 → 45.86) when we only used the CAUSATION binary patterns and their entailing and entailed patterns compared to **Proposed**. Even when adding the PREVENTION ("negative CAUSATION") patterns and their entailing and entailed patterns, the performance was still slightly worse than **Proposed**. The performance was even worse when using no semantic relation ("None" in Table 4). Consequently we conclude that not only semantic relations directly relevant

[9] It is obtained by computing the precision for each point in the ranked list where we find a positive sample and averaging all the precision figures (Manning and Schütze, 1999).

to causality like CAUSATION but also those that seem to lack direct relevance to causality like MATERIAL are somewhat effective.

Finally, Table 5 shows the performance drop by removing the Wikipedia-, definition-, web-, and CEA-based features. The CEA-based features were the most effective, while the Wikipedia-based ones slightly degraded the performance.

5.1.2 Comparison to Baseline Methods

We compared our method and two baselines based on Do et al. (2011): **CEA**$_{uns}$ is an unsupervised method that uses CEA to rank event causality candidates, and **CEA**$_{sup}$ is a supervised method using SVM and the CEA features, whose ranking is based on the SVM scores. The baselines are not complete implementations of Do et al.'s method which uses discourse relations identified based on Lin et al. (2010) and exploits them with CEA within an ILP framework. Nonetheless, we believe that this comparison is informative since CEA can be seen as the main component; they achieved a F1 of 41.7% for extracting causal event relations, but with only CEA they still achieved 38.6%.

Table 6 shows the average precision of the compared methods. **Proposed** is our proposed method. **Proposed-CEA** is **Proposed** without the CEA-features and shows their contribution. **Proposed** is the best and the CEA features slightly contribute to the performance, as **Proposed-CEA** indicates. We observed that **CEA**$_{sup}$ and **CEA**$_{uns}$ performed poorly and tended to favor event causality candidates whose phrase pairs were highly relevant to each other but described the contrasts of events rather than event causality (e.g. *build a slow muscle* and *build a fast muscle*) probably because their

Proposed	**49.64**
Cs$_{uns}$	30.38
Cs$_{sup}$	27.49

Table 7: Average precision of our proposed method and baselines using Cs.

main components are PMI values. Figure 1 shows their precision-recall curves.

Next we compared our method with the baselines based on Hashimoto et al. (2012). They developed an automatic excitation template acquisition method that assigns each template an *excitation value* in range $[-1, 1]$ that is positive if the template is excitatory and negative if it is inhibitory. They ranked event causality candidates by $Cs(p_1, p_2) = |s_1| \times |s_2|$, where p_1 and p_2 are the two phrases of event causality candidates, and $|s_1|$ and $|s_2|$ are the absolute excitation values of p_1's and p_2's templates. The baselines are as follows: **Cs**$_{uns}$ is an unsupervised method that uses Cs for ranking, and **Cs**$_{sup}$ is a supervised method using SVM with Cs as the only feature that uses SVM scores for ranking. Note that some event causality candidates were not given excitation values for their templates, since some templates were acquired by manual annotation without Hashimoto et al.'s method. To favor the baselines for fairness, the event causality candidates of the development and test data were restricted to those with excitation values. Since **Cs**$_{sup}$ performed slightly better when using all of the training data in our preliminary experiments, we used all of it.

Table 7 shows the average precision of the compared methods. **Proposed** is our method. Its average precision is different from that in Table 6 due to the difference in test data described above. **Cs**$_{uns}$ and **Cs**$_{sup}$ did not perform well. Many

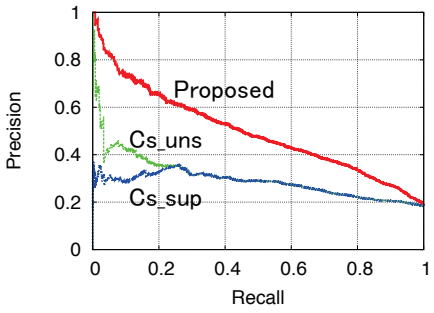

Figure 2: Precision-recall curves of proposed methods and baselines using Cs.

phrase pairs described two events that often happen in parallel but are not event causality (e.g. *reduce the intake of energy* and *increase the energy consumption*) in the highly ranked event causality candidates of **Cs**$_{uns}$ and **Cs**$_{sup}$. Figure 2 shows their precision-recall curves.

Hashimoto et al. (2012) extracted 500,000 event causalities with about 70% precision. However, as described in Section 1, our event causality criteria are different; since they regarded phrase pairs that were not self-contained as event causality (their annotators checked the original sentences of phrase pairs to see if they were event causality), their judgments tended to be more lenient than ours, which explains the performance difference.

In preliminary experiments, since our proposed method's performance degraded when Cs was incorporated, we did not use it in our method.

5.2 Future Scenario Generation

To show that our future scenario generation methods can generate many acceptable scenarios with reasonable precision, we experimentally compared four methods: **Proposed**, our scenario generation method without the two filters, **Proposed+Orig**, our method with the original sentence filter, **Proposed+Orig+Comm**, our method with the original sentence and common argument filters, and **Exact**, a method that chains event causality by exact matching.

Beginning events As the beginning event of a scenario, we extracted nouns that describe social problems (*social problem nouns*, e.g. *deforestation*) from Wikipedia to focus our evaluation on the ability to generate scenarios about them, which is a realistic use-case of scenario generation. We extracted 557 social problem nouns and used the cause phrases of the event causality candidates that consisted of one of the social problem nouns as the scenario's beginning event.

	Two-step	Three-step
Exact	1,000 (44.10)	1,000 (23.50)
Proposed	2,000 (32.25)	2,000 (12.55)
Proposed+Orig	995 (36.28)	602 (17.28)
Proposed+Orig+Comm	708 (38.70)	339 (17.99)

Table 8: Number of scenario samples and their precision (%) in parentheses.

Event causality We applied our event causality extraction method to 2,451,254 candidates (Section 3.1) and culled the top 1,200,000 phrase pairs from them (See Section F in the supplementary notes for examples). Some phrase pairs have the same noun pairs and the same template polarity pairs (e.g. *omit toothbrushing→get a cavity* and *neglect toothbrushing→have a cavity*, where *omit X* and *neglect X* are inhibitory and *get X* and *have X* are excitatory). We removed such phrase pairs except those with the highest $CScore$, and 960,561 phrase pairs remained, from which we generated two- or three-step scenarios that consisted of two or three phrase pairs.

Evaluation samples The numbers of two- and three-step scenarios generated by **Proposed** were 217,836 and 5,288,352, while those of **Exact** were 22,910 and 72,746. We sampled 2,000 from **Proposed**'s two- and three-step scenarios and 1,000 from those of **Exact**. We applied the filters to the sampled scenarios of **Proposed**, and the results were regarded as the sample scenarios of **Proposed+Orig** and **Proposed+Orig+Comm**. Table 8 shows the number and precision of the samples. Note that, for the diversity of the sampled scenarios, our sampling proceeded as follows: **(i)** Randomly sample a beginning event phrase from the generated scenarios. **(ii)** Randomly sample an effect phrase for the beginning event phrase from the scenarios. **(iii)** Regarding the effect phrase as a cause phrase, randomly sample an effect phrase for it, and repeat (iii) up to the specified number of steps (2 or 3). The samples were annotated by three annotators (not the authors), who were instructed to regard a sample as acceptable if each event causality that constitutes it is plausible and the sample as a whole constitutes a single coherent story. Final judgment was made by majority vote. Fleiss' kappa of their judgments was 0.53 (moderate agreement), which is lower than the kappa for the causality judgment. This is probably because

	Two-step	Three-step
Exact	2,085	1,237
Proposed	5,773	0
Proposed+Orig	4,107	0
Proposed+Orig+Comm	3,293	21,153

Table 9: Estimated number of acceptable scenarios with a 70% precision rate.

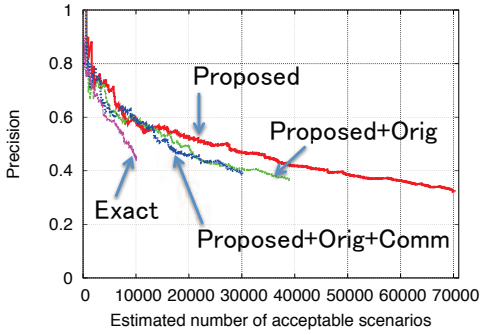

Figure 3: Precision-scenario curves (2-step).

scenario judgment requires careful consideration about various possible futures for which individual annotators tend to draw different conclusions.

Result 1 Table 9 shows the estimated number of acceptable scenarios generated with 70% precision. The estimated number is calculated as the product of the recall at 70% precision and the number of acceptable scenarios in all the generated scenarios, which is estimated by the annotated samples. Figures 3 and 4 show the *precision-scenario curves* for the two- and three-step scenarios, which illustrate how many acceptable scenarios can be generated with what precision. The curve is drawn in the same way as the precision-recall curve except that the X-axis indicates the estimated number of acceptable scenarios. At 70% precision, all of the proposed methods outperformed **Exact** in the two-step setting, and **Proposed+Orig+Comm** outperformed **Exact** in the three-step setting.

Result 2 To evaluate the top-ranked scenarios of **Proposed+Orig+Comm** in the three-step setting with more samples, the annotators labeled 500 samples from the top 50,000 of its output. 341 (68.20%) were acceptable, and the estimated number of acceptable scenarios at a precision rate of 70% and 80% are 26,700 and 5,200 (See Section H in the supplementary notes). The "*terrorist operations*" scenario and the "*slash-and-burn agriculture*" scenario in Section 1 were ranked 16,386th

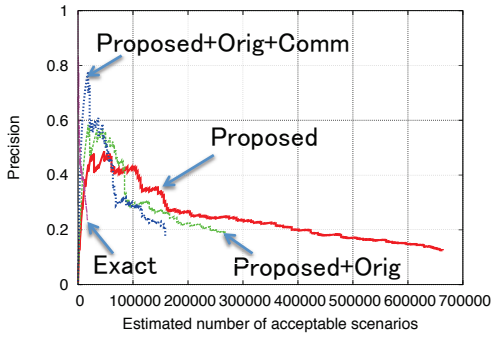

Figure 4: Precision-scenario curves (3-step).

and 21,968th. Next we examined how many of the top 50,000 scenarios were acceptable and *non-trivial*, i.e., found in no page in our input web corpus, using the 341 acceptable samples. A scenario was regarded as non-trivial if its nouns co-occur in no page of the corpus. 22 among the 341 samples were non-trivial. Accordingly, we estimate that we can generate 2,200 ($\frac{50{,}000\times 22}{500}$) acceptable and non-trivial scenarios from the top 50,000. (See Section G in the supplementary notes for examples of the generated scenarios.)

Discussion Scenario *deforestation continues→global warming worsens→sea temperatures rise→vibrio parahaemolyticus fouls (water)* was generated by **Proposed+Orig+Comm**. It is written in no page in our input web corpus, which was crawled in 2007.[10] But we did find a paper Baker-Austin et al. (2013) that observed the emerging vibrio risk in the Baltic sea due to global warming. In a sense, we "predicted" an event observed in 2013 from documents written in 2007, although the scenario was ranked as low as 240,738th.

6 Conclusion

We proposed a supervised method for event causality extraction that exploits semantic relation, context, and association features. We also proposed methods for our new task, future scenario generation. The methods chain event causality by causal-compatibility. We generated non-trivial scenarios with reasonable precision, and "predicted" future events from web documents. Increasing their rank is future work.

[10]The corpus has pages where *global warming*, *sea temperatures*, and *vibrio parahaemolyticus* happen to co-occur. But they are either diaries where the three words appear separately in different topics or lists of arbitrary words.

Abstract

Cross-narrative temporal ordering of medical events is essential to the task of generating a comprehensive timeline over a patient's history. We address the problem of aligning multiple medical event sequences, corresponding to different clinical narratives, comparing the following approaches: (1) A novel weighted finite state transducer representation of medical event sequences that enables composition and search for decoding, and (2) Dynamic programming with iterative pairwise alignment of multiple sequences using global and local alignment algorithms. The cross-narrative coreference and temporal relation weights used in both these approaches are learned from a corpus of clinical narratives. We present results using both approaches and observe that the finite state transducer approach performs performs significantly better than the dynamic programming one by 6.8% for the problem of multiple-sequence alignment.

1 Introduction

Discourse structure, logical flow of sentences, and context play a large part in ordering medical events based on temporal relations within a clinical narrative. However, cross-narrative temporal relation ordering is a challenging task as it is difficult to learn temporal relations among medical events which are not part of the logically coherent discourse of a single narrative. Resolving cross-narrative temporal relationships between medical events is essential to the task of generating an event timeline from across unstructured clinical narratives such as admission notes, radiology reports, history and physical reports and discharge summaries. Such a timeline has multiple applications in clinical trial recruitment (Luo et al., 2011), medical document summarization (Bramsen et al., 2006, Reichert et al., 2010) and clinical decision making (Demner-Fushman et al., 2009).

Given multiple temporally ordered medical event sequences generated from each clinical narrative in a patient record, how can we combine the events to create a timeline across all the narratives? The tendency to copy-paste text and summarize past information in newly generated clinical narratives leads to multiple mentions of the same medical event across narratives (Cohen et al., 2013). These cross-narrative coreferences act as important anchors for reasoning with information across narratives. We leverage cross-narrative coreference information along with confident cross-narrative temporal relation predictions and learn to align and temporally order medical event sequences across longitudinal clinical narratives. We model the problem as a sequence alignment task and propose solving this using two approaches. First, we use weighted finite state machines to represent medical events sequences, thus enabling composition and search to obtain the most probable combined sequence of medical events. As a contrast, we adapt dynamic programming algorithms (Needleman et al., 1970, Smith and Waterman, 1981) used to produce global and local alignments for aligning sequences of medical events across narratives. We also compare the proposed methods with an Integer Linear Programming (ILP) based method for timeline construction (Do et al., 2012). The cross-narrative coreference and temporal relation scores used in both these approaches are learned from a corpus of patient narratives from The Ohio State University Wexner Medical Center.

The main contribution of this paper is a general framework that allows aligning multiple event sequences using cascaded weighted finite state transducers (WFSTs) with the help of efficient composition and decoding. Moreover, we demonstrate that this method can be used for more accurate multiple sequence alignment when compared to

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 998–1008,
Baltimore, Maryland, USA, June 23-25 2014.

dynamic programming or other ILP-based methods proposed in literature.

2 Related Work

In the areas of summarization and text-to-text generation, there has been prior work on several ordering strategies to order pieces of information extracted from different input documents (Barzilay et al., 2002, Lapata, 2003, Bollegala et al., 2010). In this paper, we focus on temporal ordering of information, as discussed next.

Recent state-of-the art research has focused on the problem of temporal relation learning within the same document, and in many cases within the same sentence (Mani et al., 2006, Verhagen et al., 2009, Lapata and Lascarides, 2011). Chambers and Jurafsky (2009) describe a process to induce a partially ordered set of events related by a common protagonist by using an unsupervised distributional method to learn relations between events sharing coreferring arguments, followed by temporal classification to induce partial order. The task was carried out on the Timebank newswire corpus, but was limited to an intra-document setting. More recently, (Do et al., 2012) proposed an ILP-based method to combine the outputs of an event-interval and an event-event classifier for timeline construction on the ACE 2005 corpus. However, this approach is also restricted to events within documents and requires annotations for event intervals. We empirically compare our methods for timeline creation from longitudinal clinical narratives to such an ILP-based approach in Section 7. While a lot of this work has been done in the news domain, there is also some recent work in rule-based algorithms (Zhou et al., 2006) and machine learning (Roberts et al., 2008) applied to temporal relations between medical events in clinical text. Clinical narratives are written in a distinct sub-language with domain specific terminology and temporal characteristics, making them markedly different from newswire text.

There is limited prior work in learning relations across documents. Ji and Grishman (2008) extended the one sense per discourse idea (Yarowsky, 1995) to multiple topically related documents and propagate consistent event arguments across sentences and documents. Barzilay and McKeown (2005) propose a text-to-text generation technique for synthesizing common information across documents using sentence fusion. This involves multisequence dependency tree alignment to identify phrases conveying similar information and statistical generation to combine common phrases into a sentence. Along with syntactic features, they combine knowledge from resources like WordNet to find similar sentences. In case of clinical narratives and medical event alignment, the objective is to identify a unique sequence of temporally ordered medical events from across longitudinal clinical data.

To the best of our knowledge, there is no prior work on cross-document alignment of event sequences. Multiple sequence alignment is a problem that arises in a variety of domains including gene/protein alignments in bioinformatics (Notredame, 2002), word alignments in machine translation (Kumar and Byrne, 2003), and sentence alignments for summarization (Lacatusu et al., 2004). Dynamic programming algorithms have been popularly leveraged to produce pairwise and global genetic alignments, where edit distance based metrics are used to compute the cost of insertions, deletions and substitutions. We use dynamic programming to compute the best alignment, given the temporal and coreference information between medical events across these sequences. More importantly, we propose a cascaded WFST-based framework for cross-document temporal ordering of medical event sequences. Composition and search operations can be used to build a single transducer that integrates these components, directly mapping from input states to desired outputs, and obtain the best alignment (Mohri et al., 2000). In natural language processing, WFSTs have seen varied applications in machine translation (Kumar and Byrne, 2003), morphology (Sproat, 2006), named entity recognition (Krstev et al., 2011) and biological sequence alignment / generation (Whelan et al., 2010) among others. We demonstrate that the WFST-based approach outperforms popularly used dynamic programming algorithms for multiple sequence alignment.

3 Problem Description

Medical events are temporally-associated concepts in clinical text that describe a medical condition affecting the patient's health, or procedures performed on a patient. We represent medical events by splitting each event into a start and a stop. When there is insufficient information to discern the start or stop of an event, it is represented as a single concept. If only the start is known then the stop is set to $+\infty$, whereas when only the stop is known , the start is set to the date of birth of the

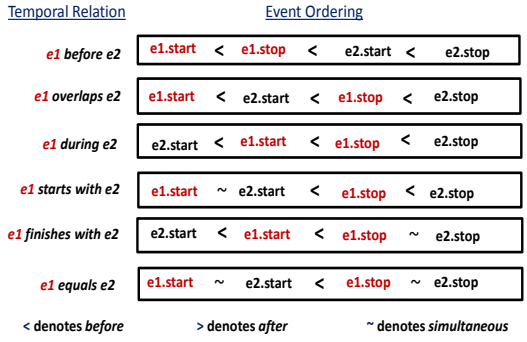

Figure 1: Medical event start / stop representation mapped to Allen's temporal relations (Allen, 1981). Temporal ordering of event starts and stops using $\{before, after, simultaenous\}$ (shown on the right) allows us learn temporal relations between the medical events (shown on the left). $e1_{start} = e2_{start}$ and $e1_{stop} = e2_{stop}$, when $e1$ and $e2$ corefer.

patient.[1] Often, for chronic ailments like *hypertension*, we would only associate a start with the medical event and set the stop to $+\infty$. The start of *hypertension* may be associated with the temporal expression *history of* in the narrative. This, when considered along with the admission date, allows us to relatively order *hypertension* with respect to other medical events. A medical event occurrence like *chest pain* may be associated with a start and a stop, where the start may be determined by the mention of "patient was complaining of chest pain *yesterday*" in the narrative text. Further, the narrative may state that "he *continued* to have chest pain *on admission*, but *currently* he is chest pain free"; this may be used to infer the relative stop of *chest pain*. Medical events may also be instantaneous, for e.g., *injected with antibiotic*. Such events are represented with the start and stop as being the same. Temporal relations exist between the start and stop of events as shown in Figure 1. Learning temporal relations *before, after* and *simultaneous* between the medical event starts and stops corresponds to learning all of Allen's temporal relations (Allen, 1981) between the medical events. Following our previous work (Raghavan et al., 2012c), such a representation allows us to temporally order the event starts and stops within each clinical narrative by learning to rank them in relative order of time. The problem definition is as follows:

[1]Patient date of birth, admission/ discharge date are usually available in the metadata associated with a clinical narrative.

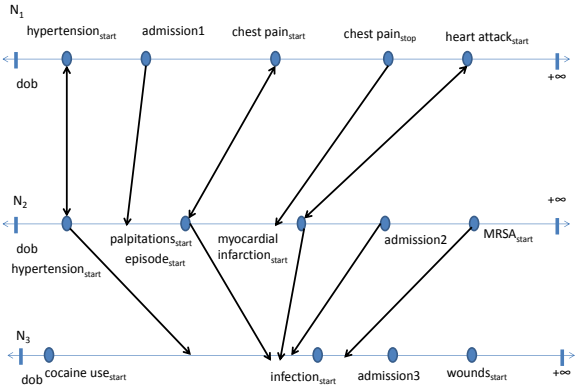

Figure 2: Given temporally ordered medical event sequences, N_1, N_2, N_3, we address the task of combining events across these sequences by merging or ordering them to create a single comprehensive timeline.

Input: Sequences of temporally ordered medical event starts and stops. This corresponds to N_1, N_2, and N_3 in Figure 2. Each sequence corresponds to a clinical narrative. The total number of sequences correspond to the number of clinical narratives for a patient.

Problem: Combine medical events across these sequences to generate a timeline i.e., a single comprehensive sequence of medical events over all clinical narratives of the patient.

Expected Output: In the example shown in Figure 2, the output would be as follows: Timeline (N_1, N_2, N_3)= $\{$cocaine use$_{start}$ $<$ hypertension$_{start}$ $=$ hypertension$_{start}$ $<$ admission1 $<$ chest pain$_{start}$ $\sim$ palpitations$_{start}$ $<$ chest pain$_{stop}$ $<$ heart attack$_{start}$ $=$ myocardial infarction$_{start}$ $<$ admission2 $<$ infection$_{start}$ $<$ MRSA$_{start}$ $<$ admission3 $<$ wounds$_{start}\}$.

The goal of multiple sequence alignment is to find an alignment that maximizes some overall alignment score. Thus, in order to align event sequences, we need to compute scores corresponding to cross-narrative medical event coreference resolution and cross-narrative temporal relations.

4 Cross-Narrative Coreference Resolution and Temporal Relation Learning

The first approach to learning a temporal ordering of medical events across all clinical narratives is to consider all pairs of events across all narratives and learn to classify them as sharing one of Allen's temporal relations (Allen, 1981) using a single learning model. Alternatively, a ranking ap-

proach, similar to the one used to generate intra-narrative temporal ordering, can also be extended to the cross-narrative case. However, the features related to narrative structure and relative and implicit temporal expressions used for temporal ordering within a clinical narrative may not be applicable across narratives. For instance, a history and physical report may have sections like "past medical history", "history of present illness", "assessment and plan", and a certain logical pattern to the flow of text within and across these sections. Further, temporal cues like "thereafter", "subsequently", follow from the context around an event mention. The absence of such features in the cross-narrative case does not allow such a model to generate accurate temporal relation predictions.

Thus, for use in our sequence alignment models, we learn two independent classifiers for medical event coreference and temporal relation learning across narratives. We train a classifier to resolve cross-narrative coreferences by extracting semantic and temporal relatedness feature sets for each pair of medical concepts. Extracting these feature sets helps us train a classifier to predict medical event coreferences (Raghavan et al., 2012a). Another classifier is then trained to classify pairs of medical event starts and stops across narratives as sharing temporal relations {before, after, overlaps}. The learned cross-narrative coreference predictions can then be used along with confident temporal relation predictions to derive a joint probability to enable cross-narrative temporal ordering.

5 Narrative Sequence Alignment for Cross-narrative Temporal Ordering

Sequence alignment algorithms have been developed and popularly used in bioinformatics. However, multiple sequence alignment (MSA) has been shown to be NP complete (Wang and Jiang, 1994) and various heuristic algorithms have been proposed to solve this problem (Notredame, 2002). We propose a novel WFST-based representation that enables accurate decoding for MSA when compared to popularly used dynamic programming algorithms (Needleman et al., 1970, Smith and Waterman, 1981) or other state of the art methods (Do et al., 2012).

In the problem of aligning events across multiple narrative sequences, we want to align temporally ordered medical events corresponding to clinical narratives of a patient. Unlike problems in biological sequence alignment where the symbols to be aligned across sequences are restricted to a fixed set, our symbol set is not fixed or certain because the symbols correspond to medical events in clinical narratives. Moreover, we cannot have fixed scores for symbol transformations since our transformations correspond to coreference and temporal relations between the medical events across sequences. The computation of these scores is described next.

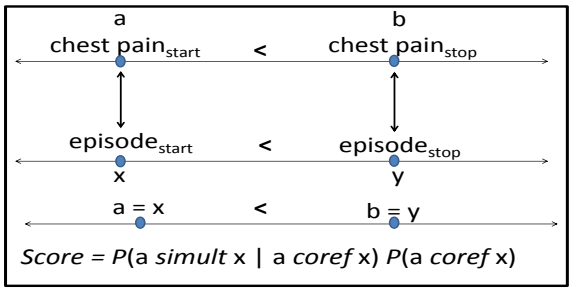

Figure 3: Score computation for aligning events across temporally ordered event sequences chest pain$_{start}$ = episode$_{start}$ < chest pain$_{stop}$ = episode$_{stop}$, where events across the sequences occur simultaneously and corefer.

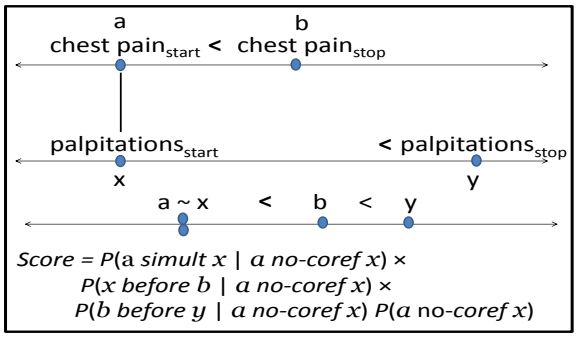

Figure 4: Score computation for aligning events across temporally ordered event sequences chest pain$_{start}$ ∼ palpitations$_{stop}$ < chest pain$_{stop}$ < palpitations$_{stop}$, where some events across the sequences occur simultaneously but do not corefer.

5.1 Scoring Scheme

Let us assume a, b are medical events in the first clinical narrative and have been temporally ordered so $a < b$. Similarly, x, y are medical events in the second clinical narrative such that $x < y$. There exists a match or an alignment between a pair of medical events, across the sequences, in the following cases:

1. If the medical events are simultaneous and coreferring, denoted as $a = x$.
2. If the medical events are simultaneous and non-coreferring, denoted as $a \sim x$.

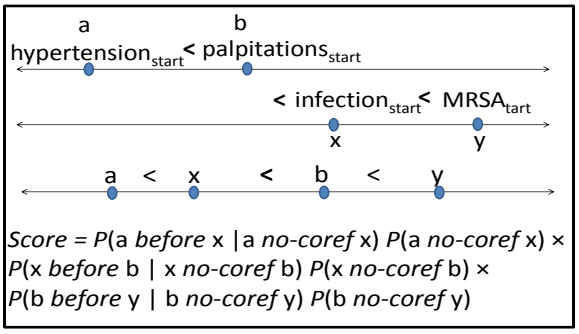

Figure 5: Score computation for aligning events across temporally ordered event sequences hypertension$_{start}$ $<$ palpitations$_{start}$ $<$ infection$_{start}$ $<$ MRSA$_{start}$, where events across the sequences do not occur simultaneously and do not corefer.

3. If the a medical event from one sequence is before a medical event from another sequence, denoted as $a < x$.
4. If the a medical event from one sequence is after a medical event from another sequence, denoted as $a > x$.

We now illustrate how the scores for candidate aligned sequences are computed using the learned cross-narrative coreference and temporal probabilities for the following three scenarios:

- The medical events across sequences are simultaneous and corefer as illustrated in Figure 3. The joint score considers the probability of event temporal relations *simultaneous* conditioned on *coreference*.
- Some medical events across sequences are simultaneous but do not corefer as illustrated in Figure 4. Here, the joint score considers the joint probability of temporal relations *simultaneous* or *before* and *no-coreference*.
- The medical events across sequences are not simultaneous and do not corefer as illustrated in Figure 5. In this case, the joint score considers the probability of the temporal relation *before* and *no coreference*.

Thus, the coreference and temporal relation scores can be leveraged for aligning sequences of medical events. These scores are used in both the WFST-based representation and decoding, as well as for dynamic programming.

5.2 Alignment using a Weighted Finite State Representation

A weighted finite-state transducer (WFST) is an automaton in which each transition between states is associated with an input symbol, an output symbol, and a weight (Mohri et al., 2005). WFSTs can be used to efficiently represent and combine sequences of medical events based coreference and temporal relation information. The WFST representation gives us the ability to talk about the global joint probability derived from coreference and temporal relation scores described in Section 5.1. It allows us to build a weighted lattice of sequences that can be searched for the most probable sequence of medical events from across all clinical narratives of a patient. We use unweighted FSAs to represent the input described in Section 3, i.e. temporally ordered sequences of medical events corresponding to clinical narratives. This corresponds to N_1 and N_2 in Figure 6.

Based on whether we want to align the sequences purely based on coreference scores or both coreference and temporal relation scores, the arc weights for the WFST can be determined. M_{12}^{c} is a WFST that maps input symbols from N_1 to output symbols in N_2 and is weighted by the probability of coreference or no-coreference between medical events across N_1 and N_2. The representation in WFST M_{12}^{c+t} shown in Figure 7 allows us to align N_1 and N_2 based on both coreference as well as temporal relation probabilities. The WFST has ϵ transitions to accommodate insertion and deletion of medical events when combining the sequences. Deletions correspond to the case when an event in the first sequence does not map to any event in the second sequence; similarly insertions correspond to the case where an event in the second sequence does not map to any event in the first sequence. The WFST composition operation allows the outputs of one WFST to be fed to the inputs of a second WFST or FSA. Thus, we build our final machine by composing the three sub-machines as,

$$D = N_1 \circ M_{12}^{i} \circ N_2. \quad (1)$$

where $i = c$ or $i = c + t$. This gives us a combined weighted graph by mapping the output symbols of the first medical event sequence to the input symbols of the second medical event sequence. The scores on the decoding graph are derived from only the coreference probabilities if $i = c$ and both coreference and temporal relation probabilities if $i = c + t$.

In the medical event sequence alignment problem, we want to align multiple sequences of medical events that correspond to multiple clinical narratives of a patient. Since we want to now combine

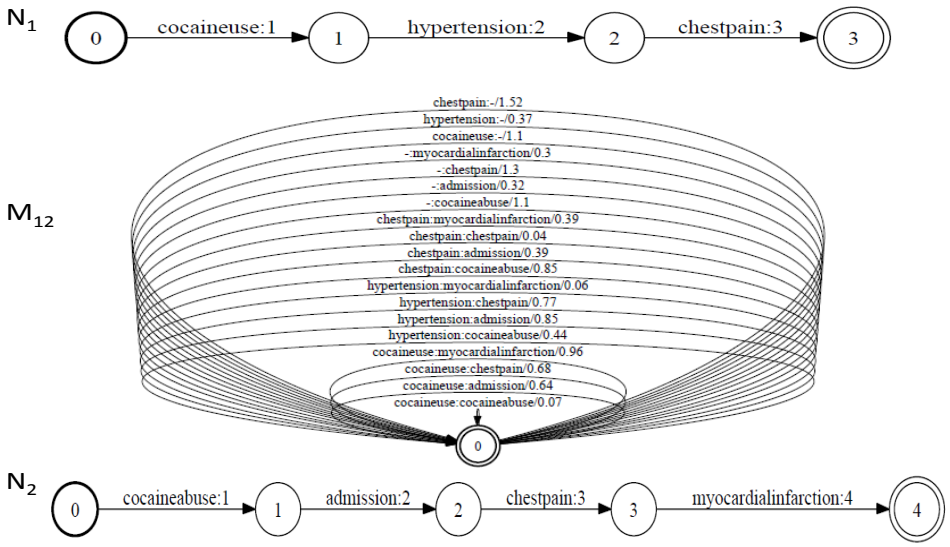

Figure 6: N_1 and N_2 are medical event sequences represented using FSAs. M^c_{12} maps medical events across N_1 and N_2 and is weighted only by the probability of coreference between events across N_1 and N_2.

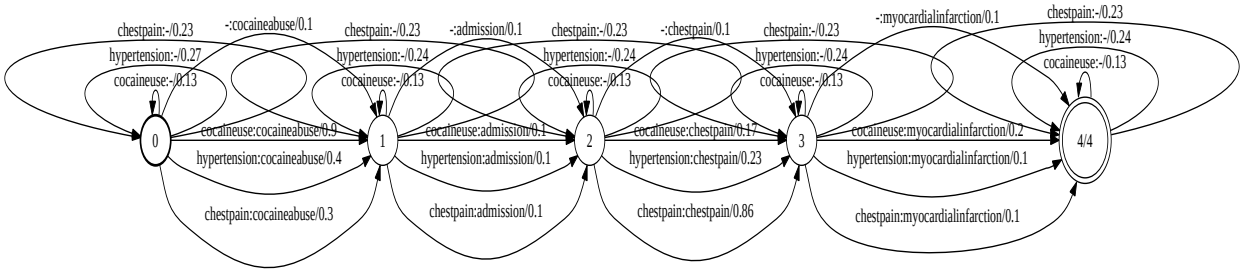

Figure 7: M^{c+t}_{12} is a WFST representation used for mapping medical events between N_1 and N_2 (from Figure 2) and is weighted by both the coreference and temporal relation probabilities

all narrative chains belonging to the same patient, the composition cascade to build the final combined sequence will be as,

$$D_f = N_1 \circ M^i_{12} \circ N_2 \circ M^i_{23} \circ N_3 \circ M^i_{34} ... \circ N_n \quad (2)$$

where $i = c$ or $i = c + t$ and n is the number of medical event sequences corresponding to clinical narratives for a patient. During composition we retain intermediate paths like M^i_{23} utilizing the ability to do lazy composition (Mohri and Pereira, 1998) in order to facilitate beam search through the multi-alignment. The best hypothesis corresponds to the highest scoring path which can be obtained using shortest path algorithms like Djikstra's algorithm. The best path corresponds to the best alignment across all medical event sequences based on the joint probability of cross-narrative medical event coreferences and temporal relations across the narrative sequences.

The complexity of decoding increases exponentially with the number of narrative sequences in the composition, and exact decoding becomes infeasible. One solution to this problem is to do the alignment greedily pairwise, starting from the most recent medical event sequences, finding the best path, and iteratively moving on to the next sequence, and proceeding until the oldest medical event sequence. The disadvantage of such a method is that it does not take into account constraints between medical events across multiple event sequences and may lead to a less accurate solution.

An alternative method is to use lazy composition to perform more efficient composition as it allows practical memory usage. We also use beam search to make for an efficient approximation to the best-path computation (Mohri et al., 2005). This allows accommodating constraints from across multiple sequences and generates a more accurate best path. Thus, this method generates more accurate alignments when we have more than two sequences to be aligned.

For instance, instance say $a, b \in N_1, x, y \in N_2$, and $m, n \in N_3$ are temporally medical event sequences corresponding to narratives N_1, N_2 and N_3. Based on the learned pairwise temporal relations, if we have the following constraints $a < x$, $m > x$, $m < a$. Aligning N_1 and N_2 greedily pairwise may give us the best combined sequence as $a, x, b, y \in N_{12}$. Now in aligning N_{12} with N_3, we won't be able to accommodate $m > x$ and $m < a$. However, performing a beam search over the composed WFST in equation 2 allows us to accommodate such constraints across multiple sequences. The complexity of composing two transducers is $O(V_1 V_2 D_1 (logD_2 + M_2))$ where each edge from the first sequence matches every edge in the second sequence and V_i is the number of states, D_i is the maximum out-degree and M_i maximum multiplicity for the i^{th} FST (Mohri et al., 2005).

We also use popular dynamic programming algorithms (Needleman et al., 1970, Smith and Waterman, 1981) for sequence alignment of medical events across narratives and compare it to the WFST-based representation and decoding.

5.3 Pairwise Alignment using Dynamic Programming

As a contrast, we adapt two dynamic programming algorithms for sequence alignment: global alignment using the Needleman Wunsch algorithm (NW) (Needleman et al., 1970) and local alignment using the Smith-Waterman algorithm (SW) (Smith and Waterman, 1981). NW allows us to align all events in one sequence with all events in another sequence. A drawback of NW is that short and highly similar sequences maybe missed because they get overweighted by the rest of the sequence. NW is suitable when the two sequences are of similar length with significant degree of similarity throughout. On the other hand, SW gives the longest sub-sequence pair that yields maximum degree of similarity between the two original sequences. It does not force all events in a sequence to align with another sequence. SW is useful in aligning sequences that differ in length and have short patches of similarity. The time complexity of these methods for sequences of length m and n are $O(mn)$.

The scoring scheme described earlier is used to update the scoring matrix for dynamic programming. In order to accommodate the temporal relations before and after, we insert a null symbol after every medical event in each sequence in the scoring matrix. A vertical or horizontal gap arises when cases 1, 2, 3 and 4 in Section 5.1 mentioned above are not true. If the medical events are not simultaneous, not before or not after, the medical events will not align. Thus, the value of each cell in the scoring matrix is determined by computing the maximum score at each position $C(i, j)$ as,

$$\max\{(C(i-1, j-1) + S_{ij}), (C(i, j-1) + w), (C(i-1, j) + w)\} \quad (3)$$

where, $S_{ij} = \max\{P(i = j), P(i < j), P(i > j)\}$, and $w = \max\{(1 - P(i = j)), (1 - P(i < j)), (1 - P(i > j))\}$. Here, $C(i-1, j-1)$ corresponds to a match, whereas $C(i, j-1)$ and $C(i-1, j)$ correspond to a gaps in sequence one and two.

In case of the SW algorithm, the negative scoring matrix cells are set to zero, thus making the positively scoring local alignments visible. Backtracking starts at the highest scoring matrix cell and proceeds until a cell with score zero is encountered, yielding the highest scoring local alignment.

The time and space complexity grows exponentially with the number of sequences to be aligned and finding the global optimum has been shown to be a NP-complete problem. The time complexity of aligning N sequences of length L is $O(2^N L^N)$ (Wang and Jiang, 1994). Thus, for MSA using dynamic programming, we use a heuristic method where we combine pairwise alignments iteratively starting with the latest narrative and progressing towards the oldest narrative.

6 Experiments and Evaluation

Corpus Description. The corpus consists of a dataset of clinical narratives obtained from the [redacted] medical center. The corpus has a total of 2060 patients, and 100704 clinical narratives. We gathered a gold standard set of seven patients (80 clinical narratives overall) with manual annotation of all medical events mentioned in the narratives, coreferences, and medical event sequence information. The annotation agreement across annotators is high, with 89.5% agreement corresponding to inter-annotator Cohen's kappa statistic of 0.86 (Raghavan et al., 2012b). The types of clinical narratives included 27 discharge summaries, 30 history and physical reports, 15 radiology reports and 8 pathology reports. The distribution of the number of medical event sequences and unique medical events across patients is shown in Table 1. The annotated dataset is used to cross-validate and train our coreference and temporal relation learning models and to evaluate our cross-narrative medical event timeline.

Table 1: The distribution of medical events across narrative sequences and sequences across patients and multiple sequence alignment results for the WFST-based framework, and dynamic programming using just coreference scores [c] and using coreference as well as temporal relation scores [c+t].

Evaluation Metric. For each patient and each method (WFST or dynamic programming), the output timeline to evaluate is the highest scoring candidate hypothesis derived as described above. Accuracy of the timeline is calculated as the number of transformations required to obtain the reference sequence in the annotated gold-standard from the one generated by our system. Transformations are measured in terms of the minimum edit distance, insertions, deletions, and substitutions of medical events.

Experiments and Results. We first temporally order medical events within each clinical narrative by learning to rank them in relative order of occurence as described in our previous work (Raghavan et al., 2012c). The overall accuracy of ranking medical events using leave-one-out cross validation is 82.1%. The resulting medical event sequences serve as the input to the problem of cross-narrative sequence alignment.

The cross-narrative coreference and temporal relation pairwise classification models described in Section 4 are trained using a Maximum entropy classifier. The coreference resolution performs with 71.5% precision and 82.3% recall. The temporal relation classifier performs with 60.2% precision and 76.3% recall. The learned pairwise coreference and temporal relation probabilities are now used to derive the score for the WFST and dynamic programming approaches.

WFST representation and decoding. We build finite-state machines using the open source OpenFST library.[2] We use a tropical semi-ring weighted using the negative log-likelihood of the computed scores. OpenFST provides tools that can search for the highest scoring sequences accepted by the machine, and can sample from high-scoring sequences probabilistically, by treating the scores of each transition within the machine as a negative log probability. The decoding process to compute the most likely combined medical event sequence can be defined as searching for the best path in the combined graph representation (Equation 2). The best path is the one that minimizes the total weight on a path (since the arcs are negative log probabilities). In searching for the best path, the beam size is set to 5. The accuracy of the WFST-based representation and beam search across all sequences using the coreference and temporal relation scores to obtain the combined aligned sequence is 78.9%.

Dynamic Programming. We use the NW and SW algorithms described in Section 5.3 to produce local and global alignments respectively. We use the scoring scheme described in Section 5.1 to update the cost matrix for dynamic programming and implement the algorithms as described in Section 5.3. The overall accuracy of sequence alignment with both coreference and temporal relation scores using NW is 68.7% whereas SW gives an accuracy of 72.1%. In case of aligning just two sequences, both methods yield the same results. The accuracy of cross-narrative MSA for each patient, for each method, using cross validation, is shown in Table 1. Results indicate that the WFST-based method outperforms the dynamic programming approach for multi-sequence alignment (statistical significance $p<0.05$). Morever, the results using both coreference and temporal realtion scores for alignment outperform using only coreference scores for alignment using all approaches. This indicates that cross-narrative temporal relations are important for accurately aligning medical event sequences across narratives.

7 Discussion

We propose and evaluate different approaches to multiple sequence alignment of medical events.

[2] www.openfst.org

Approaches to multi-alignment. We address the problem of aligning medical event sequences using a novel WFST-based framework and empirically demonstrate that it outperforms pairwise progressive alignment using dynamic programming. This is mainly because the WFST-based allows us to consider temporal constraints from across multiple sequences when performing the alignment.

Moreover, it also outperforms the integer linear programming (ILP) method for timeline construction proposed in (Do et al., 2012). We implemented the proposed method that also allows combining the output of classifiers subject to some constraints. We derive intervals from event starts and stops and learn two perceptron classifiers for classifying the temporal relations between events and assigning events to intervals. The classifier probabilities are then used to solve the optimization problem using the lpsolve solver.[3] We also use intra-document coreference information to resolve coreference before performing the global optimization. We observe that in case of MSA, the optimal solution using ILP is still intractable as the number of constraints increases exponentially with the number of sequences. Aligning pairwise iteratively gives us an overall average accuracy of 68.2% similar to dynamic programming. While this is comparable to the dynamic programming performance, the WFST-based method significantly outperforms this in case of multi-alignments for cross-narrative temporal ordering.

Performance and error analysis. We perform multi-alignments over medical event sequences for a patient, where each sequence corresponds to temporally ordered medical events in a clinical narrative generated using the ranking model described in (Raghavan et al., 2012c). The accuracy of intra-narrative temporal ordering is 82.1%. The errors in performing this intra-narrative ordering may propagate to the cross-narrative model resulting in reduced accuracy. This may be addressed by considering n-best temporally ordered medical event sequences, generated by the ranking process, and aligning the n-best sequences using the WFST-based framework. This could be feasible as, practically, the WFST-based method for multi-alignment takes only a few secs to align a pair of medical event sequences with average length 40.

The accuracy of alignments across multiple medical event sequences is also affected by the error induced by the coreference and temporal relation scores. Often, insufficient temporal cues leads to misclassification of events incorrectly as sharing the "simultaneous" temporal relation and often as coreferring. This induces errors in the score calculation and hence the alignments. Better methods to address the challenging problem of cross-document temporal relation learning, perhaps with the help of structured data from the patient record, could improve the accuracy of alignments.

There is no clear trend with respect to the number of medical events and narratives for a patient (Table 1.), and the alignment accuracy. In future work, it would be interesting to examine any such correlation and also study the scalability of the WFST-based method for sequence alignment on longer medical event sequences and a larger dataset of patients. Further, the WFST-based method may be used to model multi-alignment tasks in other speech and language problems as well.

8 Conclusion

We propose a novel framework for aligning medical event sequences across clinical narratives based on coreference and temporal relation information using cascaded WFSTs. FSTs provide a convenient and flexible framework to model sequences of temporally ordered medical events and compose them into a combined graph representation. Decoding this graph allows us to jointly maximize coreference as well as temporal relation probabilities to derive a timeline of the most likely temporal ordering of medical events. This approach to aligning multiple sequences of medical events significantly outperforms other approaches such as dynamic programming. Moreover, we demonstrate the importance of learning temporal relations for the task timeline generation from across multiple clinical narratives by empirically proving that decoding using both coreference and temporal relation scores is far more accurate than decoding with only coreference scores.

Abstract

This paper introduces FactChecker, language-aware approach to truth-finding. FactChecker differs from prior approaches in that it does not rely on iterative peer voting, instead it leverages language to infer believability of fact candidates. In particular, FactChecker makes use of linguistic features to detect if a given source objectively states facts or is speculative and opinionated. To ensure that fact candidates mentioned in similar sources have similar believability, FactChecker augments objectivity with a co-mention score to compute the overall believability score of a fact candidate. Our experiments on various datasets show that FactChecker yields higher accuracy than existing approaches.

1 Introduction

Truth-finding algorithms aim to separate true statements (facts) from false information. More specifically, given a set of statements whose truthfulness is unknown (*fact candidates*), the key goal of truth-finding algorithms is to generate a ranking such that true statements are ranked ahead of false ones. Truth-finders have the potential to address a major obstacle on the Web: the problem of sources spreading inaccurate and conflicting information. This problem continues to grow with the development of tools for easy Web authorship. Blogs, forums and social networking websites are not subject to traditional journalistic standards. Consequently, the accuracy of information reported by these sources is often unclear. Even more established newspapers and websites may sometimes report false information as they race to break stories. Therefore, truth-finding is becoming an increasingly important problem. Information extraction projects aim to distill relational facts from natural language text (Auer et al., 2007; Bollacker et al., 2008; Carlson et al., 2010; Fader et al., 2011; Nakashole et al., 2011; Del Corro and Gemulla, 2013). These projects have produced knowledge bases containing many millions of relational facts between entities. However, despite these impressive advances, there are still major limitations regarding precision. Within the context of information extraction, fact extractors assign confidence scores to extracted facts. However, such scores are often tied to the extractor's ability to *read* and *understand* natural language text. This is different from a score that indicates the degree to which a given fact candidate is *believable*. Such a believability score is sometimes also referred to as a credibility score or truthfulness score. The believability score reflects the likelihood that a given statement is true. Truth-finding algorithms aim to compute this score for each fact candidate.

Prior truth-finding methods are mostly based on iterative voting, where votes are propagated from sources to fact candidates and then back to sources (Yin et al., 2007; Galland et al., 2010; Pasternack and Roth, 2010; Li et al., 2011; Yin and Tan, 2011). At the core of iterative voting is the assumption that candidates mentioned by many sources are more likely to be true. However, additional aspects of a source influence its trustworthiness, besides external votes.

Our goal is to accurately assess truthfulness of fact candidates by taking into account the language of sources that mention them. A Mechanical Turk study we carried out revealed that there is a significant correlation between objectivity of language and trustworthiness of sources. Objectivity of language refers to the use of neutral, impartial language, which is not personal, judgmental, or emotional. Trustworthiness refers to

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1009–1019,
Baltimore, Maryland, USA, June 23-25 2014.

a source of information being reliable and truthful. We use linguistics features to detect if a given source objectively states facts or is speculative and opinionated. Additionally, in order to ensure that fact candidates mentioned in similar sources have similar believability scores, our believability computation model incorporates influence of co-mentions. However, we must avoid falsely boosting co-mentioned fact candidates. Our model addresses potential false boosts in two ways: first, by ensuring that co-mention influence is only propagated to related fact candidates; second, by ensuring that the degree of co-mention influence is determined by the trustworthiness of the sources in which co-mentions occur.

The contribution of this paper is a language-aware truth-finding approach. More precisely, we make the following contributions: (1) *Alternative Fact Candidates:* Truth-finders rank a given fact candidate with respect to its alternatives. For example, alternative places where Barack Obama could have been born. Virtually all existing truth-finders assume that the alternatives are provided. In contrast, we developed a method for generating alternative fact candidates. (2) *Objectivity-Trustworthiness Correlation:* We hypothesize that objectivity of language and trustworthiness of sources are positively correlated. To test this hypothesis, we designed a Mechanical Turk study. The study showed that this correlation does in fact hold. (3) *Objectivity Classifier:* Using labeled data from the Mechanical Turk study, we developed and trained an objectivity classifier which performed better than prior proposed lexicons from literature. (4) *Believability Computation:* We developed FactChecker, a truth-finding method that linearly combines objectivity and co-mention influence. Our experiments showed that FactChecker outperforms prior methods.

2 Fact Candidates

In this section, we formally define what constitutes a fact candidate and describe how we go about understanding semantics of fact candidates. We then present our approach for generating alternative fact candidates.

2.1 Representation

The *triple* format is the most common representation of facts in knowledge bases. A formal specification of the triple format is presented in the RDF primer[1]. In RDF, data is represented as subject-predicate-object (SPO) triples. In this work, we restrict predicates to *verbs* (or *verbal phrases* such as "plays for", "graduated from", etc.). Literature on automatic relation discovery (Fader et al., 2011) has shown that verbal phrases uncover a large fraction of binary predicates while reducing the amount of noisy phrases that do not denote any relations. Therefore, we define a fact candidate as follows:

Definition 1 (Fact Candidate) *A fact candidate f_i is an $\langle S \rangle$ V $\langle O \rangle$ triple; where S is the subject, V is a verbal phrase, and O is the object. We aim to compute the truthfulness of f_i, $\tau(f_i) \in \{T, F\}$, where T and F stand for $true$ and $false$, respectively.*

Note that in this paper we are interested in cases where $\tau(f_i)$ is either T *or* F. That is, we assess truthfulness of *factual* statements and not opinions whose truthfulness is often both T and F to some degree. For example, the triples: $\langle$*Obama*$\rangle$ *born in* $\langle$*Kenya*$\rangle$ and $\langle$*Obama*$\rangle$ *graduated from* $\langle$*Harvard*$\rangle$ are valid fact candidates. However, the triple: $\langle$*Obama*$\rangle$ *deserves* $\langle$*Nobel Peace Prize*$\rangle$ is not.

2.2 Semantics

Based on the SVO triple, the meaning of a fact candidate can be unclear and ambiguous. Therefore, we first determine the semantics of a fact candidate before computing its truthfulness.

Entity Types. We first determine the expected types of the subject and object in the SVO. For example, for the SVO $\langle$*Einstein*$\rangle$ *died in* $\langle$*Princeton*$\rangle$, the expected types are *person* $\times$ *location*. We determine this by first computing the types of entities that are valid for each verb (verbal phrase) in a large SVO collection of 114m SVO triples (Talukdar et al., 2012). Typing verbal phrases is a once-off computation. Our phrase typing method is similar to prior work on typing relational phrases (Nakashole et al., 2012). Examples of typed phrases are: $\langle$*person*$\rangle$ *died in* $\langle$*year*$\rangle$, $\langle$*person*$\rangle$ *died in* $\langle$*location*$\rangle$, and $\langle$*athlete*$\rangle$ *plays for* $\langle$*team*$\rangle$. Given a triple, we look up the types for the subject and the object and then determine which of the typed phrases are compatible with the current triple. We look up entity types in a knowledge

[1] http://www.w3.org/TR/rdf-primer/

base containing entities and their types. In particular, we use the NELL entity typing API (Carlson et al., 2010). NELL's entity typing method has high recall because when entities are not in the knowledge base, it performs on-the-fly type inference using the Web. This is not the case for other options such as (Auer et al., 2007; Bollacker et al., 2008; Hoffart et al., 2011).

Relation Cardinality. Next, we learn cardinalities of verbal phrases. Cardinality refers to how arguments of a given relation relate to one another numerically. We define the relation cardinality of a verb $Card(V)$, as the average number of expected arguments per given subject. For example, for the relation "died in", 1 location is expected for each subject. For other relations, the expected number of arguments can be greater than 1 but less than $n : n \in \mathbb{R}, n > 1$. We approximate n using statistics from the 114m SVO corpus based on the average number of arguments per given first argument. In a once-off computation, we generate cardinality approximations per typed verbal phrase V and its inverse V^{-1}. For example, we generate the cardinality estimates for both: ⟨*person*⟩ *died in* ⟨*location*⟩ and for ⟨*location*⟩ *INVERSE-OF(died in)* ⟨*person*⟩.

Synonymous Relations. Natural language is diverse. Semantically similar phrases can be syntactically different. Therefore, we learn other verbs that can be used to substitute V in SVO. We pre-compute synonymous phrases from the 114m SVO corpus using distributional semantics in the same spirit as (Lin and Pantel, 2001; Nakashole et al., 2012).

Synonymous verbs, relation cardinalities, and entity types enable us to generate alternative fact candidates.

2.3 Alternative Fact Candidates

Truth-finding methods rank f_i relative to alternative candidates. While prior methods assume the alternatives are known apriori, we developed a method for generating alternative fact candidates. For a given f_i, we first identify the *fixed argument*. The fixed argument is the argument of the SVO which when fixed, requires finding the fewest number of alternative candidates. For example, for ⟨*Einstein*⟩ *died in* ⟨*Princeton*⟩, the solution is to fix the subject. This is because the cardinality of ⟨*person*⟩ *died in* ⟨*location*⟩ is one (1). On the other hand, the cardinality of "INVERSE-OF(died in)" is many(n). In other words, the number of places where a person can be born (one) is much fewer than the number of people that can die in a place (many). In our example, alternatives are possible places, other than Princeton, where Einstein could have died. For example: ⟨*Einstein*⟩ *died in* ⟨*Germany*⟩ or ⟨*Einstein*⟩ *died in* ⟨*Switzerland*⟩. More generally, the fixed argument of fact candidate f_i, is defined as follows:

Definition 2 (Fixed Argument) *Let Card(V) be the cardinality of* V *and* $Card(V^{-1})$ *be the cardinality of the inverse of* V*, if* $Card(V) < Card(V^{-1})$*, then the fixed argument is the subject,* $Arg^{fixed}(f_i) = S$*, else it is the object,* O*. If* $Card(V) == Card(V^{-1})$*, then both arguments are fixed, one at a time.*

We use the fixed argument to define a *topic* as the fixed argument plus the verb. Therefore, for the SVO ⟨*X*⟩ *died in* ⟨*Y*⟩, the topic "places where X died", ($Arg^{fixed} = S$), is not the same as the topic "people who died in Y" ($Arg^{fixed} = O$).

To locate alternatives, we use the topic ($Arg^{fixed} + V$) as a query. We search three sources to either locate relevant documents or relevant triples: the Google Web search API, the 114m SVO collection, and the NELL KB. The SVO collection and the KB return triples, however, the Web search API returns documents. Therefore, we apply a triple extractor to the retrieved documents. For all potential alternative triples, we perform type checking to ensure that the arguments of the triples are type-compatible with f_i. Furthermore, we generate an additional query for every synonymous verb sV_i, replacing V with sV_i. Example queries are: "Einstein died in", "Einstein passed in", etc.

3 Objectivity and Trustworthiness

The principle of *objective journalism*, which is a significant part of journalistic ethics, aims to promote factual and fair reporting, undistorted by emotion or personal bias (Schudson, 1978; Kaplan, 2002). Objectivity is also required in reference sources such as encyclopedias, scientific publications, and textbooks. For example, Wikipedia enforces a neutral point-of-view policy (NPOV)[2]. Articles violating the NPOV policy are marked

[2]http://en.wikipedia.org/wiki/Wikipedia:Neutral_point_of_view

to indicate potential bias. While opinions, emotions, and speculations can also be expressed using objective language, they are often stated using subjective language (Turney et al., 2002; Riloff and Wiebe, 2003; Yu and Hatzivassiloglou, 2003; Wiebe et al., 2004; Liu et al., 2005; Recasens et al., 2013). For example, consider the following pieces of text:

(S) Well, I think Obama was born in Kenya because his grandma who lives in Kenya said he was born there.

(O) Theories allege that Obama's published birth certificate is a forgery, that his actual birthplace is not Hawaii but Kenya.

Text S is a snippet from Yahoo Answers and text O is a snippet from the Wikipedia page titled: "Barack Obama Citizenship Conspiracy Theories". S is subjective, expressing the opinion of the author. On the other hand, O is objective, stating only what has been alleged. Literature on sentiment analysis (Turney et al., 2002; Liu et al., 2005), subjectivity detection (Riloff and Wiebe, 2003; Wiebe et al., 2004), and bias detection (Yu and Hatzivassiloglou, 2003; Recasens et al., 2013) has developed lexicons for identifying subjective language. Due to the principle of objective journalism and the requirement of objectivity placed on reference sources, we hypothesize a link between objectivity and trustworthiness as follows.

Hypothesis 1 *Objective sources are more trustworthy than subjective sources. Therefore, we can assume that fact candidates stated in objective sources are more likely to be true than those stated in subjective sources.*

To test the validity of the hypothesis, we carried out a study where we solicited human input.

3.1 Mechanical Turk Study

We deployed an annotation study on Amazon Mechanical Turk (MTurk)[3], a crowd-sourcing platform for tasks requiring human input. Tasks on MTurk are small questionnaires consisting of a description and a set of questions. Our study consisted of two independent tasks. The first task was titled "Trustworthiness of News Articles", where annotators were given a link to a news article and asked to judge if they thought it was trustworthy or not. The second task was titled "Objectivity of News Articles". For this task, annotators were asked to judge if a given article is objective or subjective. For both tasks a third option of "not sure" was provided. We randomly selected 500 news articles from a corpus of about 300,000 news articles obtained from Google News from the topics of Top News, Business, Entertainment, and SciTech. For each task, every article was judged by three annotators. This produced a total of 3000 annotations. When we analyzed the output, we accepted a label as valid for a given article if the label was selected by the majority of the judges. Based on this criteria, we obtained a set of 420 articles that were both labeled for trustworthiness and objectivity.

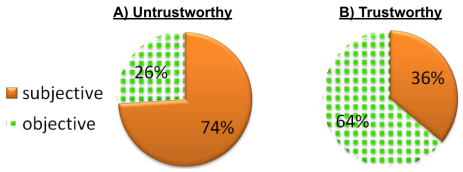

Figure 1: Summary of the results of the annotation study on objectivity and trustworthiness.

A summary of the outcome of the study is shown in Figure 1; 74% of the untrustworthy articles were independently labeled as subjective. On the other hand, 64% of trustworthy articles were independently labeled as objective. These results indicate a non-trivial positive correlation between objectivity and trustworthiness. We leverage this correlation in our believability computation model. To incorporate objectivity in FactChecker, we require for a given source document, an objectivity score $\in [0, 1]$, where 0 means the source is subjective and 1 means it is objective. Next, describe our method for automatically determining objectivity of sources.

3.2 Automatic Objectivity Detection

We trained a logistic regression classifier to predict the objectivity of a document. For training and testing data, we used the labeled data from the Mechanical Turk study. We additionally used labeled text from prior work on subjectivity detection (Pang and Lee, 2004). This resulted in a total of $4,600$ documents, half subjective and the other half objective. We used 4000 documents for

[3]http://www.mturk.com

#	Feature
1	Subjectivity lexicon of strong and weak subjective words (Riloff and Wiebe, 2003).
2	Sentiment lexicon of positive and negative words (Liu et al., 2005).
3	Wikipedia-derived bias lexicon (Recasens et al., 2013).
4	Part-of-speech (POS) tags
5	Frequent bi-grams

Table 1: Features used for the objectivity detector.

training, 2000 per label. The rest of the documents were split into a development set (380) and a test set (220).

A summary of the features we used is shown in Table 1. Features 1-3 refer to lexicons developed by prior methods on subjectivity (Wiebe et al., 2004), sentiment analysis (Liu et al., 2005) and bias detection (Recasens et al., 2013). Feature 4 refers to part-of-speech tags of the terms found in the document that are also in the lexicons. Feature 5 refers to bi-grams that frequently occur (mention frequency of > 10) in the $4,600$ documents. The most contributing features were the lexicons, features (1-3) and the frequent bi-grams, feature 5. We discovered that using *frequent* bi-gram features instead of uni-grams or bi-grams resulted in higher precision. The classifier was able to determine that for example bi-grams such as "think that", "so funny" and "you thought" are negative features for objectivity. Evaluation results of our objectivity detector vs. baselines are shown in Table 2. FactChecker's objectivity detector has precision of 0.7814 ± 0.0539, with a 0.9-confidence Wilson score interval (Brown et al., 2001) and this outperforms the baselines. Next, we describe how we leverage objectivity into FactChecker's truthfulness model.

4 Believability Computation Model

FactChecker computes the believability score of a fact candidate from its: i) objectivity score and (ii) co-mention score. In this section we define each of these scores.

The objectivity score reflects the trustworthiness of sources where a fact candidate is mentioned. Given a fact candidate f_i, mentioned in a set of documents D_i, where each document $d \in D_i$ has objectivity $\mathcal{O}(d)$, f_i's objectivity score is defined as follows:

Approach	Accuracy
Sentiment Lexicon	0.65±0.06
Wikipedia bias Lexicon	0.69±0.06
Subjectivity Lexicon	0.70±0.06
FC-Objectivity Detector	**0.78**±0.05

Table 2: Accuracy of the objectivity detector.

Definition 3 (Objectivity Score)

$$\mathcal{O}(f_i) = log|D_i|.\frac{\sum_{d_k \in D_i} \mathcal{O}(d_k)}{|D_i|} \quad (1)$$

We do not use the sum of objectivity of sources as the objectivity score because this enables fact candidates mentioned in many low objectivity sources to have high aggregate objectivity. Similarly, we avoid using average objectivity of the sources as it overestimates objectivity of candidates stated in few sources. A candidate mentioned in 10 sources with 0.9 objectivity should have higher objectivity than a candidate stated in 1 source of 0.9 objectivity. In Equation 1, $log|D_i|$ addresses this issue.

The co-mention score aims to ensure that fact candidates mentioned in similar sources have similar believability scores. Suppose candidate f_i is mentioned in many highly objective sources, another candidate f_j is stated in only one highly objective source d_k where f_i is also mentioned. Then the believability of f_j should be boosted by it being co-mentioned with f_i. If on the other hand f_i and f_j were co-mentioned in a subjective source, f_j should receive less boost from f_i. This leads us to the co-mention score $\mu(f_i)$ of a candidate.

Definition 4 (Co-Mention Score)

$$\mu(f_i) = \rho(f_i) + \sum_{f_j \in \mathcal{F}} w_{ij}\mu(f_j) \quad (2)$$

Where $\rho(f_i)$ is the normalized mention frequency of f_i. The propagation weight w_{ij} controls how much boost is obtained from a co-mentioned candidate. We define propagation weight, w_{ij}, as the average of the objectivity of the sources that mention both candidates.

$$w_{ij} = average\ \mathcal{O}(d_k) : d_k \in (D_i \cap D_j) \quad (3)$$

where $\mathcal{O}(d_k)$ is the objectivity of document d_k, D_i and D_j are the sets of documents that mention f_i and f_j, respectively. Notice that we could boost co-mentioned but not related candidates, thereby causing false boosts. To remedy this, we only allow w_{ij} to be greater than $zero$ if the fact candidates f_i and f_j are on the same topic. Recall that the topic is determined by the fixed argument (Definition 2) and the verb. Allowing only fact candidates on the same topic to influence each other is important considering that many trivial facts are often repeated in sources of diverse quality.

To leverage the inter-dependencies among *related* co-mentioned fact candidates, we model the solution with a graph ranking method. Each fact candidate is a node and there is an edge between each pair of related fact candidate nodes f_i and f_j, with w_{ij} as the edge weight. Thus, equation 2 can be reformulated as $\mu = M\mu$, where μ is the co-mention score vector and M is a Markov matrix which is stochastic, irreducible and aperiodic. Thus, a power method will converge to a solution in a similar manner to PageRank. Implementation consists of iteratively applying Equation 2 until the change in the score is less than a threshold ϵ. The solution is the final co-mention scores of fact candidates.

Finally, to compute the believability score of a fact candidate, we linearly combine its objectivity score with its co-mention as follows:

Definition 5 (Believability Score)

$$\beta(f_i) = \lambda\mathcal{O}(f_i) + (1-\lambda)\mu(f_i) \qquad (4)$$

Where λ is a weighting parameter $\in [0,1]$ which controls the relative importance of the two aspects of FactChecker. As we show in our experiments, λ can be robustly chosen within the range of 0.2 to 0.6. In our experiments we used $\lambda = 0.6$.

The entire procedure of FactChecker is summarized in Algorithm 1.

Algorithm 1 FactChecker

Input: A set $\mathcal{F}$ of fact candidates
Input: KB $\mathcal{K}$, SVO corpus $\mathcal{C}$, Web $\mathcal{W}$
Output: A set $\mathcal{L}$ of rankings $\forall f_i \in F$
$\mathcal{L} = \emptyset$
while $\mathcal{F} \neq \emptyset$ **do**
  pick f_i from $\mathcal{F}$
  $\mathcal{A}$= *getAlternatives*(f_i,$\mathcal{K}$,$\mathcal{C}$,$\mathcal{W}$)
  $PriorityQueue\ L_i = \emptyset$
  for all alternative fact candidates $f'_j \in \mathcal{A}$ **do**
    $\beta(f'_j)$ = *getBelievabilityScore*(f'_j)
    $L_i.insert(f'_j, \beta(f'_j))$
  end for
  $\beta(f_i)$ = *getBelievabilityScore*(f_i)
  $L_i.insert(f_i, \beta(f_i))$
  $\mathcal{L} \cup L_i$
  Remove f_i from F
end while
return $\mathcal{L}$

5 Evaluation

We evaluated FactChecker for accuracy. We define accuracy as the probability of a true fact candidate having a higher believability score than a false candidate. Let $\tau(f_i) \in \{T, F\}$ be the truthfulness of a fact candidate f_i, accuracy is defined as:

$$Acc = \frac{\sum_{(\tau(f_i)=T:\tau(f_j)=F)}(\beta(f_i) > \beta(f_j))}{|\{\forall(f_i,f_j) : \tau(f_i) = T \wedge \tau(f_j) = F\}|}$$

Datasets. We evaluated FactChecker on three datasets: **i) KB Fact Candidates:** The first dataset consists of fact candidates taken from the fact extraction pipeline of a state-of-the-art knowledge base, NELL (Carlson et al., 2010). The fact candidates span four different relation types: company acquisitions, book authors, movie directors and athlete teams. For each fact candidate, we applied our alternative candidate generation method. We only considered fact candidates with non-trivial alternative candidate sets; where the alternative candidate set is greater than *zero*. Since all of the baselines we compared against assume alternatives are provided, we apply all methods to the same set of alternative fact candidates discovered by our method. Details of this dataset are shown as rows starting with "KB-" in Table 3.

ii) Wikipedia Fact Candidates: For the second dataset, we did not restrict the fact candidates to specific topics from a knowledge base, instead we aimed to evaluate all fact candidates about a given entity. We selected entities from Wikipedia. For this, we chose US politicians: all current state senators, all current state governors, and all 44 presidents. First, we extracted fact candidates

	#Candidates	#Alternatives
KB-Acquisitions	50	241
KB-Authors	50	295
KB-Directors	50	228
KB-Teams	40	162
WKP Politicians	54	219
GK Quiz	18	72

Table 3: Fact candidate datasets.

from the infoboxes of the Wikipedia pages of the entities. Second, we applied our alternative candidate generation method to discover alternatives from the Web, SVO corpus, and NELL. Details of the resulting dataset are shown in the row "WKP Politicians" in Table 3.

iii) General Knowledge Quiz: The third dataset consists of questions from a general knowledge quiz [4]. We selected questions from the inventions category. Questions are multiple choice, with 4 options per question. Thus, from each question, we created one fact candidate and 3 alternative candidates. Details of the resulting dataset are shown in the row "KWP Quiz" in Table 3.

Baselines. We compared FactChecker against five baselines: **i) Vote** counts the number of sources that mention the fact candidate. **ii) TruthFinder** is an iterative voting approach where votes are propagated from sources to fact candidates and then back to sources. Implemented as described in (Yin et al., 2007). **iii) Investment** is also based on transitive voting, however scores are updated differently. A source gets a vote of trust from each candidate it "invests" in, but the vote is weighted by the proportion of trust the source previously "invested" in the candidate relative to other investors. Implemented as described in (Pasternack and Roth, 2010). **iv) PooledInvest** is a variation of investment, we report both because in their paper, there was no clear winner among the two variations. **v) 2-Estimates** is a probabilistic model which approximates error rates of sources and fact candidates (Galland et al., 2010).

5.1 Accuracy on KB Fact Candidates

Figure 2 shows accuracy on KB fact candidates. FactChecker achieves accuracy between 70% and 88% and is significantly more accurate than the other approaches on all relations except company acquisitions. On book authors, movie directors, and athlete teams, FactChecker outperforms all other approaches by at least 10%, 9%, and 8% respectively. On company acquisitions, the different methods achieve similar accuracy, with TruthFinder being the most accurate and FactChecker is 4% behind. Company acquisitions also yield the lowest difference between Vote and the highest performing method, of 6%. For book authors, movie directors, and athlete teams, the difference between majority Vote and the highest performing method (FactChecker in this case) is 13%, 12%, and 13% respectively.

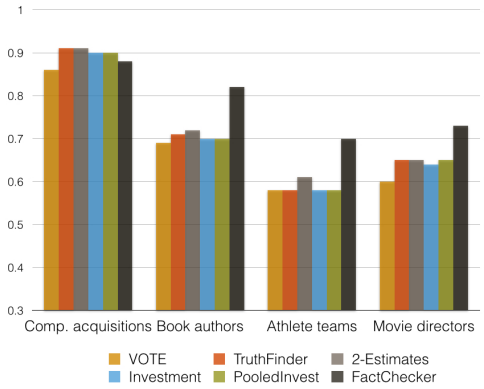

Figure 2: Accuracy of KB fact candidates.

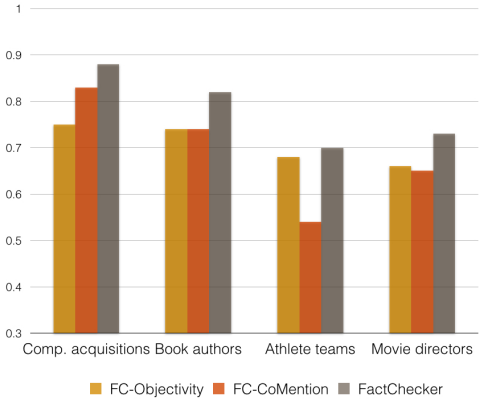

Figure 3: FactChecker variations.

5.2 Accuracy of FactChecker Variations

To quantify how various aspects of our approach affect overall performance, we studied two variations. The first variation is *FC-Objectivity* which only uses objectivity to compute believability. Thus, $\lambda = 1$ in Definition 5. The second variation is *FC-CoMention* which only uses co-mention scores to compute believability, $\lambda = 0$. The

[4] http://www.indiabix.com/general-knowledge/

Approach	WKP Politicians	GK Quiz
Vote	0.85±0.09	0.82±0.15
TruthFinder	0.85±0.09	0.82±0.15
2-Estimates	0.85±0.09	0.82±0.15
Investment	0.86±0.08	0.82±0.15
PooledInvest	0.85±0.09	0.82±0.15
FC-Objectivity	0.88±0.08	**0.87**±0.12
FC-CoMention	0.85±0.09	0.72±0.18
FactChecker	**0.90**±0.07	**0.87**±0.12

Table 4: Accuracy on politicians and quiz data sets

last variation is the full FactChecker method using both objectivity and co-mentions with $\lambda = 0.6$ From Figure 3, it is clear that both the objectivity of sources and the influence of co-mentions contribute to the overall accuracy of FactChecker. Full-fledged FactChecker performs better than both variations. In most cases, *FC-Objectivity* performs better than *FC-CoMention*.

5.3 Accuracy on Wikipedia Fact Candidates

Table 4, column "WKP Politicians", shows accuracy on Wikipedia fact candidates, with a 0.9-confidence Wilson score interval (Brown et al., 2001). For this dataset we again see FactChecker outperforming the other methods under comparison. On this dataset, FactChecker has a accuracy of 0.9 ± 0.07 and a 5% accuracy advantage over the other methods. The second best performance comes from the *FC-Objectivity* variation, with accuracy of 0.88 ± 0.08.

5.4 Accuracy on General Knowledge Quiz

Table 4, column "GK Quiz ", shows accuracy on the general knowledge quiz fact candidates. On this dataset, FactChecker and its objectivity-only variation (FC-objectivity) have the highest accuracy of 87%. Notice that this dataset was the only one where we did not generate the alternative fact candidates. Instead, we took the options of the multiple choice questions as alternatives. Since the quiz is meant to be taken by humans, the alternatives are often very close, plausible answers. Yet even in this difficult setting, we see FactChecker outperforming the baselines.

Sample fact candidates, with ranked alternatives from all three datasets are shown in Table 5.

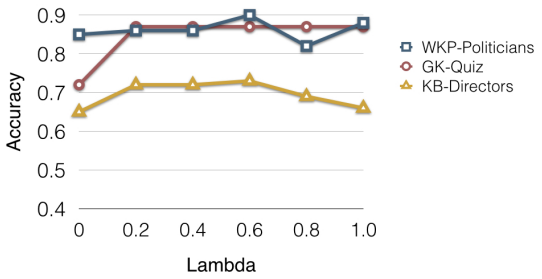

Figure 4: Effect of λ of FactChecker.

5.5 Parameter Sensitivity

We analyzed the effect of the selection of lambda λ (see Definition 5) on FactChecker's performance. The result of this analysis is shown in Figure 4. FactChecker is insensitive to this parameter when λ is varied from 0.2 to 0.6. Therefore, lambda can be robustly chosen within this range.

5.6 Discussion

Overall, from these results we make the following observations: i) Majority vote is a competitive baseline; ii) Iterative voting-based methods provide slight improvements on majority vote. This is due to the fact that at the core of iterative voting is still the assumption that fact candidates mentioned in many sources are more likely to be true. Therefore, for both majority vote and iterative voting, when mention frequencies of various alternatives are the same, accuracy suffers. Based on these observations, it is clear that truth-finding solutions need to incorporate fine-grained content-aware features outside of external votes. FactChecker takes a step in this direction by incorporating the document-level feature of objectivity.

6 Related Work

There is a fairly small body of work on truth-finding (Yin et al., 2007; Galland et al., 2010; Pasternack and Roth, 2010; Li et al., 2011; Yin and Tan, 2011; Zhao et al., 2012; Pasternack and Roth, 2013). The method underlying most truth-finding algorithms is iterative transitive voting (Yin et al., 2007; Galland et al., 2010; Pasternack and Roth, 2010; Li et al., 2011). Fact candidates are initialized with a score. Trustworthiness of sources is then computed from the believability of the fact candidates they mention. In return, believability of candidates is recomputed based on the trustworthi-

Table 5: Sample rankings by FactChecker, alternatives marked (*) are false. The ranking of the candidate from the "KB" dataset is not completely accurate.

ness of their sources. This process is repeated over several iterations until convergence. (Yin et al., 2007) was the first to implement this idea, subsequent work improved upon iterative voting in several directions. (Dong et al., 2009) incorporates copying-detection; giving high trust to sources that are independently authored. (Galland et al., 2010) approximates error rates of sources and fact candidates. (Pasternack and Roth, 2010) introduces prior knowledge in the form of linear programming constraints in order to ensure that the truth discovered is consistent with what is already known. (Yin and Tan, 2011) introduces supervision by using ground truth facts so that sources that disagree with the ground truth are penalized. (Li et al., 2011) uses search engine APIs to gather additional evidence for believability of fact candidates. WikiTrust (Adler and Alfaro, 2007) is a content-aware but domain-specific method. It computes trustworthiness of wiki authors based on the revision history of the articles they have authored. Motivated by interpretability of probabilistic scores, two recent papers addressed the truth-finding problem as a probabilistic inference problem over the sources and the fact candidates (Zhao et al., 2012; Pasternack and Roth, 2013). Truth-finders based on textual entailment such as TruthTeller (Lotan et al., 2013) determine if a sentence states something or not. The focus is on understanding natural language, including the use of negation. This is similar to the goal of fact extraction (Banko et al., 2007; Carlson et al., 2010; Fader et al., 2011; Nakashole et al., 2011; Del Corro and Gemulla, 2013).

In a departure from prior work, our method leverages language of sources in its believability computation model. Furthermore, we introduced a co-mention score which is designed to avoid potential false boots among fact candidates. Additionally, we developed a method for generating alternative fact candidates. Prior methods assume these are readily available. Only (Li et al., 2011) uses the Web to identify alternatives, however, this is only done after manually specifying the fixed argument. In contrast, we introduced a method for identifying the fixed argument based on relation cardinalities learned from SVO statistics.

7 Conclusion

In this paper, we presented FactChecker, a language-aware approach to truth-finding. In contrast to prior approaches, which rely on external votes, FactChecker includes objectivity of sources in its believability computation model.

FactChecker can be seen as a first step towards language-aware truth-finding. Future directions include using more sentence-level features such the use of hedges, assertive verbs, and factive verbs. These types of words fall into a class of words used to express certainties, speculations or doubts — these are important cues that FactChecker can leverage.

Abstract

In this paper, we propose an unsupervised method to identify noun sense changes based on rigorous analysis of time-varying text data available in the form of millions of digitized books. We construct distributional thesauri based networks from data at different time points and cluster each of them separately to obtain word-centric sense clusters corresponding to the different time points. Subsequently, we compare these sense clusters of two different time points to find if (i) there is birth of a new sense or (ii) if an older sense has got split into more than one sense or (iii) if a newer sense has been formed from the joining of older senses or (iv) if a particular sense has died. We conduct a thorough evaluation of the proposed methodology both manually as well as through comparison with WordNet. Manual evaluation indicates that the algorithm could correctly identify 60.4% birth cases from a set of 48 randomly picked samples and 57% split/join cases from a set of 21 randomly picked samples. Remarkably, in 44% cases the birth of a novel sense is attested by WordNet, while in 46% cases and 43% cases split and join are respectively confirmed by WordNet. Our approach can be applied for lexicography, as well as for applications like word sense disambiguation or semantic search.

1 Introduction

Two of the fundamental components of a natural language communication are word sense discovery (Jones, 1986) and word sense disambiguation (Ide and Veronis, 1998). While discovery corresponds to acquisition of vocabulary, disambiguation forms the basis of understanding. These two aspects are not only important from the perspective of developing computer applications for natural languages but also form the key components of language evolution and change.

Words take different senses in different contexts while appearing with other words. Context plays a vital role in disambiguation of word senses as well as in the interpretation of the actual meaning of words. For instance, the word "bank" has several distinct interpretations, including that of a "financial institution" and the "shore of a river." Automatic discovery and disambiguation of word senses from a given text is an important and challenging problem which has been extensively studied in the literature (Jones, 1986; Ide and Veronis, 1998; Schütze, 1998; Navigli, 2009). However, another equally important aspect that has not been so far well investigated corresponds to one or more changes that a word might undergo in its sense. This particular aspect is getting increasingly attainable as more and more time-varying text data become available in the form of millions of digitized books (Goldberg and Orwant, 2013) gathered over the last centuries. As a motivating example one could consider the word "sick" – while according to the standard English dictionaries the word is normally used to refer to some sort of illness, a new meaning of "sick" referring to something that is "crazy" or "cool" is currently getting popular in the English vernacular. This change is further interesting because while traditionally "sick" has been associated to something negative in general, the current meaning associates positivity with it. In fact, a rock band by the name of "Sick Puppies" has been founded which probably is inspired by the newer sense of the word sick. The title of this paper has been motivated by the above observation. Note that this phenomena of change in word senses has existed ever since the beginning of human communication (Bamman and Crane, 2011; Michel et

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1020–1029,
Baltimore, Maryland, USA, June 23-25 2014.

al., 2011; Wijaya and Yeniterzi, 2011; Mihalcea and Nastase, 2012); however, with the advent of modern technology and the availability of huge volumes of time-varying data it now has become possible to automatically track such changes and, thereby, help the lexicographers in word sense discovery, and design engineers in enhancing various NLP/IR applications (e.g., disambiguation, semantic search etc.) that are naturally sensitive to change in word senses.

The above motivation forms the basis of the central objective set in this paper, which is to devise a completely unsupervised approach to track noun sense changes in large texts available over multiple timescales. Toward this objective we make the following contributions: (a) devise a time-varying graph clustering based sense induction algorithm, (b) use the time-varying sense clusters to develop a split-join based approach for identifying new senses of a word, and (c) evaluate the performance of the algorithms on various datasets using different suitable approaches along with a detailed error analysis. Remarkably, comparison with the English WordNet indicates that in 44% cases, as identified by our algorithm, there has been a birth of a completely novel sense, in 46% cases a new sense has split off from an older sense and in 43% cases two or more older senses have merged in to form a new sense.

The remainder of the paper is organized as follows. In the next section we present a short review of the literature. In Section 3 we briefly describe the datasets and outline the process of co-occurrence graph construction. In Section 4 we present an approach based on graph clustering to identify the time-varying sense clusters and in Section 5 we present the split-merge based approach for tracking word sense changes. Evaluation methods are summarized in Section 6. Finally, conclusions and further research directions are outlined in Section 7.

2 Related work

Word sense disambiguation as well as word sense discovery have both remained key areas of research right from the very early initiatives in natural language processing research. Ide and Veronis (1998) present a very concise survey of the history of ideas used in word sense disambiguation; for a recent survey of the state-of-the-art one can refer to (Navigli, 2009). Some of the first attempts to automatic word sense discovery were made by Karen Spärck Jones (1986); later in lexicography, it has been extensively used as a pre-processing step for preparing mono- and multi-lingual dictionaries (Kilgarriff and Tugwell, 2001; Kilgarriff, 2004). However, as we have already pointed out that none of these works consider the temporal aspect of the problem.

In contrast, the current study, is inspired by works on language dynamics and opinion spreading (Mukherjee et al., 2011; Maity et al., 2012; Loreto et al., 2012) and automatic topic detection and tracking (Allan et al., 1998). However, our work differs significantly from those proposed in the above studies. Opinion formation deals with the self-organisation and emergence of shared vocabularies whereas our work focuses on how the different senses of these vocabulary words change over time and thus become "out-of-vocabulary". Topic detection involves detecting the occurrence of a new event such as a plane crash, a murder, a jury trial result, or a political scandal in a stream of news stories from multiple sources and tracking is the process of monitoring a stream of news stories to find those that track (or discuss) the same event. This is done on shorter timescales (hours, days), whereas our study focuses on larger timescales (decades, centuries) and we are interested in common nouns, verbs and adjectives as opposed to events that are characterized mostly by named entities. Other similar works on dynamic topic modelling can be found in (Blei and Lafferty, 2006; Wang and McCallum, 2006). Google books n-gram viewer[1] is a phrase-usage graphing tool which charts the yearly count of selected letter combinations, words, or phrases as found in over 5.2 million digitized books. It only reports frequency of word usage over the years, but does not give any correlation among them as e.g., in (Heyer et al., 2009), and does not analyze their senses.

A few approaches suggested by (Bond et al., 2009; Pääkkö and Lindén, 2012) attempt to augment WordNet synsets primarily using methods of annotation. Another recent work by Cook et al. (2013) attempts to induce word senses and then identify novel senses by comparing two different corpora: the "focus corpora" (i.e., a recent version of the corpora) and the "reference corpora" (older version of the corpora). However, this method is limited as it only considers two time points to

[1] https://books.google.com/ngrams

identify sense changes as opposed to our approach which is over a much larger timescale, thereby, effectively allowing us to track the points of change and the underlying causes. One of the closest work to what we present here has been put forward by (Tahmasebi et al., 2011), where the authors analyze a newspaper corpus containing articles between 1785 and 1985. The authors mainly report the frequency patterns of certain words that they found to be candidates for change; however a detailed cause analysis as to why and how a particular word underwent a sense change has not been demonstrated. Further, systematic evaluation of the results obtained by the authors has not been provided.

All the above points together motivated us to undertake the current work where we introduce, for the first time, a completely unsupervised and automatic method to identify the change of a word sense and the cause for the same. Further, we also present an extensive evaluation of the proposed algorithm in order to test its overall accuracy and performance.

3 Datasets and graph construction

In this section, we outline a brief description of the dataset used for our experiments and the graph construction procedure. The primary source of data have been the millions of digitized books made available through the Google Book project (Goldberg and Orwant, 2013). The Google Book syntactic n-grams dataset provides dependency fragment counts by the years. However, instead of using the plain syntactic n-grams, we use a far richer representation of the data in the form of a distributional thesaurus (Lin, 1997; Rychlý and Kilgarriff, 2007). In specific, we prepare a distributional thesaurus (DT) for each of the time periods separately and subsequently construct the required networks. We briefly outline the procedure of thesauri construction here referring the reader to (Riedl and Biemann, 2013) for further details. In this approach, we first extract each word and a set of its context features, which are formed by labeled and directed dependency parse edges as provided in the dataset. Following this, we compute the frequencies of the word, the context and the words along with their context. Next we calculate the lexicographer's mutual information LMI (Kilgarriff, 2004) between a word and its features and retain only the top 1000 ranked features for every word. Finally, we construct the DT network as follows: each word is a node in the network and the edge weight between two nodes is defined as the number of features that the two corresponding words share in common.

4 Tracking sense changes

The basic idea of our algorithm for tracking sense changes is as follows. If a word undergoes a sense change, this can be detected by comparing its senses obtained from two different time periods. Since we aim to detect this change automatically, we require distributional representations corresponding to word senses for different time periods. We, therefore, utilize the basic hypothesis of unsupervised sense induction to induce the sense clusters over various time periods and then compare these clusters to detect sense change. The basic premises of the 'unsupervised sense induction' are briefly described below.

4.1 Unsupervised sense induction

We use the co-occurrence based graph clustering framework introduced in (Biemann, 2006). The algorithm proceeds in three basic steps. Firstly, a co-occurrence graph is created for every target word found in DT. Next, the neighbourhood/ego graph is clustered using the Chinese Whispers (CW) algorithm (see (McAuley and Leskovec, 2012) for similar approaches). The algorithm, in particular, produces a set of clusters for each target word by decomposing its open neighborhood. We hypothesize that each different cluster corresponds to a particular sense of the target word. For a detailed description, the reader is referred to (Biemann, 2011).

If a word undergoes sense change, this can be detected by comparing the sense clusters obtained from two different time periods by the algorithm outlined above. For this purpose, we use statistics from the DT corresponding to two different time intervals, say tv_i and tv_j. We then run the sense induction algorithm over these two different datasets. Now, for a given word w that appears in both the datasets, we get two different set of clusters, say C_i and C_j. Without loss of generality, let us assume that our algorithm detects m sense clusters for the word w in tv_i and n sense clusters in tv_j. Let $C_i = \{s_{i1}, s_{i2}, \ldots, s_{im}\}$ and $C_j = \{s_{j1}, s_{j2}, \ldots, s_{jn}\}$, where s_{kz} denotes z^{th} sense cluster for word w during time interval tv_k.

We next describe our algorithm for detecting sense change from these sets of sense clusters.

4.2 Split, join, birth and death

We hypothesize that word w can undergo sense change from one time interval (tv_i) to another (tv_j) as per one of the following scenarios:

Split A sense cluster s_{iz} in tv_i *splits* into two (or more) sense clusters, s_{jp_1} and s_{jp_2} in tv_j

Join Two sense clusters s_{iz_1} and s_{iz_2} in tv_i *join* to make a single cluster s_{jp} in tv_j

Birth A new sense cluster s_{jp} appears in tv_j, which was absent in tv_i

Death A sense cluster s_{iz} in tv_i dies out and does not appear in tv_j

To detect split, join, birth or death, we build an $(m+1) \times (n+1)$ matrix I to capture the intersection between sense clusters of two different time periods. The first m rows and n columns correspond to the sense clusters in tv_i and tv_j espectively. We append an additional row and column to capture the fraction of words, which did not show up in any of the sense clusters in another time interval. So, an element I_{kl} of the matrix

- $1 \leq k \leq m, 1 \leq l \leq n$: denotes the fraction of words in a newer sense cluster s_{jl}, that were also present in an older sense cluster s_{ik}.
- $k = m+1, 1 \leq l \leq n$: denotes the fraction of words in the sense cluster s_{jl}, that were not present in any of the m clusters in tv_i.
- $1 \leq k \leq m, l = n+1$: denotes the fraction of words in the sense cluster s_{ik}, that did not show up in any of the n clusters in tv_j.

Thus, the matrix I captures all the four possible scenarios for sense change. Since we can not expect a perfect split, birth etc., we used certain threshold values to detect if a candidate word is undergoing sense change via one of these four cases. In Figure 1, as an example, we illustrate the birth of a new sense for the word 'compiler'.

4.3 Multi-stage filtering

To make sure that the candidate words obtained via our algorithm are meaningful, we applied multi-stage filtering to prune the candidate word list. The following criterion were used for the filtering:

Stage 1 We utilize the fact that the CW algorithm is non-deterministic in nature. We apply CW three times over the source and target time intervals. We obtain the candidate word lists using our algorithm for the three runs, then take the intersection to output those words, which came up in all the three runs.

Stage 2 From the above list, we retain only those candidate words, which have a part-of-speech tag 'NN' or 'NNS', as we focus on nouns for this work.

Stage 3 We sort the candidate list obtained in Stage 2 as per their occurrence in the first time period. Then, we remove the top 20% and the bottom 20% words from this list. Therefore, we consider the *torso* of the frequency distribution which is the most informative part for this type of an analysis.

5 Experimental framework

For our experiments, we utilized DTs created for 8 different time periods: 1520-1908, 1909-1953, 1954-1972, 1973-1986, 1987-1995, 1996-2001, 2002-2005 and 2006-2008 (Riedl et al., 2014). The time periods were set such that the amount of data in each time period is roughly the same. We will also use T_1 to T_8 to denote these time periods. The parameters for CW clustering were set as follows. The size of the neighbourhood (N) to be clustered was set to 200. The parameter n regulating the edge density in this neighbourhood was set to 200 as well. The parameter a was set to lin, which corresponds to favouring smaller clusters by hub downweighing[2]. The threshold values used to detect the sense changes were as follows. For birth, at least 80% words of the target cluster should be novel. For split, each split cluster should have at least 30% words of the source cluster and the total intersection of all the split clusters should be $> 80\%$. The same parameters were used for the join and death case with the interchange of source and target clusters.

5.1 Signals of sense change

Making comparisons between all the pairs of time periods gave us 28 candidate words lists. For

[2]data available at `http://sf.net/p/jobimtext/wiki/LREC2014_Google_DT/`

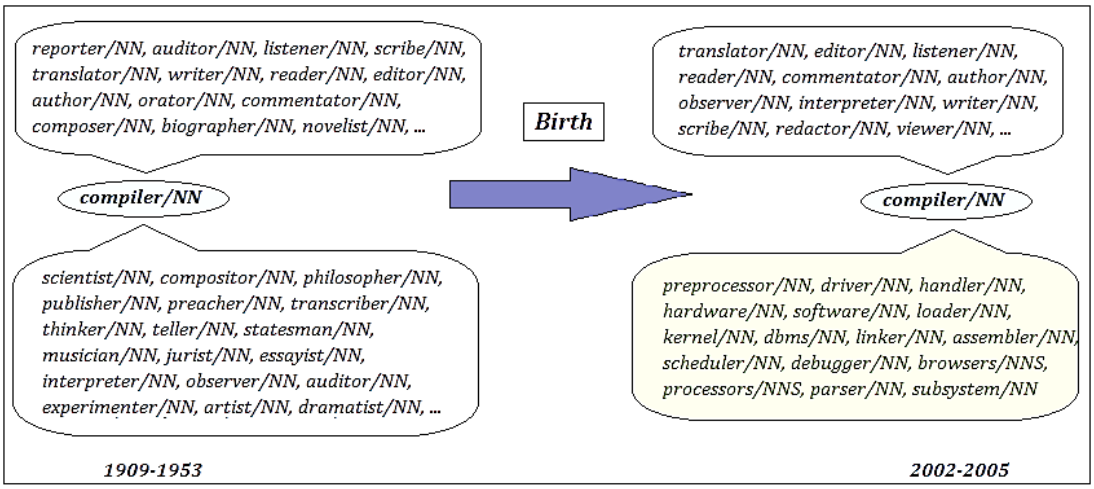

Figure 1: Example of the birth of a new sense for the word 'compiler'

each of these comparison, we applied the multi-stage filtering to obtain the pruned list of candidate words. Table 1 provides some statistics about the number of candidate words obtained corresponding to the birth case. The rows correspond to the source time-period and the columns correspond to the target time periods. An element of the table shows the number of candidate words obtained by comparing the corresponding source and target time periods.

Table 1: Number of candidate birth senses between all time periods

	T_2	T_3	T_4	T_5	T_6	T_7	T_8
T_1	2498	3319	3901	4220	4238	4092	3578
T_2		1451	2330	2789	2834	2789	2468
T_3			917	1460	1660	1827	1815
T_4				517	769	1099	1416
T_5					401	818	1243
T_6						682	1107
T_7							609

The table clearly shows a trend. For most of the cases, the number of candidate birth senses tends to increase as we go from left to right. Similarly, this number decreases as we go down in the table. This is quite intuitive since going from left to right corresponds to increasing the gap between two time periods while going down corresponds to decreasing this gap. As the gap increases (decreases), one would expect more (less) new senses coming in. Even while moving diagonally, the candidate words tend to decrease as we move downwards. This corresponds to the fact that the number of years in the time periods decreases as we move downwards, and therefore, the gap also decreases.

5.2 Stability analysis & sense change location

Formally, we consider a sense change from tv_i to tv_j **stable** if it was also detected while comparing tv_i with the following time periods tv_ks. This number of subsequent time periods, where the same sense change is detected, helps us to determine the **age** of a new sense. Similarly, for a candidate sense change from tv_i to tv_j, we say that the **location** of the sense change is tv_j if and only if that sense change does not get detected by comparing tv_i with any time interval tv_k, intermediate between tv_i and tv_j.

Table 1 gives a lot of candidate words for sense change. However, not all the candidate words were stable. Thus, it was important to prune these results using stability analysis. Also, it is to be noted that these results do not pin-point to the exact time-period, when the sense change might have taken place. For instance, among the 4238 candidate birth sense detected by comparing T_1 and T_6, many of these new senses might have come up in between T_2 to T_5 as well. We prune these lists further based on the stability of the sense, as well as to locate the approximate time interval, in which the sense change might have occurred.

Table 2 shows the number of stable (at least twice) senses as well as the number of stable sense changes located in that particular time period. While this decreases recall, we found this to be beneficial for the accuracy of the method.

Once we were able to locate the senses as well as to find the age of the senses, we attempted to

Table 2: Number of candidate birth senses obtained for different time periods

	T_2	T_3	T_4	T_5	T_6	T_7
T_1	2498	3319	3901	4220	4238	4092
stable	537	989	1368	1627	1540	1299
located	537	754	772	686	420	300
T_2		1451	2330	2789	2834	2789
stable		343	718	938	963	810
located		343	561	517	357	227

select some representative words and plotted them on a timeline as per the birth period and their age in Figure 2. The source time period here is 1909-1953.

6 Evaluation framework

During evaluation, we considered the clusters obtained using the 1909-1953 time-slice as our reference and attempted to track sense change by comparing these with the clusters obtained for 2002-2005. The sense change detected was categorized as to whether it was a new sense (birth), a single sense got split into two or more senses (split) or two or more senses got merged (join) or a particular sense died (death). We present a few instances of the resulting clusters in the paper and refer the reader to the supplementary material[3] for the rest of the results.

6.1 Manual evaluation

The algorithm detected a lot of candidate words for the cases of birth, split/join as well as death. Since it was difficult to go through all the candidate sense changes for all the comparisons manually, we decided to randomly select some candidate words, which were flagged by our algorithm as undergoing sense change, while comparing 1909-1953 and 2002-2005 DT. We selected 48 random samples of candidate words for birth cases and 21 random samples for split/join cases. One of the authors annotated each of the birth cases identifying whether or not the algorithm signalled a true sense change while another author did the same task for the split/join cases. The accuracy as per manual evaluation was found to be 60.4% for the birth cases and 57% for the split/join cases.

Table 3 shows the evaluation results for a few candidate words, flagged due to birth. Columns correspond to the candidate words, words obtained in the cluster of each candidate word (we will use the term 'birth cluster' for these words, henceforth), which indicated a new sense, the results of manual evaluation as well as the possible sense this birth cluster denotes.

Table 4 shows the corresponding evaluation results for a few candidate words, flagged due to split or join.

A further analysis of the words marked due to birth in the random samples indicates that there are 22 technology-related words, 2 slangs, 3 economics related words and 2 general words. For the split-join case we found that there are 3 technology-related words while the rest of the words are general. Therefore one of the key observations is that most of the technology related words (where the neighborhood is completely new) could be extracted from our birth results. In contrast, for the split-join instances most of the results are from the general category since the neighborhood did not change much here; it either got split or merged from what it was earlier.

6.2 Automated evaluation with WordNet

In addition to manual evaluation, we also performed automated evaluation for the candidate words. We chose WordNet for automated evaluation because not only does it have a wide coverage of word senses but also it is being maintained and updated regularly to incorporate new senses. We did this evaluation for the candidate birth, join and split sense clusters obtained by comparing 1909-1953 time period with respect to 2002-2005. For our evaluation, we developed an aligner to align the word clusters obtained with WordNet senses. The aligner constructs a WordNet dictionary for the purpose of synset alignment. The CW cluster is then aligned to WordNet synsets by comparing the clusters with WordNet graph and the synset with the maximum alignment score is returned as the output. In summary, the aligner tool takes as input the CW cluster and returns a WordNet synset id that corresponds to the cluster words. The evaluation settings were as follows:

Birth: For a candidate word flagged as birth, we first find out the set of all WordNet synset ids for its CW clusters in the source time period (1909-1953 in this case). Let S_{init} denote the union of these synset ids. We then find WordNet synset id for its birth-cluster, say s_{new}. Then, if $s_{new} \notin$

[3] http://cse.iitkgp.ac.in/resgrp/cnerg/acl2014_wordsense/

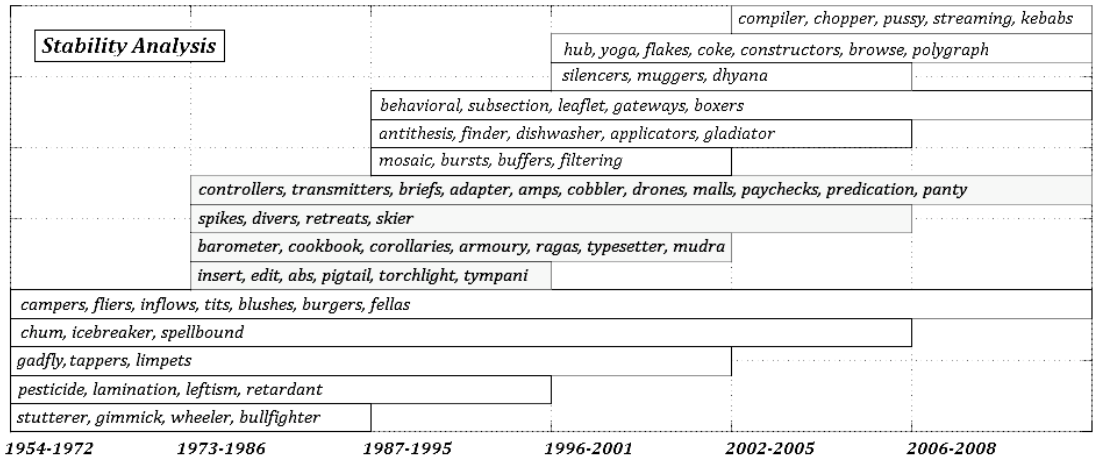

Figure 2: Examples of birth senses placed on a timeline as per their location as well as age

Table 3: Manual evaluation for seven randomly chosen candidate birth clusters between time periods 1909-1953 and 2002-2005

Sl No.	Candidate Word	birth cluster	Evaluation judgement, comments
1	implant	*gel, fibre, coatings, cement, materials, metal, filler silicone, composite, titanium, polymer, coating*	**No**, New set of words but similar sense already existed
2	passwords	*browsers, server, functionality, clients, workstation printers, software, protocols, hosts, settings, utilities*	**Yes**, New sense related to 'a computer sense'
3	giants	*multinationals, conglomerates, manufacturers corporations, competitors, enterprises, companies businesses, brands, firms*	**Yes**, New sense as 'an organization with very great size or force'
4	donation	*transplantation, donation, fertilization, transfusions transplant, transplants, insemination, donors, donor ...*	**Yes**, The new usage of donation associated with body organs etc.
5	novice	*negro, fellow, emigre, yankee, realist, quaker, teen male, zen, lady, admiring, celebrity, thai, millionaire ...*	**No**, this looks like a false positive
6	partitions	*server, printers, workstation, platforms, arrays modules, computers, workstations, kernel ...*	**Yes**, New usage related to the 'computing' domain
7	yankees	*athletics, cubs, tigers, sox, bears, braves, pirates cardinals, dodgers, yankees, giants, cardinals ...*	**Yes**, related to the 'New York Yankees' team

S_{init}, it implies that this is a new sense that was not present in the source clusters and we call it a 'success' as per WordNet.

Join: For the join case, we find WordNet synset ids s_1 and s_2 for the clusters obtained in the source time period and s_{new} for the join cluster in the target time period. If $s_1 \neq s_2$ and s_{new} is either s_1 or s_2, we call it a 'success'.

Split: For the split case, we find WordNet synset id s_{old} for the source cluster and synset ids s_1 and s_2 for the target split clusters. If $s_1 \neq s_2$ and either s_1, or s_2 retains the id s_{old}, we call it a 'success'.

Table 5 show the results of WordNet based evaluation. In case of birth we observe a success of 44% while for split and join we observe a success of 46% and 43% respectively. We then manually verified some of the words that were deemed as successes, as well as investigated WordNet sense they were mapped to. Table 6 shows some of the words for which the evaluation detected success along with WordNet senses. Clearly, the cluster words correspond to a newer sense for these words

Table 5: Results of the automatic evaluation using WordNet

Category	No. of Candidate Words	Success Cases
Birth	810	44%
Split	24	46%
Join	28	43%

Table 4: Manual evaluation for five randomly chosen candidate split/join clusters between time periods 1909-1953 and 2002-2005

Sl No.	Candidate Word	Source and target clusters
1	intonation (**split**)	S: *whisper, glance, idioms, gesture, chant, sob, inflection, diction, sneer, rhythm, accents ...* T_1: *nod, tone, grimace, finality, gestures, twang, shake, shrug, irony, scowl, twinkle ...* T_2: *accents, phrase, rhythm, style, phonology, diction, utterance, cadence, harmonies ...*
	Yes, T_1 corresponds to intonation in normal conversations while T_2 corresponds to the use of accents in formal and research literature	
2	diagonal (**split**)	S: *coast, edge, shoreline, coastline, border, surface, crease, edges, slope, sides, seaboard ...* T_1: *circumference, center, slant, vertex, grid, clavicle, margin, perimeter, row, boundary ..* T_2: *border, coast, seaboard, seashore, shoreline, waterfront, shore, shores, coastline, coasts*
	Yes, the split T_1 is based on mathematics where as T_2 is based on geography	
3	mantra (**join**)	S_1: *sutra, stanza, chanting, chants, commandments, monologue, litany, verse, verses ...* S_2: *praise, imprecation, benediction, praises, curse, salutation, benedictions, eulogy ...* T: *blessings, spell, curses, spells, rosary, prayers, blessing, prayer, benediction ...*
	Yes, the two seemingly distinct senses of mantra - a contextual usage for chanting and prayer (S_1) and another usage in its effect - salutations, benedictions (S_2) have now merged in T.	
4	continuum (**split**)	S: *circumference, ordinate, abscissa, coasts, axis, path, perimeter, arc, plane axis ...* T_1: *roadsides, corridors, frontier, trajectories, coast, shore, trail, escarpment, highways ...* T_2: *arc, ellipse, meridians, equator, axis, axis, plane, abscissa, ordinate, axis, meridian ....*
	Yes, the split S_1 denotes the usage of 'continuum' with physical objects while the the split S_2 corresponds to its usages in mathematics domain.	
5	headmaster (**join**)	S_1: *master, overseer, councillor, chancellor, tutors, captain, general, principal ...* S_2: *mentor, confessor, tutor, founder, rector, vicar, graduate, counselor, lawyer ...* T: *chaplain, commander, surveyor, coordinator, consultant, lecturer, inspector ...*
	No, it seems a false positive	

and the mapped WordNet synset matches the birth cluster to a very high degree.

6.3 Evaluation with a slang list

Slangs are words and phrases that are regarded as very informal, and are typically restricted to a particular context. New slang words come up every now and then, and this plays an integral part in the phenomena of sense change. We therefore decided to perform an evaluation as to how many slang words were being detected by our candidate birth clusters. We used a list of slangs available from the slangcity website[4]. We collected slangs for the years 2002-2005 and found the intersection with our candidate birth words. Note that the website had a large number of multi-word expressions that we did not consider in our study. Further, some of the words appeared as either erroneous or very transient (not existing more than a few months) entires, which had to be removed from the list. All these removal left us with a very little space for comparison; however, despite this we found 25 slangs from the website that were present in our birth results, e.g. 'bum', 'sissy', 'thug', 'dude' etc.

[4] http://slangcity.com/email_archive/index_2003.htm

6.4 Evaluation of candidate death clusters

Much of our evaluation was focussed on the birth sense clusters, mainly because these are more interesting from a lexicographic perspective. Additionally, the main theme of this work was to detect new senses for a given word. To detect a true death of a sense, persistence analysis was required, that is, to verify if the sense was persisting earlier and vanished after a certain time period. While such an analysis goes beyond the scope of this paper, we selected some interesting candidate "death" senses. Table 7 shows some of these interesting candidate words, their death cluster along with the possible vanished meaning, identified by the authors. While these words are still used in a related sense, the original meaning does not exist in the modern usage.

7 Conclusions

In this paper, we presented a completely unsupervised method to detect word sense changes by analyzing millions of digitized books archived spanning several centuries. In particular, we constructed DT networks over eight different time windows, clustered these networks and compared these clusters to identify the emergence of novel

Table 6: Example of randomly chosen candidate birth clusters mapped to WordNet

Sl No.	Candidate Word	birth cluster	Synset Id, WordNet sense
1	macro	*code, query, handler, program, procedure, subroutine module, script*	**6582403**, a set sequence of steps, part of larger computer program
2	caller	*browser, compiler, sender, routers, workstation, cpu host, modem, router, server*	**4175147**, a computer that provides client stations with access to files
3	searching	*coding, processing, learning, computing, scheduling planning, retrieval, routing, networking, navigation*	**1144355**, programming: setting an order and time for planned events
4	hooker	*bitch, whore, stripper, woman slut, prostitute girl, dancer ...*	**10485440**, a woman who engages in sexual intercourse for money
5	drones	*helicopters, fighters, rockets, flights, planes vehicles, bomber, missions, submarines ...*	**4264914**, a craft capable of traveling in outer space
6	amps	*inverters, capacitor, oscillators, switches, mixer transformer, windings, capacitors, circuits ...*	**2955247**, electrical device characterized by its capacity to store an electric charge
7	compilers	*interfaces, algorithms, programming, software modules, libraries, routines, tools, utilities ...*	**6566077**, written programs pertaining to the operation of a computer system

Table 7: Some representative examples for candidate death sense clusters

Sl No.	Candidate Word	death cluster	Vanished meaning
1	slop	*jeans, velveteen, tweed, woollen, rubber, sealskin, wear oilskin, sheepskin, velvet, calico, deerskin, goatskin, cloth ...*	clothes and bedding supplied to sailors by the navy
2	blackmail	*subsidy, rent, presents, tributes, money, fine, bribes dues, tolls, contributions, contribution, customs, duties ...*	Origin: denoting protection money levied by Scottish chiefs
3	repertory	*dictionary, study, compendium, bibliography, lore, directory catalogues, science, catalog, annals, digest, literature ...*	Origin: denoting an index or catalog: from late Latin repertorium
4	phrasing	*contour, outline, construction, handling, grouping, arrangement structure, modelling, selection, form ...*	in the sense 'style or manner of expression': via late Latin Greek phrasis

senses. The performance of our method has been evaluated manually as well as by comparison with WordNet and a list of slang words. Through manual evaluation we found that the algorithm could correctly identify 60.4% birth cases from a set of 48 random samples and 57% split/join cases from a set of 21 randomly picked samples. Quite strikingly, we observe that (i) in 44% cases the birth of a novel sense is attested by WordNet, (ii) in 46% cases the split of an older sense is signalled on comparison with WordNet and (iii) in 43% cases the join of two senses is attested by WordNet. These results might have strong lexicographic implications – even if one goes by very moderate estimates almost half of the words would be candidate entries in WordNet if they were not already part of it. This method can be extremely useful in the construction of lexico-semantic networks for low-resource languages, as well as for keeping lexico-semantic resources up to date in general.

Future research directions based on this work are manifold. On one hand, our method can be used by lexicographers in designing new dictionaries where candidate new senses can be semi-automatically detected and included, thus greatly reducing the otherwise required manual effort. On the other hand, this method can be directly used for various NLP/IR applications like semantic search, automatic word sense discovery as well as disambiguation. For semantic search, taking into account the newer senses of the word can increase the relevance of the query result. Similarly, a disambiguation engine informed with the newer senses of a word can increase the efficiency of disambiguation, and recognize senses uncovered by the inventory that would otherwise have to be wrongly assigned to covered senses. In addition, this method can be also extended to the 'NNP' part-of-speech (i.e., named entities) to identify changes in role of a person/place. Furthermore, it would be interesting to apply this method to languages other than English and to try to align new senses of cognates across languages.

A Step-wise Usage-based Method for Inducing Polysemy-aware Verb Classes

Abstract

We present an unsupervised method for inducing verb classes from verb uses in giga-word corpora. Our method consists of two clustering steps: verb-specific semantic frames are first induced by clustering verb uses in a corpus and then verb classes are induced by clustering these frames. By taking this step-wise approach, we can not only generate verb classes based on a massive amount of verb uses in a scalable manner, but also deal with verb polysemy, which is bypassed by most of the previous studies on verb clustering. In our experiments, we acquire semantic frames and verb classes from two giga-word corpora, the larger comprising 20 billion words. The effectiveness of our approach is verified through quantitative evaluations based on polysemy-aware gold-standard data.

1 Introduction

A verb plays a primary role in conveying the meaning of a sentence. Capturing the sense of a verb is essential for natural language processing (NLP), and thus lexical resources for verbs play an important role in NLP.

Verb classes are one such lexical resource. Manually-crafted verb classes have been developed, such as Levin's classes (Levin, 1993) and their extension, VerbNet (Kipper-Schuler, 2005), in which verbs are organized into classes on the basis of their syntactic and semantic behavior. Such verb classes have been used in many NLP applications that need to consider semantics in particular, such as word sense disambiguation (Dang, 2004), semantic parsing (Swier and Stevenson, 2005; Shi and Mihalcea, 2005) and discourse parsing (Subba and Di Eugenio, 2009).

There have also been many attempts to automatically acquire verb classes with the goal of either adding frequency information to an existing resource or of inducing similar verb classes for other languages. Most of these approaches assume that all target verbs are monosemous (Stevenson and Joanis, 2003; Schulte im Walde, 2006; Joanis et al., 2008; Li and Brew, 2008; Sun et al., 2008; Sun and Korhonen, 2009; Vlachos et al., 2009; Parisien and Stevenson, 2010; Parisien and Stevenson, 2011; Falk et al., 2012; Lippincott et al., 2012; Reichart and Korhonen, 2013; Sun et al., 2013). This monosemous assumption, however, is not realistic because many frequent verbs actually have multiple senses. Moreover, to the best of our knowledge, none of the following approaches attempt to quantitatively evaluate soft clusterings of verb classes induced by polysemy-aware unsupervised approaches (Korhonen et al., 2003; Lapata and Brew, 2004; Li and Brew, 2007; Schulte im Walde et al., 2008).

In this paper, we propose an unsupervised method for inducing verb classes that is aware of verb polysemy. Our method consists of two clustering steps: verb-specific semantic frames are first induced by clustering verb uses in a corpus and then verb classes are induced by clustering these frames. By taking this step-wise approach, we can not only induce verb classes with frequency information from a massive amount of verb uses in a scalable manner, but also deal with verb polysemy.

Our novel contributions are summarized as follows:

- induce both semantic frames and verb classes from a massive amount of verb uses by a scalable method,
- explicitly deal with verb polysemy,
- discover effective features for each of the clustering steps, and
- quantitatively evaluate a soft clustering of verbs.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1030–1040,
Baltimore, Maryland, USA, June 23-25 2014.

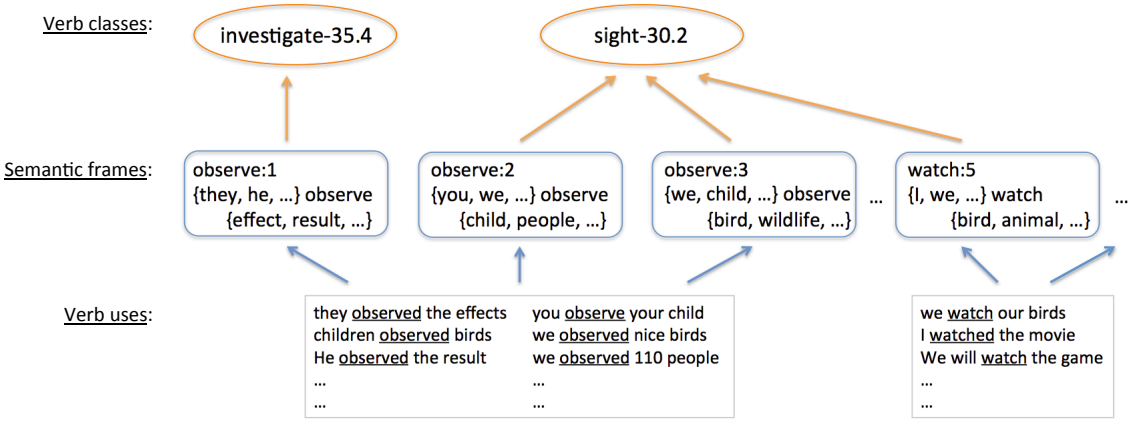

Figure 1: Overview of our two-step approach. Verb-specific semantic frames are first induced from verb uses (lower part) and then verb classes are induced from the semantic frames (upper part). The labels of verb classes are manually assigned here for better understanding.

2 Related Work

As stated in Section 1, most of the previous studies on verb clustering assume that verbs are monosemous. A typical method in these studies is to represent each verb as a single data point and apply classification (e.g., Joanis et al. (2008)) or clustering (e.g., Sun and Korhonen (2009)) to these data points. As a representation for a data point, distributions of subcategorization frames are often used, and other semantic features (e.g., selectional preferences) are sometimes added to improve the performance.

Among these studies on monosemous verb clustering (i.e., predominant class induction), there have been several Bayesian methods. Vlachos et al. (2009) proposed a Dirichlet process mixture model (DPMM; Neal (2000)) to cluster verbs based on subcategorization frame distributions. They evaluated their result with a gold-standard test set, where a single class is assigned to a verb. Parisien and Stevenson (2010) proposed a hierarchical Dirichlet process (HDP; Teh et al. (2006)) model to jointly learn argument structures (subcategorization frames) and verb classes by using syntactic features. Parisien and Stevenson (2011) extended their model by adding semantic features. They tried to account for verb learning by children and did not evaluate the resultant verb classes. Modi et al. (2012) extended the model of Titov and Klementiev (2012), which is an unsupervised model for inducing semantic roles, to jointly induce semantic roles and frames across verbs using the Chinese Restaurant Process (Aldous, 1985). All of the above methods considered verbs to be monosemous and did not deal with verb polysemy. Our approach also uses Bayesian methods, but is designed to capture verb polysemy.

We summarize a few studies that consider polysemy of verbs in the rest of this section.

Miyao and Tsujii (2009) proposed a supervised method that can handle verb polysemy. Their method represents a verb's syntactic and semantic features, and learns a log-linear model from the SemLink corpus (Loper et al., 2007). Boleda et al. (2007) also proposed a supervised method for Catalan adjectives considering the polysemy of adjectives.

The most closely related work to our polysemy-aware task of unsupervised verb class induction is the work of Korhonen et al. (2003), who used distributions of subcategorization frames to cluster verbs. They adopted the Nearest Neighbor (NN) and Information Bottleneck (IB) methods for clustering. In particular, they tried to consider verb polysemy by using the IB method, which is a soft clustering method (Tishby et al., 1999). However, the verb itself is still represented as a single data point. After performing soft clustering, they noted that most verbs fell into a single class, and they decided to assign a single class to each verb by hardening the clustering. They considered multiple classes only in the gold-standard data used for their evaluations. We also evaluate our induced verb classes on this gold-standard data, which was created on the basis of Levin's classes (Levin, 1993).

Lapata and Brew (2004) and Li and Brew (2007) proposed probabilistic models for calculating prior probabilities of verb classes for a verb. These models are approximated to condition not

on verbs but on subcategorization frames. As mentioned in Li and Brew (2007), it is desirable to extend the model to depend on verbs to further improve accuracy. They conducted several evaluations including predominant class induction and token-level verb sense disambiguation, but did not evaluate multiple classes output by their models. Schulte im Walde et al. (2008) also applied probabilistic soft clustering to verbs by incorporating subcategorization frames and selectional preferences based on WordNet. This model is based on the Expectation-Maximization algorithm and the Minimum Description Length principle. Since they focused on the incorporation of selectional preferences, they did not evaluate verb classes but evaluated only selectional preferences using a language model-based measure.

Materna proposed LDA-frames, which are defined across verbs and can be considered to be a kind of verb class (Materna, 2012; Materna, 2013). LDA-frames are probabilistic semantic frames automatically induced from a raw corpus. He used a model based on latent Dirichlet allocation (LDA; Blei et al. (2003)) and the Dirichlet process to cluster verb instances of a triple (subject, verb, object) to produce semantic frames and roles. Both of these are represented as a probabilistic distribution of words across verbs. He applied this method to the BNC and acquired 1,200 frames and 400 roles (Materna, 2012). He did not evaluate the resulting frames as verb classes.

In sum, there have been no studies that quantitatively evaluate polysemous verb classes automatically induced by unsupervised methods.

3 Our Approach

3.1 Overview

Our objective is to automatically learn semantic frames and verb classes from a massive amount of verb uses following usage-based approaches. Although Bayesian approaches are a possible solution to simultaneously induce frames and verb classes from a corpus as used in previous studies, it has prohibitive computational cost. For instance, Parisien and Stevenson applied HDP only to a small-scale child speech corpus that contains 170K verb uses to jointly induce subcategorization frames and verb classes (Parisien and Stevenson, 2010; Parisien and Stevenson, 2011). Materna applied an LDA-based method to the BNC, which contains 1.4M verb uses, to induce semantic frames across verbs that can be considered to be verb classes (Materna, 2012; Materna, 2013). However, it would take three months for this experiment using this 100 million word corpus.[1] Although it is best to use the largest possible corpus for this kind of knowledge acquisition tasks (Sasano et al., 2009), it is infeasible to scale to giga-word corpora using such joint models.

In this paper, we propose a two-step approach for inducing semantic frames and verb classes. First, we make multiple data points for each verb to deal with verb polysemy (cf. polysemy-aware previous studies still represented a verb as one data point (Korhonen et al., 2003; Miyao and Tsujii, 2009)). To do that, we induce verb-specific semantic frames by clustering verb uses. Then, we induce verb classes by clustering these verb-specific semantic frames across verbs. An interesting point here is that we can use exactly the same method for these two clustering steps.

Our procedure to automatically induce verb classes from verb uses is summarized as follows:

1. induce verb-specific semantic frames by clustering predicate-argument structures for each verb extracted from automatic parses as shown in the lower part of Figure 1, and
2. induce verb classes by clustering the induced semantic frames across verbs as shown in the upper part of Figure 1.

Each of these two steps is described in the following sections in detail.

3.2 Inducing Verb-specific Semantic Frames

We induce verb-specific semantic frames from verb uses based on the method of Kawahara et al. (2014). Our semantic frames consist of case slots, each of which consists of word instances that can be filled. The procedure for inducing these semantic frames is as follows:

1. apply dependency parsing to a raw corpus and extract predicate-argument structures for each verb from the automatic parses,
2. merge the predicate-argument structures that have presumably the same meaning based on the assumption of one sense per collocation (Yarowsky, 1993) to get a set of initial frames, and

[1] In our replication experiment, it took a week to perform 70 iterations using Materna's code and an Intel Xeon E5-2680 (2.7GHz) CPU. To reach 1,000 iterations, which are reported to be optimum, it would take three months.

3. apply clustering to the initial frames based on the Chinese Restaurant Process (Aldous, 1985) to produce verb-specific semantic frames.

These three steps are briefly described below.

3.2.1 Extracting Predicate-argument Structures from a Raw Corpus

We apply dependency parsing to a large raw corpus. We use the Stanford parser with Stanford dependencies (de Marneffe et al., 2006).[2] Collapsed dependencies are adopted to directly extract prepositional phrases.

Then, we extract predicate-argument structures from the dependency parses. Dependents that have the following dependency relations to a verb are extracted as arguments:

> nsubj, xsubj, dobj, iobj, ccomp, xcomp, prep_$*$

In this process, the verb and arguments are lemmatized, and only the head of an argument is preserved for compound nouns.

Predicate-argument structures are collected for each verb and the subsequent processes are applied to the predicate-argument structures of each verb.

3.2.2 Constructing Initial Frames from Predicate-argument Structures

To make the computation feasible, we merge the predicate-argument structures that have the same or similar meaning to get initial frames. These initial frames are the input of the subsequent clustering process. For this merge, we assume one sense per collocation (Yarowsky, 1993) for predicate-argument structures.

For each predicate-argument structure of a verb, we couple the verb and an argument to make a unit for sense disambiguation. We select an argument in the following order by considering the degree of effect on the verb sense:[3]

> dobj, ccomp, nsubj, prep_$*$, iobj.

Then, the predicate-argument structures that have the same verb and argument pair (slot and word, e.g., "dobj:effect") are merged into an initial frame. After this process, we discard minor initial frames that occur fewer than 10 times.

[2] http://nlp.stanford.edu/software/lex-parser.shtml

[3] If a predicate-argument structure has multiple prepositional phrases, one of them is randomly selected.

3.2.3 Clustering Method

We cluster initial frames for each verb to produce semantic frames using the Chinese Restaurant Process (Aldous, 1985), regarding each initial frame as an instance.

We calculate the posterior probability of a cluster c_j given an initial frame f_i as follows:

$$P(c_j|f_i) \propto \begin{cases} \frac{n(c_j)}{N+\alpha} \cdot P(f_i|c_j) & c_j \neq new \\ \frac{\alpha}{N+\alpha} \cdot P(f_i|c_j) & c_j = new, \end{cases} \quad (1)$$

where N is the number of initial frames for the target verb and $n(c_j)$ is the current number of initial frames assigned to the cluster c_j. α is a hyper-parameter that determines how likely it is for a new cluster to be created. In this equation, the first term is the Dirichlet process prior and the second term is the likelihood of f_i.

$P(f_i|c_j)$ is defined based on the Dirichlet-Multinomial distribution as follows:

$$P(f_i|c_j) = \prod_{w \in V} P(w|c_j)^{count(f_i,w)}, \quad (2)$$

where V is the vocabulary in all case slots cooccurring with the verb and $count(f_i, w)$ is the number of w in the initial frame f_i. The original method in Kawahara et al. (2014) defined w as pairs of slots and words, e.g., "nsubj:child" and "dobj:bird," but does not consider slot-only features, e.g., "nsubj" and "dobj," which ignore lexical information. Here we experiment with both representations and compare the results.

$P(w|c_j)$ is defined as follows:

$$P(w|c_j) = \frac{count(c_j, w) + \beta}{\sum_{t \in V} count(c_j, t) + |V| \cdot \beta}, \quad (3)$$

where $count(c_j, w)$ is the current number of w in the cluster c_j, and β is a hyper-parameter of Dirichlet distribution. For a new cluster, this probability is uniform ($1/|V|$).

We regard each output cluster as a semantic frame, by merging the initial frames in a cluster into a semantic frame. In this way, semantic frames for each verb are acquired.

We use Gibbs sampling to realize this clustering.

3.3 Inducing Verb Classes from Semantic Frames

To induce verb classes across verbs, we apply clustering to the induced verb-specific semantic

frames. We can use exactly the same clustering method as described in Section 3.2.3 by using semantic frames for multiple verbs as an input instead of initial frames for a single verb. This is because an initial frame has the same structure as a semantic frame, which is produced by merging initial frames. We regard each output cluster as a verb class this time.

For the features, w, in equation (2), we try the two representations again: slot-only features and slot-word pair features. The representation using only slots corresponds to the consideration of only syntactic argument patterns. The other representation using the slot-word pairs means that semantic similarity based on word overlap is naturally considered by looking at lexical information. We will compare in our experiments four possible combinations: two feature representations for each of the two clustering steps.

4 Experiments and Evaluations

We first describe our experimental settings and define evaluation metrics to evaluate induced soft clusterings of verb classes. Then, we conduct type-level multi-class evaluations, type-level single-class evaluations and token-level multi-class evaluations. These two levels of evaluations are performed by considering the work of Reichart et al. (2010) on clustering evaluation. Finally, we discuss the results of our full experiments.

4.1 Experimental Settings

We use two kinds of large-scale corpora: a web corpus and the English Gigaword corpus.

To prepare a web corpus, we extracted sentences from crawled web pages that are judged to be written in English based on the encoding information. Then, we selected sentences that consist of at most 40 words, and removed duplicated sentences. From this process, we obtained a corpus of one billion sentences, totaling approximately 20 billion words. We focused on verbs whose frequency in the web corpus was more than 1,000. There were 19,649 verbs, including phrasal verbs, and separating passive and active constructions. We extracted 2,032,774,982 predicate-argument structures.

We also used the English Gigaword corpus (LDC2011T07; English Gigaword Fifth Edition). This corpus consists of approximately 180 million sentences, which totaling four billion words. There were 7,356 verbs after applying the same frequency threshold as the web corpus. We extracted 423,778,278 predicate-argument structures from this corpus.

We set the hyper-parameters α in (1) and β in (3) to 1.0. The cluster assignments for all the components were initialized randomly. We took 100 samples for each input frame and selected the cluster assignment that has the highest probability.

4.2 Evaluation Metrics

To measure the precision and recall of a clustering, modified purity and inverse purity (also called collocation or weighted class accuracy) are commonly used in previous studies on verb clustering (e.g., Sun and Korhonen (2009)). However, since these measures are only applicable to a hard clustering, it is necessary to extend them to be applicable to a soft clustering, because in our task a verb can belong to multiple clusters or classes.[4] We propose a normalized version of modified purity and inverse purity. This kind of normalization for soft clusterings was performed for other evaluation metrics as in Springorum et al. (2013).

To measure the precision of a clustering, a normalized version of modified purity is defined as follows. Suppose K is the set of automatically induced clusters and G is the set of gold classes. Let K_i be the verb vector of the i-th cluster and G_j be the verb vector of the j-th gold class. Each component of these vectors is a normalized frequency, which equals a cluster/class attribute probability given a verb. Where there is no frequency information available for class distribution, such as the gold-standard data described in Section 4.3, we use a uniform distribution across the verb's classes. The core idea of purity is that each cluster K_i is associated with its most prevalent gold class. In addition, to penalize clusters that consist of only one verb, such singleton clusters in K are considered as errors, as is usual with modified purity. The normalized modified purity (nmPU) can then be written as follows:

$$\text{nmPU} = \frac{1}{N} \sum_{i \text{ s.t. } |K_i|>1} \max_j \delta_{K_i}(K_i \cap G_j), \quad (4)$$

$$\delta_{K_i}(K_i \cap G_j) = \sum_{v \in K_i \cap G_j} c_{iv}, \quad (5)$$

[4] Korhonen et al. (2003) evaluated hard clusterings based on a gold standard with multiple classes per verb. They reported only precision measures including modified purity, and avoided extending the evaluation metrics for soft clusterings.

verb	classes	verb	classes

glow	**43**	invent	**26**, 27

Table 1: An excerpt of the gold-standard verb classes for several verbs from Korhonen et al. (2003). The classes starting with '0' were derived from the LCS database, those starting with 'A' were defined by Korhonen et al., and the other classes were from Levin's classes. A bolded class is the predominant class for each verb.

where N denotes the total number of verbs, $|K_i|$ denotes the number of positive components in K_i, and c_{iv} denotes the v-th component of K_i. $\delta_{K_i}(K_i \cap G_j)$ means the total mass of the set of verbs in $K_i \cap G_j$, given by summing up the values in K_i. In case of evaluating a hard clustering, this is equal to $|K_i \cap G_j|$ because all the values of c_{iv} are equal to 1.

As usual, the following normalized inverse purity (niPU) is used to measure the recall of a clustering:

$$\text{niPU} = \frac{1}{N} \sum_j \max_i \delta_{G_j}(K_i \cap G_j). \quad (6)$$

Finally, we use the harmonic mean (F_1) of nmPU and niPU as a single measure of clustering quality.

4.3 Type-level Multi-class Evaluations

We first evaluate our induced verb classes on the test set created by Korhonen et al. (2003) (Table 1 of their paper) which was created by considering verb polysemy on the basis of Levin's classes and the LCS database (Dorr, 1997). It consists of 62 classes and 110 verbs, out of which 35 verbs are monosemous and 75 verbs are polysemous. The average number of verb classes per verb is 2.24. An excerpt from this data is shown in Table 1.

As our baselines, we adopt two previously proposed methods. We first implemented a soft clustering method for verb class induction proposed by Korhonen et al. (2003). They used the information bottleneck (IB) method for assigning probabilities of classes to each verb. Note that Korhonen et al. (2003) actually hardened the clusterings and left the evaluations of soft clusterings for their future work. For input data, we employ VALEX (Korhonen et al., 2006), which is a publicly-available large-scale subcategorization lexicon.[5] By following the method of Korhonen et al. (2003), prepositional phrases (pp) are parameterized for two frequent subcategorization frames (NP and NP_PP), and the unfiltered raw frequencies of subcategorization frames are used as features to represent a verb. It is necessary to specify the number of clusters, k, for the IB method beforehand, and we adopt 35 and 42 clusters according to their reported high accuracies. To output multiple classes for each verb, we set a threshold, t, for class attribute probabilities. That is, classes that have a higher class attribute probability than the threshold are output for each verb. We report the results of the following threshold values: 0.01, 0.02, 0.05 and 0.10.

The other baseline is LDA-frames (Materna, 2012). We use the induced LDA-frames that are

method	K	nmPU	niPU	F_1
IB (k=35, t=0.10)	35.0	53.59	51.44	52.44
IB (k=35, t=0.05)	35.0	53.67	52.62	53.10

Table 3: Type-level single-class evaluations against predominant/multiple classes. K represents the (average) number of induced classes.

available on the web site.[6] This frame data was induced from the BNC and consists of 1,200 frames and 400 semantic roles. Again, we set a threshold for frame attribute probabilities.

We report results using our methods with four feature combinations (slot-only (S) and slot-word pair (SW) features each used for both the frame-generation and verb-class clustering steps) for both the Gigaword and web corpora. Table 2 lists evaluation results for the baseline methods and our methods.[7] The results of the IB baseline and our methods are obtained by averaging five runs.

We can see that "web/SW-S" achieved the best performance and obtained a higher F_1 than the baselines by more than nine points. "Web/SW-S" uses the combination of slot-word pair features for clustering verb-specific frames and slot-only features for clustering across verbs. Interestingly, this result indicates that slot distributions are more effective than lexical information in slot-word pairs for inducing verb classes similar to the gold standard. This result is consistent with expectations, given a gold standard based on Levin's verb classes, which are organized according to the syntactic behavior of verbs. The use of slot-word pairs for verb class induction generally merged too many frames into each class, apparently due to accidental word overlaps across verbs.

The verb classes induced from the web corpus achieved a higher F_1 than those from the Gigaword corpus. This can be attributed to the larger size of the web corpus. The employment of this kind of huge corpus is enabled by our scalable method.

[6] http://nlp.fi.muni.cz/projekty/lda-frames/

[7] Although we do not think that the classes with very small attribute probabilities are meaningful, the F_1 scores for lower thresholds than 0.01 converged to about 66 in the case of LDA-frames.

4.4 Type-level Single-class Evaluations against Predominant/Multiple Classes

Since we focus on the handling of verb polysemy, predominant class induction for each verb is not our main objective. However, we wish to compare our method with previous work on the induction of a predominant (monosemous) class for each verb.

To output a single class for each verb by using our proposed method, we skip the induction of verb-specific semantic frames and instead create a single frame for each verb by merging all predicate-argument structures of the verb. Then, we apply clustering to these frames across verbs. For clustering features, we again compare two representations: slot-only features (S) and slot-word pair features (SW).

We evaluate the single-class output for each verb based on the predominant gold-standard classes, which are defined for each verb in the test set of Korhonen et al. (2003). This data contains 110 verbs and 33 classes. We evaluate these single-class outputs in the same manner as Korhonen et al. (2003), using the gold standard with multiple classes, which we also use for our multi-class evaluations.

As we did with the multi-class evaluations, we adopt modified purity (mPU), inverse purity (iPU) and their harmonic mean (F_1) as the metrics for the evaluation with predominant classes. It is not necessary to normalize these metrics when we treat verbs as monosemous, and evaluate against the predominant sense. When we evaluate against the multiple classes in the gold standard, we do normalize the inverse purity.

For baselines, we once more adopt the Nearest Neighbor (NN) and Information Bottleneck (IB) methods proposed by Korhonen et al. (2003), and LDA-frames proposed by Materna (2012). The

clusterings with the NN and IB methods are obtained by using the VALEX subcategorization lexicon. To harden the clusterings of the IB method and the LDA-frames, the class with the highest probability is selected for each verb. This hardening process is exactly the same as Korhonen et al. (2003). Note that our results of the NN and IB methods are different from those reported in their paper since the data source is different.[8]

Table 3 lists accuracies of baseline methods and our methods. Our proposed method using the web corpus achieved comparable performance with the baseline methods on the predominant class evaluation and outperformed them on the multiple class evaluation. More sophisticated methods for predominant class induction, such as the method of Sun and Korhonen (2009) using selectional preferences, could produce better single-class outputs, but have difficulty in producing polysemy-aware verb classes.

From the result, we can see that the induced verb classes based on slot-only features did not achieve a higher F_1 than those based on slot-word pair features in many cases. This result is different from that of multi-class evaluations in Section 4.3. We speculate that slot distributions are not so different among verbs when all uses of a verb are merged into one frame, and thus their discrimination power is lower than that in the intermediate construction of semantic frames.

4.5 Token-level Multi-class Evaluations

We conduct token-level multi-class evaluations using 119 verbs, which appear 100 or more times in sections 02-21 of the SemLink WSJ corpus. These 119 verbs cover 102 VerbNet classes, and 48 of them are polysemous in the sense of being in more than one VerbNet class. Each instance of these 119 verbs in this corpus belongs to one of 102 VerbNet classes. We first add these instances to the instances from a raw corpus and apply the two-step clustering to these merged instances. Then, we compare the induced verb classes of the SemLink instances with their gold-standard VerbNet classes. We report the values of modified purity (mPU), inverse purity (iPU) and their harmonic mean (F_1). It is not necessary to normalize these metrics because the clustering of these instances is hard.

[8] Korhonen et al. (2003) reported that the highest modified purity was 49% against predominant classes and 60% against multiple classes.

method	K	mPU	iPU	F_1
Gigaword/S-NIL	–	93.43	20.06	33.03
Gigaword/SW-NIL	–	94.45	41.07	57.25
Gigaword/S-S	512.2	75.06	45.26	56.47
Gigaword/SW-S	260.6	73.98	56.45	64.04

web/SW-NIL	–	**94.51**	44.95	60.92
web/S-S	500.0	72.25	52.48	60.79
web/SW-S	255.2	72.65	**61.00**	**66.31**

Table 4: Token-level evaluations against VerbNet classes. K represents the average number of induced classes.

For clustering features, we compare two feature combinations: "S-S" and "SW-S," which achieved high performance in the type-level multi-class evaluations (Section 4.3). The results of these methods are obtained by averaging five runs. For a baseline, we use verb-specific semantic frames without clustering across verbs ("S-NIL" and "SW-NIL"), where these frames are considered to be verb classes but not shared across verbs. Table 4 lists accuracies of these methods for the two corpora. We can see that "SW-S" achieved a higher F_1 than "S-S" and the baselines without verb class induction ("S-NIL" and "SW-NIL").

Modi et al. (2012) induced semantic frames across verbs using the monosemous assumption and reported an F_1 of 44.7% (77.9% PU and 31.4% iPU) for the assignment of FrameNet frames to the FrameNet corpus. We also conducted the above evaluation against FrameNet frames for 75 verbs.[9] We achieved an F_1 of 62.79% (66.97% mPU and 59.09% iPU) for "web/SW-S," and an F_1 of 60.06% (65.58% mPU and 55.39% iPU) for "Gigaword/SW-S." It is difficult to directly compare these results with Modi et al. (2012), but our induced verb classes seem to have higher F_1 accuracy.

4.6 Full Experiments and Discussions

We finally induce verb classes from the semantic frames of 1,667 verbs, which appear at least once in sections 02-21 of the WSJ corpus. Based on the best results in the above evaluations, we induced semantic frames using slot-word pair features, and then induced verb classes using slot-only features. We ended with 38,481 semantic frames and 699 verb classes from the Gigaword

[9] Since FrameNet frames are not assigned to all verbs of SemLink, the number of verbs is different from the evaluations against VerbNet classes.

class	semantic frames

corpus, and 61,903 semantic frames and 840 verb classes from the web corpus. It took two days to induce verb classes from the Gigaword corpus and three days from the web corpus.

Examples of verb classes and semantic frames induced from the web corpus are shown in Table 5 and Table 6. While there are many classes with consistent meanings, such as "Class 4" and "Class 16," some classes have mixed meanings. For instance, "Class 2" consists of the semantic frames "need:2" and "say:2." These frames were merged due to the high syntactic similarity of constituting slot distributions, which are comprised of a subject and a sentential complement. To improve the quality of verb classes, it is necessary to develop a clustering model that can consider syntactic and lexical similarity in a balanced way.

5 Conclusion

We presented a step-wise unsupervised method for inducing verb classes from instances in gigaword corpora. This method first clusters predicate-argument structures to induce verb-specific semantic frames and then clusters these semantic frames across verbs to induce verb classes. Both clustering steps are performed with exactly the same method, which is based on the Chinese Restaurant Process. The resulting semantic frames and verb classes are open to the public and also can be searched via our web interface.[10]

From the results, we can see that the combination of the slot-word pair features for clustering verb-specific frames and the slot-only features for clustering across verbs is the most effective and outperforms the baselines by approximately 10 points. This indicates that slot distributions are more effective than lexical information in slot-word pairs for the induction of verb classes, when Levin-style classes are used for evaluation. This is consistent with Levin's principle of organizing verb classes according to the syntactic behavior of verbs.

As applications of the resulting semantic frames and verb classes, we plan to integrate them into syntactic parsing, semantic role labeling and verb sense disambiguation. For instance, Kawahara and Kurohashi (2006) improved accuracy of dependency parsing based on Japanese semantic frames automatically induced from a raw corpus. It is also valuable and promising to apply the induced verb classes to NLP applications as used in metaphor identification (Shutova et al., 2010) and argumentative zoning (Guo et al., 2011).

Abstract

We present a structured learning approach to inducing hypernym taxonomies using a probabilistic graphical model formulation. Our model incorporates heterogeneous relational evidence about both hypernymy and siblinghood, captured by semantic features based on patterns and statistics from Web n-grams and Wikipedia abstracts. For efficient inference over taxonomy structures, we use loopy belief propagation along with a directed spanning tree algorithm for the core hypernymy factor. To train the system, we extract sub-structures of WordNet and discriminatively learn to reproduce them, using adaptive subgradient stochastic optimization. On the task of reproducing sub-hierarchies of WordNet, our approach achieves a 51% error reduction over a chance baseline, including a 15% error reduction due to the non-hypernym-factored sibling features. On a comparison setup, we find up to 29% relative error reduction over previous work on ancestor F1.

1 Introduction

Many tasks in natural language understanding, such as question answering, information extraction, and textual entailment, benefit from lexical semantic information in the form of types and hypernyms. A recent example is IBM's Jeopardy! system Watson (Ferrucci et al., 2010), which used type information to restrict the set of answer candidates. Information of this sort is present in term taxonomies (e.g., Figure 1), ontologies, and thesauri. However, currently available taxonomies such as WordNet are incomplete in coverage (Pennacchiotti and Pantel, 2006; Hovy et al., 2009), unavailable in many domains and languages, and time-intensive to create or extend manually. There has thus been considerable interest in building lexical taxonomies automatically.

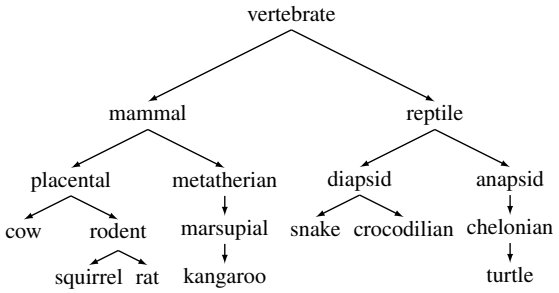

Figure 1: An excerpt of WordNet's vertebrates taxonomy.

In this work, we focus on the task of taking collections of terms as input and predicting a complete taxonomy structure over them as output. Our model takes a loglinear form and is represented using a factor graph that includes both 1st-order scoring factors on directed hypernymy edges (a parent and child in the taxonomy) and 2nd-order scoring factors on sibling edge pairs (pairs of hypernym edges with a shared parent), as well as incorporating a global (directed spanning tree) structural constraint. Inference for both learning and decoding uses structured loopy belief propagation (BP), incorporating standard spanning tree algorithms (Chu and Liu, 1965; Edmonds, 1967; Tutte, 1984). The belief propagation approach allows us to efficiently and effectively incorporate heterogeneous relational evidence via hypernymy and siblinghood (e.g., coordination) cues, which we capture by semantic features based on simple surface patterns and statistics from Web n-grams and Wikipedia abstracts. We train our model to maximize the likelihood of existing example ontologies using stochastic optimization, automatically learning the most useful relational patterns for full taxonomy induction.

As an example of the relational patterns that our

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1041–1051,
Baltimore, Maryland, USA, June 23-25 2014.

system learns, suppose we are interested in building a taxonomy for types of mammals (see Figure 1). Frequent attestation of hypernymy patterns like *rat is a rodent* in large corpora is a strong signal of the link *rodent* → *rat*. Moreover, sibling or coordination cues like *either rats or squirrels* suggest that *rat* is a sibling of *squirrel* and adds evidence for the links *rodent* → *rat* and *rodent* → *squirrel*. Our supervised model captures exactly these types of intuitions by automatically discovering such heterogeneous relational patterns as features (and learning their weights) on edges and on sibling edge pairs, respectively.

There have been several previous studies on taxonomy induction. e.g., the incremental taxonomy induction system of Snow et al. (2006), the longest path approach of Kozareva and Hovy (2010), and the maximum spanning tree (MST) approach of Navigli et al. (2011) (see Section 4 for a more detailed overview). The main contribution of this work is that we present the first discriminatively trained, structured probabilistic model over the full space of taxonomy trees, using a structured inference procedure through both the learning and decoding phases. Our model is also the first to directly learn relational patterns as part of the process of training an end-to-end taxonomic induction system, rather than using patterns that were hand-selected or learned via pairwise classifiers on manually annotated co-occurrence patterns. Finally, it is the first end-to-end (i.e., non-incremental) system to include sibling (e.g., coordination) patterns at all.

We test our approach in two ways. First, on the task of recreating fragments of WordNet, we achieve a 51% error reduction on ancestor-based F1 over a chance baseline, including a 15% error reduction due to the non-hypernym-factored sibling features. Second, we also compare to the results of Kozareva and Hovy (2010) by predicting the large *animal* subtree of WordNet. Here, we get up to 29% relative error reduction on ancestor-based F1. We note that our approach falls at a different point in the space of performance tradeoffs from past work – by producing complete, highly articulated trees, we naturally see a more even balance between precision and recall, while past work generally focused on precision.[1] To avoid presumption of a single optimal tradeoff, we also present results for precision-based decoding, where we trade off recall for precision.

2 Structured Taxonomy Induction

Given an input term set $\boldsymbol{x} = \{x_1, x_2, \ldots, x_n\}$, we wish to compute the conditional distribution over taxonomy trees $\boldsymbol{y}$. This distribution $P(\boldsymbol{y}|\boldsymbol{x})$ is represented using the graphical model formulation shown in Figure 2. A taxonomy tree $\boldsymbol{y}$ is composed of a set of indicator random variables y_{ij} (circles in Figure 2), where $y_{ij} = \text{ON}$ means that x_i is the parent of x_j in the taxonomy tree (i.e. there exists a directed edge from x_i to x_j). One such variable exists for each pair (i, j) with $0 \leq i \leq n$, $1 \leq j \leq n$, and $i \neq j$.[2]

In a factor graph formulation, a set of factors (squares and rectangles in Figure 2) determines the probability of each possible variable assignment. Each factor F has an associated scoring function ϕ_F, with the probability of a total assignment determined by the product of all these scores:

$$P(\boldsymbol{y}|\boldsymbol{x}) \propto \prod_F \phi_F(\boldsymbol{y}) \quad (1)$$

2.1 Factor Types

In the models we present here, there are three types of factors: EDGE factors that score individual edges in the taxonomy tree, SIBLING factors that score pairs of edges with a shared parent, and a global TREE factor that imposes the structural constraint that $\boldsymbol{y}$ form a legal taxonomy tree.

EDGE Factors. For each edge variable y_{ij} in the model, there is a corresponding factor E_{ij} (small blue squares in Figure 2) that depends only on y_{ij}. We score each edge by extracting a set of features $\mathbf{f}(x_i, x_j)$ and weighting them by the (learned) weight vector $\mathbf{w}$. So, the factor scoring function is:

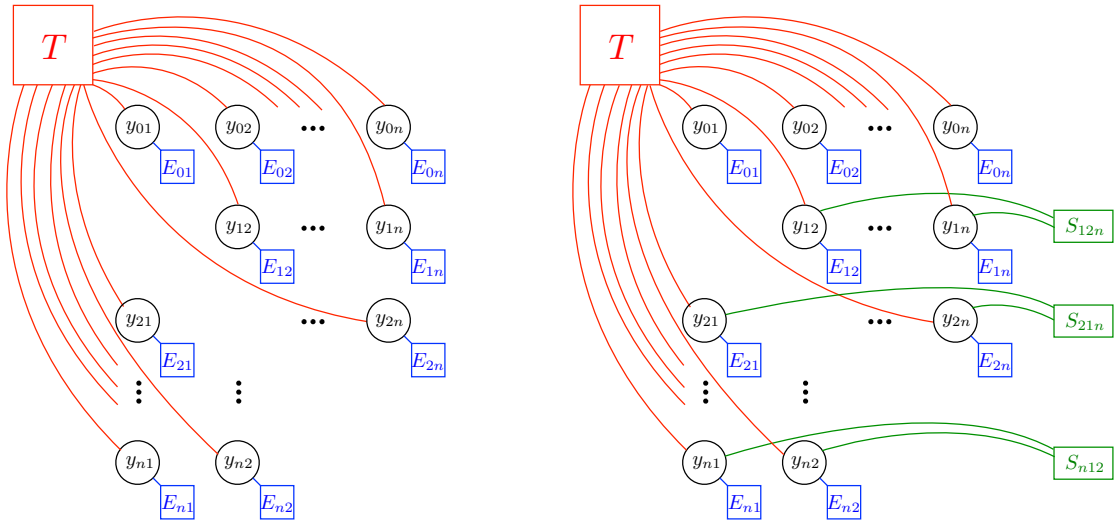
$$\phi_{E_{ij}}(y_{ij}) = \begin{cases} \exp(\mathbf{w} \cdot \mathbf{f}(x_i, x_j)) & y_{ij} = \text{ON} \\ \exp(0) = 1 & y_{ij} = \text{OFF} \end{cases}$$

SIBLING Factors. Our second model also includes factors that permit 2nd-order features looking at terms that are siblings in the taxonomy tree. For each triple (i, j, k) with $i \neq j$, $i \neq k$, and $j < k$,[3] we have a factor S_{ijk} (green rectangles in

[1] While different applications will value precision and recall differently, and past work was often intentionally precision-focused, it is certainly the case that an ideal solution would maximize both.

[2] We assume a special dummy root symbol x_0.

[3] The ordering of the siblings x_j and x_k doesn't matter here, so having separate factors for (i, j, k) and (i, k, j) would be redundant.



(a) Edge Features Only (b) Full Model

Figure 2: Factor graph representation of our model, both without (a) and with (b) SIBLING factors.

Figure 2b) that depends on y_{ij} and y_{ik}, and thus can be used to encode features that should be active whenever x_j and x_k share the same parent, x_i. The scoring function is similar to the one above:

$$\phi_{S_{ijk}}(y_{ij}, y_{ik}) = \begin{cases} \exp(\mathbf{w} \cdot \mathbf{f}(x_i, x_j, x_k)) & y_{ij} = y_{ik} = \text{ON} \\ 1 & \text{otherwise} \end{cases}$$

TREE Factor. Of course, not all variable assignments $\boldsymbol{y}$ form legal taxonomy trees (i.e., directed spanning trees). For example, the assignment $\forall i, j,\ y_{ij} = \text{ON}$ might get a high score, but would not be a valid output of the model. Thus, we need to impose a structural constraint to ensure that such illegal variable assignments are assigned 0 probability by the model. We encode this in our factor graph setting using a single global factor T (shown as a large red square in Figure 2) with the following scoring function:

$$\phi_T(\boldsymbol{y}) = \begin{cases} 1 & \boldsymbol{y} \text{ forms a legal taxonomy tree} \\ 0 & \text{otherwise} \end{cases}$$

Model. For a given global assignment $\boldsymbol{y}$, let

$$\mathbf{f}(\boldsymbol{y}) = \sum_{\substack{i,j \\ y_{ij}=\text{ON}}} \mathbf{f}(x_i, x_j) + \sum_{\substack{i,j,k \\ y_{ij}=y_{ik}=\text{ON}}} \mathbf{f}(x_i, x_j, x_k)$$

Note that by substituting our model's factor scoring functions into Equation 1, we get:

$$P(\boldsymbol{y}|\boldsymbol{x}) \propto \begin{cases} \exp(\mathbf{w} \cdot \mathbf{f}(\boldsymbol{y})) & \boldsymbol{y} \text{ is a tree} \\ 0 & \text{otherwise} \end{cases}$$

Thus, our model has the form of a standard loglinear model with feature function $\mathbf{f}$.

2.2 Inference via Belief Propagation

With the model defined, there are two main inference tasks we wish to accomplish: computing expected feature counts and selecting a particular taxonomy tree for a given set of input terms (decoding). As an initial step to each of these procedures, we wish to compute the marginal probabilities of particular edges (and pairs of edges) being on. In a factor graph, the natural inference procedure for computing marginals is belief propagation. Note that finding taxonomy trees is a structurally identical problem to directed spanning trees (and thereby non-projective dependency parsing), for which belief propagation has previously been worked out in depth (Smith and Eisner, 2008). Therefore, we will only briefly sketch the procedure here.

Belief propagation is a general-purpose inference method that computes marginals via directed messages passed from variables to adjacent factors (and vice versa) in the factor graph. These messages take the form of (possibly unnormalized) distributions over values of the variable. The two types of messages (variable to factor or factor to variable) have mutually recursive definitions. The message from a factor F to an adjacent variable V involves a sum over all possible values of every other variable that F touches. While the EDGE and SIBLING factors are simple enough to compute this sum by brute force, performing the sum naïvely for computing messages from the TREE factor would take exponential time. How-

ever, due to the structure of that particular factor, all of its outgoing messages can be computed simultaneously in $O(n^3)$ time via an efficient adaptation of Kirchhoff's Matrix Tree Theorem (MTT) (Tutte, 1984) which computes partition functions and marginals for directed spanning trees.

Once message passing is completed, marginal beliefs are computed by merely multiplying together all the messages received by a particular variable or factor.

2.2.1 Loopy Belief Propagation

Looking closely at Figure 2a, one can observe that the factor graph for the first version of our model, containing only EDGE and TREE factors, is acyclic. In this special case, belief propagation is exact: after one round of message passing, the beliefs computed (as discussed in Section 2.2) will be the true marginal probabilities under the current model. However, in the full model, shown in Figure 2b, the SIBLING factors introduce cycles into the factor graph, and now the messages being passed around often depend on each other and so they will change as they are recomputed. The process of iteratively recomputing messages based on earlier messages is known as *loopy* belief propagation. This procedure only finds *approximate* marginal beliefs, and is not actually guaranteed to converge, but in practice can be quite effective for finding workable marginals in models for which exact inference is intractable, as is the case here. All else equal, the more rounds of message passing that are performed, the closer the computed marginal beliefs will be to the true marginals, though in practice, there are usually diminishing returns after the first few iterations. In our experiments, we used a fairly conservative upper bound of 20 iterations, but in most cases, the messages converged much earlier than that.

2.3 Training

We used gradient-based maximum likelihood training to learn the model parameters $\mathbf{w}$. Since our model has a loglinear form, the derivative of $\mathbf{w}$ with respect to the likelihood objective is computed by just taking the gold feature vector and subtracting the vector of expected feature counts. For computing expected counts, we run belief propagation until completion and then, for each factor in the model, we simply read off the marginal probability of that factor being active (as computed in Section 2.2), and accumulate a partial count for each feature that is fired by that factor. This method of computing the gradient can be incorporated into any gradient-based optimizer in order to learn the weights $\mathbf{w}$. In our experiments we used AdaGrad (Duchi et al., 2011), an adaptive subgradient variant of standard stochastic gradient ascent for online learning.

2.4 Decoding

Finally, once the model parameters have been learned, we want to use the model to find taxonomy trees for particular sets of input terms. Note that if we limit our scores to be edge-factored, then finding the highest scoring taxonomy tree becomes an instance of the MST problem (also known as the maximum arborescence problem for the directed case), which can be solved efficiently in $O(n^2)$ quadratic time (Tarjan, 1977) using the greedy, recursive Chu-Liu-Edmonds algorithm (Chu and Liu, 1965; Edmonds, 1967).[4]

Since the MST problem can be solved efficiently, the main challenge becomes finding a way to ensure that our scores are edge-factored. In the first version of our model, we could simply set the score of each edge to be $\mathbf{w} \cdot \mathbf{f}(x_i, x_j)$, and the MST recovered in this way would indeed be the highest scoring tree: $\arg\max_{\boldsymbol{y}} P(\boldsymbol{y}|\boldsymbol{x})$. However, this straightforward approach doesn't apply to the full model which also uses sibling features. Hence, at decoding time, we instead start out by once more using belief propagation to find marginal beliefs, and then set the score of each edge to be its belief odds ratio: $\frac{b_{Y_{ij}}(\text{ON})}{b_{Y_{ij}}(\text{OFF})}$.[5]

3 Features

While spanning trees are familiar from non-projective dependency parsing, features based on the linear order of the words or on lexical identi-

[4] See Georgiadis (2003) for a detailed algorithmic proof, and McDonald et al. (2005) for an illustrative example. Also, we constrain the Chu-Liu-Edmonds MST algorithm to output only *single-root* MSTs, where the (dummy) root has exactly one child (Koo et al., 2007), because multi-root spanning 'forests' are not applicable to our task.
Also, note that we currently assume one node per term. We are following the task description from previous work where the goal is to create a taxonomy for a specific domain (e.g., animals). Within a specific domain, terms typically just have a single sense. However, our algorithms could certainly be adapted to the case of multiple term senses (by treating the different senses as unique nodes in the tree) in future work.

[5] The MST that is found using these edge scores is actually the minimum Bayes risk tree (Goodman, 1996) for an edge accuracy loss function (Smith and Eisner, 2008).

ties or syntactic word classes, which are primary drivers for dependency parsing, are mostly uninformative for taxonomy induction. Instead, inducing taxonomies requires world knowledge to capture the semantic relations between various unseen terms. For this, we use semantic cues to hypernymy and siblinghood via features on simple surface patterns and statistics in large text corpora. We fire features on both the edge and the sibling factors. We first describe all the edge features in detail (Section 3.1 and Section 3.2), and then briefly describe the sibling features (Section 3.3), which are quite similar to the edge ones.

For each edge factor E_{ij}, which represents the potential parent-child term pair (x_i, x_j), we add the surface and semantic features discussed below. Note that since edges are directed, we have separate features for the factors E_{ij} versus E_{ji}.

3.1 Surface Features

Capitalization: Checks which of x_i and x_j are capitalized, with one feature for each value of the tuple (isCap(x_i), isCap(x_j)). The intuition is that leaves of a taxonomy are often proper names and hence capitalized, e.g., (*bison, American bison*). Therefore, the feature for (*true, false*) (i.e., parent capitalized but not the child) gets a substantially negative weight.

Ends with: Checks if x_j ends with x_i, or not. This captures pairs such as (*fish, bony fish*) in our data.

Contains: Checks if x_j contains x_i, or not. This captures pairs such as (*bird, bird of prey*).

Suffix match: Checks whether the k-length suffixes of x_i and x_j match, or not, for $k = 1, 2, \ldots, 7$.

LCS: We compute the longest common substring of x_i and x_j, and create indicator features for rounded-off and binned values of $|LCS|/((|x_i| + |x_j|)/2)$.

Length difference: We compute the signed length difference between x_j and x_i, and create indicator features for rounded-off and binned values of $(|x_j| - |x_i|)/((|x_i| + |x_j|)/2)$. Yang and Callan (2009) use a similar feature.

3.2 Semantic Features

3.2.1 Web n-gram Features

Patterns and counts: Hypernymy for a term pair (*P*=x_i, *C*=x_j) is often signaled by the presence of surface patterns like *C is a P*, *P such as C* in large text corpora, an observation going back to Hearst (1992). For each potential parent-child edge (*P*=x_i, *C*=x_j), we mine the top k strings (based on count) in which both x_i and x_j occur (we use k=200). We collect patterns in both directions, which allows us to judge the correct direction of an edge (e.g., *C is a P* is a positive signal for hypernymy whereas *P is a C* is a negative signal).[6] Next, for each pattern in this top-k list, we compute its normalized pattern count c, and fire an indicator feature on the tuple $(pattern, t)$, for all thresholds t (in a fixed set) s.t. $c \geq t$. Our supervised model then automatically learns which patterns are good indicators of hypernymy.

Pattern order: We add features on the order (direction) in which the pair (x_i, x_j) found a pattern (in its top-k list) – indicator features for boolean values of the four cases: $P \ldots C$, $C \ldots P$, neither direction, and both directions. Ritter et al. (2009) used the 'both' case of this feature.

Individual counts: We also compute the individual Web-scale term counts c_{x_i} and c_{x_j}, and add a comparison feature ($c_{x_i} > c_{x_j}$), plus features on values of the signed count difference $(|c_{x_i}| - |c_{x_j}|)/((|c_{x_i}| + |c_{x_j}|)/2)$, after rounding off, and binning at multiple granularities. The intuition is that this feature could learn whether the relative popularity of the terms signals their hypernymy direction.

3.2.2 Wikipedia Abstract Features

The Web n-grams corpus has broad coverage but is limited to up to 5-grams, so it may not contain pattern-based evidence for various longer multiword terms and pairs. Therefore, we supplement it with a full-sentence resource, namely *Wikipedia abstracts*, which are concise descriptions (hence useful to signal hypernymy) of a large variety of world entities.

Presence and distance: For each potential edge (x_i, x_j), we mine patterns from all abstracts in which the two terms co-occur in either order, allowing a maximum term distance of 20 (because beyond that, co-occurrence may not imply a relation). We add a presence feature based on whether the process above found at least one pattern for that term pair, or not. We also fire features on the value of the minimum distance d_{min} at which

[6] We also allow patterns with surrounding words, e.g., ***the*** *C is a P* and *C , P* ***of***.

the two terms were found in some abstract (plus thresholded versions).

Patterns: For each term pair, we take the top-k' patterns (based on count) of length up to l from its full list of patterns, and add an indicator feature on each pattern string (without the counts). We use k'=5, l=10. Similar to the Web n-grams case, we also fire Wikipedia-based pattern order features.

3.3 Sibling Features

We also incorporate similar features on sibling factors. For each sibling factor S_{ijk} which represents the potential parent-children term triple (x_i, x_j, x_k), we consider the potential sibling term pair (x_j, x_k). Siblinghood for this pair would be indicated by the presence of surface patterns such as *either* C_1 *or* C_2, C_1 *is similar to* C_2 in large corpora. Hence, we fire Web n-gram pattern features and Wikipedia presence, distance, and pattern features, similar to those described above, on each potential sibling term pair.[7] The main difference here from the edge factors is that the sibling factors are symmetric (in the sense that S_{ijk} is redundant to S_{ikj}) and hence the patterns are undirected. Therefore, for each term pair, we first symmetrize the collected Web n-grams and Wikipedia patterns by accumulating the counts of symmetric patterns like *rats or squirrels* and *squirrels or rats*.[8]

4 Related Work

In our work, we assume a known term set and do not address the problem of extracting related terms from text. However, a great deal of past work has considered automating this process, typically taking one of two major approaches. The clustering-based approach (Lin, 1998; Lin and Pantel, 2002; Davidov and Rappoport, 2006; Yamada et al., 2009) discovers relations based on the assumption that similar concepts appear in similar contexts (Harris, 1954). The pattern-based approach uses special lexico-syntactic patterns to extract pairwise relation lists (Phillips and Riloff, 2002; Girju et al., 2003; Pantel and Pennacchiotti, 2006; Suchanek et al., 2007; Ritter et al., 2009; Hovy et al., 2009; Baroni et al., 2010; Ponzetto and Strube, 2011) and semantic classes or class-instance pairs (Riloff and Shepherd, 1997; Katz and Lin, 2003; Paşca, 2004; Etzioni et al., 2005; Talukdar et al., 2008).

We focus on the second step of taxonomy induction, namely the structured organization of terms into a complete and coherent tree-like hierarchy.[9] Early work on this task assumes a starting partial taxonomy and inserts missing terms into it. Widdows (2003) place unknown words into a region with the most semantically-similar neighbors. Snow et al. (2006) add novel terms by greedily maximizing the conditional probability of a set of relational evidence given a taxonomy. Yang and Callan (2009) incrementally cluster terms based on a pairwise semantic distance. Lao et al. (2012) extend a knowledge base using a random walk model to learn binary relational inference rules.

However, the task of inducing full taxonomies without assuming a substantial initial partial taxonomy is relatively less well studied. There is some prior work on the related task of hierarchical clustering, or grouping together of semantically related words (Cimiano et al., 2005; Cimiano and Staab, 2005; Poon and Domingos, 2010; Fountain and Lapata, 2012). The task we focus on, though, is the discovery of direct taxonomic relationships (e.g., hypernymy) between words.

We know of two closely-related previous systems, Kozareva and Hovy (2010) and Navigli et al. (2011), that build full taxonomies from scratch. Both of these systems use a process that starts by finding basic level terms (leaves of the final taxonomy tree, typically) and then using relational patterns (hand-selected ones in the case of Kozareva and Hovy (2010), and ones learned separately by a pairwise classifier on manually annotated co-occurrence patterns for Navigli and Velardi (2010), Navigli et al. (2011)) to find intermediate terms and all the attested hypernymy links between them.[10] To prune down the resulting tax-

[7] One can also add features on the full triple (x_i, x_j, x_k) but most such features will be sparse.

[8] All the patterns and counts for our Web and Wikipedia edge and sibling features described above are extracted after stemming the words in the terms, the n-grams, and the abstracts (using the Porter stemmer). Also, we threshold the features (to prune away the sparse ones) by considering only those that fire for at least t trees in the training data ($t = 4$ in our experiments).
Note that one could also add various complementary types of useful features presented by previous work, e.g., bootstrapping using syntactic heuristics (Phillips and Riloff, 2002), dependency patterns (Snow et al., 2006), doubly anchored patterns (Kozareva et al., 2008; Hovy et al., 2009), and Web definition classifiers (Navigli et al., 2011).

[9] Determining the set of input terms is orthogonal to our work, and our method can be used in conjunction with various term extraction approaches described above.

[10] Unlike our system, which assumes a complete set of terms and only attempts to induce the taxonomic structure,

onomy graph, Kozareva and Hovy (2010) use a procedure that iteratively retains the longest paths between root and leaf terms, removing conflicting graph edges as they go. The end result is acyclic, though not necessarily a tree; Navigli et al. (2011) instead use the longest path intuition to weight edges in the graph and then find the highest weight taxonomic tree using a standard MST algorithm.

Our work differs from the two systems above in that ours is the first discriminatively trained, structured probabilistic model over the full space of taxonomy trees that uses structured inference via spanning tree algorithms (MST and MTT) through both the learning and decoding phases. Our model also automatically learns relational patterns as a part of the taxonomic training phase, instead of relying on hand-picked rules or pairwise classifiers on manually annotated co-occurrence patterns, and it is the first end-to-end (i.e., non-incremental) system to include heterogeneous relational information via sibling (e.g., coordination) patterns.

5 Experiments

5.1 Data and Experimental Regime

We considered two distinct experimental setups, one that illustrates the general performance of our model by reproducing various medium-sized WordNet domains, and another that facilitates comparison to previous work by reproducing the much larger *animal* subtree provided by Kozareva and Hovy (2010).

General setup: In order to test the accuracy of structured prediction on medium-sized full-domain taxonomies, we extracted from WordNet 3.0 all bottomed-out full subtrees which had a tree-height of 3 (i.e., 4 nodes from root to leaf), and contained (10, 50] terms.[11] This gives us 761 non-overlapping trees, which we partition into 70/15/15% (533/114/114 trees) train/dev/test sets.

Comparison setup: We also compare our method (as closely as possible) with related previous work by testing on the much larger *animal* subtree made available by Kozareva and Hovy (2010), who created this dataset by selecting a set of 'harvested' terms and retrieving all the WordNet hypernyms between each input term and the root (i.e., *animal*), resulting in ∼700 terms and ∼4,300 *is-a* ancestor-child links.[12] Our training set for this *animal* test case was generated from WordNet using the following process: First, we strictly remove the *full* animal subtree from WordNet in order to avoid any possible overlap with the test data. Next, we create random 25-sized trees by picking random nodes as singleton trees, and repeatedly adding child edges from WordNet to the tree. This process gives us a total of ∼1600 training trees.[13]

Feature sources: The n-gram semantic features are extracted from the Google n-grams corpus (Brants and Franz, 2006), a large collection of English n-grams (for $n = 1$ to 5) and their frequencies computed from almost 1 trillion tokens (95 billion sentences) of Web text. The Wikipedia abstracts are obtained via the publicly available dump, which contains almost ∼4.1 million articles.[14] Preprocessing includes standard XML parsing and tokenization. Efficient collection of feature statistics is important because these must be extracted for millions of query pairs (for each potential edge and sibling pair in each term set). For this, we use a hash-trie on term pairs (similar to that of Bansal and Klein (2011)), and scan once through the n-gram (or abstract) set, skipping many n-grams (or abstracts) based on fast checks of missing unigrams, exceeding length, suffix mismatches, etc.

5.2 Evaluation Metric

Ancestor F1: Measures the precision, recall, and $F_1 = 2PR/(P+R)$ of correctly predicted ances-

both these systems include term discovery in the taxonomy building process.

[11] Subtrees that had a smaller or larger tree height were discarded in order to avoid overlap between the training and test divisions. This makes it a much *stricter setting* than other tasks such as parsing, which usually has repeated sentences, clauses and phrases between training and test sets.
To project WordNet synsets to terms, we used the first (most frequent) term in each synset. A few WordNet synsets have multiple parents so we only keep the first of each such pair of overlapping trees. We also discard a few trees with duplicate terms because this is mostly due to the projection of different synsets to the same term, and theoretically makes the tree a graph.

[12] This is somewhat different from our general setup where we work with any given set of terms; they start with a large set of leaves which have substantial Web-based relational information based on their selected, hand-picked patterns. Their data is available at `http://www.isi.edu/~kozareva/downloads.html`.

[13] We tried this training regimen as different from that of the general setup (which contains only bottomed-out subtrees), so as to match the *animal* test tree, which is of depth 12 and has intermediate nodes from higher up in WordNet.

[14] We used the *20130102* dump.

System	P	R	F1
Edges-Only Model			
Baseline	5.9	8.3	6.9
Surface Features	17.5	41.3	24.6
Semantic Features	37.0	49.1	42.2
Surface+Semantic	41.1	54.4	46.8
Edges + Siblings Model			
Surface+Semantic	**53.1**	**56.6**	**54.8**
Surface+Semantic (Test)	48.0	55.2	51.4

Table 1: Main results on our general setup. On the development set, we present incremental results on the edges-only model where we start with the chance baseline, then use surface features only, semantic features only, and both. Finally, we add sibling factors and features to get results for the full, edges+siblings model with all features, and also report the final test result for this setting.

System	P	R	F1

Fixed Prediction	84.2	**55.1**	**66.6**
Free Prediction	79.3	49.0	60.6

Table 2: Comparison results on the *animal* dataset of Kozareva and Hovy (2010). Here, 'Kozareva2010' refers to Kozareva and Hovy (2010) and 'Navigli2011' refers to Navigli et al. (2011). For appropriate comparison to each previous work, we show our results both for the 'Fixed Prediction' setup, which assumes the true root and leaves, and for the 'Free Prediction' setup, which doesn't assume any prior information. The $\star\star$ results of Navigli et al. (2011) represent a different ground-truth data condition, making them incomparable to our results; see Section 5.3 for details.

tors, i.e., pairwise *is-a* relations:

$$P = \frac{|\text{isa}_{\text{gold}} \cap \text{isa}_{\text{predicted}}|}{|\text{isa}_{\text{predicted}}|}, \; R = \frac{|\text{isa}_{\text{gold}} \cap \text{isa}_{\text{predicted}}|}{|\text{isa}_{\text{gold}}|}$$

5.3 Results

Table 1 shows our main results for ancestor-based evaluation on the general setup. We present a development set ablation study where we start with the edges-only model (Figure 2a) and its random tree baseline (which chooses any arbitrary spanning tree for the term set). Next, we show results on the edges-only model with surface features (Section 3.1), semantic features (Section 3.2), and both. We see that both surface and semantic features make substantial contributions, and they also stack. Finally, we add the sibling factors and features (Figure 2b, Section 3.3), which further improves the results significantly (8% absolute and 15% relative error reduction over the edges-only results on the ancestor F1 metric). The last row shows the final test set results for the full model with all features.

Table 2 shows our results for comparison to the larger *animal* dataset of Kozareva and Hovy (2010).[15] In the table, 'Kozareva2010' refers to Kozareva and Hovy (2010) and 'Navigli2011' refers to Navigli et al. (2011).[16] For appropriate comparison to each previous work, we show results for two different setups. The first setup 'Fixed Prediction' assumes that the model knows the true root and leaves of the taxonomy to provide for a somewhat fairer comparison to Kozareva and Hovy (2010). We get substantial improvements on ancestor-based recall and F1 (a 29% relative error reduction). The second setup 'Free Prediction' assumes no prior knowledge and predicts the full tree (similar to the general setup case). On this setup, we do compare as closely as possible to Navigli et al. (2011) and see a small gain in F1, but regardless, we should note that their results are incomparable (denoted by $\star\star$ in Table 2) because they have a different ground-truth data condition: their definition and hypernym extraction phase involves using the Google `define` keyword, which often returns WordNet glosses itself.

We note that previous work achieves higher ancestor precision, while our approach achieves a more even balance between precision and recall. Of course, precision and recall should both ideally be high, even if some applications weigh one over the other. This is why our tuning optimized for F1, which represents a neutral combination for comparison, but other F_α metrics could also be optimized. In this direction, we also tried an experiment on *precision-based decoding* (for the 'Free Prediction' scenario), where we discard any edges with score (i.e., the belief odds ratio described in Section 2.4) less than a certain threshold. This allowed us to achieve high values of precision (e.g., 90.8%) at still high enough F1 values (e.g., 61.7%).

[15] These results are for the 1st order model due to the scale of the animal taxonomy (∼700 terms). For scaling the 2nd order sibling model, one can use approximations, e.g., pruning the set of sibling factors based on 1st order link marginals, or a hierarchical coarse-to-fine approach based on taxonomy induction on subtrees, or a greedy approach of adding a few sibling factors at a time. This is future work.

[16] The Kozareva and Hovy (2010) ancestor results are obtained by using the output files provided on their webpage.

Hypernymy features

Table 3: Examples of high-weighted hypernymy and siblinghood features learned during development.

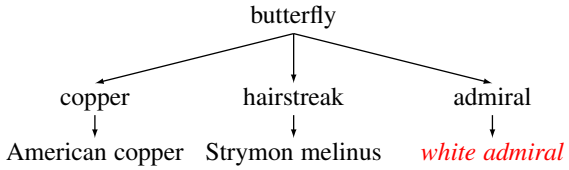

Figure 3: Excerpt from the predicted *butterfly* tree. The terms attached erroneously according to WordNet are marked in red and italicized.

6 Analysis

Table 3 shows some of the hypernymy and siblinghood features given highest weight by our model (in general-setup development experiments). The training process not only rediscovers most of the standard Hearst-style hypernymy patterns (e.g., *C and other P*, *C is a P*), but also finds various novel, intuitive patterns. For example, the pattern *C, american P* is prominent because it captures pairs like *Lemmon, american actor* and *Bryon, american politician*, etc. Another pattern *> P > C* captures webpage navigation breadcrumb trails (representing category hierarchies). Similarly, the algorithm also discovers useful siblinghood features, e.g., *either* C_1 *or* C_2, C_1 *and / or* C_2, etc.

Finally, we look at some specific output errors to give as concrete a sense as possible of some system confusions, though of course any hand-chosen examples must be taken as illustrative. In Figure 3, we attach *white admiral* to *admiral*, whereas the gold standard makes these two terms siblings. In reality, however, white admirals are indeed a species of admirals, so WordNet's ground truth turns out to be incomplete. Another such example is that we place *logistic assessment* in the *evaluation* subtree of *judgment*, but WordNet makes it a direct child of *judgment*. However, other dictionaries do consider logistic assessments to be evaluations. Hence, this illustrates that there may be more than one right answer, and that the low results on this task should only be interpreted as such. In Figure 4, our algorithm did not recognize that *thermos* is a hyponym of *vacuum flask*, and that *jeroboam* is a kind of wine bottle. Here, our Web n-grams dataset (which only contains frequent n-grams) and Wikipedia abstracts do not suffice and we would need to add richer Web data for such world knowledge to be reflected in the features.

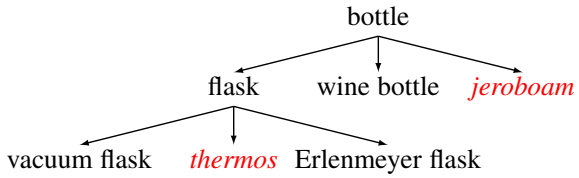

Figure 4: Excerpt from the predicted *bottle* tree. The terms attached erroneously according to WordNet are marked in red and italicized.

7 Conclusion

Our approach to taxonomy induction allows heterogeneous information sources to be combined and balanced in an error-driven way. Direct indicators of hypernymy, such as Hearst-style context patterns, are the core feature for the model and are discovered automatically via discriminative training. However, other indicators, such as coordination cues, can indicate that two words might be siblings, independently of what their shared parent might be. Adding second-order factors to our model allows these two kinds of evidence to be weighed and balanced in a discriminative, structured probabilistic framework. Empirically, we see substantial gains (in ancestor F1) from sibling features, and also over comparable previous work. We also present results on the precision and recall trade-offs inherent in this task.

A Provably Correct Learning Algorithm for Latent-Variable PCFGs

Abstract

We introduce a provably correct learning algorithm for latent-variable PCFGs. The algorithm relies on two steps: first, the use of a matrix-decomposition algorithm applied to a co-occurrence matrix estimated from the parse trees in a training sample; second, the use of EM applied to a convex objective derived from the training samples in combination with the output from the matrix decomposition. Experiments on parsing and a language modeling problem show that the algorithm is efficient and effective in practice.

1 Introduction

Latent-variable PCFGs (L-PCFGs) (Matsuzaki et al., 2005; Petrov et al., 2006) give state-of-the-art performance on parsing problems. The standard approach to parameter estimation in L-PCFGs is the EM algorithm (Dempster et al., 1977), which has the usual problems with local optima. Recent work (Cohen et al., 2012) has introduced an alternative algorithm, based on spectral methods, which has provable guarantees. Unfortunately this algorithm does not return parameter estimates for the underlying L-PCFG, instead returning the parameter values up to an (unknown) linear transform. In practice, this is a limitation.

We describe an algorithm that, like EM, returns estimates of the original parameters of an L-PCFG, but, unlike EM, does not suffer from problems of local optima. The algorithm relies on two key ideas:

1) A *matrix decomposition algorithm* (section 5) which is applicable to matrices Q of the form $Q_{f,g} = \sum_h p(h)p(f \mid h)p(g \mid h)$ where $p(h), p(f \mid h)$ and $p(g \mid h)$ are multinomial distributions. This matrix form has clear relevance to latent variable models. We apply the matrix decomposition algorithm to a co-occurrence matrix that can be estimated directly from a training set consisting of parse trees without latent annotations. The resulting parameter estimates give us significant leverage over the learning problem.

2) *Optimization of a convex objective function using EM.* We show that once the matrix decomposition step has been applied, parameter estimation of the L-PCFG can be reduced to a convex optimization problem that is easily solved by EM.

The algorithm provably learns the parameters of an L-PCFG (theorem 1), under an assumption that each latent state has at least one "pivot" feature. This assumption is similar to the "pivot word" assumption used by Arora et al. (2013) and Arora et al. (2012) in the context of learning topic models.

We describe experiments on learning of L-PCFGs, and also on learning of the latent-variable language model of Saul and Pereira (1997). A hybrid method, which uses our algorithm as an initializer for EM, performs at the same accuracy as EM, but requires significantly fewer iterations for convergence: for example in our L-PCFG experiments, it typically requires 2 EM iterations for convergence, as opposed to 20-40 EM iterations for initializers used in previous work.

While this paper's focus is on L-PCFGs, the techniques we describe are likely to be applicable to many other latent-variable models used in NLP.

2 Related Work

Recently a number of researchers have developed provably correct algorithms for parameter estimation in latent variable models such as hidden Markov models, topic models, directed graphical models with latent variables, and so on (Hsu et al., 2009; Bailly et al., 2010; Siddiqi et al., 2010; Parikh et al., 2011; Balle et al., 2011; Arora et al., 2013; Dhillon et al., 2012; Anandkumar et al., 2012; Arora et al., 2012; Arora et al., 2013). Many of these algorithms have their roots in spectral methods such as canonical correlation analysis (CCA) (Hotelling, 1936), or higher-order tensor decompositions. Previous work (Cohen et al., 2012; Cohen et al., 2013) has developed a spectral method for learning of L-PCFGs; this method learns parameters of the model up to an unknown

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1052–1061,
Baltimore, Maryland, USA, June 23-25 2014.

linear transformation, which cancels in the inside-outside calculations for marginalization over latent states in the L-PCFG. The lack of direct parameter estimates from this method leads to problems with negative or unnormalized probablities; the method does not give parameters that are interpretable, or that can be used in conjunction with other algorithms, for example as an initializer for EM steps that refine the model.

Our work is most directly related to the algorithm for parameter estimation in topic models described by Arora et al. (2013). This algorithm forms the core of the matrix decomposition algorithm described in section 5.

3 Background

This section gives definitions and notation for L-PCFGs, taken from (Cohen et al., 2012).

3.1 L-PCFGs: Basic Definitions

An L-PCFG is an 8-tuple $(\mathcal{N}, \mathcal{I}, \mathcal{P}, m, n, \pi, t, q)$ where: $\mathcal{N}$ is the set of non-terminal symbols in the grammar. $\mathcal{I} \subset \mathcal{N}$ is a finite set of *in-terminals*. $\mathcal{P} \subset \mathcal{N}$ is a finite set of *pre-terminals*. We assume that $\mathcal{N} = \mathcal{I} \cup \mathcal{P}$, and $\mathcal{I} \cap \mathcal{P} = \emptyset$. Hence we have partitioned the set of non-terminals into two subsets. $[m]$ is the set of possible hidden states.[1] $[n]$ is the set of possible words. For all $(a, b, c) \in \mathcal{I} \times \mathcal{N} \times \mathcal{N}$, and $(h_1, h_2, h_3) \in [m] \times [m] \times [m]$, we have a context-free rule $a(h_1) \rightarrow b(h_2) \;\; c(h_3)$. The rule has an associated parameter $t(a \rightarrow b\, c, h_2, h_3 \mid a, h_1)$. For all $a \in \mathcal{P}$, $h \in [m]$, $x \in [n]$, we have a context-free rule $a(h) \rightarrow x$. The rule has an associated parameter $q(a \rightarrow x \mid a, h)$. For all $a \in \mathcal{I}$, $h \in [m]$, $\pi(a, h)$ is a parameter specifying the probability of $a(h)$ being at the root of a tree.

A *skeletal tree* (s-tree) is a sequence of rules $r_1 \ldots r_N$ where each r_i is either of the form $a \rightarrow b \;\; c$ or $a \rightarrow x$. The rule sequence forms a top-down, left-most derivation under a CFG with skeletal rules.

A *full tree* consists of an s-tree $r_1 \ldots r_N$, together with values $h_1 \ldots h_N$. Each h_i is the value for the hidden variable for the left-hand-side of rule r_i. Each h_i can take any value in $[m]$.

For a given skeletal tree $r_1 \ldots r_N$, define a_i to be the non-terminal on the left-hand-side of rule r_i. For any $i \in [N]$ such that r_i is of the form $a \rightarrow b\, c$, define $h_i^{(2)}$ and $h_i^{(3)}$ as the hidden state value of the left and right child respectively. The model then defines a distribution as

$$p(r_1 \ldots r_N, h_1 \ldots h_N) = \pi(a_1, h_1) \prod_{i: a_i \in \mathcal{I}} t(r_i, h_i^{(2)}, h_i^{(3)} \mid a_i, h_i) \prod_{i: a_i \in \mathcal{P}} q(r_i \mid a_i, h_i)$$

The distribution over skeletal trees is $p(r_1 \ldots r_N) = \sum_{h_1 \ldots h_N} p(r_1 \ldots r_N, h_1 \ldots h_N)$.

3.2 Definition of Random Variables

Throughout this paper we will make reference to random variables derived from the distribution over full trees from an L-PCFG. These random variables are defined as follows. First, we select a random internal node, from a random tree, as follows: 1) Sample a full tree $r_1 \ldots r_N, h_1 \ldots h_N$ from the PMF $p(r_1 \ldots r_N, h_1 \ldots h_N)$; 2) Choose a node i uniformly at random from $[N]$. We then give the following definition:

Definition 1 (Random Variables)**.** If the rule r_i for the node i is of the form $a \rightarrow b\, c$, we define random variables as follows: R_1 is equal to the rule r_i (e.g., `NP` $\rightarrow$ `D N`). A, B, C are the labels for node i, the left child of node i, and the right child of node i respectively. (E.g., $A =$ `NP`, $B =$ `D`, $C =$ `N`.) T_1 is the inside tree rooted at node i. T_2 is the inside tree rooted at the left child of node i, and T_3 is the inside tree rooted at the right child of node i. O is the outside tree at node i. H_1, H_2, H_3 are the hidden variables associated with node i, the left child of node i, and the right child of node i respectively. E is equal to 1 if node i is at the root of the tree (i.e., $i = 1$), 0 otherwise.

If the rule r_i for the selected node i is of the form $a \rightarrow x$, we have random variables R_1, T_1, H_1, A_1, O, E as defined above, but H_2, H_3, T_2, T_3, B, and C are not defined.

4 The Learning Algorithm for L-PCFGs

Our goal is to design a learning algorithm for L-PCFGs. The input to the algorithm will be a training set consisting of skeletal trees, assumed to be sampled from some underlying L-PCFG. The output of the algorithm will be estimates for the π, t, and q parameters. The training set does not include values for the latent variables; this is the main challenge in learning.

This section focuses on an algorithm for recovery of the t parameters. A description of the algorithms for recovery of the π and q parameters is deferred until section 6.1 of this paper; these

[1] For any integer n, we use $[n]$ to denote the set $\{1, 2, \ldots n\}$.

steps are straightforward once we have derived the method for the t parameters.

We describe an algorithm that correctly recovers the parameters of an L-PCFG as the size of the training set goes to infinity (this statement is made more precise in section 4.2). The algorithm relies on an assumption—the "pivot" assumption—that we now describe.

4.1 Features, and the Pivot Assumption

We assume a function τ from inside trees to a finite set $\mathcal{F}$, and a function ρ that maps outside trees to a finite set $\mathcal{G}$. The function $\tau(t)$ ($\rho(o)$) can be thought of as a function that maps an inside tree t (outside tree o) to an underlying feature. As one example, the function $\tau(t)$ might return the context-free rule at the root of the inside tree t; in this case the set $\mathcal{F}$ would be equal to the set of all context-free rules in the grammar. As another example, the function $\rho(o)$ might return the context-free rule at the foot of the outside tree o.

In the more general case, we might have K separate functions $\tau^{(k)}(t)$ for $k = 1 \ldots K$ mapping inside trees to K separate features, and similarly we might have multiple features for outside trees. Cohen et al. (2013) describe one such feature definition, where features track single context-free rules as well as larger fragments such as two or three-level sub-trees. For simplicity of presentation we describe the case of single features $\tau(t)$ and $\rho(o)$ for the majority of this paper. The extension to multiple features is straightforward, and is discussed in section 6.2; the flexibility allowed by multiple features is important, and we use multiple features in our experiments.

Given functions τ and ρ, we define additional random variables: $F = \tau(T_1), F_2 = \tau(T_2), F_3 = \tau(T_3)$, and $G = \rho(O)$.

We can now give the following assumption:

Assumption 1 (The Pivot Assumption)**.** *Under the L-PCFG being learned, there exist values $\alpha > 0$ and $\beta > 0$ such that for each non-terminal a, for each hidden state $h \in [m]$, the following statements are true: 1) $\exists f \in \mathcal{F}$ such that $P(F = f \mid H_1 = h, A = a) > \alpha$ and for all $h' \neq h$, $P(F = f \mid H_1 = h', A = a) = 0$; 2) $\exists g \in \mathcal{G}$ such that $P(G = g \mid H_1 = h, A = a) > \beta$ and for all $h' \neq h$, $P(G = g \mid H_1 = h', A = a) = 0$.*

This assumption is very similar to the assumption made by Arora et al. (2012) in the context of learning topic models. It implies that for each (a, h) pair, there are inside and outside tree features—which following Arora et al. (2012) we refer to as pivot features—that occur only[2] in the presence of latent-state value h. As in (Arora et al., 2012), the pivot features will give us considerable leverage in learning of the model.

4.2 The Learning Algorithm

Figure 1 shows the learning algorithm for L-PCFGs. The algorithm consists of the following steps:

Step 0: Calculate estimates $\hat{p}(a \rightarrow b\ c \mid a)$, $\hat{p}(g, f_2, f_3 \mid a \rightarrow b\ c)$ and $\hat{p}(f, g \mid a)$. These estimates are easily calculated using counts taken from the training examples.

Step 1: Calculate values $\hat{r}(f \mid h, a)$ and $\hat{s}(g \mid h, a)$; these are estimates of $p(f \mid h_1, a)$ and $p(g \mid h_1, a)$ respectively. This step is achieved using a matrix decomposition algorithm, described in section 5 of this paper, on the matrix $\hat{Q}^a$ with entries $[\hat{Q}^a]_{f,g} = \hat{p}(f, g \mid a)$.

Step 2: Use the EM algorithm to find $\hat{t}$ values that maximize the objective function in Eq. 1 (see figure 1). Crucially, this is a convex optimization problem, and the EM algorithm will converge to the global maximum of this likelihood function.

Step 3: Rule estimates are calculated using an application of the laws of probability.

Before giving a theorem concerning correctness of the algorithm we introduce two assumptions:

Assumption 2 (Strict Convexity)**.** *If we have the equalities $\hat{s}(g \mid h_1, a) = P(G = g \mid H_1 = h_1, A = a)$, $\hat{r}(f_2 \mid h_2, b) = P(F_2 = f_2 \mid H_2 = h_2, B = b)$ and $\hat{r}(f_3 \mid h_3, c) = P(F_3 = f_3 \mid H_2 = h_3, C = c)$, then the function in Eq. 1 (figure 1) is strictly concave.*

The function in Eq. 1 is always concave; this assumption adds the restriction that the function must be *strictly* concave—that is, it has a unique global maximum—in the case that the $\hat{r}$ and $\hat{s}$ estimates are exact estimates.

Assumption 3 (Infinite Data)**.** *After running Step 0 of the algorithm we have*

$$\begin{aligned} \hat{p}(a \rightarrow b\ c \mid a) &= p(a \rightarrow b\ c \mid a) \\ \hat{p}(g, f_2, f_3 \mid a \rightarrow b\ c) &= p(g, f_2, f_3 \mid a \rightarrow b\ c) \\ \hat{p}(f, g \mid a) &= p(f, g \mid a) \end{aligned}$$

where $p(\ldots)$ is the probability under the underlying L-PCFG.

[2] The requirements $P(F = f \mid H_1 = h', A = a) = 0$ and $P(G = g \mid H_1 = h', A = a) = 0$ are almost certainly overly strict; in theory and practice these probabilities should be able to take small but strictly positive values.

We use the term "infinite data" because under standard arguments, $\hat{p}(\ldots)$ converges to $p(\ldots)$ as M goes to ∞.

The theorem is then as follows:

Theorem 1. *Consider the algorithm in figure 1. Assume that assumptions 1-3 (the pivot, strong convexity, and infinite data assumptions) hold for the underlying L-PCFG. Then there is some permutation $\sigma : [m] \rightarrow [m]$ such that for all $a \rightarrow b\ c, h_1, h_2, h_3$,*

$$\begin{aligned} & \hat{t}(a \rightarrow b\ c, h_2, h_3 \mid a \rightarrow b\ c, h_1) \\ = \ & t(a \rightarrow b\ c, \sigma(h_2), \sigma(h_3) \mid a \rightarrow b\ c, \sigma(h_1)) \end{aligned}$$

where $\hat{t}$ are the parameters in the output, and t are the parameters of the underlying L-PCFG.

This theorem states that under assumptions 1-3, the algorithm correctly learns the t parameters of an L-PCFG, up to a permutation over the latent states defined by σ. Given the assumptions we have made, it is not possible to do better than recovering the correct parameter values up to a permutation, due to symmetries in the model. Assuming that the π and q parameters are recovered in addition to the t parameters (see section 6.1), the resulting model will define exactly the same distribution over full trees as the underlying L-PCFG up to this permutation, and will define exactly the same distribution over skeletal trees, so in this sense the permutation is benign.

Proof of theorem 1: Under the assumptions of the theorem, $\hat{Q}^a_{f,g} = p(f, g \mid a) = \sum_h p(h \mid a) p(f \mid h, a) p(g \mid h, a)$. Under the pivot assumption, and theorem 2 of section 5, step 1 (the matrix decomposition step) will therefore recover values $\hat{r}$ and $\hat{s}$ such that $\hat{r}(f \mid h, a) = p(f \mid \sigma(h), a)$ and $\hat{s}(g \mid h, a) = p(g \mid \sigma(h), a)$ for some permutation $\sigma : [m] \rightarrow [m]$. For simplicity, assume that $\sigma(j) = j$ for all $j \in [m]$ (the argument for other permutations involves a straightforward extension of the following argument). Under the assumptions of the theorem, $\hat{p}(g, f_2, f_3 \mid a \rightarrow b\ c) = p(g, f_2, f_3 \mid a \rightarrow b\ c)$, hence the function being optimized in Eq. 1 is equal to

$$\sum_{g, f_2, f_3} p(g, f_2, f_3 \mid a \rightarrow b\ c) \log \kappa(g, f_2, f_3)$$

where

$$\begin{aligned} \kappa(g, f_2, f_3) = \sum_{h_1, h_2, h_3} & \big(\hat{t}(h_1, h_2, h_3 \mid a \rightarrow b\ c) \\ & \times p(g \mid h_1, a) p(f_2 \mid h_2, b) p(f_3 \mid h_3, c)\big) \end{aligned}$$

Now consider the optimization problem in Eq. 1. By standard results for cross entropy, the maximum of the function

$$\sum_{g, f_2, f_3} p(g, f_2, f_3 \mid a \rightarrow b\ c) \log q(g, f_2, f_3 \mid a \rightarrow b\ c)$$

with respect to the q values is achieved at $q(g, f_2, f_3 \mid a \rightarrow b\ c) = p(g, f_2, f_3 \mid a \rightarrow b\ c)$. In addition, under the assumptions of the L-PCFG,

$$\begin{aligned} & p(g, f_2, f_3 \mid a \rightarrow b\ c) \\ = & \sum_{h_1, h_2, h_3} (p(h_1, h_2, h_3 \mid a \rightarrow b\ c) \\ & \times p(g \mid h_1, a) p(f_2 \mid h_2, b) p(f_3 \mid h_3, c)) \end{aligned}$$

Hence the maximum of Eq. 1 is achieved at

$$\hat{t}(h_1, h_2, h_3 \mid a \rightarrow b\ c) = p(h_1, h_2, h_3 \mid a \rightarrow b\ c) \tag{2}$$

because this gives $\kappa(g, f_2, f_3) = p(g, f_2, f_3 \mid a \rightarrow b\ c)$. Under the strict convexity assumption the maximum of Eq. 1 is unique, hence the $\hat{t}$ values must satisfy Eq. 2. Finally, it follows from Eq. 2, and the equality $\hat{p}(a \rightarrow b\ c \mid a) = p(a \rightarrow b\ c \mid a)$, that Step 3 of the algorithm gives $\hat{t}(a \rightarrow b\ c, h_2, h_3 \mid a, h_1) = t(a \rightarrow b\ c, h_2, h_3 \mid a, h_1)$. □

We can now see how the strict convexity assumption is needed. Without this assumption, there may be multiple settings for $\hat{t}$ that achieve $\kappa(g, f_2, f_3) = p(g, f_2, f_3 \mid a \rightarrow b\ c)$; the values $\hat{t}(h_1, h_2, h_3 \mid a \rightarrow b\ c) = p(h_1, h_2, h_3 \mid a \rightarrow b\ c)$ will be included in this set of solutions, but other, inconsistent solutions will also be included.

As an extreme example of the failure of the strict convexity assumption, consider a feature-vector definition with $|\mathcal{F}| = |\mathcal{G}| = 1$. In this case the function in Eq. 1 reduces to $\log \sum_{h_1, h_2, h_3} \hat{t}(h_1, h_2, h_3 \mid a \rightarrow b\ c)$. This function has a maximum value of 0, achieved at all values of $\hat{t}$. Intuitively, this definition of inside and outside tree features loses all information about the latent states, and does not allow successful learning of the underlying L-PCFG. More generally, it is clear that the strict convexity assumption will depend directly on the choice of feature functions $\tau(t)$ and $\rho(o)$.

Remark: The infinite data assumption, and sample complexity. The infinite data assumption deserves more discussion. It is clearly a strong assumption that there is sufficient data for

Input: A set of M skeletal trees sampled from some underlying L-PCFG. The count[...] function counts the number of times that event ... occurs in the training sample. For example, count$[A = a]$ is the number of times random variable A takes value a in the training sample.

Step 0: Calculate the following estimates from the training samples:

- $\hat{p}(a \rightarrow b\ c \mid a) = \text{count}[R_1 = a \rightarrow b\ c]/\text{count}[A = a]$
- $\hat{p}(g, f_2, f_3 \mid a \rightarrow b\ c) = \text{count}[G = g, F_2 = f_2, F_3 = f_3, R_1 = a \rightarrow b\ c]/\text{count}[R_1 = a \rightarrow b\ c]$
- $\hat{p}(f, g \mid a) = \text{count}[F = f, G = g, A = a]/\text{count}[A = a]$
- $\forall a \in \mathcal{I}$, define a matrix $\hat{Q}^a \in \mathbb{R}^{d \times d'}$ where $d = |\mathcal{F}|$ and $d' = |\mathcal{G}|$ as $[\hat{Q}^a]_{f,g} = \hat{p}(f, g \mid a)$.

Step 1: $\forall a \in \mathcal{I}$, use the algorithm in figure 2 with input $\hat{Q}^a$ to derive estimates $\hat{r}(f \mid h, a)$ and $\hat{s}(g \mid h, a)$.

Remark: These quantities are estimates of $P(F_1 = f \mid H_1 = h, A = a)$ and $P(G = g \mid H = h, A = a)$ respectively. Note that under the independence assumptions of the L-PCFG,
$P(F_1 = f \mid H_1 = h, A = a) = P(F_2 = f \mid H_2 = h, A_2 = a) = P(F_3 = f \mid H_3 = h, A_3 = a)$.

Step 2: For each rule $a \rightarrow b\ c$, find $\hat{t}(h_1, h_2, h_3 \mid a \rightarrow b\ c)$ values that maximize

$$\sum_{g, f_2, f_3} \hat{p}(g, f_2, f_3 \mid a \rightarrow b\ c) \log \sum_{h_1, h_2, h_3} \hat{t}(h_1, h_2, h_3 \mid a \rightarrow b\ c) \hat{s}(g \mid h_1, a) \hat{r}(f_2 \mid h_2, b) \hat{r}(f_3 \mid h_3, c) \quad (1)$$

under the constraints $\hat{t}(h_1, h_2, h_3 \mid a \rightarrow b\ c) \geq 0$, and $\sum_{h_1, h_2, h_3} \hat{t}(h_1, h_2, h_3 \mid a \rightarrow b\ c) = 1$.

Remark: the function in Eq. 1 is concave in the values $\hat{t}$ being optimized over. We use the EM algorithm, which converges to a global optimum.

Step 3: $\forall a \rightarrow b\ c, h_1, h_2, h_3$, calculate rule parameters as follows:

$$\hat{t}(a \rightarrow b\ c, h_2, h_3 \mid a, h_1) = \hat{t}(a \rightarrow b\ c, h_1, h_2, h_3 \mid a) / \sum_{b, c, h_2, h_3} \hat{t}(a \rightarrow b\ c, h_1, h_2, h_3 \mid a)$$

where $\hat{t}(a \rightarrow b\ c, h_1, h_2, h_3 \mid a) = \hat{p}(a \rightarrow b\ c \mid a) \times \hat{t}(h_1, h_2, h_3 \mid a \rightarrow b\ c)$.

Output: Parameter estimates $\hat{t}(a \rightarrow b\ c, h_2, h_3 \mid a, h_1)$ for all rules $a \rightarrow b\ c$, for all $(h_1, h_2, h_3) \in [m] \times [m] \times [m]$.

Figure 1: The learning algorithm for the $t(a \rightarrow b\ c, h_1, h_2, h_3 \mid a)$ parameters of an L-PCFG.

the estimates $\hat{p}$ in assumption 3 to have converged to the correct underlying values. A more detailed analysis of the algorithm would derive sample complexity results, giving guarantees on the sample size M required to reach a level of accuracy ϵ in the estimates, with probability at least $1 - \delta$, as a function of ϵ, δ, and other relevant quantities such as $n, d, d', m, \alpha, \beta$ and so on.

In spite of the strength of the infinite data assumption, we stress the importance of this result as a guarantee for the algorithm. First, a guarantee of correct parameter values in the limit of infinite data is typically the starting point for a sample complexity result (see for example (Hsu et al., 2009; Anandkumar et al., 2012)). Second, our sense is that a sample complexity result can be derived for our algorithm using standard methods: specifically, the analysis in (Arora et al., 2012) gives one set of guarantees; the remaining optimization problems we solve are convex maximum-likelihood problems, which are also relatively easy to analyze. Note that several pieces of previous work on spectral methods for latent-variable models focus on algorithms that are correct under the infinite data assumption.

5 The Matrix Decomposition Algorithm

This section describes the matrix decomposition algorithm used in Step 1 of the learning algorithm.

5.1 Problem Setting

Our goal will be to solve the following matrix decomposition problem:

Matrix Decomposition Problem (MDP) 1. *Design an algorithm with the following inputs, assumptions, and outputs:*

Inputs: *Integers m, d and d', and a matrix $Q \in \mathbb{R}^{d \times d'}$ such that $Q_{f,g} = \sum_{h=1}^{m} \pi(h) r(f \mid h) s(g \mid h)$ for some unknown parameters $\pi(h)$, $r(f \mid h)$ and $s(g \mid h)$ satisfying:*
1) $\pi(h) \geq 0$, $\sum_{h=1}^{m} \pi(h) = 1$;
2) $r(f \mid h) \geq 0$, $\sum_{f=1}^{d} r(f \mid h) = 1$;
3) $s(g \mid h) \geq 0$, $\sum_{g=1}^{d'} s(g \mid h) = 1$.
Assumptions: *There are values $\alpha > 0$ and $\beta > 0$ such that the r parameters of the model are α-separable, and the s parameters of the model are β-separable.*
Outputs: *Estimates $\hat{\pi}(h)$, $\hat{r}(f \mid h)$ and $\hat{s}(g \mid h)$ such that there is some permutation $\sigma : [m] \rightarrow [m]$ such that $\forall h, \ \hat{\pi}(h) = \pi(\sigma(h))$, $\forall f, h, \quad \hat{r}(f \mid h) = r(f \mid \sigma(h))$, and $\forall g, h, \quad \hat{s}(g \mid h) = s(g \mid \sigma(h))$.*

The definition of α-separability is as follows (β-separability for $s(g \mid h)$ is analogous):

Definition 2 (α-separability)**.** *The parameters $r(f \mid h)$ are α-separable if for all $h \in [m]$, there is some $j \in [d]$ such that: 1) $r(j \mid h) \geq \alpha$; and 2) $r(j \mid h') = 0$ for $h' \neq h$.*

This matrix decomposition problem has clear relevance to problems in learning of latent-variable models, and in particular is a core step of the algorithm in figure 1. When given a matrix $\hat{Q}^a$ with entries $\hat{Q}^a_{f,g} = \sum_h p(h \mid a) p(f \mid h, a) p(g \mid h, a)$, where $p(\ldots)$ refers to a distribution derived from an underlying L-PCFG which satisfies the pivot assumption, the method will recover the values for $p(h \mid a)$, $p(f \mid h, a)$ and $p(g \mid h, a)$ up to a permutation over the latent states.

5.2 The Algorithm of Arora et al. (2013)

This section describes a variant of the algorithm of Arora et al. (2013), which is used as a component of our algorithm for MDP 1. One of the properties of this algorithm is that it solves the following problem:

Matrix Decomposition Problem (MDP) 2. *Design an algorithm with the following inputs, assumptions, and outputs:*
Inputs: *Same as matrix decomposition problem 1.*
Assumptions: *The parameters $r(f \mid h)$ of the model are α-separable for some value $\alpha > 0$.*
Outputs: *Estimates $\hat{\pi}(h)$ and $\hat{r}(f \mid h)$ such that $\exists \sigma : [m] \rightarrow [m]$ such that $\forall h, \ \hat{\pi}(h) = \pi(\sigma(h))$, $\forall f, h, \quad \hat{r}(f \mid h) = r(f \mid \sigma(h))$.*

This is identical to Matrix Decomposition Problem 1, but without the requirement that the values $s(g \mid h)$ are returned by the algorithm. Thus an algorithm that solves MDP 2 in some sense solves "one half" of MDP 1.

For completeness we give a sketch of the algorithm that we use; it is inspired by the algorithm of Arora et al. (2012), but has some important differences. The algorithm is as follows:

Step 1: Derive a function $\phi : [d'] \rightarrow \mathbb{R}^l$ that maps each integer $g \in [d']$ to a representation $\phi(g) \in \mathbb{R}^l$. The integer l is typically much smaller than d', implying that the representation is of low dimension. Arora et al. (2012) derive ϕ as a random projection with a carefully chosen dimension l. In our experiments, we use canonical correlation analysis (CCA) on the matrix Q to give a representation $\phi(g) \in \mathbb{R}^l$ where $l = m$.

Step 2: For each $f \in [d]$, calculate

$$v_f \ = \ \mathbf{E}[\phi(g) \mid f] = \sum_{g=1}^{d'} p(g \mid f) \phi(g)$$

where $p(g \mid f) = Q_{f,g} / \sum_g Q_{f,g}$. It follows that

$$v_f = \sum_{g=1}^{d'} \sum_{h=1}^{m} p(h \mid f) p(g \mid h) \phi(g) = \sum_{h=1}^{m} p(h \mid f) w_h$$

where $w_h \in \mathbb{R}^l$ is equal to $\sum_{g=1}^{d'} p(g \mid h) \phi(g)$.

Hence the v_f vectors lie in the convex hull of a set of vectors $w_1 \ldots w_m \in \mathbb{R}^l$. Crucially, for any pivot word f for latent state h, we have $p(h \mid f) = 1$, hence $v_f = w_h$. *Thus by the pivot assumption, the set of points $v_1 \ldots v_d$ includes the vertices of the convex hull. Each point v_j is a convex combination of the vertices $w_1 \ldots w_m$, where the weights in this combination are equal to $p(h \mid j)$.*

Step 3: Use the `FastAnchorWords` algorithm of (Arora et al., 2012) to identify m vectors $v_{s_1}, v_{s_2}, \ldots v_{s_m}$. The `FastAnchorWords` algorithm has the guarantee that there is a permutation $\sigma : [m] \rightarrow [m]$ such that $v_{s_i} = w_{\sigma(i)}$ for all i. This algorithm recovers the vertices of the convex hull described in step 2, using a method that greedily picks points that are as far as possible from the subspace spanned by previously picked points.

Step 4: For each $f \in [d]$ solve the problem

$$\arg \min_{\gamma_1, \gamma_2, \ldots, \gamma_m} || \sum_h \gamma_h v_{s_h} - v_f ||^2$$

subject to $\gamma_h \geq 0$ and $\sum_h \gamma_h = 1$. We use the algorithm of (Frank and Wolfe, 1956; Clarkson, 2010) for this purpose. Set $q(h \mid f) = \gamma_h$.

Return the final quantities:

$$\hat{\pi}(h) = \sum_f p(f)q(h|f) \quad \hat{r}(f|h) = \frac{p(f)q(h|f)}{\sum_f p(f)q(h|f)}$$

where $p(f) = \sum_g Q_{f,g}$.

5.3 An Algorithm for MDP 1

Figure 2 shows an algorithm that solves MDP 1. In steps 1 and 2 of the algorithm, the algorithm of section 5.2 is used to recover estimates $\hat{r}(f \mid h)$ and $\hat{s}(g \mid h)$. These distributions are equal to $p(f \mid h)$ and $p(g \mid h)$ up to permutations σ and σ' of the latent states respectively; unfortunately there is no guarantee that σ and σ' are the same permutation. Step 3 estimates parameters $t(h' \mid h)$ that effectively map the permutation implied by $\hat{r}(f \mid h)$ to the permutation implied by $\hat{s}(g \mid h)$; the latter distribution is recalculated as $\sum_{h'} \hat{t}(h' \mid h)\hat{s}(g \mid h')$.

We now state the following theorem:

Theorem 2. *The algorithm in figure 2 solves Matrix Decomposition Problem 1.*

Proof: See the supplementary material.

Remark: A natural alternative to the algorithm presented would be to run Step 1 of the original algorithm, but to replace steps 2 and 3 with a step that finds $\hat{s}(g \mid h)$ values that maximize

$$\sum_{f,g} Q_{f,g} \log \sum_h \hat{r}(h \mid f)\hat{s}(g \mid h)$$

This is again a convex optimization problem. We may explore this algorithm in future work.

6 Additional Details of the Algorithm

6.1 Recovery of the π and q Parameters

The recovery of the π and q parameters relies on the following additional (but benign) assumptions on the functions τ and ρ:

1) For any inside tree t such that t is a unary rule of the form $a \rightarrow x$, the function τ is defined as $\tau(t) = t$.[3]

2) The set of outside tree features $\mathcal{G}$ contains a special symbol $\square$, and $g(o) = \square$ if and only if the outside tree o is derived from a non-terminal node at the root of a skeletal tree.

[3]Note that if other features on unary rules are desired, we can use multiple feature functions $\tau^1(t) \ldots \tau^K(t)$, where $\tau^1(t) = t$ for inside trees, and the functions $\tau^2(t) \ldots \tau^K(t)$ define other features.

Inputs: As in Matrix Decomposition Problem 1.

Assumptions: As in Matrix Decomposition Problem 1.

Algorithm:

Step 1. Run the algorithm of section 5.2 on the matrix Q to derive estimates $\hat{r}(f \mid h)$ and $\hat{\pi}(h)$. Note that under the guarantees of the algorithm, there is some permutation σ such that $\hat{r}(f \mid h) = r(f \mid \sigma(h))$. Define

$$\hat{r}(h \mid f) = \frac{\hat{r}(f \mid h)\hat{\pi}(h)}{\sum_h \hat{r}(f \mid h)\hat{\pi}(h)}$$

Step 2. Run the algorithm of section 5.2 on the matrix $Q^\top$ to derive estimates $\hat{s}(g \mid h)$. Under the guarantees of the algorithm, there is some permutation σ' such that $\hat{s}(g \mid h) = s(g \mid \sigma'(h))$. Note however that it is not necessarily the case that $\sigma = \sigma'$.

Step 3. Find $\hat{t}(h' \mid h)$ for all $h, h' \in [m]$ that maximize

$$\sum_{f,g} Q_{f,g} \log \sum_{h,h'} \hat{r}(h \mid f)\hat{t}(h' \mid h)\hat{s}(g \mid h') \qquad (3)$$

subject to $\hat{t}(h' \mid h) \geq 0$, and $\forall h,\ \sum_{h'} \hat{t}(h' \mid h) = 1$.

Remark: the function in Eq. 3 is concave in the $\hat{t}$ parameters. We use the EM algorithm to find a global optimum.

Step 4. Return the following values:

- $\hat{\pi}(h)$ for all h, as an estimate of $\pi(\sigma(h))$ for some permutation σ.
- $\hat{r}(f \mid h)$ for all f, h as an estimate of $r(f \mid \sigma(h))$ for the same permutation σ.
- $\sum_{h'} \hat{t}(h' \mid h)\hat{s}(g \mid h')$ as an estimate of $s(f \mid \sigma(h))$ for the same permutation σ.

Figure 2: The algorithm for Matrix Decomposition Problem 1

Under these assumptions, the algorithm in figure 1 recovers estimates $\hat{\pi}(a, h)$ and $\hat{q}(a \rightarrow x \mid a, h)$. Simply set

$$\hat{q}(a \rightarrow x \mid a, h) = \hat{r}(f \mid h, a) \text{ where } f = a \rightarrow x$$

and $\hat{\pi}(a, h) = \hat{p}(\square, h, a)/\sum_{h,a} \hat{p}(\square, h, a)$ where $\hat{p}(\square, h, a) = \hat{g}(\square \mid h, a)\hat{p}(h \mid a)\hat{p}(a)$. Note that $\hat{p}(h \mid a)$ can be derived from the matrix decomposition step when applied to $\hat{Q}^a$, and $\hat{p}(a)$ is easily recovered from the training examples.

6.2 Extension to Include Multiple Features

We now describe an extension to allow K separate functions $\tau^{(k)}(t)$ for $k = 1 \ldots K$ mapping inside trees to features, and L feature functions $\rho^{(l)}(o)$ for $l = 1 \ldots L$ over outside trees.

The algorithm in figure 1 can be extended as follows. First, Step 1 of the algorithm (the matrix

decomposition step) can be extended to provide estimates $\hat{r}^{(k)}(f^{(k)} \mid h, a)$ and $\hat{s}^{(l)}(g^{(l)} \mid h, a)$. In brief, this involves running CCA on a matrix $\mathbf{E}[\phi(T)(\psi(O))^\top \mid A = a]$ where ϕ and ψ are inside and outside binary feature vectors derived directly from the inside and outside features, using a one-hot representation. CCA results in a low-dimensional representation that can be used in the steps described in section 5.2; the remainder of the algorithm is the same. In practice, the addition of multiple features may lead to better CCA representations.

Next, we modify the objective function in Eq. 1 to be the following:

$$\sum_{i,j,k} \sum_{g^i, f_2^j, f_3^k} p(g^i, f_2^j, f_3^k \mid a \rightarrow b\ c) \log \kappa^{i,j,k}(g^i, f_2^j, f_3^k)$$

where

$$\begin{aligned} &\kappa^{i,j,k}(g^i, f_2^j, f_3^k) \\ &= \sum_{h_1,h_2,h_3} \Big(\hat{t}(h_1, h_2, h_3 \mid a \rightarrow b\ c) \\ &\quad \times \hat{s}^i(g^i \mid h_1, a)\hat{r}^j(f_2^j \mid h_2, b)\hat{r}^k(f_3^k \mid h_3, c)\Big) \end{aligned}$$

Thus the new objective function consists of a sum of $L \times M^2$ terms, each corresponding to a different combination of inside and outside features. The function remains concave.

6.3 Use as an Initializer for EM

The learning algorithm for L-PCFGs can be used as an initializer for the EM algorithm for L-PCFGs. Two-step estimation methods such as these are well known in statistics; there are guarantees for example that if the first estimator is consistent, and the second step finds the closest local maxima of the likelihood function, then the resulting estimator is both consistent and efficient (in terms of number of samples required). See for example page 453 or Theorem 4.3 (page 454) of (Lehmann and Casella, 1998).

7 Experiments on Parsing

This section describes parsing experiments using the learning algorithm for L-PCFGs. We use the Penn WSJ treebank (Marcus et al., 1993) for our experiments. Sections 2–21 were used as training data, and sections 0 and 22 were used as development data. Section 23 was used as the test set.

The experimental setup is the same as described by Cohen et al. (2013). The trees are binarized (Petrov et al., 2006) and for the EM algorithm we use the initialization method described in Matsuzaki et al. (2005). For the pivot algorithm we use multiple features $\tau^1(t) \ldots \tau^K(t)$ and $\rho^1(o) \ldots \rho^L(o)$ over inside and outside trees, using the features described by Cohen et al. (2013).

	sec. 22				sec. 23
m	8	16	24	32	
EM	86.69 40	88.32 30	88.35 30	88.56 20	87.76
Spectral	85.60	87.77	88.53	88.82	88.05
Pivot	83.56	86.00	86.87	86.40	85.83
Pivot+EM	86.83 2	88.14 6	88.64 2	88.55 2	88.03

Table 1: Results on the development data (section 22) and test data (section 23) for various learning algorithms for L-PCFGs. For EM and pivot+EM experiments, the second line denotes the number of iterations required to reach the given optimal performance on development data. Results for section 23 are used with the best model for section 22 in the corresponding row. The results for EM and spectral are reported from Cohen et al. (2013).

Table 1 gives the F1 accuracy on the development and test sets for the following methods:

EM: The EM algorithm as used by Matsuzaki et al. (2005) and Petrov et al. (2006).

Spectral: The spectral algorithm of Cohen et al. (2012) and Cohen et al. (2013).

Pivot: The algorithm described in this paper.

Pivot+EM: The algorithm described in this paper, followed by 1 or more iterations of the EM algorithm with parameters initialized by the pivot algorithm. (See section 6.3.)

For the EM and Pivot+EM algorithms, we give the number of iterations of EM required to reach optimal performance on the development data.

The results show that the EM, Spectral, and Pivot+EM algorithms all perform at a very similar level of accuracy. The Pivot+EM results show that very few EM iterations—just 2 iterations in most conditions—are required to reach optimal performance when the Pivot model is used as an initializer for EM. The Pivot results lag behind the Pivot+EM results by around 2-3%, but they are close enough to optimality to require very few EM iterations when used as an initializer.

8 Experiments on the Saul and Pereira (1997) Model for Language Modeling

We now describe a second set of experiments, on the Saul and Pereira (1997) model for language modeling. Define V to be the set of words in the vocabulary. For any $w_1, w_2 \in V$, the Saul and Pereira (1997) model then defines $p(w_2 \mid w_1) = \sum_{h=1}^{m} r(h \mid w_1)s(w_2 \mid h)$ where $r(h \mid w_1)$ and

Table 2: Language model perplexity with the Brown corpus and the Gigaword corpus (New York Times portion) for the second half of the development set, and the test set. With EM and Pivot+EM, the number of iterations for EM to reach convergence is given below the perplexity. The best result for each column (for each m value) is in bold. The "test" column gives perplexity results on the test set. Each perplexity calculation on the test set is done using the best model on the development set. bi-KN+int and tri-KN+int are bigram and trigram Kneser-Ney interpolated models (Kneser and Ney, 1995), using the SRILM toolkit.

$s(w_2 \mid h)$ are parameters of the approach. The conventional approach to estimation of the parameters $r(h \mid w_1)$ and $s(w_2 \mid h)$ from a corpus is to use the EM algorithm. In this section we compare the EM algorithm to a pivot-based method. It is straightforward to represent this model as an L-PCFG, and hence to use our implementation for estimation.

In this special case, the L-PCFG learning algorithm is equivalent to a simple algorithm, with the following steps: 1) define the matrix Q with entries $Q_{w_1,w_2} = \text{count}(w_1, w_2)/N$ where $\text{count}(w_1, w_2)$ is the number of times that bigram (w_1, w_2) is seen in the data, and $N = \sum_{w_1,w_2} \text{count}(w_1, w_2)$. Run the algorithm of section 5.2 on Q to recover estimates $\hat{s}(w_2 \mid h)$; 2) estimate $\hat{r}(h \mid w_1)$ using the EM algorithm to optimize the function $\sum_{w_1,w_2} Q_{w_1,w_2} \log \sum_h \hat{r}(h \mid w_1)\hat{s}(w_2 \mid h)$ with respect to the $\hat{r}$ parameters; this function is concave in these parameters.

We performed the language modeling experiments for a number of reasons. First, because in this case the L-PCFG algorithm reduces to a simple algorithm, it allows us to evaluate the core ideas in the method very directly. Second, it allows us to test the pivot method on the very large datasets that are available for language modeling.

We use two corpora for our experiments. The first is the Brown corpus, as used by Bengio et al. (2006) in language modeling experiments. Following Bengio et al. (2006), we use the first 800K words for training (and replace all words that appear once with an UNK token), the next 200K words for development, and the remaining data (165,171 tokens) as a test set. The size of the vocabulary is 24,488 words. The second corpus we use is the New York Times portion of the Gigaword corpus. Here, the training set consists of 1.31 billion tokens. We use 159 million tokens for development set and 156 million tokens for test. All words that appeared less than 20 times in the training set were replaced with the UNK token. The size of the vocabulary is 235,223 words. Unknown words in test data are ignored when calculating perplexity (this is the standard set-up in the SRILM toolkit).

In our experiments we use the first half of each development set to optimize the number of iterations of the EM or Pivot+EM algorithms. As before, Pivot+EM uses 1 or more EM steps with parameter initialization from the Pivot method.

Table 2 gives perplexity results for the different algorithms. As in the parsing experiments, the Pivot method alone performs worse than EM, but the Pivot+EM method gives results that are competitive with EM. The Pivot+EM method requires fewer iterations of EM than the EM algorithm. On the Brown corpus the difference is quite dramatic, with only 1 or 2 iterations required, as opposed to 10 or more for EM. For the NYT corpus the Pivot+EM method requires more iterations (around 10 or 20), but still requires significantly fewer iterations than the EM algorithm.

On the Gigaword corpus, with $m = 256$, EM takes 12h57m (32 iterations at 24m18s per iteration) compared to 1h50m for the Pivot method. On Brown, EM takes 1m47s (8 iterations) compared to 5m44s for the Pivot method. Both the EM and pivot algorithm implementations were highly optimized, and written in Matlab. Results at other values of m are similar. From these results the Pivot method appears to become more competitive speed-wise as the data size increases (the Gigaword corpus is more than 1,300 times larger than the Brown corpus).

9 Conclusion

We have described a new algorithm for parameter estimation in L-PCFGs. The algorithm is provably correct, and performs well in practice when used in conjunction with EM.

Abstract

We propose a spectral approach for unsupervised constituent parsing that comes with theoretical guarantees on latent structure recovery. Our approach is grammarless – we directly learn the bracketing structure of a given sentence without using a grammar model. The main algorithm is based on lifting the concept of additive tree metrics for structure learning of latent trees in the phylogenetic and machine learning communities to the case where the tree structure varies across examples. Although finding the "minimal" latent tree is NP-hard in general, for the case of projective trees we find that it can be found using bilexical parsing algorithms. Empirically, our algorithm performs favorably compared to the constituent context model of Klein and Manning (2002) without the need for careful initialization.

1 Introduction

Solutions to the problem of grammar induction have been long sought after since the early days of computational linguistics and are interesting both from cognitive and engineering perspectives. Cognitively, it is more plausible to assume that children obtain only terminal strings of parse trees and not the actual parse trees. This means the unsupervised setting is a better model for studying language acquisition. From the engineering perspective, training data for unsupervised parsing exists in abundance (i.e. sentences and part-of-speech tags), and is much cheaper than the syntactically annotated data required for supervised training.

Most existing solutions treat the problem of unsupervised parsing by assuming a generative process over parse trees e.g. probabilistic context free grammars (Jelinek et al., 1992), and the constituent context model (Klein and Manning, 2002). Learning then reduces to finding a set of parameters that are estimated by identifying a local maximum of an objective function such as the likelihood (Klein and Manning, 2002) or a variant of it (Smith and Eisner, 2005; Cohen and Smith, 2009; Headden et al., 2009; Spitkovsky et al., 2010b; Gillenwater et al., 2010; Golland et al., 2012). Unfortunately, finding the global maximum for these objective functions is usually intractable (Cohen and Smith, 2012) which often leads to severe local optima problems (but see Gormley and Eisner, 2013). Thus, strong experimental results are often achieved by initialization techniques (Klein and Manning, 2002; Gimpel and Smith, 2012), incremental dataset use (Spitkovsky et al., 2010a) and other specialized techniques to avoid local optima such as count transforms (Spitkovsky et al., 2013). These approaches, while empirically promising, generally lack theoretical justification.

On the other hand, recently proposed spectral methods approach the problem via restriction of the PCFG model (Hsu et al., 2012) or matrix completion (Bailly et al., 2013). These novel perspectives offer strong theoretical guarantees but are not designed to achieve competitive empirical results.

In this paper, we suggest a different approach, to provide a first step to bridging this theory-experiment gap. More specifically, we approach unsupervised constituent parsing from the perspective of *structure learning* as opposed to parameter learning. We associate each sentence with an undirected latent tree graphical model, which is a tree consisting of both observed variables (corresponding to the words in the sentence) and an additional set of latent variables that are unobserved in the data. This undirected latent tree is then directed via a *direction mapping* to give the final constituent parse.

In our framework, parsing reduces to finding the best latent structure for a given sentence. However, due to the presence of latent variables, structure learning of latent trees is substantially more complicated than in observed models. As before, one solution would be local search heuristics.

Intuitively, however, latent tree models encode low rank dependencies among the observed variables permitting the development of "spec-

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1062–1072,
Baltimore, Maryland, USA, June 23-25 2014.

tral" methods that can lead to provably correct solutions. In particular we leverage the concept of additive tree metrics (Buneman, 1971; Buneman, 1974) in phylogenetics and machine learning that can create a special distance metric among the observed variables as a function of the underlying spectral dependencies (Choi et al., 2011; Song et al., 2011; Anandkumar et al., 2011; Ishteva et al., 2012). Additive tree metrics can be leveraged by "meta-algorithms" such as neighbor-joining (Saitou and Nei, 1987) and recursive grouping (Choi et al., 2011) to provide consistent learning algorithms for latent trees.

Moreover, we show that it is desirable to learn the "minimal" latent tree based on the tree metric ("minimum evolution" in phylogenetics). While this criterion is in general NP-hard (Desper and Gascuel, 2005), for projective trees we find that a bilexical parsing algorithm can be used to find an exact solution efficiently (Eisner and Satta, 1999).

Unlike in phylogenetics and graphical models, where a single latent tree is constructed for all the data, in our case, each part of speech sequence is associated with its own parse tree. This leads to a severe data sparsity problem even for moderately long sentences. To handle this issue, we present a strategy that is inspired by ideas from kernel smoothing in the statistics community (Zhou et al., 2010; Kolar et al., 2010b; Kolar et al., 2010a). This allows principled sharing of samples from different but similar underlying distributions.

We provide theoretical guarantees on the recovery of the correct underlying latent tree and characterize the associated sample complexity under our technique. Empirically we evaluate our method on data in English, German and Chinese. Our algorithm performs favorably to Klein and Manning's (2002) constituent-context model (CCM), without the need for careful initialization. In addition, we also analyze CCM's sensitivity to initialization, and compare our results to Seginer's algorithm (Seginer, 2007).

2 Learning Setting and Model

In this section, we detail the learning setting and a conditional tree model we learn the structure for.

2.1 Learning Setting

Let $\boldsymbol{w} = (w_1, ..., w_\ell)$ be a vector of words corresponding to a sentence of length ℓ. Each w_i is represented by a vector in $\mathbb{R}^p$ for $p \in \mathbb{N}$. The vector is an embedding of the word in some space, chosen from a fixed dictionary that maps word types to $\mathbb{R}^p$. In addition, let $\boldsymbol{x} = (x_1, ..., x_\ell)$ be the associated vector of part-of-speech (POS) tags (i.e. x_i is the POS tag of w_i).

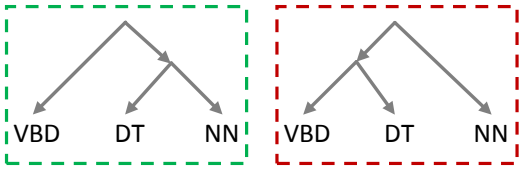

Figure 2: Candidate constituent parses for $\boldsymbol{x} = (\texttt{VBD}, \texttt{DT}, \texttt{NN})$ (left-correct, right -incorrect)

In our learning algorithm, we assume that examples of the form $(\boldsymbol{w}^{(i)}, \boldsymbol{x}^{(i)})$ for $i \in [N] = \{1, \ldots, N\}$ are given, and the goal is to predict a bracketing parse tree for each of these examples. The word embeddings are used during the learning process, but the final decoder that the learning algorithm outputs maps a POS tag sequence $\boldsymbol{x}$ to a parse tree. While ideally we would want to use the word information in decoding as well, much of the syntax of a sentence is determined by the POS tags, and relatively high level of accuracy can be achieved by learning, for example, a supervised parser from POS tag sequences.

Just like our decoder, our model assumes that the bracketing of a given sentence is a function of its POS tags. The POS tags are generated from some distribution, followed by a deterministic generation of the bracketing parse tree. Then, latent states are generated for each bracket, and finally, the latent states at the yield of the bracketing parse tree generate the words of the sentence (in the form of embeddings). The latent states are represented by vectors $z \in \mathbb{R}^m$ where $m < p$.

2.2 Intuition

For intuition, consider the simple tag sequence $\boldsymbol{x} = (\texttt{VBD}, \texttt{DT}, \texttt{NN})$. Two candidate constituent parse structures are shown in Figure 2 and the correct one is boxed in green (the other in red). Recall that our training data contains word phrases that have the tag sequence $\boldsymbol{x}$ e.g. $\boldsymbol{w}^{(1)} = (\texttt{hit}, \texttt{the}, \texttt{ball})$, $\boldsymbol{w}^{(2)} = (\texttt{ate}, \texttt{an}, \texttt{apple})$.

Intuitively, the words in the above phrases exhibit dependencies that can reveal the parse structure. The determiner (w_2) and the direct object (w_3) are correlated in that the choice of determiner depends on the plurality of w_3. However, the choice of verb (w_1) is mostly independent of the determiner. We could thus conclude that w_2 and w_3 should be closer in the parse tree than w_1

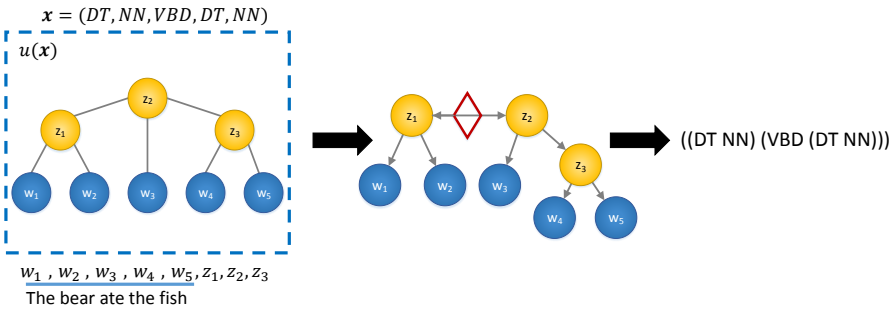

Figure 1: Example for the tag sequence (DT, NN, VBD, DT, NN) showing the overview of our approach. We first learn a undirected latent tree for the sequence (left). We then apply a direction mapping h_{dir} to direct the latent tree (center). This can then easily be converted into a bracketing (right).

and w_2, giving us the correct structure. Informally, the latent state z corresponding to the (w_2, w_3) bracket would store information about the plurality of z, the key to the dependence between w_2 and w_3. It would then be reasonable to assume that w_2 and w_3 are independent given z.

2.3 A Conditional Latent Tree Model

Following this intuition, we propose to model the distribution over the latent bracketing states and words for each tag sequence $\boldsymbol{x}$ as a latent tree graphical model, which encodes conditional independences among the words given the latent states.

Let $\mathcal{V} := \{w_1, ..., w_\ell, z_1, ..., z_H\}$, with w_i representing the word embeddings, and z_i representing the latent states of the bracketings. Then, according to our base model it holds that:

$$p(\boldsymbol{w}, \boldsymbol{z}|\boldsymbol{x}) = \prod_{i=1}^{H} p(z_i|\pi_{\boldsymbol{x}}(z_i), \theta(\boldsymbol{x})) \times \prod_{i=1}^{\ell(\boldsymbol{x})} p(w_i|\pi_{\boldsymbol{x}}(w_i), \theta(\boldsymbol{x})) \quad (1)$$

where $\pi_{\boldsymbol{x}}(\cdot)$ returns the parent node index of the argument in the latent tree corresponding to tag sequence $\boldsymbol{x}$.[1] If z is the root, then $\pi_{\boldsymbol{x}}(z) = \emptyset$. All the w_i are assumed to be leaves while all the z_i are internal (i.e. non-leaf) nodes. The parameters $\theta(\boldsymbol{x})$ control the conditional probability tables. We do not commit to a certain parametric family, but see more about the assumptions we make about θ in §3.2. The parameter space is denoted Θ. The model assumes a factorization according to a latent-variable tree. The latent variables can incorporate various linguistic properties, such as head information, valence of dependency being generated, and so on. This information is expected to be learned automatically from data.

Our generative model deterministically maps a POS sequence to a bracketing via an undirected latent-variable tree. The orientation of the tree is determined by a *direction mapping* $h_{\text{dir}}(u)$, which is fixed during learning and decoding. This means our decoder first identifies (given a POS sequence) an undirected tree, and then orients it by applying h_{dir} on the resulting tree (see below).

Define $\mathcal{U}$ to be the set of undirected latent trees where all internal nodes have degree exactly 3 (i.e. they correspond to binary bracketing), and in addition $h_{\text{dir}}(u)$ for any $u \in \mathcal{U}$ is projective (explained in the h_{dir} section). In addition, let $\mathcal{T}$ be the set of binary bracketings. The complete generative model that we follow is then:

- Generate a tag sequence $\boldsymbol{x} = (x_1, \ldots, x_\ell)$
- Decide on $u(\boldsymbol{x}) \in \mathcal{U}$, the undirected latent tree that $\boldsymbol{x}$ maps to.
- Set $t \in \mathcal{T}$ by computing $t = h_{\text{dir}}(u)$.
- Set $\theta \in \Theta$ by computing $\theta = \theta(\boldsymbol{x})$.
- Generate a tuple $\boldsymbol{v} = (w_1, \ldots, w_\ell, z_1, ..., z_H)$ where $w_i \in \mathbb{R}^p, z_j \in \mathbb{R}^m$ according to Eq. 1.

See Figure 1 (left) for an example.

The Direction Mapping h_{dir}. Generating a bracketing via an undirected tree enables us to build on existing methods for structure learning of latent-tree graphical models (Choi et al., 2011; Anandkumar et al., 2011). Our learning algorithm focuses on recovering the undirected tree based for the generative model that was described above. This undirected tree is converted into a directed tree by applying h_{dir}. The mapping h_{dir} works in three steps:

- It first chooses a top bracket $([1, R-1], [R, \ell])$ where R is the mid-point of the bracket and ℓ is the length of the sentence.
- It marks the edge $e_{i,j}$ that splits the tree according to the top bracket as the "root edge" (marked in red in Figure 1(center))
- It then creates t from u by directing the tree outward from $e_{i,j}$ as shown in Figure 1(center)

[1] At this point, π refers to an arbitrary direction of the undirected tree $u(\boldsymbol{x})$.

The resulting t is a binary bracketing parse tree. As implied by the above definition of h_{dir}, selecting which edge is the root can be interpreted as determining the top bracket of the constituent parse. For example, in Figure 1, the top bracket is $([1,2],[3,5]) = ([\texttt{DT},\texttt{NN}],[\texttt{VBD},\texttt{DT},\texttt{NN}])$. Note that the "root" edge e_{z_1,z_2} partitions the leaves into precisely this bracketing. As indicated in the above section, we restrict the set of undirected trees to be those such that after applying h_{dir} the resulting t is projective i.e. there are no crossing brackets. In §4.1, we discuss an effective heuristic to find the top bracket without supervision.

3 Spectral Learning Algorithm based on Additive Tree Metrics

Our goal is to recover $t \in \mathcal{T}$ for tag sequence $\boldsymbol{x}$ using the data $\mathcal{D} = [(\boldsymbol{w}^{(i)}, \boldsymbol{x}^{(i)})]_{i=1}^{N}$. To get an intuition about the algorithm, consider a partition of the set of examples $\mathcal{D}$ into $\mathcal{D}(\boldsymbol{x}) = \{(\boldsymbol{w}^{(i)}, \boldsymbol{x}^{(i)}) \in \mathcal{D} | \boldsymbol{x}^{(i)} = \boldsymbol{x}\}$, i.e. each section in the partition has an identical sequence of part of speech tags. Assume for this section $|\mathcal{D}(\boldsymbol{x})|$ is large (we address the data sparsity issue in §3.4).

We can then proceed by learning how to map a POS sequence $\boldsymbol{x}$ to a tree $t \in \mathcal{T}$ (through $u \in \mathcal{U}$) by focusing only on examples in $\mathcal{D}(\boldsymbol{x})$.

Directly attempting to maximize the likelihood unfortunately results in an intractable optimization problem and greedy heuristics are often employed (Harmeling and Williams, 2011). Instead we propose a method that is provably consistent and returns a tree that can be mapped to a bracketing using h_{dir}.

If all the variables were observed, then the Chow-Liu algorithm (Chow and Liu, 1968) could be used to find the most likely tree structure $u \in \mathcal{U}$. The Chow-Liu algorithm essentially computes the distances among all pairs of variables (the negative of the mutual information) and then finds the minimum cost tree. However, the fact that the z_i are latent variables makes this strategy substantially more complicated. In particular, it becomes challenging to compute the distances among pairs of latent variables. What is needed is a "special" distance function that allows us to reverse engineer the distances among the latent variables given the distances among the observed variables. This is the key idea behind additive tree metrics that are the basis of our approach.

In the following sections, we describe the key steps to our method. §3.1 and §3.2 largely describe existing background on additive tree metrics and latent tree structure learning, while §3.3 and §3.4 discuss novel aspects that are unique to our problem.

3.1 Additive Tree Metrics

Let $u(\boldsymbol{x})$ be the true undirected tree of sentence $\boldsymbol{x}$ and assume the nodes $\mathcal{V}$ to be indexed by $[M] = \{1, \ldots, M\}$ such that $M = |\mathcal{V}| = H + \ell$. Furthermore, let $v \in \mathcal{V}$ refer to a node in the undirected tree (either observed or latent). We assume the existence of a distance function that allows us to compute distances between pairs of nodes. For example, as we see in §3.2 we will define the distance $d(i,j)$ to be a function of the covariance matrix $\mathbb{E}[v_i v_j^\top | u(\boldsymbol{x}), \theta(\boldsymbol{x})]$. Thus if v_i and v_j are both observed variables, the distance can be directly computed from the data.

Moreover, the metrics we construct are such that they are *tree additive*, defined below:

Definition 1 *A function $d_{u(\boldsymbol{x})} : [M] \times [M] \to \mathbb{R}$ is an* additive tree metric *(Erdős et al., 1999) for the undirected tree $u(\boldsymbol{x})$ if it is a distance metric,[2] and furthermore, $\forall i, j \in [M]$ the following relation holds:*

$$d_{u(\boldsymbol{x})}(i,j) = \sum_{(a,b) \in \text{path}_{u(\boldsymbol{x})}(i,j)} d_{u(\boldsymbol{x})}(a,b) \quad (2)$$

where $\text{path}_{u(\boldsymbol{x})}(i,j)$ is the set of all the edges in the (undirected) path from i to j in the tree $u(\boldsymbol{x})$.

As we describe below, given the tree structure, the additive tree metric property allows us to compute "backwards" the distances among the latent variables as a function of the distances among the observed variables.

Define $\boldsymbol{D}$ to be the $M \times M$ distance matrix among the M variables, i.e. $D_{ij} = d_{u(\boldsymbol{x})}(i,j)$. Let $\boldsymbol{D}_{WW}$, $\boldsymbol{D}_{ZW}$ (equal to $\boldsymbol{D}_{WZ}^\top$), and $\boldsymbol{D}_{ZZ}$ indicate the word-word, latent-word and latent-latent sub-blocks of $\boldsymbol{D}$ respectively. In addition, since $u(\boldsymbol{x})$ is assumed to be known from context, we denote $d_{u(\boldsymbol{x})}(i,j)$ just by $d(i,j)$.

Given the fact that the distance between a pair of nodes is a function of the random variables they represent (according to the true model), only $\boldsymbol{D}_{WW}$ can be empirically estimated from data. However, if the underlying tree structure is known, then Definition 1 can be leveraged to compute $\boldsymbol{D}_{ZZ}$ and $\boldsymbol{D}_{ZW}$ as we show below.

[2] This means that it satisfies $d(i,j) = 0$ if and only if $i = j$, the triangle inequality and is also symmetric.

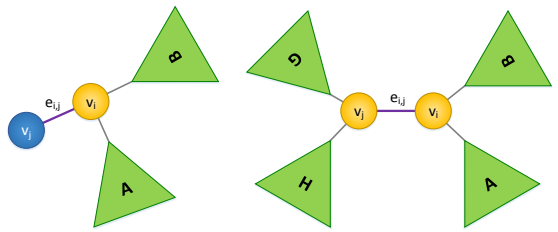

Figure 3: Two types of edges in general undirected latent trees. (a) leaf edge, (b) internal edge

We first show how to compute $d(i,j)$ for all i,j such that i and j are adjacent to each other in $u(\boldsymbol{x})$, based only on observed nodes. It then follows that the other elements of the distance matrix can be computed based on Definition 1. To show how to compute distances between adjacent nodes, consider the two cases: **(1)** (i,j) is a leaf edge; **(2)** (i,j) is an internal edge.

Case 1 (leaf edge, figure 3(a)) Assume without loss of generality that j is the leaf and i is an internal latent node. Then i must have exactly two other neighbors $a \in [M]$ and $b \in [M]$. Let A denote the set of nodes that are closer to a than i and similarly let B denote the set of nodes that are closer to b than i. Let A^* and B^* denote all the leaves (word nodes) in A and B respectively. Then using path additivity (Definition 1), it can be shown that for any $a^* \in A^*, b^* \in B^*$ it holds that:

$$d(i,j) = \frac{1}{2}\left(d(j,a^*) + d(j,b^*) - d(a^*,b^*)\right) \quad (3)$$

Note that the right-hand side only depends on distances between observed random variables.

Case 2 (internal edge, figure 3(b)) Both i and j are internal nodes. In this case, i has exactly two other neighbors $a \in [M]$ and $b \in [M]$, and similarly, j has exactly other two neighbors $g \in [M]$ and $h \in [M]$. Let A denote the set of nodes closer to a than i, and analogously for B, G, and H. Let A^*, B^*, G^*, and H^* refer to the leaves in A, B, G, and H respectively. Then for any $a^* \in A^*$, $b^* \in B^*$, $g^* \in G^*$, and $h^* \in H^*$ it can be shown that:

$$d(i,j) = \tfrac{1}{4}\Big(d(a^*,g^*) + d(a^*,h^*) + d(b^*,g^*) + d(b^*,h^*) - 2d(a^*,b^*) - 2d(g^*,h^*)\Big) \quad (4)$$

Empirically, one can obtain a more robust empirical estimate $\widehat{d}(i,j)$ by averaging over all valid choices of a^*, b^* in Eq. 3 and all valid choices of a^*, b^*, g^*, h^* in Eq. 4 (Desper and Gascuel, 2005).

3.2 Constructing a Spectral Additive Metric

In constructing our distance metric, we begin with the following assumption on the distribution in Eq. 1 (analogous to the assumptions made in Anandkumar et al., 2011).

Assumption 1 (Linear, Rank m, Means)

$$\mathbb{E}[z_i|\pi_{\boldsymbol{x}}(z_i), \boldsymbol{x}] = \boldsymbol{A}_{(z_i|z_{\pi_{\boldsymbol{x}}(z_i)},\boldsymbol{x})}\pi_{\boldsymbol{x}}(z_i)\ \forall i \in [H]$$

where $\boldsymbol{A}_{(z_i|\pi_{\boldsymbol{x}}(z_i),\boldsymbol{x})} \in \mathbb{R}^{m\times m}$ *has rank* m.

$$\mathbb{E}[w_i|\pi_{\boldsymbol{x}}(w_i), \boldsymbol{x}] = \boldsymbol{C}_{(w_i|\pi_{\boldsymbol{x}}(w_i),\boldsymbol{x})}\pi_{\boldsymbol{x}}(w_i)\ \forall i \in [\ell(\boldsymbol{x})]$$

where $\boldsymbol{C}_{(w_i|\pi_{\boldsymbol{x}}(w_i),\boldsymbol{x})} \in \mathbb{R}^{p\times m}$ *has rank* m.

Also assume that $\mathbb{E}[z_i z_i^\top|\boldsymbol{x}]$ *has rank* $m\ \forall i \in [H]$.

Note that the matrices $\boldsymbol{A}$ and $\boldsymbol{C}$ are a direct function of $\theta(\boldsymbol{x})$, but we do not specify a model family for $\theta(\boldsymbol{x})$. The only restriction is in the form of the above assumption. If w_i and z_i were discrete, represented as binary vectors, the above assumption would correspond to requiring all conditional probability tables in the latent tree to have rank m. Assumption 1 allows for the w_i to be high dimensional features, as long as the expectation requirement above is satisfied. Similar assumptions are made with spectral parameter learning methods e.g. Hsu et al. (2009), Bailly et al. (2009), Parikh et al. (2011), and Cohen et al. (2012).

Furthermore, Assumption 1 makes it explicit that regardless of the size of p, the relationships among the variables in the latent tree are restricted to be of rank m, and are thus *low rank* since $p > m$. To leverage this low rank structure, we propose using the following additive metric, a normalized variant of that in Anandkumar et al. (2011):

$$d^{\text{spectral}}(i,j) = -\log\Lambda_m(\boldsymbol{\Sigma}_{\boldsymbol{x}}(i,j)) + \tfrac{1}{2}\log\Lambda_m(\boldsymbol{\Sigma}_{\boldsymbol{x}}(i,i)) + \tfrac{1}{2}\log\Lambda_m(\boldsymbol{\Sigma}_{\boldsymbol{x}}(j,j)) \quad (5)$$

where $\Lambda_m(\boldsymbol{A})$ denotes the product of the top m singular values of $\boldsymbol{A}$ and $\boldsymbol{\Sigma}_{\boldsymbol{x}}(i,j) := \mathbb{E}[v_i v_j^\top|\boldsymbol{x}]$, i.e. the uncentered cross-covariance matrix.

We can then show that this metric is additive:

Lemma 1 *If Assumption 1 holds then,* d^{spectral} *is an additive tree metric (Definition 1).*

A proof is in the supplementary for completeness. From here, we use d to denote d^{spectral}, since that is the metric we use for our learning algorithm.

3.3 Recovering the Minimal Projective Latent Tree

It has been shown (Rzhetsky and Nei, 1993) that for any additive tree metric, $u(\boldsymbol{x})$ can be recovered by solving $\arg\min_{u \in \mathcal{U}} c(u)$ for $c(u)$:

$$c(u) = \sum_{(i,j) \in \mathcal{E}_u} d(i,j). \quad (6)$$

where $\mathcal{E}_u$ is the set of pairs of nodes which are adjacent to each other in u and $d(i,j)$ is computed using Eq. 3 and Eq. 4.

Note that the metric d we use in defining $c(u)$ is based on the expectations from the true distribution. In practice, the true distribution is unknown, and therefore we use an approximation for the distance metric $\hat{d}$. As we discussed in §3.1 all elements of the distance matrix are functions of observable quantities if the underlying tree u is known. However, only the word-word sub-block $\boldsymbol{D}_{WW}$ can be directly estimated from the data without knowledge of the tree structure.

This subtlety makes solving the minimization problem in Eq. 6 NP-hard (Desper and Gascuel, 2005) if u is allowed to be an arbitrary undirected tree. However, if we restrict u to be in $\mathcal{U}$, as we do in the above, then maximizing $\hat{c}(u)$ over $\mathcal{U}$ can be solved using the bilexical parsing algorithm from Eisner and Satta (1999). This is because the computation of the other sub-blocks of the distance matrix only depend on the partitions of the nodes shown in Figure 3 into A, B, G, and H, and not on the entire tree structure.

Therefore, the procedure to find a bracketing for a given POS tag $\boldsymbol{x}$ is to first estimate the distance matrix sub-block $\widehat{\boldsymbol{D}}_{WW}$ from raw text data (see §3.4), and then solve the optimization problem $\arg\min_{u \in \mathcal{U}} \hat{c}(u)$ using a variant of the Eisner-Satta algorithm where $\hat{c}(u)$ is identical to $c(u)$ in Eq. 6, with d replaced with $\hat{d}$.

Summary. We first defined a generative model that describes how a sentence, its sequence of POS tags, and its bracketing is generated (§2.3). First an undirected $u \in \mathcal{U}$ is generated (only as a function of the POS tags), and then u is mapped to a bracketing using a direction mapping h_{dir}. We then showed that we can define a distance metric between nodes in the undirected tree, such that minimizing it leads to a recovery of u. This distance metric can be computed based only on the text, without needing to identify the latent information (§3.2). If the true distance metric is known, with respect to the true distribution that generates the words in a sentence, then u can be fully recovered by optimizing the cost function $c(u)$. However, in practice the distance metric must be estimated from data, as discussed below.

Algorithm 1 The learning algorithm for finding the latent structure from a set of examples $(\boldsymbol{w}^{(i)}, \boldsymbol{x}^{(i)})$, $i \in [N]$.

Inputs: Set of examples $(\boldsymbol{w}^{(i)}, \boldsymbol{x}^{(i)})$ for $i \in [N]$, a kernel $K_\gamma(j,k,j',k'|\boldsymbol{x},\boldsymbol{x}')$, an integer m

Data structures: For each $i \in [N], j,k \in \ell(\boldsymbol{x}^{(i)})$ there is a (uncentered) covariance matrix $\widehat{\boldsymbol{\Sigma}}_{\boldsymbol{x}^{(i)}}(j,k) \in \mathbb{R}^{p \times p}$, and a distance $\hat{d}^{\text{spectral}}(j,k)$.

Algorithm:

(Covariance estimation) $\forall i \in [N], j,k \in \ell(\boldsymbol{x}^{(i)})$

- Let $C_{j',k'|i'} = w^{(i')}_{j'} (w^{(i')}_{k'})^\top$, $k_{j,k,j',k',i,i'} = K_\gamma(j,k,j',k'|\boldsymbol{x}^{(i)}, \boldsymbol{x}^{(i')})$ and $\ell_{i'} = \ell(\boldsymbol{x}^{(i')})$, and estimate each $p \times p$ covariance matrix as:

$$\widehat{\boldsymbol{\Sigma}}_{\boldsymbol{x}}(j,k) = \frac{\sum_{i'=1}^{N} \sum_{j'=1}^{\ell_{i'}} \sum_{k'=1}^{\ell_{i'}} k_{j,k,j',k',i,i'} C_{j',k'|i'}}{\sum_{i'=1}^{N} \sum_{j'=1}^{\ell_{i'}} \sum_{k'=1}^{\ell_{i'}} k_{j,k,j',k',i,i'}}$$

- Compute $\hat{d}^{\text{spectral}}(j,k)$ $\forall j,k \in \ell(\boldsymbol{x}^{(i)})$ using Eq. 5.

(Uncover structure) $\forall i \in [N]$

- Find $\hat{u}^{(i)} = \arg\min_{u \in \mathcal{U}} \hat{c}(u)$, and for the ith example, return the structure $h_{\text{dir}}(\hat{u}^{(i)})$.

3.4 Estimation of d from Sparse Data

We now address the data sparsity problem, in particular that $\mathcal{D}(\boldsymbol{x})$ can be very small, and therefore estimating d for each POS sequence separately can be problematic.[3]

In order to estimate d from data, we need to estimate the covariance matrices $\boldsymbol{\Sigma}_{\boldsymbol{x}}(i,j)$ (for $i,j \in \{1,\ldots,\ell(\boldsymbol{x})\}$) from Eq. 5.

To give some motivation to our solution, consider estimating the covariance matrix $\boldsymbol{\Sigma}_{\boldsymbol{x}}(1,2)$ for the tag sequence $\boldsymbol{x} = (\texttt{DT}_1, \texttt{NN}_2, \texttt{VBD}_3, \texttt{DT}_4, \texttt{NN}_5)$. $\mathcal{D}(\boldsymbol{x})$ may be insufficient for an accurate empirical es-

[3] This data sparsity problem is quite severe – for example, the Penn treebank (Marcus et al., 1993) has a total number of 43,498 sentences, with 42,246 *unique* POS tag sequences, averaging $|\mathcal{D}(\boldsymbol{x})|$ to be 1.04.

timate. However, consider another sequence $\boldsymbol{x}' = (\texttt{RB}_1, \texttt{DT}_2, \texttt{NN}_3, \texttt{VBD}_4, \texttt{DT}_5, \texttt{ADJ}_6, \texttt{NN}_7)$. Although $\boldsymbol{x}$ and $\boldsymbol{x}'$ are not identical, it is likely that $\boldsymbol{\Sigma}_{\boldsymbol{x}'}(2,3)$ is similar to $\boldsymbol{\Sigma}_{\boldsymbol{x}}(1,2)$ because the determiner and the noun appear in similar syntactic context. $\boldsymbol{\Sigma}_{\boldsymbol{x}'}(5,7)$ also may be somewhat similar, but $\boldsymbol{\Sigma}_{\boldsymbol{x}'}(2,7)$ should not be very similar to $\boldsymbol{\Sigma}_{\boldsymbol{x}}(1,2)$ because the noun and the determiner appear in a different syntactic context.

The observation that the covariance matrices depend on local syntactic context is the main driving force behind our solution. The local syntactic context acts as an "anchor," which enhances or replaces a word index in a sentence with local syntactic context. More formally, an anchor is a function G that maps a word index j and a sequence of POS tags $\boldsymbol{x}$ to a local context $G(j, \boldsymbol{x})$. The anchor we use is $G(j, \boldsymbol{x}) = (j, x_j)$. Then, the covariance matrices $\boldsymbol{\Sigma}_{\boldsymbol{x}}$ are estimated using kernel smoothing (Hastie et al., 2009), where the smoother tests similarity between the different anchors $G(j, \boldsymbol{x})$.

The full learning algorithm is given in Figure 1. The first step in the algorithm is to estimate the covariance matrix block $\widehat{\boldsymbol{\Sigma}}_{\boldsymbol{x}^{(i)}}(j,k)$ for each training example $\boldsymbol{x}^{(i)}$ and each pair of preterminal positions (j,k) in $\boldsymbol{x}^{(i)}$. Instead of computing this block by computing the empirical covariance matrix for positions (j,k) in the data $\mathcal{D}(\boldsymbol{x})$, the algorithm uses all of the pairs (j',k') from all of N training examples. It averages the empirical covariance matrices from these contexts using a kernel weight, which gives a similarity measure for the position (j,k) in $\boldsymbol{x}^{(i)}$ and (j',k') in another example $\boldsymbol{x}^{(i')}$. γ is the kernel "bandwidth", a user-specified parameter that controls how inclusive the kernel will be with respect to examples in $\mathcal{D}$ (see § 4.1 for a concrete example). Note that the learning algorithm is such that it ensures that $\widehat{\boldsymbol{\Sigma}}_{\boldsymbol{x}^{(i)}}(j,k) = \widehat{\boldsymbol{\Sigma}}_{\boldsymbol{x}^{(i')}}(j',k')$ if $G(j, \boldsymbol{x}^{(i)}) = G(j', \boldsymbol{x}^{(i')})$ and $G(k, \boldsymbol{x}^{(i)}) = G(k', \boldsymbol{x}^{(i')})$.

Once the empirical estimates for the covariance matrices are obtained, a variant of the Eisner-Satta algorithm is used, as mentioned in §3.3.

3.5 Theoretical Guarantees

Our main theoretical guarantee is that Algorithm 1 will recover the correct tree $u \in \mathcal{U}$ with high probability, if the given top bracket is correct and if we obtain enough examples $(\boldsymbol{w}^{(i)}, \boldsymbol{x}^{(i)})$ from the model in §2. We give the theorem statement below. The constants lurking in the O-notation and the full proof are in the supplementary.

Denote $\sigma_{\boldsymbol{x}}(j,k)^{(r)}$ as the r^{th} singular value of $\boldsymbol{\Sigma}_{\boldsymbol{x}}(j,k)$. Let $\sigma^*(x) := \min_{j,k \in \ell(\boldsymbol{x})} \min\left(\sigma_{\boldsymbol{x}}(j,k)^{(m)}\right)$.

Theorem 1 *Define $\hat{u}$ as the estimated tree for tag sequence $\boldsymbol{x}$ and $u(\boldsymbol{x})$ as the correct tree. Let*

$$\triangle(\boldsymbol{x}) := \min_{u' \in \mathcal{U}: u' \neq u(\boldsymbol{x})} (c(u(\boldsymbol{x})) - c(u'))/(8|\ell(\boldsymbol{x})|)$$

Assume that

$$N \geq \mathcal{O}\left(\frac{m^2 \log\left(\frac{p^2 \ell(\boldsymbol{x})^2}{\delta}\right)}{\min(\sigma^*(\boldsymbol{x})^2 \triangle(\boldsymbol{x})^2, \sigma^*(\boldsymbol{x})^2)\nu_{\boldsymbol{x}}(\gamma)^2}\right)$$

Then with probability $1-\delta$, $\hat{u} = u(\boldsymbol{x})$.

where $\nu_{\boldsymbol{x}}(\gamma)$, defined in the supplementary, is a function of the underlying distribution over the tag sequences $\boldsymbol{x}$ and the kernel bandwidth γ.

Thus, the sample complexity of our approach depends on the dimensionality of the latent and observed states (m and p), the underlying singular values of the cross-covariance matrices ($\sigma^*(\boldsymbol{x})$) and the difference in the cost of the true tree compared to the cost of the incorrect trees ($\triangle(\boldsymbol{x})$).

4 Experiments

We report results on three different languages: English, German, and Chinese. For English we use the Penn treebank (Marcus et al., 1993), with sections 2–21 for training and section 23 for final testing. For German and Chinese we use the Negra treebank and the Chinese treebank respectively and the first 80% of the sentences are used for training and the last 20% for testing. All punctuation from the data is removed.[4]

We primarily compare our method to the constituent-context model (CCM) of Klein and Manning (2002). We also compare our method to the algorithm of Seginer (2007).

4.1 Experimental Settings

Top bracket heuristic Our algorithm requires the top bracket in order to direct the latent tree. In practice, we employ the following heuristic to find the bracket using the following three steps:

- If there exists a comma/semicolon/colon at index i that has at least a verb before i and both a noun followed by a verb after i, then return $([0, i-1], [i, \ell(x)])$ as the top bracket. (Pick the rightmost comma/semicolon/colon if multiple satisfy the criterion).

[4]We make brief use of punctuation for our top bracket heuristic detailed below before removing it.

Length	CCM	CCM-U	CCM-OB	CCM-UB
≤ 10	72.5	57.1	58.2	62.9
≤ 15	54.1	36	24	23.7
≤ 20	50	34.7	19.3	19.1
≤ 25	47.2	30.7	16.8	16.6
≤ 30	44.8	29.6	15.3	15.2
≤ 40	26.3	13.5	13.9	13.8

Table 1: Comparison of different CCM variants on English (training). U stands for universal POS tagset, OB stands for conjoining original POS tags with Brown clusters and UB stands for conjoining universal POS tags with Brown clusters. The best setting is just the vanilla setting, CCM.

- Otherwise find the first non-participle verb (say at index j) and return $([0, j-1], [j, \ell(\boldsymbol{x})])$.
- If no verb exists, return $([0, 1], [1, \ell(\boldsymbol{x})])$.

Word embeddings As mentioned earlier, each w_i can be an arbitrary feature vector. For all languages we use Brown clustering (Brown et al., 1992) to construct a $\log(C) + C$ feature vector where the first $\log(C)$ elements indicate which mergable cluster the word belongs to, and the last C elements indicate the cluster identity. For English, more sophisticated word embeddings are easily obtainable, and we experiment with neural word embeddings Turian et al. (2010) of length 50. We also explored two types of CCA embeddings: OSCCA and TSCCA, given in Dhillon et al. (2012). The OSCCA embeddings behaved better, so we only report its results.

Choice of kernel For our experiments, we use the kernel

$$K_\gamma(j,k,j',k'|\boldsymbol{x},\boldsymbol{x}') = \max\left\{0, 1 - \frac{\kappa(j,k,j',k'|\boldsymbol{x},\boldsymbol{x}')}{\gamma}\right\}$$

where γ denotes the user-specified bandwidth, and $\kappa(j,k,j',k'|\boldsymbol{x},\boldsymbol{x}') = \dfrac{|j-k|-|j'-k'|}{|j-k|+|j'-k'|}$ if $\boldsymbol{x}(j) = \boldsymbol{x}(j')$ and $\boldsymbol{x}(k') = \boldsymbol{x}(k)$, and $\text{sign}(j-k) = \text{sign}(j'-k')$ (and ∞ otherwise).

The kernel is non-zero if and only if the tags at position j and k in $\boldsymbol{x}$ are identical to the ones in position j' and k' in $\boldsymbol{x}'$, and if the direction between j and k is identical to the one between j' and k'. Note that the kernel is not binary, as opposed to the theoretical kernel in the supplementary material. Our experiments show that using a non-zero value different than 1 that is a function of the distance between j and k compared to the distance between j' and k' does better in practice.

Choice of data For CCM, we found that if the full dataset (all sentence lengths) is used in training, then performance degrades when evaluating on sentences of length ≤ 10. We therefore restrict the data used with CCM to sentences of length $\leq \ell$, where ℓ is the maximal sentence length being evaluated. This does not happen with our algorithm, which manages to leverage lexical information whenever more data is available. We therefore use the full data for our method for all lengths.

We also experimented with the original POS tags and the universal POS tags of Petrov et al. (2011). Here, we found out that our method does better with the universal part of speech tags. For CCM, we also experimented with the original parts of speech, universal tags (CCM-U), the cross-product of the original parts of speech with the Brown clusters (CCM-OB), and the cross-product of the universal tags with the Brown clusters (CCM-UB). The results in Table 1 indicate that the vanilla setting is the best for CCM.

Thus, for all results, we use universal tags for our method and the original POS tags for CCM. We believe that our approach substitutes the need for fine-grained POS tags with the lexical information. CCM, on the other hand, is fully unlexicalized.

Parameter Selection Our method requires two parameters, the latent dimension m and the bandwidth γ. CCM also has two parameters, the number of extra constituent/distituent counts used for smoothing. For both methods we chose the best parameters for sentences of length $\ell \leq 10$ on the English Penn Treebank (training) and used this set for all other experiments. This resulted in $m = 7, \gamma = 0.4$ for our method and 2, 8 for CCM's extra constituent/distituent counts respectively. We also tried letting CCM choose different hyperparameters for different sentence lengths based on dev-set likelihood, but this gave worse results than holding them fixed.

4.2 Results

Test I: Accuracy Table 2 summarizes our results. CCM is used with the initializer proposed in Klein and Manning (2002).[5] NN, CC, and BC indicate the performance of our method for neural embeddings, CCA embeddings, and Brown clustering respectively, using the heuristic for h_{dir} de-

Table 2: F_1 bracketing measure for the test sets and train sets in three languages. NN, CC, and BC indicate the performance of our method for neural embeddings, CCA embeddings, and Brown clustering respectively, using the heuristic for h_{dir} described in § 4.1. NN-O, CC-O, and BC-O indicate that the oracle (i.e. true top bracket) was used for h_{dir}.

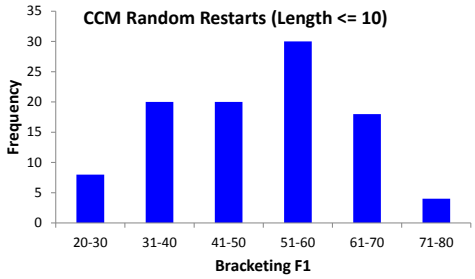

Figure 4: Histogram showing performance of CCM across 100 random restarts for sentences of length ≤ 10.

scribed in § 4.1. NN-O, CC-O, and BC-O indicate that the oracle (i.e. true top bracket) was used for h_{dir}. For our method, test set results can be obtained by using Algorithm 1 (except the distances are computed using the training data).

For English, while CCM behaves better for short sentences ($\ell \leq 10$), our algorithm is more robust with longer sentences. This is especially noticeable for length ≤ 40, where CCM breaks down and our algorithm is more stable. We find that the neural embeddings modestly outperform the CCA and Brown cluster embeddings.

The results for German are similar, except CCM breaks down earlier at sentences of $\ell \leq 30$. For Chinese, our method substantially outperforms CCM for all lengths. Note that CCM performs very poorly, obtaining only around 20% accuracy even for sentences of $\ell \leq 20$. We didn't have neural embeddings for German and Chinese (which worked best for English) and thus only used Brown cluster embeddings.

For English, the disparity between NN-O (oracle top bracket) and NN (heuristic top bracket) is rather low suggesting that our top bracket heuristic is rather effective. However, for German and Chinese note that the "BC-O" performs substantially better, suggesting that if we had a better top bracket heuristic our performance would increase.

Test II: Sensitivity to initialization The EM algorithm with the CCM requires very careful initialization, which is described in Klein and Manning (2002). If, on the other hand, random initialization is used, the variance of the performance of the CCM varies greatly. Figure 4 shows a histogram of the performance level for sentences of length ≤ 10 for different random initializers. As one can see, for some restarts, CCM obtains accuracies lower than 30% due to local optima. Our method does not suffer from local optima and thus does not require careful initialization.

Test III: Comparison to Seginer's algorithm Our approach is not directly comparable to Seginer's because he uses punctuation, while we use POS tags. Using Seginer's parser we were able to get results on the training sets. On English: 75.2% ($\ell \leq 10$), 64.2% ($\ell \leq 20$), 56.7% ($\ell \leq 40$). On German: 57.8% ($\ell \leq 10$), 45.0% ($\ell \leq 20$), and 39.9% ($\ell \leq 40$). On Chinese: 56.6% ($\ell \leq 10$), 45.1% ($\ell \leq 20$), and 38.9% ($\ell \leq 40$).

Thus, while Seginer's method performs better on English, our approach performs 2-3 points better on German, and both methods give similar performance on Chinese.

5 Conclusion

We described a spectral approach for unsupervised constituent parsing that comes with theoretical guarantees on latent structure recovery. Empirically, our algorithm performs favorably to the CCM of Klein and Manning (2002) without the need for careful initialization.

Abstract

Learning phonetic categories is one of the first steps to learning a language, yet is hard to do using only distributional phonetic information. Semantics could potentially be useful, since words with different meanings have distinct phonetics, but it is unclear how many word meanings are known to infants learning phonetic categories. We show that attending to a weaker source of semantics, in the form of a distribution over topics in the current context, can lead to improvements in phonetic category learning. In our model, an extension of a previous model of joint word-form and phonetic category inference, the probability of word-forms is topic-dependent, enabling the model to find significantly better phonetic vowel categories and word-forms than a model with no semantic knowledge.

1 Introduction

Infants begin learning the phonetic categories of their native language in their first year (Kuhl et al., 1992; Polka and Werker, 1994; Werker and Tees, 1984). In theory, semantic information could offer a valuable cue for phoneme induction[1] by helping infants distinguish between minimal pairs, as linguists do (Trubetzkoy, 1939). However, due to a widespread assumption that infants do not know the meanings of many words at the age when they are learning phonetic categories (see Swingley, 2009 for a review), most recent models of early phonetic category acquisition have explored the phonetic learning problem in the absence of semantic information (de Boer and Kuhl, 2003; Dillon et al., 2013; Feldman et al., 2013a; McMurray et al., 2009; Vallabha et al., 2007).

Models without any semantic information are likely to underestimate infants' ability to learn phonetic categories. Infants learn language in the wild, and quickly attune to the fact that words have (possibly unknown) meanings. The extent of infants' semantic knowledge is not yet known, but existing evidence shows that six-month-olds can associate some words with their referents (Bergelson and Swingley, 2012; Tincoff and Jusczyk, 1999, 2012), leverage non-acoustic contexts such as objects or articulations to distinguish similar sounds (Teinonen et al., 2008; Yeung and Werker, 2009), and map meaning (in the form of objects or images) to new word-forms in some laboratory settings (Friedrich and Friederici, 2011; Gogate and Bahrick, 2001; Shukla et al., 2011). These findings indicate that young infants are sensitive to co-occurrences between linguistic stimuli and at least some aspects of the world.

In this paper we explore the potential contribution of semantic information to phonetic learning by formalizing a model in which learners attend to the word-level context in which phones appear (as in the lexical-phonetic learning model of Feldman et al., 2013a) and also to the situations in which word-forms are used. The modeled situations consist of combinations of categories of salient activities or objects, similar to the activity contexts explored by Roy et al. (2012), e.g.,'getting dressed' or 'eating breakfast'. We assume that child learners are able to infer a representation of the situational context from their non-linguistic environment. However, in our simulations we approximate the environmental information by running a topic model (Blei et al., 2003) over a corpus of child-directed speech to infer a topic distribution for each situation. These topic distributions are then used as input to our model to represent situational contexts.

The situational information in our model is simi-

[1] The models in this paper do not distinguish between phonetic and phonemic categories, since they do not capture phonological processes (and there are also none present in our synthetic data). We thus use the terms interchangeably.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1073–1083,
Baltimore, Maryland, USA, June 23-25 2014.

lar to that assumed by theories of cross-situational word learning (Frank et al., 2009; Smith and Yu, 2008; Yu and Smith, 2007), but our model does not require learners to map individual words to their referents. Even in the absence of word-meaning mappings, situational information is potentially useful because similar-sounding words uttered in similar situations are more likely to be tokens of the same lexeme (containing the same phones) than similar-sounding words uttered in different situations.

In simulations of vowel learning, inspired by Vallabha et al. (2007) and Feldman et al. (2013a), we show a clear improvement over previous models in both phonetic and lexical (word-form) categorization when situational context is used as an additional source of information. This improvement is especially noticeable when the word-level context is providing less information, arguably the more realistic setting. These results demonstrate that relying on situational co-occurrence can improve phonetic learning, even if learners do not yet know the meanings of individual words.

2 Background and overview of models

Infants attend to distributional characteristics of their input (Maye et al., 2002, 2008), leading to the hypothesis that phonetic categories could be acquired on the basis of bottom-up distributional learning alone (de Boer and Kuhl, 2003; Vallabha et al., 2007; McMurray et al., 2009). However, this would require sound categories to be well separated, which often is not the case—for example, see Figure 1, which shows the English vowel space that is the focus of this paper.

Recent work has investigated whether infants could overcome such distributional ambiguity by incorporating top-down information, in particular, the fact that phones appear within words. At six months, infants begin to recognize word-forms such as their name and other frequently occurring words (Mandel et al., 1995; Jusczyk and Hohne, 1997), without necessarily linking a meaning to these forms. This "protolexicon" can help differentiate phonetic categories by adding word contexts in which certain sound categories appear (Swingley, 2009; Feldman et al., 2013b). To explore this idea further, Feldman et al. (2013a) implemented the Lexical-Distributional (LD) model, which jointly learns a set of phonetic vowel categories and a set of word-forms containing those categories. Simulations showed that the use of lexical context greatly improved phonetic learning.

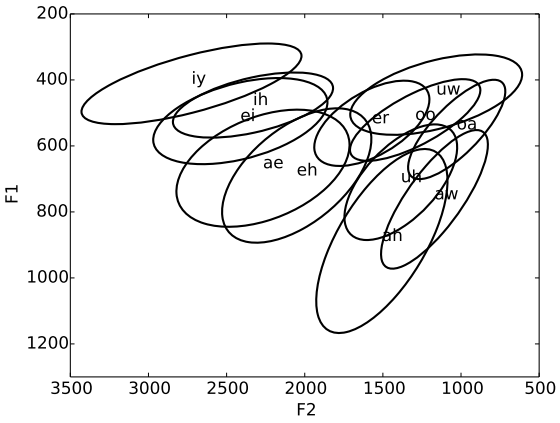

Figure 1: The English vowel space (generated from Hillenbrand et al. (1995), see Section 6.2), plotted using the first two formants.

Our own Topic-Lexical-Distributional (TLD) model extends the LD model to include an additional type of context: the situations in which words appear. To motivate this extension and clarify the differences between the models, we now provide a high-level overview of both models; details are given in Sections 3 and 4.

2.1 Overview of LD model

Both the LD and TLD models are computational-level models of phonetic (specifically, vowel) categorization where phones (vowels) are presented to the model in the context of words.[2] The task is to infer a set of phonetic categories and a set of lexical items on the basis of the data observed for each word token x_i. In the original LD model, the observations for token x_i are its frame f_i, which consists of a list of consonants and slots for vowels, and the list of vowel tokens $\boldsymbol{w}_i$. (The TLD model includes additional observations, described below.) A single vowel token, w_{ij}, is a two dimensional vector representing the first two formants (peaks in the frequency spectrum, ordered from lowest to highest). For example, a token of the word *kitty* would have the frame $f_i = \texttt{k\_t\_}$, containing two consonant phones, /k/ and /t/, with two vowel phone slots in between, and two vowel formant vectors,

[2]For a related model that also tackles the word segmentation problem, see Elsner et al. (2013). In a model of phonological learning, Fourtassi and Dupoux (submitted) show that semantic context information similar to that used here remains useful despite segmentation errors.

$w_{i0} = [464, 2294]$ and $w_{i1} = [412, 2760]$.[3]

Given the data, the model must assign each vowel token to a vowel category, $w_{ij} = c$. Both the LD and the TLD models do this using intermediate lexemes, $\boldsymbol{\ell}$, which contain vowel category assignments, $v_{\ell j} = c$, as well as a frame f_ℓ. If a word token is assigned to a lexeme, $x_i = \ell$, the vowels within the word are assigned to that lexeme's vowel categories, $w_{ij} = v_{\ell j} = c$.[4] The word and lexeme frames must match, $f_i = f_\ell$.

Lexical information helps with phonetic categorization because it can disambiguate highly overlapping categories, such as the *ae* and *eh* categories in Figure 1. A purely distributional learner who observes a cluster of data points in the *ae-eh* region is likely to assume all these points belong to a single category because the distributions of the categories are so similar. However, a learner who attends to lexical context will notice a difference: contexts that only occur with *ae* will be observed in one part of the *ae-eh* region, while contexts that only occur with *eh* will be observed in a different (though partially overlapping) space. The learner then has evidence of two different categories occurring in different sets of lexemes.

Simulations with the LD model show that using lexical information to constrain phonetic learning can greatly improve categorization accuracy (Feldman et al., 2013a), but it can also introduce errors. When two word tokens contain the same consonant frame but different vowels (i.e., minimal pairs), the model is more likely to categorize those two vowels together. Thus, the model has trouble distinguishing minimal pairs. Although young children also have trouble with minimal pairs (Stager and Werker, 1997; Thiessen, 2007), the LD model may overestimate the degree of the problem. We hypothesize that if a learner is able to associate words with the contexts of their use (as children likely are), this could provide a weak source of information for disambiguating minimal pairs even without knowing their exact meanings. That is, if the learner hears kV_1t and kV_2t in different situational contexts, they are likely to be different lexical items (and V_1 and V_2 different phones), despite the lexical similarity between them.

[3] In simulations we also experiment with frames in which consonants are not represented perfectly.

[4] The notation is overloaded: w_{ij} refers both to the vowel formants and the vowel category assignments, and x_i refers to both the token identity and its assignment to a lexeme.

2.2 Overview of TLD model

To demonstrate the benefit of situational information, we develop the Topic-Lexical-Distributional (TLD) model, which extends the LD model by assuming that words appear in *situations* analogous to documents in a topic model. Each situation h is associated with a mixture of topics θ_h, which is assumed to be observed. Thus, for the ith token in situation h, denoted x_{hi}, the observed data will be its frame f_{hi}, vowels $\boldsymbol{w}_{hi}$, and topic vector θ_h.

From an acquisition perspective, the observed topic distribution represents the child's knowledge of the context of the interaction: she can distinguish bathtime from dinnertime, and is able to recognize that some topics appear in certain contexts (e.g. animals on walks, vegetables at dinnertime) and not in others (few vegetables appear at bathtime). We assume that the child would learn these topics from observing the world around her and the co-occurrences of entities and activities in the world. Within any given situation, there might be a mixture of different (actual or possible) topics that are salient to the child. We assume further that as the child learns the language, she will begin to associate specific words with each topic as well.

Thus, in the TLD model, the words used in a situation are topic-dependent, implying meaning, but without pinpointing specific referents. Although the model observes the distribution of topics in each situation (corresponding to the child observing her non-linguistic environment), it must learn to associate each (phonetically and lexically ambiguous) word token with a particular topic from that distribution. The occurrence of similar-sounding words in different situations with mostly non-overlapping topics will provide evidence that those words belong to different topics and that they are therefore different lexemes. Conversely, potential minimal pairs that occur in situations with similar topic distributions are more likely to belong to the same topic and thus the same lexeme.

Although we assume that children infer topic distributions from the non-linguistic environment, we will use transcripts from CHILDES to create the word/phone learning input for our model. These transcripts are not annotated with environmental context, but Roy et al. (2012) found that topics learned from similar transcript data using a topic model were strongly correlated with immediate activities and contexts. We therefore obtain the topic distributions used as input to the TLD model by

training an LDA topic model (Blei et al., 2003) on a superset of the child-directed transcript data we use for lexical-phonetic learning, dividing the transcripts into small sections (the 'documents' in LDA) that serve as our distinct situations $\boldsymbol{h}$. As noted above, the learned document-topic distributions $\boldsymbol{\theta}$ are treated as observed variables in the TLD model to represent the situational context. The topic-word distributions learned by LDA are discarded, since these are based on the (correct and unambiguous) words in the transcript, whereas the TLD model is presented with phonetically ambiguous versions of these word tokens and must learn to disambiguate them and associate them with topics.

3 Lexical-Distributional Model

In this section we describe more formally the generative process for the LD model (Feldman et al., 2013a), a joint Bayesian model over phonetic categories and a lexicon, before describing the TLD extension in the following section.

The set of phonetic categories and the lexicon are both modeled using non-parametric Dirichlet Process priors, which return a potentially infinite number of categories or lexemes. A DP is parametrized as $DP(\alpha, H)$, where α is a real-valued hyperparameter and H is a base distribution. H may be continuous, as when it generates phonetic categories in formant space, or discrete, as when it generates lexemes as a list of phonetic categories.

A draw from a DP, $G \sim DP(\alpha, H)$, returns a distribution over a set of draws from H, i.e., a discrete distribution over a set of categories or lexemes generated by H. In the mixture model setting, the category assignments are then generated from G, with the datapoints themselves generated by the corresponding components from H. If H is infinite, the support of the DP is likewise infinite. During inference, we marginalize over G.

3.1 Phonetic Categories: IGMM

Following previous models of vowel learning (de Boer and Kuhl, 2003; Vallabha et al., 2007; McMurray et al., 2009; Dillon et al., 2013) we assume that vowel tokens are drawn from a Gaussian mixture model. The Infinite Gaussian Mixture Model (IGMM) (Rasmussen, 2000) includes a DP prior, as described above, in which the base distribution H_C generates multivariate Gaussians drawn from a Normal Inverse-Wishart prior.[5] Each observation, a formant vector w_{ij}, is drawn from the Gaussian corresponding to its category assignment c_{ij}:

$$\mu_c, \Sigma_c \sim H_C = \mathit{NIW}(\mu_0, \Sigma_0, \nu_0) \quad (1)$$

$$G_C \sim DP(\alpha_c, H_C) \quad (2)$$

$$c_{ij} \sim G_C \quad (3)$$

$$w_{ij} | c_{ij} = c \sim N(\mu_c, \Sigma_c) \quad (4)$$

The above model generates a category assignment c_{ij} for each vowel token w_{ij}. This is the baseline IGMM model, which clusters vowel tokens using bottom-up distributional information only; the LD model adds top-down information by assigning categories in the lexicon, rather than on the token level.

3.2 Lexicon

In the LD model, vowel phones appear within words drawn from the lexicon. Each such lexeme is represented as a frame plus a list of vowel categories $\boldsymbol{v}_\ell$. Lexeme assignments for each token are drawn from a DP with a lexicon-generating base distribution H_L. The category for each vowel token in the word is determined by the lexeme; the formant values are drawn from the corresponding Gaussian as in the IGMM:

$$G_L \sim DP(\alpha_l, H_L) \quad (5)$$

$$x_i = \ell \sim G_L \quad (6)$$

$$w_{ij} | v_{\ell j} = c \sim N(\mu_c, \Sigma_c) \quad (7)$$

H_L generates lexemes by first drawing the number of phones from a geometric distribution and the number of consonant phones from a binomial distribution. The consonants are then generated from a DP with a uniform base distribution (but note they are fixed at inference time, i.e., are observed categorically), while the vowel phones $\boldsymbol{v}_\ell$ are generated by the IGMM DP above, $v_{\ell j} \sim G_C$.

Note that two draws from H_L may result in identical lexemes; these are nonetheless considered to be separate (homophone) lexemes.

4 Topic-Lexical-Distributional Model

The TLD model retains the IGMM vowel phone component, but extends the lexicon of the LD model by adding topic-specific lexicons, which capture the notion that lexeme probabilities are topic-dependent. Specifically, the TLD model replaces

[5] This compound distribution is equivalent to $\Sigma_c \sim \mathit{IW}(\Sigma_0, \nu_0)$, $\mu_c | \Sigma_c \sim N(\mu_0, \frac{\Sigma_c}{\nu_0})$

the Dirichlet Process lexicon with a Hierarchical Dirichlet Process (HDP; Teh (2006)). In the HDP lexicon, a top-level global lexicon is generated as in the LD model. Topic-specific lexicons are then drawn from the global lexicon, containing a subset of the global lexicon (but since the size of the global lexicon is unbounded, so are the topic-specific lexicons). These topic-specific lexicons are used to generate the tokens in a similar manner to the LD model. There are a fixed number of lower level topic-lexicons; these are matched to the number of topics in the LDA model used to infer the topic distributions (see Section 6.4).

More formally, the global lexicon is generated as a top-level DP: $G_L \sim DP(\alpha_l, H_L)$ (see Section 3.2; remember H_L includes draws from the IGMM over vowel categories). G_L is in turn used as the base distribution in the topic-level DPs, $G_k \sim DP(\alpha_k, G_L)$. In the Chinese Restaurant Franchise metaphor often used to describe HDPs, G_L is a global menu of dishes (lexemes). The topic-specific lexicons are restaurants, each with its own distribution over dishes; this distribution is defined by seating customers (word tokens) at *tables*, each of which serves a single dish from the menu: all tokens x at the same table t are assigned to the same lexeme ℓ_t. Inference (Section 5) is defined in terms of tables rather than lexemes; if multiple tables draw the same dish from G_L, tokens at these tables share a lexeme.

In the TLD model, tokens appear within situations, each of which has a distribution over topics θ_h. Each token x_{hi} has a co-indexed topic assignment variable, z_{hi}, drawn from θ_h, designating the topic-lexicon from which the table for x_{hi} is to be drawn. The formant values for w_{hij} are drawn in the same way as in the LD model, given the lexeme assignment at x_{hi}. This results in the following model, shown in Figure 2:

$$G_L \sim DP(\alpha_l, H_L) \quad (8)$$

$$G_k \sim DP(\alpha_k, G_L) \quad (9)$$

$$z_{hi} \sim Mult(\theta_h) \quad (10)$$

$$x_{hi} = t | z_{hi} = k \sim G_k \quad (11)$$

$$w_{hij} | x_{hi} = t, v_{\ell_t j} = c \sim N(\mu_c, \Sigma_c) \quad (12)$$

5 Inference: Gibbs Sampling

We use Gibbs sampling to infer three sets of variables in the TLD model: assignments to vowel categories in the lexemes, assignments of tokens to topics, and assignments of tokens to tables (from which the assignment to lexemes can be read off).

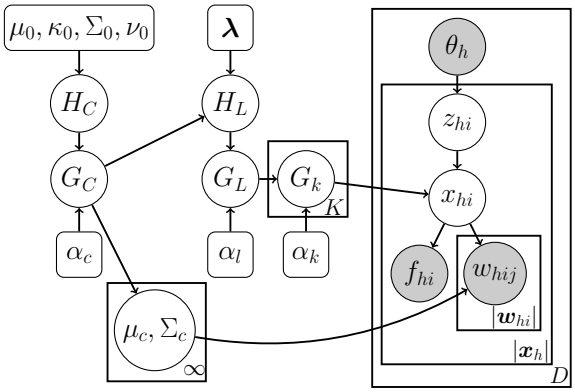

Figure 2: TLD model, depicting, from left to right, the IGMM component, the LD lexicon component, the topic-specific lexicons, and finally the token x_{hi}, appearing in document h, with observed vowel formants w_{hij} and frame f_{hi}. The lexeme assignment x_{hi} and the topic assignment z_{hi} are inferred, the latter using the observed document-topic distribution θ_h. Note that f_i is deterministic given the lexeme assignment. Squared nodes depict hyperparameters. $\boldsymbol{\lambda}$ is the set of hyperparameters used by H_L when generating lexical items (see Section 3.2).

5.1 Sampling lexeme vowel categories

Each vowel in the lexicon must be assigned to a category in the IGMM. The posterior probability of a category assignment is composed of the DP prior over categories and the likelihood of the observed vowels belonging to that category. We use $\boldsymbol{w}_{\ell j}$ to denote the set of vowel formants at position j in words that have been assigned to lexeme ℓ. Then,

$$P(v_{\ell j} = c | \boldsymbol{w}, \boldsymbol{x}, \boldsymbol{\ell}^{\setminus \ell}) \propto P(v_{\ell j} = c | \boldsymbol{\ell}^{\setminus \ell}) p(\boldsymbol{w}_{\ell j} | v_{\ell j} = c, \boldsymbol{w}^{\setminus \ell j}) \quad (13)$$

The first (DP prior) factor is defined as:

$$P(v_{\ell j} = c | \boldsymbol{v}^{\setminus \ell j}) = \begin{cases} \frac{n_c}{\sum_c n_c + \alpha_c} & \text{if } c \text{ exists} \\ \frac{\alpha_c}{\sum_c n_c + \alpha_c} & \text{if } c \text{ new} \end{cases} \quad (14)$$

where n_c is the number of other vowels in the lexicon, $\boldsymbol{v}^{\setminus lj}$, assigned to category c. Note that there is always positive probability of creating a new category.

The likelihood of the vowels is calculated by marginalizing over all possible means and variances of the Gaussian category parameters, given

the NIW prior. For a single point (if $|\boldsymbol{w}_{\ell j}| = 1$), this predictive posterior is in the form of a Student-t distribution; for the more general case see Feldman et al. (2013a), Eq. B3.

5.2 Sampling table & topic assignments

We jointly sample $\boldsymbol{x}$ and $\boldsymbol{z}$, the variables assigning tokens to tables and topics. Resampling the table assignment includes the possibility of changing to a table with a different lexeme or drawing a new table with a previously seen or novel lexeme. The joint conditional probability of a table and topic assignment, given all other current token assignments, is:

$$\begin{aligned} &P(x_{hi} = t, z_{hi} = k | \boldsymbol{w}_{hi}, \theta_h, \boldsymbol{t}^{\setminus hi}, \boldsymbol{\ell}, \boldsymbol{w}^{\setminus hi}) \\ &\quad = P(k|\theta_h) P(t|k, \ell_t, \boldsymbol{t}^{\setminus hi}) \\ &\qquad \prod_{c \in C} p(\boldsymbol{w}_{hi\cdot} | v_{\ell_t \cdot} = c, \boldsymbol{w}^{\setminus hi}) \end{aligned} \tag{15}$$

The first factor, the prior probability of topic k in document h, is given by θ_{hk} obtained from the LDA. The second factor is the prior probability of assigning word x_i to table t with lexeme ℓ given topic k. It is given by the HDP, and depends on whether the table t exists in the HDP topic-lexicon for k and, likewise, whether any table in the topic-lexicon has the lexeme ℓ:

$$P(t|k, \ell, \boldsymbol{t}^{\setminus hi}) \propto \begin{cases} \frac{n_{kt}}{n_k + \alpha_k} & \text{if } t \text{ in } k \\ \frac{\alpha_k}{n_k + \alpha_k} \frac{m_\ell}{m + \alpha_l} & \text{if } t \text{ new, } \ell \text{ known} \\ \frac{\alpha_k}{n_k + \alpha_k} \frac{\alpha_\ell}{m + \alpha_l} & \text{if } t \text{ and } \ell \text{ new} \end{cases} \tag{16}$$

Here n_{kt} is the number of other tokens at table t, n_k are the total number of tokens in topic k, m_ℓ is the number of tables across all topics with the lexeme ℓ, and m is the total number of tables.

The third factor, the likelihood of the vowel formants $\boldsymbol{w}_{hi}$ in the categories given by the lexeme $\boldsymbol{v}_l$, is of the same form as the likelihood of vowel categories when resampling lexeme vowel assignments. However, here it is calculated over the set of vowels in the token assigned to each vowel category (i.e., the vowels at indices where $v_{\ell_t \cdot} = c$). For a new lexeme, we approximate the likelihood using 100 samples drawn from the prior, each weighted by $\alpha/100$ (Neal, 2000).

5.3 Hyperparameters

The three hyperparameters governing the HDP over the lexicon, α_l and α_k, and the DP over vowel categories, α_c, are estimated using a slice sampler. The remaining hyperparameters for the vowel category and lexeme priors are set to the same values used by Feldman et al. (2013a).

6 Experiments

6.1 Corpus

We test our model on situated child directed speech, taken from the C1 section of the Brent corpus in CHILDES (Brent and Siskind, 2001; MacWhinney, 2000). This corpus consists of transcripts of speech directed at infants between the ages of 9 and 15 months, captured in a naturalistic setting as parent and child went about their day. This ensures variability of situations.

Utterances with unintelligible words or quotes are removed. We restrict the corpus to content words by retaining only words tagged as `adj`, `n`, `part` and `v` (adjectives, nouns, particles, and verbs). This is in line with evidence that infants distinguish content and function words on the basis of acoustic signals (Shi and Werker, 2003). Vowel categorization improves when attending only to more prosodically and phonologically salient tokens (Adriaans and Swingley, 2012), which generally appear within content, not function words. The final corpus consists of 13138 tokens and 1497 word types.

6.2 Hillenbrand Vowels

The transcripts do not include phonetic information, so, following Feldman et al. (2013a), we synthesize the formant values using data from Hillenbrand et al. (1995). This dataset consists of a set of 1669 manually gathered formant values from 139 American English speakers (men, women and children) for 12 vowels. For each vowel category, we construct a Gaussian from the mean and covariance of the datapoints belonging to that category, using the first and second formant values measured at steady state. We also construct a second dataset using only datapoints from adult female speakers.

Each word in the dataset is converted to a phonemic representation using the CMU pronunciation dictionary, which returns a sequence of Arpabet phoneme symbols. If there are multiple possible pronunciations, the first one is used. Each vowel phoneme in the word is then replaced by formant values drawn from the corresponding Hillenbrand Gaussian for that vowel.

6.3 Merging Consonant Categories

The Arpabet encoding used in the phonemic representation includes 24 consonants. We construct datasets both using the full set of consonants—the 'C24' dataset—and with less fine-grained consonant categories. Distinguishing all consonant categories assumes perfect learning of consonants prior to vowel categorization and is thus somewhat unrealistic (Polka and Werker, 1994), but provides an upper limit on the information that word-contexts can give.

In the 'C15' dataset, the voicing distinction is collapsed, leaving 15 consonant categories. The collapsed categories are B/P, G/K, D/T, CH/JH, V/F, TH/DH, S/Z, SH/ZH, R/L while HH, M, NG, N, W, Y remain separate phonemes. This dataset mirrors the finding in Mani and Plunkett (2010) that 12 month old infants are not sensitive to voicing mispronunciations.

The 'C6' dataset distinguishes between only 6 coarse consonant phonemes, corresponding to stops (B,P,G,K,D,T), affricates (CH,JH), fricatives (V, F, TH, DH, S, Z, SH, ZH, HH), nasals (M, NG, N), liquids (R, L), and semivowels/glides (W, Y). This dataset makes minimal assumptions about the category categories that infants could use in this learning setting.

Decreasing the number of consonants increases the ambiguity in the corpus: *bat* not only shares a frame (b_t) with *boat* and *bite*, but also, in the C15 dataset, with *put*, *pad* and *bad* (b/p_d/t), and in the C6 dataset, with *dog* and *kite*, among many others (STOP_STOP). Table 1 shows the percentage of types and tokens that are ambiguous in each dataset, that is, words in frames that match multiple wordtypes. Note that we always evaluate against the *gold* word identities, even when these are not distinguished in the model's input. These datasets are intended to evaluate the degree of reliance on consonant information in the LD and TLD models, and to what extent the topics in the TLD model can replace this information.

6.4 Topics

The input to the TLD model includes a distribution over topics for each situation, which we infer in advance from the full Brent corpus (not only the C1 subset) using LDA. Each transcript in the Brent corpus captures about 75 minutes of parent-child interaction, and thus multiple situations will be included in each file. The transcripts do not delimit situations, so we do this somewhat arbitrarily by splitting each transcript after 50 CDS utterances, resulting in 203 situations for the Brent C1 dataset. As well as function words, we also remove the five most frequent content words (*be, go, get, want, come*). On average, situations are only 59 words long, reflecting the relative lack of content words in CDS utterances.

Dataset	C24	C15	C6
Input Types	1487	1426	1203
Frames	1259	1078	702
Ambig Types %	27.2	42.0	80.4
Ambig Tokens %	41.3	56.9	77.2

Table 1: Corpus statistics showing the increasing amount of ambiguity as consonant categories are merged. Input types are the number of word types with distinct input representations (as opposed to gold orthographic word types, of which there are 1497). Ambiguous types and tokens are those with frames that match multiple (orthographic) word types.

We infer 50 topics for this set of situations using the `mallet` toolkit (McCallum, 2002). Hyperparameters are inferred, which leads to a dominant topic that includes mainly light verbs (*have, let, see, do*). The other topics are less frequent but capture stronger semantic meaning (e.g. *yummy, peach, cookie, daddy, bib* in one topic, *shoe, let, put, hat, pants* in another). The word-topic assignments are used to calculate unsmoothed situation-topic distributions $\boldsymbol{\theta}$ used by the TLD model.

6.5 Evaluation

We evaluate against adult categories, i.e., the 'gold-standard', since all learners of a language eventually converge on similar categories. (Since our model is not a model of the learning process, we do not compare the infant learning process to the learning algorithm.) We evaluate both the inferred phonetic categories and words using the clustering evaluation measure V-Measure (VM; Rosenberg and Hirschberg, 2007).[6] VM is the harmonic mean of two components, similar to F-score, where the components (VC and VH) are measures of cross entropy between the gold and model categorization.

[6]Other clustering measures, such as 1-1 matching and pairwise precision and recall (accuracy and completeness) showed the same trends, but VM has been demonstrated to be the most stable measure when comparing solutions with varying numbers of clusters (Christodoulopoulos et al., 2010).

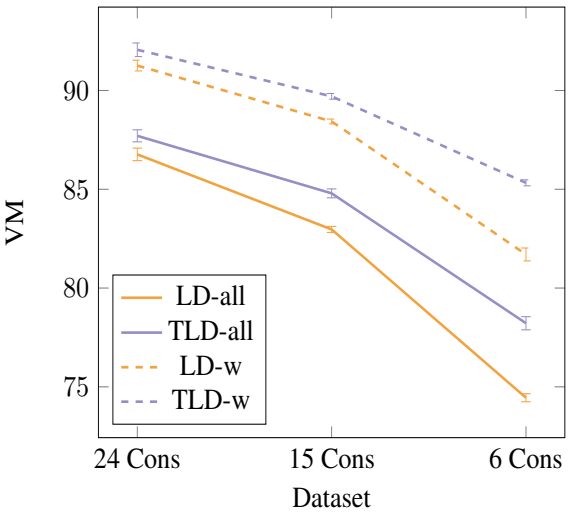

Figure 3: Vowel evaluation. 'all' refers to datasets with vowels synthesized from all speakers, 'w' to datasets with vowels synthesized from adult female speakers' vowels. The bars show a 95% Confidence Interval based on 5 runs. IGMM-all results in a VM score of 53.9 (CI=0.5); IGMM-w has a VM score of 65.0 (CI=0.2), not shown.

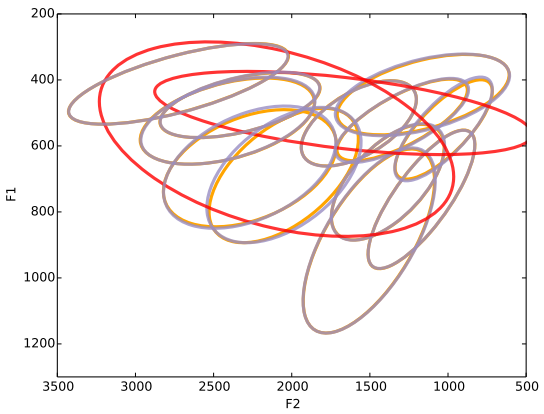

Figure 4: Vowels found by the TLD model; supervowels are indicated in red. The gold-standard vowels are shown in gold in the background but are mostly overlapped by the inferred categories.

For vowels, VM measures how well the inferred phonetic categorizations match the gold categories; for lexemes, it measures whether tokens have been assigned to the same lexemes both by the model and the gold standard. Words are evaluated against gold orthography, so homophones, e.g. *hole* and *whole*, are distinct gold words.

6.6 Results

We compare all three models—TLD, LD, and IGMM—on the vowel categorization task, and TLD and LD on the lexical categorization task (since IGMM does not infer a lexicon). The datasets correspond to two sets of conditions: firstly, either using vowel categories synthesized from all speakers or only adult female speakers, and secondly, varying the coarseness of the observed consonant categories. Each condition (model, vowel speakers, consonant set) is run five times, using 1500 iterations of Gibbs sampling with hyperparameter sampling. Overall, we find that TLD outperforms the other models in both tasks, across all conditions.

Vowel categorization results are shown in Figure 3. IGMM performs substantially worse than both TLD and LD, with scores more than 30 points lower than the best results for these models, clearly showing the value of the protolexicon and replicating the results found by Feldman et al. (2013a) on this dataset. Furthermore, TLD consistently outperforms the LD model, finding better phonetic categories, both for vowels generated from the combined categories of all speakers ('all') and vowels generated from adult female speakers only ('w'), although the latter are clearly much easier for both models to learn. Both models perform less well when the consonant frames provide less information, but the TLD model performance degrades less than the LD performance.

Both the TLD and the LD models find 'supervowel' categories, which cover multiple vowel categories and are used to merge minimal pairs into a single lexical item. Figure 4 shows example vowel categories inferred by the TLD model, including two supervowels. The TLD supervowels are used much less frequently than the supervowels found by the LD model, containing, on average, only two-thirds as many tokens.

Figure 5 shows that TLD also outperforms LD on the lexeme/word categorization task. Again performance decreases as the consonant categories become coarser, but the additional semantic information in the TLD model compensates for the lack of consonant information. In the individual components of VM, TLD and LD have similar VC ("recall"), but TLD has higher VH ("precision"), demonstrating that the semantic information given by the topics can separate potentially ambiguous words, as hypothesized.

Overall, the contextual semantic information

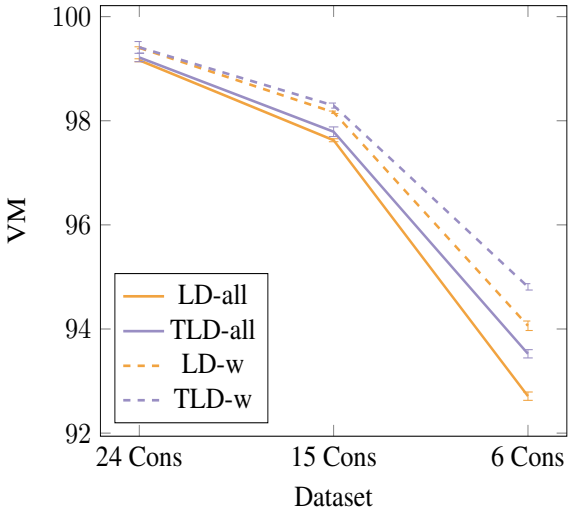

Figure 5: Lexeme evaluation. 'all' refers to datasets with vowels synthesized from all speakers, 'w' to datasets with vowels synthesized from adult female speakers' vowels.

added in the TLD model leads to both better phonetic categorization and to a better protolexicon, especially when the input is noisier, using degraded consonants. Since infants are not likely to have perfect knowledge of phonetic categories at this stage, semantic information is a potentially rich source of information that could be drawn upon to offset noise from other domains. The form of the semantic information added in the TLD model is itself quite weak, so the improvements shown here are in line with what infant learners could achieve.

7 Conclusion

Language acquisition is a complex task, in which many heterogeneous sources of information may be useful. In this paper, we investigated whether contextual semantic information could be of help when learning phonetic categories. We found that this contextual information can improve phonetic learning performance considerably, especially in situations where there is a high degree of phonetic ambiguity in the word-forms that learners hear. This suggests that previous models that have ignored semantic information may have underestimated the information that is available to infants. Our model illustrates one way in which language learners might harness the rich information that is present in the world without first needing to acquire a full inventory of word meanings.

The contextual semantic information that the TLD model tracks is similar to that potentially used in other linguistic learning tasks. Theories of cross-situational word learning (Smith and Yu, 2008; Yu and Smith, 2007) assume that sensitivity to situational co-occurrences between words and non-linguistic contexts is a precursor to learning the meanings of individual words. Under this view, contextual semantics is available to infants well before they have acquired large numbers of semantic minimal pairs. However, recent experimental evidence indicates that learners do not always retain detailed information about the referents that are present in a scene when they hear a word (Medina et al., 2011; Trueswell et al., 2013). This evidence poses a direct challenge to theories of cross-situational word learning. Our account does not necessarily require learners to track co-occurrences between words and individual objects, but instead focuses on more abstract information about salient events and topics in the environment; it will be important to investigate to what extent infants encode this information and use it in phonetic learning.

Regardless of the specific way in which infants encode semantic information, our method of adding this information by using LDA topics from transcript data was shown to be effective. This method is practical because it can approximate semantic information without relying on extensive manual annotation.

The LD model extended the phonetic categorization task by adding word contexts; the TLD model presented here goes even further, adding larger situational contexts. Both forms of top-down information help the low-level task of classifying acoustic signals into phonetic categories, furthering a holistic view of language learning with interaction across multiple levels.

Bootstrapping into Filler-Gap: An Acquisition Story

Marten van Schijndel **Micha Elsner**
The Ohio State University
{vanschm,melsner}@ling.ohio-state.edu

Abstract

Analyses of filler-gap dependencies usually involve complex syntactic rules or heuristics; however recent results suggest that filler-gap comprehension begins earlier than seemingly simpler constructions such as ditransitives or passives. Therefore, this work models filler-gap acquisition as a byproduct of learning word orderings (e.g. SVO vs OSV), which must be done at a very young age anyway in order to extract meaning from language. Specifically, this model, trained on part-of-speech tags, represents the preferred locations of semantic roles relative to a verb as Gaussian mixtures over real numbers.

This approach learns role assignment in filler-gap constructions in a manner consistent with current developmental findings and is extremely robust to initialization variance. Additionally, this model is shown to be able to account for a characteristic error made by learners during this period (*A and B gorped* interpreted as *A gorped B*).

1 Introduction

The phenomenon of filler-gap, where the argument of a predicate appears outside its canonical position in the phrase structure (e.g. *[the apple]$_i$ that the boy ate t_i* or *[what]$_i$ did the boy eat t_i*), has long been an object of study for syntacticians (Ross, 1967) due to its apparent processing complexity. Such complexity is due, in part, to the arbitrary length of the dependency between a filler and its gap (e.g. *[the apple]$_i$ that Mary said the boy ate t_i*).

Recent studies indicate that comprehension of filler-gap constructions begins around 15 months (Seidl et al., 2003; Gagliardi et al., 2014). This finding raises the question of how such a complex phenomenon could be acquired so early since children at that age do not yet have a very advanced grasp of language (e.g. ditransitives do not seem to be generalized until at least 31 months; Goldberg et al. 2004, Bello 2012). This work shows that filler-gap comprehension in English may be acquired through learning word orderings rather than relying on hierarchical syntactic knowledge.

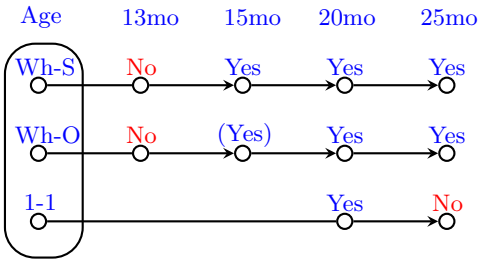

Figure 1: The developmental timeline of subject (Wh-S) and object (Wh-O) *wh*-clause extraction comprehension suggested by experimental results (Seidl et al., 2003; Gagliardi et al., 2014). Parentheses indicate weak comprehension. The final row shows the timeline of 1-1 role bias errors (Naigles, 1990; Gertner and Fisher, 2012). Missing nodes denote a lack of studies.

This work describes a cognitive model of the developmental timecourse of filler-gap comprehension with the goal of setting a lower bound on the modeling assumptions necessary for an ideal learner to display filler-gap comprehension. In particular, the model described in this paper takes chunked child-directed speech as input and learns orderings over semantic roles. These orderings then permit the model to successfully resolve filler-gap dependencies.[1] Further, the model presented here is also shown to initially reflect an idiosyncratic role assignment error observed in development (e.g. *A and B kradded* interpreted as *A kradded B*; Gertner and Fisher, 2012), though after training, the model is able to avoid the error. As such, this work may be said to model a learner from 15 months to between 25 and 30 months.

[1]This model does not explicitly learn gap positions, but rather assigns thematic roles to arguments based on where those arguments are expected to manifest. This approach to filler-gap comprehension is supported by findings that show people do not actually link fillers to gap positions but instead link the filler to a verb with missing arguments (Pickering and Barry, 1991)

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1084–1093,
Baltimore, Maryland, USA, June 23-25 2014.

2 Background

The developmental timeline during which children acquire the ability to process filler-gap constructions is not well-understood. Language comprehension precedes production, and the developmental literature on the acquisition of filler-gap constructions is sparsely populated due to difficulties in designing experiments to test filler-gap comprehension in preverbal infants. Older studies typically looked at verbal children and the mistakes they make to gain insight into the acquisition process (de Villiers and Roeper, 1995).

Recent studies, however, indicate that filler-gap comprehension likely begins earlier than production (Seidl et al., 2003; Gagliardi and Lidz, 2010; Gagliardi et al., 2014). Therefore, studies of verbal children are probably actually testing the acquisition of production mechanisms (planning, motor skills, greater facility with lexical access, etc) rather than the acquisition of filler-gap. Note that these may be related since filler-gap could introduce greater processing load which could overwhelm the child's fragile production capacity (Phillips, 2010).

Seidl et al. (2003) showed that children are able to process *wh*-extractions from subject position (e.g. *[who]$_i$ t_i ate pie*) as young as 15 months while similar extractions from object position (e.g. *[what]$_i$ did the boy eat t_i*) remain unparseable until around 20 months of age.[2] This line of investigation has been reopened and expanded by Gagliardi et al. (2014) whose results suggest that the experimental methodology employed by Seidl et al. (2003) was flawed in that it presumed infants have ideal performance mechanisms. By providing more trials of each condition and controlling for the pragmatic felicity of test statements, Gagliardi et al. (2014) provide evidence that 15-month old infants can process *wh*-extractions from both subject and object positions. Object extractions are more difficult to comprehend than subject extractions, however, perhaps due to additional processing load in object extractions (Gibson, 1998; Phillips, 2010). Similarly, Gagliardi and Lidz (2010) show that relativized extractions with a *wh*-relativizer (e.g. *find [the boy]$_i$ who t_i ate the apple*) are easier to comprehend than relativized extractions with *that* as the relativizer (e.g. *find [the boy]$_i$ that t_i ate the apple*).

Yuan et al. (2012) demonstrate that 19-month olds use their knowledge of nouns to learn both verbs and their associated argument structure. In their study, infants were shown video of a person talking on a phone using a nonce verb with either one or two nouns (e.g. *Mary kradded Susan*). Under the assumption that infants look longer at things that correspond to their understanding of a prompt, the infants were then shown two images that potentially depicted the described action – one picture where two actors acted independently (reflecting an intransitive proposition) and one picture where one actor acted on the other (reflecting a transitive proposition).[3] Even though the infants had no extralinguistic knowledge about the verb, they consistently treated the verb as transitive if two nouns were present and intransitive if only one noun was present.

Similarly, Gertner and Fisher (2012) show that intransitive phrases with conjoined subjects (e.g. *John and Mary gorped*) are given a transitive interpretation (i.e. *John gorped Mary*) at 21 months (henceforth termed '1-1 role bias'), though this effect is no longer present at 25 months (Naigles, 1990). This finding suggests both that learners will ignore canonical structure in favor of using all possible arguments and that children have a bias to assign a unique semantic role to each argument. It is important to note, however, that cross-linguistically children do not seem to generalize beyond two arguments until after at least 31 months of age (Goldberg et al., 2004; Bello, 2012), so a predicate occurring with three nouns would still likely be interpreted as merely transitive rather than ditransitive.

Computational modeling provides a way to test the computational level of processing (Marr, 1982). That is, given the input (child-directed speech, adult-directed speech, and environmental experiences), it is possible to probe the computational processes that result in the observed output. However, previous computational models of grammar induction (Klein and Manning, 2004), including infant grammar induction (Kwiatkowski et al., 2012), have not addressed filler-gap comprehension.[4]

The closest work to that presented here is the work on BabySRL (Connor et al., 2008; Connor et al., 2009; Connor et al., 2010). BabySRL is a computational model of semantic role acquistion using a similar set of assumptions to the current work. BabySRL learns weights over ordering constraints (e.g. preverbal, second noun, etc.) to acquire semantic role labelling while still exhibiting 1-1 role bias. However, no analysis has evaluated the abil-

[2] Since the *wh*-phrase is in the same (or a very similar) position as the original subject when the *wh*-phrase takes subject position, it is not clear that these constructions are true extractions (Culicover, 2013), however, this paper will continue to refer to them as such for ease of exposition.

[3] There were two actors in each image to avoid biasing the infants to look at the image with more actors.

[4] As one reviewer notes, Joshi et al. (1990) and subsequent work show that filler-gap phenomena can be formally captured by mildly context-sensitive grammar formalisms; these have the virtue of scaling up to adult grammar, but due to their complexity, do not seem to have been described as models of early acquisition.

Susan	said	**John**	gave	**girl**	**book**

ity of BabySRL to acquire filler-gap constructions. Further comparison to BabySRL may be found in Section 6.

3 Assumptions

The present work restricts itself to acquiring filler-gap comprehension in English. The model presented here learns a single, non-recursive ordering for the semantic roles in each sentence relative to the verb since several studies have suggested that early child grammars may consist of simple linear grammars that are dictated by semantic roles (Diessel and Tomasello, 2001; Jackendoff and Wittenberg, in press). This work assumes learners can already identify nouns and verbs, which is supported by Shi et al. (1999) who show that children at an extremely young age can distinguish between content and function words and by Waxman and Booth (2001) who show that children can distinguish between different types of content words. Further, since Waxman and Booth (2001) demonstrate that, by 14 months, children are able to distinguish nouns from modifiers, this work assumes learners can already chunk nouns and access the nominal head. To handle recursion, this work assumes that children treat the final verb in each sentence as the main verb (implicitly assuming sentence segmentation), which ideally assigns roles to each of the nouns in the sentence.

Due to the findings of Yuan et al. (2012), this work adopts a 'syntactic bootstrapping' theory of acquisition (Gleitman, 1990), where structural properties (e.g. number of nouns) inform the learner about semantic properties of a predicate (e.g. how many semantic roles it confers). Since infants infer the number of semantic roles, this work further assumes they already have expectations about where these roles tend to be realized in sentences, if they appear. These positions may correspond to different semantic roles for different predicates (e.g. the subject of *run* and of *melt*); however, the role for predicates with a single argument is usually assigned to the noun that precedes the verb while a second argument is usually assigned after the verb. The semantic properties of these roles may be learned lexically for each predicate, but that is beyond the scope of this work. Therefore, this work uses syntactic and semantic roles interchangeably (e.g. *subject* and *agent*).

	μ	σ	π
G_{SC}	-1	0.5	.999
G_{SN}	-1	3	.001
G_{OC}	1	0.5	.999
G_{ON}	1	3	.001
Φ	.00001		

Table 2: Initial values for the mean (μ), standard deviation (σ), and prior (π) of each Gaussian as well as the skip penalty (Φ) used in this paper.

Finally, following the finding by Gertner and Fisher (2012) that children interpret intransitives with conjoined subjects as transitives, this work assumes that semantic roles have a one-to-one correspondence with nouns in a sentence (similarly used as a soft constraint in the semantic role labelling work of Titov and Klementiev, 2012).

4 Model

The model represents the preferred locations of semantic roles relative to the verb as distributions over real numbers. This idea is adapted from Boersma (1997) who uses it to learn constraint rankings in optimality theory.

In this work, the final (main) verb is placed at position 0; words (and chunks) before the verb are given progressively more negative positions, and words after the verb are given progressively more positive positions (see Table 1). Learner expectations of where an argument will appear relative to the verb are modelled as two-component Gaussian mixtures: one mixture of Gaussians ($G_{S\cdot}$) corresponds to the subject argument, another ($G_{O\cdot}$) corresponds to the object argument. There is no mixture for a third argument since children do not generalize beyond two arguments until later in development (Goldberg et al., 2004; Bello, 2012).

One component of each mixture learns to represent the canonical position for the argument ($G_{\cdot C}$) while the other ($G_{\cdot N}$) represents some alternate, non-canonical position such as the filler position in filler-gap constructions. To reflect the fact that learners have had 15 months of exposure to their language before acquiring filler-gap, the mixture is initialized so that there is a stronger probability associated with the canonical Gaussian than with the non-canonical Gaussian of each mixture.[5] Finally, the one-to-one role bias is explicitly encoded such that the model cannot use a label that has already been used elsewhere in the sentence.

[5] Akhtar (1999) finds that learners may not have strong expectations of canonical argument positions until four years of age, but the results of the current study are extremely robust to changes in initialization, as discussed in Section 7 of this paper, so this assumption is mostly adopted for ease of exposition.

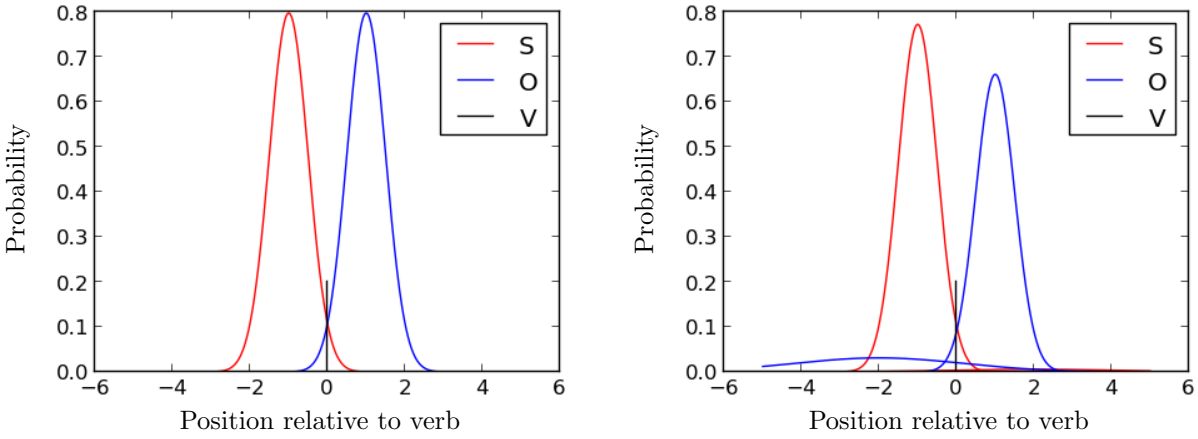

Figure 2: Visual representations of (Left) the initial model's expectations of where arguments will appear, given the initial parameters in Table 2 and (Right) the converged model's expectations of where arguments will appear.

Thus, the initial model conditions (see Figure 2) are most likely to realize an SVO ordering, although it is possible to obtain SOV (by sampling a negative number from the blue curve) or even OSV (by also sampling the red curve very close to 0). The model is most likely to hypothesize a preverbal object when it has already assigned the subject role to something and, in addition, there is no postverbal noun competing for the object label. In other words, the model infers that an object extraction may have occurred if there is a 'missing' postverbal argument.

Finally, the probability of a given sequence is the product of the label probabilities for the component argument positions (e.g. G_{SC} generating an argument at position -2, etc). Since many sentences have more than two nouns, the model is allowed to skip nouns by multiplying a penalty term (Φ) into the product for each skipped noun; the cost is set at 0.00001 for this study, though see Section 7 for a discussion of the constraints on this parameter. See Table 2 for initialization parameters and Figure 2 for a visual representation of the initial expectations of the model.

This work uses a model with 2-component mixtures for both subjects and objects (termed the *symmetric model*). This formulation achieves the best fit to the training data according to the Bayesian Information Criterion (BIC).[6] However, follow-up experiments find that the non-canonical subject Gaussian only improves the likelihood of the data by erroneously modeling postverbal nouns in imperative statements. The lack of a canonical subject in English imperatives allows the model to improve the likelihood of the data by using the non-canonical subject Gaussian to capture fictitious postverbal arguments. When imperatives are filtered out of the training corpus, the symmetric model obtains a worse BIC fit than a model that lacks the non-canonical subject Gaussian. Therefore, if one makes the assumption that imperatives are prosodically-marked for learners (e.g. the learner is the implicit subject), the best model is one that lacks a non-canonical subject.[7] The remainder of this paper assumes a symmetric model to demonstrate what happens if such an assumption is not made; for the evaluations described in this paper, the results are similar in either case.

This model differs from other non-recursive computational models of grammar induction (e.g. Goldwater and Griffiths, 2007) since it is not based on Hidden Markov Models. Instead, it determines the best ordering for the sentence as a whole. This approach bears some similarity to a Generalized Mallows model (Chen et al., 2009), but the current formulation was chosen due to being independently posited as cognitively plausible (Boersma, 1997).

Figure 2 (Right) shows the converged, final state of the model. The model expects the first argument (usually agent) to be assigned preverbally and expects the second (say, patient) to be assigned postverbally; however, there is now a larger chance that the second argument will appear preverbally.

5 Evaluation

The model in this work is trained using transcribed child-directed speech (CDS) from the BabySRL portions (Connor et al., 2008) of CHILDES (MacWhinney, 2000). Chunking is performed us-

[6]The BIC rewards improved log-likelihood but penalizes increased model complexity.

[7]This finding suggests that a Dirichlet Process or other means of dynamically determining the number of components in each mixture would converge to a model that lacks non-canonical subjects if imperative filtering were employed.

ing a basic noun-chunker from NLTK (Bird et al., 2009). Based on an initial analysis of chunker performance, *yes* is hand-corrected to not be a noun. Poor chunker perfomance is likely due to a mismatch in chunker training and testing domains (Wall Street Journal text vs transcribed speech), but chunking noise may be a good estimation of learner uncertainty, so the remaining text is left uncorrected. All noun phrase chunks are then replaced with their final noun (presumed the head) to approximate the ability of children to distinguish nouns from modifiers (Waxman and Booth, 2001). Finally, for each sentence, the model assigns sentence positions to each word with the final verb at zero.

Viterbi Expectation-Maximization is performed over each sentence in the corpus to infer the parameters of the model. During the Expectation step, the model uses the current Gaussian parameters to label the nouns in each sentence with argument roles. Since the model is not lexicalized, these roles correspond to the semantic roles most commonly associated with subject and object. The model then chooses the best label sequence for each sentence.

These newly labelled sentences are used during the Maximization step to determine the Gaussian parameters that maximize the likelihood of that labelling. The mean of each Gaussian is updated to the mean position of the words it labels. Similarly, the standard deviation of each Gaussian is updated with the standard deviation of the positions it labels. A learning rate of 0.3 is used to prevent large parameter jumps. The prior probability of each Gaussian is updated as the ratio of that Gaussian's labellings to the total number of labellings from that mixture in the corpus:

$$\pi_{\rho\theta} = \frac{|\ G_{\rho\theta}\ |}{|\ G_{\rho\cdot}\ |} \quad (1)$$

where $\rho \in \{S, O\}$ and $\theta \in \{C, N\}$.

Best results seem to be obtained when the skip-penalty is loosened by an order of magnitude during testing. Essentially, this forces the model to tightly adhere to the perceived argument structure during training to learn more rigid parameters, but the model is allowed more leeway to skip arguments it has less confidence in during testing. Convergence (see Figure 2) tends to occur after four iterations but can take up to ten iterations depending on the initial parameters.

Since the model is unsupervised, it is trained on a given corpus (e.g. Eve) before being tested on the role annotations of that same corpus. The Eve corpus was used for development purposes,[8] and the Adam data was used only for testing.

For testing, this study uses the semantic role annotations in the BabySRL corpus. These annotations were obtained by automatically semantic role labelling portions of CHILDES with the system of Punyakanok et al. (2008) before roughly hand-correcting them (Connor et al., 2008). The BabySRL corpus is annotated with 5 different roles, but the model described in this paper only uses 2 roles. Therefore, overall accuracy results (see Table 3) are presented both for the raw BabySRL corpus and for a collapsed BabySRL corpus where all non-agent roles are collapsed into a single role (denoted by a subscript $_c$ in all tables).

Since children do not generalize above two arguments during the modelled age range (Goldberg et al., 2004; Bello, 2012), the collapsed numbers more closely reflect the performance of a learner at this age than the raw numbers. The increase in accuracy obtained from collapsing non-agent arguments indicates that children may initially generalize incorrectly to some verbs and would need to learn lexically-specific role assignments (e.g. double-object constructions of *give*). Since the current work is interested in general filler-gap comprehension at this age, including over unknown verbs, the remaining analyses in this paper con-

[8]This is included for transparency, though the initial parameters have very little bearing on the final results as stated in Section 7, so the danger of overfitting to development data is very slight.

	P	R	F	P	R	F

sider performance when non-agent arguments are collapsed.[9]

Next, a filler-gap version of the BabySRL corpus is created using a coarse filtering process: the new corpus is comprised of all sentences where an associated object precedes the final verb and all sentences where the relevant subject is not immediately followed by the final verb (see Table 4). For these filler-gap evaluations, the model is trained on the full version of the corpus in question (e.g. Eve) before being tested on the filler-gap subset of that corpus. The overall results of the filler-gap evaluation (see Table 4) indicate that the model improves significantly at parsing filler-gap constructions after training.

The performance of the model on role-assignment in filler-gap constructions may be analyzed further in terms of how the model performs on subject-extractions compared with object-extractions and in terms of how the model performs on *that*-relatives compared with *wh*-relatives (see Table 5).

The model actually performs worse at subject-extractions after training than before training. This is unsurprising because, prior to training, subjects have little-to-no competition for preverbal role assignments; after training, there is a preverbal extracted object category, which the model can erroneously use. This slight, though significant in Eve, deficit is counter-balanced by a very substantial and significant improvement in object-extraction labelling accuracy.

Similarly, training confers a large and significant improvement for role assignment in *wh*-relative constructions, but it yields less of an improvement for *that*-relative constructions. This difference mimics a finding observed in the developmental literature where children seem slower to acquire comprehension of *that*-relatives than of *wh*-relatives (Gagliardi and Lidz, 2010).

[9]Though performance is slightly worse when arguments are not collapsed, all the same patterns emerge.

6 Comparison to BabySRL

The acquisition of semantic role labelling (SRL) by the BabySRL model (Connor et al., 2008; Connor et al., 2009; Connor et al., 2010) bears many similarities to the current work and is, to our knowledge, the only comparable line of inquiry to the current one. The primary function of BabySRL is to model the acquisition of semantic role labelling while making an idiosyncratic error which infants also make (Gertner and Fisher, 2012), the 1-1 role bias error (*John and Mary gorped* interpreted as *John gorped Mary*). Similar to the model presented in this paper, BabySRL is based on simple ordering features such as argument position relative to the verb and argument position relative to the other arguments.

This section will demonstrate that the model in this paper initially reflects 1-1 role bias comparably to BabySRL, though it progresses beyond this bias after training.[10] Further, the model in this paper is able to reflect the concurrent acquisition of filler-gap whereas BabySRL does not seem well-suited to such a task. Finally, BabySRL performs undesirably in intransitive settings whereas the model in this paper does not.

Connor et al. (2008) demonstrate that a supervised perceptron classifier, based on positional features and trained on the silver role label annotations of the BabySRL corpus, manifests 1-1 role bias errors. Follow-up studies show that supervision may be lessened (Connor et al., 2009) or removed (Connor et al., 2010) and BabySRL will still reflect a substantial 1-1 role bias.

Connor et al. (2008) and Connor et al. (2009) run direct analyses of how frequently their models make 1-1 role bias errors. A comparable evaluation may be run on the current model by generating 1000 sentences with a structure of NNV and reporting how many times the model chooses a subject-first labelling (see Table 6).[11]

[10]All evaluations in this section are preceded by training on the chunked Eve corpus.

[11]While Table 6 analyzes erroneous labellings of NNV structure, the 'Obj' column of Table 5 (Left)

	Error rate
Initial	.36
Trained	.11
Initial (given 2 args)	.66
Trained (given 2 args)	.13
2008 arg-arg position	.65
2008 arg-verb position	0
2009 arg-arg position	.82
2009 arg-verb position	.63

Table 6: 1-1 role bias error in this model compared to the models of Connor et al. (2008) and Connor et al. (2009). That is, how frequently each model labelled an NNV sentence SOV. Since the Connor et al. models are perceptron-based, they require both arguments be labelled. The model presented in this paper does not share this restriction, so the raw error rate for this model is presented in the first two lines; the error rate once this additional restriction is imposed is given in the second two lines.

The results of Connor et al. (2008) and Connor et al. (2009) depend on whether BabySRL uses argument-argument relative position as a feature or argument-verb relative position as a feature (there is no combined model). Further, the model presented here from Connor et al. (2009) has a unique argument constraint, similar to the model in this paper, in order to make comparison as direct as possible.

The 1-1 role bias error rate (before training) of the model presented in this paper is comparable to that of Connor et al. (2008) and Connor et al. (2009), which shows that the current model provides comparable developmental modeling benefits to the BabySRL models. Further, similar to real children (see Figure 1) the model presented in this paper develops beyond this error by the end of its training,[12] whereas the BabySRL models still make this error after training.

Connor et al. (2010) look at how frequently their model correctly labels the agent in transitive and intransitive sentences with unknown verbs (to demonstrate that it exhibits an agent-first bias). This evaluation can be replicated for the current study by generating 1,000 sentences with the transitive form of NVN and a further 1,000 sentences with the intransitive form of NV (see Table 7).

Since Connor et al. (2010) investigate the effects of different initial lexicons, this evaluation compares against the resulting BabySRL from each initializer: they initially seed their part-of-speech tagger with either the 10 or 365 most frequent nouns in the corpus or they dispense with the tagger and use gold part-of-speech tags.

	NVN	NV
Sents in Eve	1173	1513
Sents in Adam	1029	1353
Initial	.67	1
Trained	.65	.96
Weak (10) lexical	.71	.59
Strong (365) lexical	.74	.41
Gold Args	.77	.58

Table 7: Agent-prediction recall accuracy in transitive (NVN) and intransitive (NV) settings of the model presented in this paper (middle) and the combined model of Connor et al. (2010) (bottom), which has features for argument-argument relative position as well as argument-predicate relative position and so is closest to the model presented in this paper.

As with subject extraction, the model in this paper gets less accurate after training because of the newly minted extracted object category that can be mistakenly used in these canonical settings. While the model of Connor et al. (2010) outperforms the model presented here when in a transitive setting, their model does much worse in an intransitive setting. The difference in transitive settings stems from increased lexicalization, as is apparent from their results alone; the model presented here initially performs close to their weakly lexicalized model, though training impedes agent-prediction accuracy due to an increased probability of non-canonical objects.

For the intransitive case, however, whereas the model presented in this paper is generally able to successfully label the lone noun as the subject, the model of Connor et al. (2010) chooses to label lone nouns as objects about 40% of the time. This likely stems from their model's reliance on argument-argument relative position as a feature; when there is no additional argument to use for reference, the model's accuracy decreases. This is borne out by their model (not shown in Table 7) that omits the argument-argument relative position feature and solely relies on verb-argument position, which achieves up to 70% accuracy in intransitive settings. Even in that case, however, BabySRL still chooses to label lone nouns as objects 30% of the time. The fact that intransitive sentences are more common than transitive sentences in both the Eve and Adam sections of the BabySRL corpus suggests that learners should be more likely to assign

shows model accuracy on NNV structures.

[12] It is important to note that the unique argument constraint prevents the current model from actually getting the correct, conjoined-subject parse, but it no longer exhibits agent-first bias, an important step for acquiring passives, which occurs between 3 and 4 years (Thatcher et al., 2008).

correct roles in an intransitive setting, which is not reflected in the BabySRL results.

The overall reason for the different results between the current work and BabySRL is that BabySRL relies on positional features that measure the relative position of two individual elements (e.g. where a given noun is relative to the verb). Since the model in this paper operates over global orderings, it implicitly takes into account the positions of other nouns as it models argument position relative to the verb; object and subject are in competition as labels for preverbal nouns, so a preverbal object is usually only assigned once a subject has already been detected.

Further, while BabySRL consistently reflects 1-1 role bias (corresponding to a pre 25-month old learner), it also learns to productively label five roles, which developmental studies have shown does not take place until at least 31 months (Goldberg et al., 2004; Bello, 2012). Finally, it does not seem likely that BabySRL could be easily extended to capture filler-gap acquisition. The argument-verb position features impede acquisition of filler-gap by classifying preverbal arguments as agents, and the argument-argument position features inhibit accurate labelling in intransitive settings and result in an agent-first bias which would tend to label extracted objects as agents. In fact, these observations suggest that any linear classifier which relies on positioning features will have difficulties modeling filler-gap acquisition.

In sum, the unlexicalized model presented in this paper is able to achieve greater labelling accuracy than the lexicalized BabySRL models in intransitive settings, though this model does perform slightly worse in the less common transitive setting. Further, the unsupervised model in this paper initially reflects developmental 1-1 role bias as well as the supervised BabySRL models, and it is able to progress beyond this bias. Finally, unlike BabySRL, the model presented here provides a cognitive model of the acquisition of filler-gap comprehension, which BabySRL does not seem well-suited to model.

7 Discussion

This paper has presented a simple cognitive model of filler-gap acquisition, which is able to capture several findings from developmental psychology. Training significantly improves role labelling in the case of object-extractions, which improves the overall accuracy of the model. This boost is accompanied by a slight decrease in labelling accuracy in subject-extraction settings. The asymmetric ease of subject versus object comprehension is well-documented in both children and adults (Gibson, 1998), and while training improves the model's ability to process object-extractions, there is still a gap between object-extraction and subject-extraction comprehension even after training.

Further, the model exhibits better comprehension of *wh*-relatives than *that*-relatives similar to children (Gagliardi and Lidz, 2010). This could also be an area where a lexicalized model could do better. As Gagliardi and Lidz (2010) point out, whereas *wh*-relatives such as *who* or *which* always signify a filler-gap construction, *that* can occur for many different reasons (demonstrative, determiner, complementizer, etc) and so is a much weaker filler-gap cue. A lexical model could potentially pick up on clues which could indicate when *that* is a relativizer or simply improve on its comprehension of *wh*-relatives even more.

It is interesting to note that the cuurent model does not make use of *that* as a cue at all and yet is still slower at acquiring *that*-relatives than *wh*-relatives. This fact suggests that the findings of Gagliardi and Lidz (2010) may be partially explained by a frequency effect: perhaps the input to children is simply biased such that *wh*-relatives are much more common than *that*-relatives (as shown in Table 5).

This model also initially reflects the 1-1 role bias observed in children (Gertner and Fisher, 2012) as well as previous models (Connor et al., 2008; Connor et al., 2009; Connor et al., 2010) without sacrificing accuracy in canonical intransitive settings.

Finally, this model is extremely robust to different initializations. The canonical Gaussian expectations can begin far from the verb (± 3) or close to the verb (± 0.1), and the standard deviations of the distributions and the skip-penalty can vary widely; the model always converges to give comparable results to those presented here. The only constraint on the initial parameters is that the probability of the extracted object occurring preverbally must exceed the skip-penalty (i.e. extraction must be possible). In short, this paper describes a simple, robust cognitive model of the development of a learner between 15 months until somewhere between 25- and 30-months old (since 1-1 role bias is no longer present but no more than two arguments are being generalized).

In future, it would be interesting to incorporate lexicalization into the model presented in this paper, as this feature seems likely to bridge the gap between this model and BabySRL in transitive settings. Lexicalization should also help further distinguish modifiers from arguments and improve the overall accuracy of the model.

It would also be interesting to investigate how well this model generalizes to languages besides English. Since the model is able to use the verb position as a semi-permeable boundary between canonical subjects and objects, it may not work as

well in verb-final languages, and thus makes the prediction that filler-gap comprehension may be acquired later in development in such languages due to a greater reliance on hierarchical syntax.

Ordering is one of the definining characteristics of a language that must be acquired by learners (e.g. SVO vs SOV), and this work shows that filler-gap comprehension can be acquired as a by-product of learning orderings rather than having to resort to higher-order syntax. Note that this model cannot capture the constraints on filler-gap usage which require a hierarchical grammar (e.g. subjacency), but such knowledge is really only needed for successful production of filler-gap constructions, which occurs much later (around 5 years; de Villiers and Roeper, 1995). Further, the kind of ordering system proposed in this paper may form an initial basis for learning such grammars (Jackendoff and Wittenberg, in press).

Abstract

We present a method to jointly learn features and weights directly from distributional data in a log-linear framework. Specifically, we propose a non-parametric Bayesian model for learning phonological markedness constraints directly from the distribution of input-output mappings in an Optimality Theory (OT) setting. The model uses an Indian Buffet Process prior to learn the feature values used in the log-linear method, and is the first algorithm for learning phonological constraints without presupposing constraint structure. The model learns a system of constraints that explains observed data as well as the phonologically-grounded constraints of a standard analysis, with a violation structure corresponding to the standard constraints. These results suggest an alternative data-driven source for constraints instead of a fully innate constraint set.

1 Introduction

Many aspects of human cognition involve the interaction of constraints that push a decision-maker toward different options, whether in something so trivial as choosing a movie or so important as a fight-or-flight response. These constraint-driven decisions can be modeled with a log-linear system. In these models, a set of constraints is weighted and their violations are used to determine a probability distribution over outcomes. But where do these constraints come from?

We consider this question by examining the dominant framework in modern phonology, Optimality Theory (Prince and Smolensky, 1993, OT), implemented in a log-linear framework, MaxEnt OT (Goldwater and Johnson, 2003), with output forms' probabilities based on a weighted sum of constraint violations. OT analyses generally assume that the constraints are innate and universal, both to obviate the problem of learning constraints' identities and to limit the set of possible languages.

We propose a new approach: to learn constraints with limited innate phonological knowledge by identifying sets of constraint violations that explain the observed distributional data, instead of selecting constraints from an innate set of constraint definitions. Because the constraints are identified as sets of violations, this also permits constraints specific to a given language to be learned. This method, which we call IBPOT, uses an Indian Buffet Process (IBP) prior to define the space of possible constraint violation matrices, and uses Bayesian reasoning to identify constraint matrices likely to have generated the observed data. In identifying constraints solely by their extensional violation profiles, this method does not directly identify the intensional definitions of the identified constraints, but to the extent that the resulting violation profiles are phonologically interpretable, we may conclude that the data themselves guide constraint identification. We test IBPOT on tongue-root vowel harmony in Wolof, a West African language.

The set of constraints learned by the model satisfy two major goals: they explain the data as well as the standard phonological analysis, and their violation structures correspond to the standard constraints. This suggests an alternative data-driven genesis for constraints, rather than the traditional assumption of fully innate constraints.

2 Phonology and Optimality Theory

2.1 OT structure

Optimality Theory has been used for constraint-based analysis of many areas of language, but we focus on its most successful application: phonology. We consider an OT analysis of the mappings

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1094–1103,
Baltimore, Maryland, USA, June 23-25 2014.

between underlying forms and their phonological manifestations – i.e., mappings between forms in the mental lexicon and the actual vocalized forms of the words.[1]

Stated generally, an OT system takes some input, generates a set of candidate outputs, determines what constraints each output violates, and then selects a candidate output with a relatively unobjectionable violation profile. To do this, an OT system contains four major components: a generator GEN, which generates candidate output forms for the input; a set of constraints CON, which penalize candidates; a evaluation method EVAL, which selects an winning candidate; and H, a language-particular weighting of constraints that EVAL uses to determine the winning candidate. Previous OT work has focused on identifying the appropriate formulation of EVAL and the values and acquisition of H, while taking GEN and CON as given. Here, we expand the learning task by proposing an acquisition method for CON.

To learn CON, we propose a data-driven markedness constraint learning system that avoids both innateness and tractability issues. Unlike previous OT learning methods, which assume known constraint definitions and only learn the relative strength of these constraints, the IBPOT learns constraint violation profiles and weights for them simultaneously. The constraints are derived from sets of violations that effectively explain the observed data, rather than being selected from a preexisting set of possible constraints.

2.2 OT as a weighted-constraint method

Although all OT systems share the same core structure, different choices of EVAL lead to different behaviors. In IBPOT, we use the log-linear EVAL developed by Goldwater and Johnson (2003) in their MaxEnt OT system. MEOT extends traditional OT to account for variation (cases in which multiple candidates can be the winner), as well as gradient/probabilistic productions (Anttila, 1997) and other constraint interactions (e.g., cumulativity) that traditional OT cannot handle (Keller, 2000). MEOT also is motivated by the general MaxEnt framework, whereas most other OT formulations are ad hoc constructions specific to phonology.

In MEOT, each constraint C_i is associated with a weight $w_i < 0$. (Weights are always negative in OT; a constraint violation can never make a candidate more likely to win.) For a given input-candidate pair (x, y), $f_i(y, x)$ is the number of violations of constraint C_i by the pair. As a maximum entropy model, the probability of y given x is proportional to the exponential of the weighted sum of violations, $\sum_i w_i f_i(y, x)$. If $\mathcal{Y}(x)$ is the set of all output candidates for the input x, then the probability of y as the winning output is:

$$p(y|x) = \frac{\exp\left(\sum_i w_i f_i(y, x)\right)}{\sum_{z \in \mathcal{Y}(x)} \exp\left(\sum_i w_i f_i(z, x)\right)} \quad (1)$$

This formulation represents a probabilistic extension of the traditional formulation of OT (Prince and Smolensky, 1993). Traditionally, constraints form a strict hierarchy, where a single violation of a high-ranked constraint is worse than any number of violations of lower-ranked constraints. Traditional OT is also deterministic, with the optimal candidate always selected. In MEOT, the constraint weights define hierarchies of varying strictness, and some probability is assigned to all candidates. If constraints' weights are close together, multiple violations of lower-weighted constraints can reduce a candidate's probability below that of a competitor with a single high-weight violation. As the distance between weights in MEOT increases, the probability of a suboptimal candidate being chosen approaches zero; thus the traditional formulation is a limit case of MEOT.

2.3 OT in practice

Figure 1 shows *tableaux*, a visualization for OT, applied in Wolof (Archangeli and Pulleyblank, 1994; Boersma, 1999). We are interested in four Wolof constraints that combine to induce vowel harmony: *ɪ, PARSE[rtr], HARMONY, and PARSE[atr]. The meaning of these constraints will be discussed in Sect. 4.1; for now, we will only consider their violation profiles. Each column represents a constraint, with weights decreasing left-to-right. Each tableau looks at a single input form, noted in the top-left cell: ete, ɛtɛ, ɪte, or itɛ.

Each row is a candidate output form. A black cell indicates that the candidate, or input-candidate pair, violates the constraint in that column.[2] A white cell indicates no violation. Grey stripes are

[1] Although phonology is usually framed in terms of sound, sign languages also have components that serve equivalent roles in the physical realization of signs (Stokoe, 1960).

[2] In general, a constraint can be violated multiple times by a given candidate, but we will be using binary constraints (violated or not) in this work. See Sect. 5.2 for further discussion.

Figure 1: Tableaux for the Wolof input forms ete, ɛtɛ, ɪte, and itɛ. Black indicates violation, white no violation. Scores are calculated for a MaxEnt OT system with constraint weights of -64, -32, -16, and -8, approximating a traditional hierarchical OT design. Values of grey-striped cells have negligible effects on the distribution (see Sect. 4.3).

overlaid on cells whose value will have a negligible impact on the distribution due to the values of higher-ranked constraint.

Constraints fall into two categories, faithfulness and markedness, which differ in what information they use to assign violations. Faithfulness constraints penalize mismatches between the input and output, while markedness constraints consider only the output. Faithfulness violations include phoneme additions or deletions between the input and output; markedness violations include penalizing specific phonemes in the output form, regardless of whether the phoneme is present in the input.

In MaxEnt OT, each constraint has a weight, and the candidates' scores are the sums of the weights of violated constraints. In the ete tableau at top left, output ete has no violations, and therefore a score of zero. Outputs ɛte and etɛ violate both HARMONY (weight 16) and PARSE[atr] (weight 8), so their scores are 24. Output ɛtɛ violates PARSE[atr], and has score 8. Thus the log-probability of output ɛtɛ is 1/8 that of ete, and the log-probability of disharmonious ɛte and etɛ are each 1/24 that of ete. As the ratio between scores increases, the log-probability ratios can become arbitrarily close to zero, approximating the deterministic situation of traditional OT.

2.4 Learning Constraints

Choosing a winning candidate presumes that a set of constraints CON is available, but where do these constraints come from? The standard assumption within OT is that CON is innate and universal. But in the absence of direct evidence of innate constraints, we should prefer a method that can derive the constraints from cognitively-general learning over one that assumes they are pre-specified. Learning appropriate model features has been an important idea in the development of constraint-based models (Della Pietra et al., 1997).

The innateness assumption can induce tractability issues as well. The strictest formulation of innateness posits that virtually all constraints are shared across all languages, even when there is no evidence for the constraint in a particular language (Tesar and Smolensky, 2000). Strict universality is undermined by the extremely large set of constraints it must weight, as well as the possible existence of language-particular constraints (Smith, 2004).

A looser version of universality supposes that constraints are built compositionally from a set of constraint templates or primitives or phonological features (Hayes, 1999; Smith, 2004; Idsardi, 2006; Riggle, 2009). This version allows language-particular constraints, but it comes with a computational cost, as the learner must be able to generate and evaluate possible constraints while learning the language's phonology. Even with relatively simple constraint templates, such as the phonological constraint learner of Hayes and Wilson (2008), the number of possible constraints expands exponentially. Depending on the specific formulation of the constraints, the constraint identification problem may even be NP-hard (Idsardi, 2006; Heinz et al., 2009). Our approach of casting the learning problem as one of identifying violation profiles is an attempt to determine the amount that can be learned about the active constraints in a paradigm without hypothesizing intensional constraint definitions. The violation profile informa-

tion used by our model could then be used to narrow the search space for intensional constraints, either by performing post-hoc analysis of the constraints identified by our model or by combining intensional constraint search into the learning process. We discuss each of these possibilities in Section 5.2.

Innateness is less of a concern for faithfulness than markedness constraints. Faithfulness violations are determined by the changes between an input form and a candidate, yielding an independent motivation for a universal set of faithfulness constraints (McCarthy, 2008). Some markedness constraints can also be motivated in a universal manner (Hayes, 1999), but many markedness constraints lack such grounding.[3] As such, it is unclear where a universal set of markedness constraints would come from.

3 The IBPOT Model

3.1 Structure

The IBPOT model defines a generative process for mappings between input and output forms based on three latent variables: the constraint violation matrices F (faithfulness) and M (markedness), and the weight vector w. The cells of the violation matrices correspond to the number of violations of a constraint by a given input-output mapping. F_{ijk} is the number of violations of faithfulness constraint F_k by input-output pair type (x_i, y_j); M_{jl} is the number of violations of markedness constraint $M_{\cdot l}$ by output candidate y_j. Note that M is shared across inputs, as M_{jl} has the same value for all input-output pairs with output y_j. The weight vector w provides weight for both F and M. Probabilities of output forms are given by a log-linear function:

$$p(y_j|x_i) = \frac{\exp\left(\sum_k w_k F_{ijk} + \sum_l w_l M_{jl}\right)}{\sum_{y_z \in \mathcal{Y}(x_i)} \exp\left(\sum_k w_k F_{izk} + \sum_l w_l M_{zl}\right)} \quad (2)$$

Note that this is the same structure as Eq. 1 but with faithfulness and markedness constraints listed separately. As discussed in Sect. 2.4, we assume that F is known as part of the output of GEN (Riggle, 2009). The goal of the IBPOT model is to learn the markedness matrix M and weights w for both the markedness and faithfulness constraints.

As for M, we need a non-parametric prior, as there is no inherent limit to the number of markedness constraints a language will use. We use the Indian Buffet Process (Griffiths and Ghahramani, 2005), which defines a proper probability distribution over binary feature matrices with an unbounded number of columns. The IBP can be thought of as representing the set of dishes that diners eat at an infinite buffet table. Each diner (i.e., output form) first draws dishes (i.e., constraint violations) with probability proportional to the number of previous diners who drew it: $p(M_{jl} = 1|\{M_{zl}\}_{z<j}) = n_l/j$. After choosing from the previously taken dishes, the diner can try additional dishes that no previous diner has had. The number of new dishes that the j-th customer draws follows a Poisson(α/j) distribution. The complete specification of the model is then:

$$M \sim IBP(\alpha); \qquad \mathcal{Y}(x_i) = Gen(x_i)$$
$$w \sim -\Gamma(1,1); \quad y|x_i \sim LogLin(M, F, w, \mathcal{Y}(x_i))$$

3.2 Inference

To perform inference in this model, we adopt a common Markov chain Monte Carlo estimation procedure for IBPs (Görür et al., 2006; Navarro and Griffiths, 2007). We alternate approximate Gibbs sampling over the constraint matrix M, using the IBP prior, with a Metropolis-Hastings method to sample constraint weights w.

We initialize the model with a randomly-drawn markedness violation matrix M and weight vector w. To learn, we iterate through the output forms y_j; for each, we split $M_{-j\cdot}$ into "represented" constraints (those that are violated by at least one output form other than y_j) and "non-represented" constraints (those violated only by y_j). For each represented constraint $M_{\cdot l}$, we re-sample the value for the cell M_{jl}. All non-represented constraints are removed, and we propose new constraints, violated only by y_j, to replace them. After each iteration through M, we use Metropolis-Hastings to update the weight vector w.

Represented constraint sampling We begin by resampling M_{jl} for all represented constraints $M_{\cdot l}$, conditioned on the rest of the violations $(M_{-(jl)}, F)$ and the weights w. This is the sampling counterpart of drawing existing features in the IBP generative process. By Bayes' Rule, the

[3] McCarthy (2008, §4.8) gives examples of "ad hoc" intersegmental constraints. Even well-known constraint types, such as generalized alignment, can have disputed structures (Hyde, 2012).

posterior probability of a violation is proportional to product of the likelihood $p(Y|M_{jl} = 1, M_{-jl}, F, w)$ from Eq. 2 and the IBP prior probability $p(M_{jl} = 1|M_{-jl}) = n_{-jl}/n$, where n_{-jl} is the number of outputs other than y_j that violate constraint $M_{\cdot l}$.

Non-represented constraint sampling After sampling the represented constraints for y_j, we consider the addition of new constraints that are violated only by y_j. This is the sampling counterpart to the Poisson draw for new features in the IBP generative process. Ideally, this would draw new constraints from the infinite feature matrix; however, this requires marginalizing the likelihood over possible weights, and we lack an appropriate conjugate prior for doing so. We approximate the infinite matrix with a truncated Bernoulli draw over unrepresented constraints (Görür et al., 2006). We consider in each sample at most K^* new constraints, with weights based on the auxiliary vector w^*. This approximation retains the unbounded feature set of the IBP, as repeated sampling can add more and more constraints without limit.

The auxiliary vector w^* contains the weights of all the constraints that have been removed in the previous step. If the number of constraints removed is less than K^*, w^* is filled out with draws from the prior distribution over weights. We then consider adding any subset of these new constraints to M, each of which would be violated only by y_j. Let M^* represent a (possibly empty) set of constraints paired with a subset of w^*. The posterior probability of drawing M^* from the truncated Bernoulli distribution is the product of the prior probability of M^* $\left(\frac{\frac{\alpha}{K^*}}{N_Y + \frac{\alpha}{K^*}}\right)$ and the likelihood $p(Y|M^*, w^*, M, w, F)$, including the new constraints M^*.

Weight sampling After sampling through all candidates, we use Metropolis-Hastings to estimate new weights for both constraint matrices. Our proposal distribution is $Gamma({w_k}^2/\eta, \eta/w_k)$, with mean w_k and mode $w_k - \frac{\eta}{w_k}$ (for $w_k > 1$). Unlike Gibbs sampling on the constraints, which occurs only on markedness constraints, weights are sampled for both markedness and faithfulness features.

4 Experiment

4.1 Wolof vowel harmony

We test the model by learning the markedness constraints driving Wolof vowel harmony (Archangeli and Pulleyblank, 1994). Vowel harmony in general refers to a phonological phenomenon wherein the vowels of a word share certain features in the output form even if they do not share them in the input. In the case of Wolof, harmony encourages forms that have consistent tongue root positions.

The Wolof vowel system has two relevant features, tongue root position and vowel height. The tongue root can either be advanced (ATR) or retracted (RTR), and the body of the tongue can be in the high, middle, or low part of the mouth. These features define six vowels:

	high	mid	low
ATR	i	e	ə
RTR	ɪ	ɛ	a

We test IBPOT on the harmony system provided in the Praat program (Boersma, 1999), previously used as a test case by Goldwater and Johnson (2003) for MEOT learning with known constraints. This system has four constraints:[4]

- Markedness:
  - *ɪ: do not have ɪ (high RTR vowel)
  - HARMONY: do not have RTR and ATR vowels in the same word
- Faithfulness:
  - PARSE[rtr]: do not change RTR input to ATR output
  - PARSE[atr]: do not change ATR input to RTR output

These constraints define the phonological standard that we will compare IBPOT to, with a ranking from strongest to weakest of *ɪ >> PARSE[rtr] >> HARMONY >> PARSE[atr]. Under this ranking, Wolof harmony is achieved by changing a disharmonious ATR to an RTR, unless this creates an ɪ vowel. We see this in Figure 1, where three of the four winners are harmonic, but with input itɛ, harmony would require violating one of the two higher-ranked constraints. As in previous MEOT work, all Wolof candidates are faithful

[4]The version in Praat includes a fifth constraint, but its value never affects the choice of output in our data and is omitted in this analysis.

with respect to vowel height, either because height changes are not considered by GEN, or because of a high-ranked faithfulness constraint blocking height changes.[5]

The Wolof constraints provide an interesting testing ground for the model, because it is a small set of constraints to be learned, but contains the HARMONY constraint, which can be violated by non-adjacent segments. Non-adjacent constraints are difficult for string-based approaches because of the exponential number of possible relationships across non-adjacent segments. However, the Wolof results show that by learning violations directly, IBPOT does not encounter problems with non-adjacent constraints.

The Wolof data has 36 input forms, each of the form $V_1 t V_2$, where V_1 and V_2 are vowels that agree in height. Each input form has four candidate outputs, with one output always winning. The outputs appear for multiple inputs, as shown in Figure 1. The candidate outputs are the four combinations of tongue-roots for the given vowel heights; the inputs and candidates are known to the learner. We generate simulated data by observing 1000 instances of the winning output for each input.[6] The model must learn the markedness constraints *ɪ and HARMONY, as well as the weights for all four constraints.

We make a small modification to the constraints for the test data: all constraints are limited to binary values. For constraints that can be violated multiple times by an output (e.g., *ɪ twice by ɪtɪ), we use only a single violation. This is necessary in the current model definition because the IBP produces a prior over binary matrices. We generate the simulated data using only single violations of each constraint by each output form. Overcoming the binarity restriction is discussed in Sect. 5.2.

4.2 Experiment Design

We run the model for 10000 iterations, using deterministic annealing through the first 2500 iterations. The model is initialized with a random markedness matrix drawn from the IBP and weights from the exponential prior. We ran versions of the model with parameter settings between 0.01 and 1 for α, 0.05 and 0.5 for η, and 2 and 5 for K^*. All these produced quantitatively similar results; we report values for $\alpha = 1$, $\eta = 0.5$, and $K^* = 5$, which provides the least bias toward small constraint sets.

To establish performance for the phonological standard, we use the IBPOT learner to find constraint weights but do not update M. The resultant learner is essentially MaxEnt OT with the weights estimated through Metropolis sampling instead of gradient ascent. This is done so that the IBPOT weights and phonological standard weights are learned by the same process and can be compared. We use the same parameters for this baseline as for the IBPOT tests. The results in this section are based on nine runs each of IBPOT and MEOT; ten MEOT runs were performed but one failed to converge and was removed from analysis.

4.3 Results

A successful set of learned constraints will satisfy two criteria: achieving good data likelihood (no worse than the phonological-standard constraints) and acquiring constraint violation profiles that are phonologically interpretable. We find that both of these criteria are met by IBPOT on Wolof.

Likelihood comparison First, we calculate the joint probability of the data and model given the priors, $p(Y, M, w|F, \alpha)$, which is proportional to the product of three terms: the data likelihood $p(Y|M, F, w)$, the markedness matrix probability $p(M|\alpha)$, and the weight probability $p(w)$. We present both the mean and MAP values for these over the final 1000 iterations of each run. Results are shown in Table 1.

All eight differences are significant according to t-tests over the nine runs. In all cases but mean M, the IBPOT method has a better log-probability. The most important differences are those in the data probabilities, as the matrix and weight probabilities are reflective primarily of the choice of prior. By both measures, the IBPOT constraints explain the observed data better than the phonologically standard constraints.

Interestingly, the mean M probability is lower for IBPOT than for the phonological standard. Though the phonologically standard constraints

[5] In the present experiment, we assume that GEN does not generate candidates with unfaithful vowel heights. If unfaithful vowel heights were allowed by GEN, these unfaithful candidates would incur a violation approximately as strong as *ɪ, as neither unfaithful-height candidates nor ɪ candidates are attested in the Wolof data.

[6] Since data, matrix, and weight likelihoods all shape the learned constraints, there must be enough data for the model to avoid settling for a simple matrix that poorly explains the data. This represents a similar training set size to previous work (Goldwater and Johnson, 2003; Boersma and Hayes, 2001).

	MAP		Mean	
	IBPOT	PS	IBPOT	PS
Data	-1.52	-3.94	-5.48	-9.23
M	-51.7	-53.3	-54.7	-53.3
w	-44.2	-71.1	-50.6	-78.1
Joint	-97.4	-128.4	-110.6	-140.6

Table 1: Data, markedness matrix, weight vector, and joint log-probabilities for the IBPOT and the phonological standard constraints. MAP and mean estimates over the final 1000 iterations for each run. All IBPOT/PS differences are significant ($p < .005$ for MAP M; $p < .001$ for others).

exist independently of the IBP prior, they fit the prior better than the average IBPOT constraints do. This shows that the IBP's prior preferences can be overcome in order to have constraints that better explain the data.

Constraint comparison Our second criterion is the acquisition of meaningful constraints, that is, ones whose violation profiles have phonologically-grounded explanations. IBPOT learns the same number of markedness constraints as the phonological standard (two); over the final 1000 iterations of the model runs, 99.2% of the iterations had two markedness constraints, and the rest had three.

Turning to the form of these constraints, Figure 2 shows violation profiles from the last iteration of a representative IBPOT run.[7] Because vowel heights must be faithful between input and output, the Wolof data is divided into nine separate *paradigms*, each containing the four candidates (ATR/RTR $\times$ ATR/RTR) for the vowel heights in the input.

The violations on a given output form only affect probabilities within its paradigm. As a result, learned constraints are consistent within paradigms, but across paradigms, the same constraint may serve different purposes.

For instance, the strongest learned markedness constraint, shown as *M1* in Figure 2, has the same violations as the top-ranked constraint that actively distinguishes between candidates in each paradigm. For the five paradigms with at least one high vowel (the top row and left column), *M1* has the same violations as *ɪ, as *ɪ penalizes some but not all of the candidates. In the other four paradigms, *ɪ penalizes none of the candidates, and the IBPOT learner has no reason to learn it. Instead, it learns that *M1* has the same violations as HARMONY, which is the highest-weighted constraint that distinguishes between candidates in these paradigms. Thus in the high-vowel paradigms, *M1* serves as *ɪ, while in the low/mid-vowel paradigms, it serves as HARMONY.

The lower-weighted *M2* is defined noisily, as the higher-ranked *M1* makes some values of *M2* inconsequential. Consider the top-left paradigm of Figure 2, the high-high input, in which only one candidate does not violate *M1* (*ɪ). Because *M1* has a much higher weight than *M2*, a violation of *M2* has a negligible effect on a candidate's probability.[8] In such cells, the constraint's value is influenced more by the prior than by the data. These inconsequential cells are overlaid with grey stripes in Figure 2.

The meaning of *M2*, then, depends only on the consequential cells. In the high-vowel paradigms, *M2* matches HARMONY, and the learned and standard constraints agree on all consequential violations, despite being essentially at chance on the indistinguishable violations (58%). On the non-high paradigms, the meaning of *M2* is unclear, as HARMONY is handled by *M1* and *ɪ is unviolated. In all four paradigms, the model learns that the RTR-RTR candidate violates *M2* and the ATR-ATR candidate does not; this appears to be the model's attempt to reinforce a pattern in the lowest-ranked faithfulness constraint (PARSE[atr]), which the ATR-ATR candidate never violates.

Thus, while the IBPOT constraints are not identical to the phonologically standard ones, they reflect a version of the standard constraints that is consistent with the IBPOT framework.[9] In paradigms where each markedness constraint distinguishes candidates, the learned constraints match the standard constraints. In paradigms where only one constraint distinguishes candidates, the top learned constraint matches it and the second learned constraint exhibits a pattern consistent with a low-ranked faithfulness constraint.

[7] Specifically, from the run with the median joint posterior.

[8] Given the learned weights in Fig. 2, if the losing candidate violates *M1*, its probability changes from 10^{-12} when the preferred candidate does not violate *M2* to 10^{-8} when it does.

[9] In fact, it appears this constraint organization is favored by IBPOT as it allows for lower weights, hence the large difference in w log-probability in Table 1.

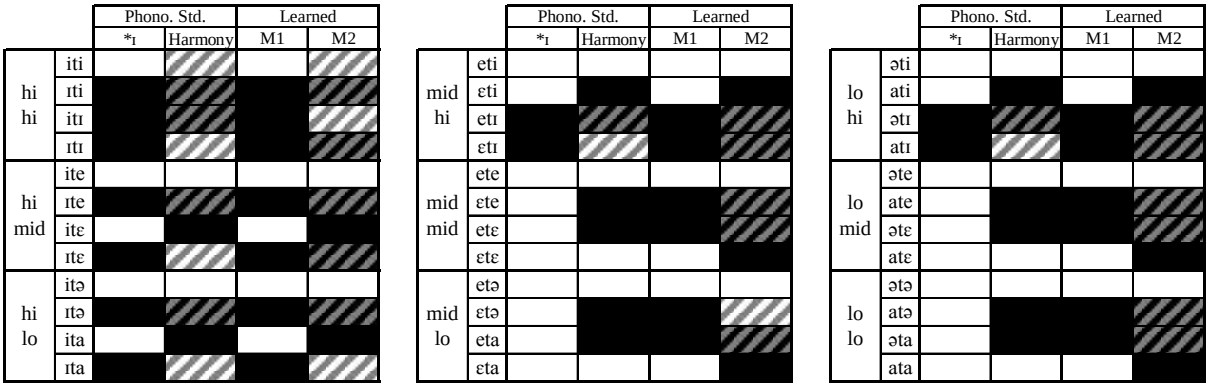

Figure 2: Phonologically standard (*ɪ, HARMONY) and learned (*M1,M2*) constraint violation profiles for the output forms. Learned weights for the standard constraints are -32.8 and -15.3; for *M1* and *M2*, they are -26.5 and -8.4. Black indicates violation, white no violation. Grey stripes indicate cells whose values have negligible effects on the probability distribution.

5 Discussion and Future Work

5.1 Relation to phonotactic learning

Our primary finding from IBPOT is that it is possible to identify constraints that are both effective at explaining the data and representative of theorized phonologically-grounded constraints, given only input-output mappings and faithfulness violations. Furthermore, these constraints are successfully acquired without any knowledge of the phonological structure of the data beyond the faithfulness violation profiles. The model's ability to infer constraint violation profiles without theoretical constraint structure provides an alternative solution to the problems of the traditionally innate and universal OT constraint set.

As it jointly learns constraints and weights, the IBPOT model calls to mind Hayes and Wilson's (2008) joint phonotactic learner. Their learner also jointly learns weights and constraints, but directly selects its constraints from a compositional grammar of constraint definitions. This limits their learner in practice by the rapid explosion in the number of constraints as the maximum constraint definition size grows. By directly learning violation profiles, the IBPOT model avoids this explosion, and the violation profiles can be automatically parsed to identify the constraint definitions that are consistent with the learned profile. The inference method of the two models is different as well; the phonotactic learner selects constraints greedily, whereas the sampling on M in IBPOT asymptotically approaches the posterior.

The two learners also address related but different phonological problems. The phonotactic learner considers phonotactic problems, in which only output matters. The constraints learned by Hayes and Wilson's learner are essentially OT markedness constraints, but their learner does not have to account for varied inputs or effects of faithfulness constraints.

5.2 Extending the learning model

IBPOT, as proposed here, learns constraints based on binary violation profiles, defined extensionally. A complete model of constraint acquisition should provide intensional definitions that are phonologically grounded and cover potentially non-binary constraints. We discuss how to extend the model toward these goals.

IBPOT currently learns extensional constraints, defined by which candidates do or do not violate the constraint. Intensional definitions are needed to extend constraints to unseen forms. Post hoc violation profile analysis, as in Sect. 4.3, provides a first step toward this goal. Such analysis can be integrated into the learning process using the Rational Rules model (Goodman et al., 2008) to identify likely constraint definitions compositionally. Alternately, phonological knowledge could be integrated into a joint constraint learning process in the form of a naturalness bias on the constraint weights or a phonologically-motivated replacement for the IBP prior.

The results presented here use binary constraints, where each candidate violates each constraint only once, a result of the IBP's restriction to binary matrices. Non-binarity can be handled by using the binary matrix M to indicate whether a candidate violates a constraint, with a second

distribution determining the number of violations. Alternately, a binary matrix can directly capture non-binary constraints; Frank and Satta (1998) converted existing non-binary constraints into a binary OT system by representing non-binary constraints as a set of equally-weighted overlapping constraints, each accounting for one violation. The non-binary harmony constraint, for instance, becomes a set {*(at least one disharmony), *(at least two disharmonies), etc.}.

Lastly, the Wolof vowel harmony problem provides a test case with overlaps in the candidate sets for different inputs. This candidate overlap helps the model find appropriate constraint structures. Analyzing other phenomena may require the identification of appropriate abstractions to find this same structural overlap. English regular plurals, for instance, fall into broad categories depending on the features of the stem-final phoneme. IBPOT learning in such settings may require learning an appropriate abstraction as well.

6 Conclusion

A central assumption of Optimality Theory has been the existence of a fixed inventory of universal markedness constraints innately available to the learner, an assumption by arguments regarding the computational complexity of constraint identification. However, our results show for the first time that nonparametric, data-driven learning can identify sparse constraint inventories that both accurately predict the data and are phonologically meaningful, providing a serious alternative to the strong nativist view of the OT constraint inventory.

Abstract

Many machine learning datasets are noisy with a substantial number of mislabeled instances. This noise yields sub-optimal classification performance. In this paper we study a large, low quality annotated dataset, created quickly and cheaply using Amazon Mechanical Turk to crowdsource annotations. We describe computationally cheap feature weighting techniques and a novel non-linear distribution spreading algorithm that can be used to iteratively and interactively correcting mislabeled instances to significantly improve annotation quality at low cost. Eight different emotion extraction experiments on Twitter data demonstrate that our approach is just as effective as more computationally expensive techniques. Our techniques save a considerable amount of time.

1 Introduction

Supervised classification algorithms require annotated data to teach the machine, by example, how to perform a specific task. There are generally two ways to collect annotations of a dataset: through a few expert annotators, or through crowdsourcing services (e.g., Amazon's Mechanical Turk). High-quality annotations can be produced by expert annotators, but the process is usually slow and costly. The latter option is appealing since it creates a large annotated dataset at low cost. In recent years, there have been an increasing number of studies (Su et al., 2007; Kittur et al., 2008; Sheng et al., 2008; Snow et al., 2008; Callison-Burch, 2009) using crowdsourcing for data annotation. However, because annotators that are recruited this way may lack expertise and motivation, the annotations tend to be more noisy and unreliable, which significantly reduces the performance of the classification model. This is a challenge faced by many real world applications – *given a large, quickly and cheaply created, low quality annotated dataset, how can one improve its quality and learn an accurate classifier from it?*

Re-annotating the whole dataset is too expensive. To reduce the annotation effort, it is desirable to have an algorithm that selects the most likely mislabeled examples first for re-labeling. The process of selecting and re-labeling data points can be conducted with multiple rounds to iteratively improve the data quality. This is similar to the strategy of active learning. The basic idea of active learning is to learn an accurate classifier using less training data. An active learner uses a small set of labeled data to iteratively select the most informative instances from a large pool of unlabeled data for human annotators to label (Settles, 2010). In this work, we borrow the idea of active learning to interactively and iteratively correct labeling errors.

The crucial step is to *effectively and efficiently* select the most likely mislabeled instances. An intuitive idea is to design algorithms that classify the data points and rank them according to the decreasing confidence scores of their labels. The data points with the highest confidence scores but conflicting preliminary labels are most likely mislabeled. The algorithm should be computationally cheap as well as accurate, so it fits well with active learning and other problems that require frequent iterations on large datasets. Specifically, we propose a novel non-linear distribution spreading algorithm, which first uses Delta IDF technique (Martineau and Finin, 2009) to weight features, and then leverages the distribution of Delta IDF scores of a feature across different classes to efficiently recognize discriminative features for the classification task in the presence of mislabeled data. The idea is that some effective fea-

*This author's research was done during an internship with Samsung Research America.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1104–1112,
Baltimore, Maryland, USA, June 23-25 2014.

tures may be subdued due to label noise, and the proposed techniques are capable of counteracting such effect, so that the performance of classification algorithms could be less affected by the noise. With the proposed algorithm, the active learner becomes more accurate and resistant to label noise, thus the mislabeled data points can be more easily and accurately identified.

We consider emotion analysis as an interesting and challenging problem domain of this study, and conduct comprehensive experiments on Twitter data. We employ Amazon's Mechanical Turk (AMT) to label the emotions of Twitter data, and apply the proposed methods to the AMT dataset with the goals of improving the annotation quality at low cost, as well as learning accurate emotion classifiers. Extensive experiments show that, the proposed techniques are as effective as more computational expensive techniques (e.g, Support Vector Machines) but require significantly less time for training/running, which makes it well-suited for active learning.

2 Related Work

Research on handling noisy dataset of mislabeled instances has focused on three major groups of techniques: (1) noise tolerance, (2) noise elimination, and (3) noise correction.

Noise tolerance techniques aim to improve the learning algorithm itself to avoid over-fitting caused by mislabeled instances in the training phase, so that the constructed classifier becomes more noise-tolerant. Decision tree (Mingers, 1989; Vannoorenberghe and Denoeux, 2002) and boosting (Jiang, 2001; Kalaia and Servediob, 2005; Karmaker and Kwek, 2006) are two learning algorithms that have been investigated in many studies. Mingers (1989) explores pruning methods for identifying and removing unreliable branches from a decision tree to reduce the influence of noise. Vannoorenberghe and Denoeux (2002) propose a method based on belief decision trees to handle uncertain labels in the training set. Jiang (2001) studies some theoretical aspects of regression and classification boosting algorithms in dealing with noisy data. Kalaia and Servediob (2005) present a boosting algorithm which can achieve arbitrarily high accuracy in the presence of data noise. Karmaker and Kwek (2006) propose a modified AdaBoost algorithm – ORBoost, which minimizes the impact of outliers and becomes more tolerant to class label noise. One of the main disadvantages of noise tolerance techniques is that they are learning algorithm-dependent. In contrast, noise elimination/correction approaches are more generic and can be more easily applied to various problems.

A large number of studies have explored noise elimination techniques (Brodley and Friedl, 1999; Verbaeten and Van Assche, 2003; Zhu et al., 2003; Muhlenbach et al., 2004; Guan et al., 2011), which identifies and removes mislabeled examples from the dataset as a pre-processing step before building classifiers. One widely used approach (Brodley and Friedl, 1999; Verbaeten and Van Assche, 2003) is to create an ensemble classifier that combines the outputs of multiple classifiers by either majority vote or consensus, and an instance is tagged as mislabeled and removed from the training set if it is classified into a different class than its training label by the ensemble classifier. The similar approach is adopted by Guan et al. (2011) and they further demonstrate that its performance can be significantly improved by utilizing unlabeled data. To deal with the noise in large or distributed datasets, Zhu et al. (2003) propose a partition-based approach, which constructs classification rules from each subset of the dataset, and then evaluates each instance using these rules. Two noise identification schemes, majority and non-objection, are used to combine the decision from each set of rules to decide whether an instance is mislabeled. Muhlenbach et al. (2004) propose a different approach, which represents the proximity between instances in a geometrical neighborhood graph, and an instance is considered suspect if in its neighborhood the proportion of examples of the same class is not significantly greater than in the dataset itself.

Removing mislabeled instances has been demonstrated to be effective in increasing the classification accuracy in prior studies, but there are also some major drawbacks. For example, useful information can be removed with noise elimination, since annotation errors are likely to occur on ambiguous instances that are potentially valuable for learning algorithms. In addition, when the noise ratio is high, there may not be adequate amount of data remaining for building an accurate classifier. The proposed approach does not suffer these limitations.

Instead of eliminating the mislabeled examples

from training data, some researchers (Zeng and Martinez, 2001; Rebbapragada et al., 2012; Laxman et al., 2013) propose to correct labeling errors either with or without consulting human experts. Zeng and Martinez (2001) present an approach based on backpropagation neural networks to automatically correct the mislabeled data. Laxman et al. (2012) propose an algorithm which first trains individual SVM classifiers on several small, class-balanced, random subsets of the dataset, and then reclassifies each training instance using a majority vote of these individual classifiers. However, the automatic correction may introduce new noise to the dataset by mistakenly changing a correct label to a wrong one.

In many scenarios, it is worth the effort and cost to fix the labeling errors by human experts, in order to obtain a high quality dataset that can be reused by the community. Rebbapragada et al. (2012) propose a solution called Active Label Correction (ALC) which iteratively presents the experts with small sets of suspected mislabeled instances at each round. Our work employs a similar framework that uses active learning for data cleaning.

In Active Learning (Settles, 2010) a small set of labeled data is used to find documents that should be annotated from a large pool of unlabeled documents. Many different strategies have been used to select the best points to annotate. These strategies can be generally divided into two groups: (1) selecting points in poorly sampled regions, and (2) selecting points that will have the greatest impact on models that were constructed using the dataset.

Active learning for data cleaning differs from traditional active learning because the data already has low quality labels. It uses the difference between the low quality label for each data point and a prediction of the label using supervised machine learning models built upon the low quality labels. Unlike the work in (Rebbapragada et al., 2012), this paper focuses on developing algorithms that can enhance the ability of active learner on identifying labeling errors, which we consider as a key challenge of this approach but ALC has not addressed.

3 An Active Learning Framework for Label Correction

Let $\hat{D} = \{(x_1, y_1), ..., (x_n, y_n)\}$ be a dataset of binary labeled instances, where the instance x_i belongs to domain X, and its label $y_i \in \{-1, +1\}$. $\hat{D}$ contains an unknown number of mislabeled data points. The problem is to obtain a high-quality dataset D by fixing labeling errors in $\hat{D}$, and learn an accurate classifier C from it.

Algorithm 1 illustrates an active learning approach to the problem. This algorithm takes the noisy dataset $\hat{D}$ as input. The training set T is initialized with the data in $\hat{D}$ and then updated each round with new labels generated during re-annotation. Data sets S_r and S are used to maintain the instances that have been selected for re-annotation in the whole process and in the current iteration, respectively.

Data: noisy data $\hat{D}$
Result: cleaned data D, classifier C
Initialize training set $T = \hat{D}$;
Initialize re-annotated data sets $S_r = \emptyset$;
$S = \emptyset$;
repeat
  Train classifier C using T ;
  Use C to select a set S of m suspected mislabeled instances from T ;
  Experts re-annotate the instances in $S - (S_r \cap S)$;
  Update T with the new labels in S ;
  $S_r = S_r \cup S$; $S = \emptyset$;
until *for I iterations*;
$D = T$;

Algorithm 1: Active Learning Approach for Label Correction

In each iteration, the algorithm trains classifiers using the training data in T. In practice, we apply k-fold cross-validation. We partition T into k subsets, and each time we keep a different subset as testing data and train a classifier using the other $k-1$ subsets of data. This process is repeated k times so that we get a classifier for each of the k subsets. The goal is to use the classifiers to efficiently and accurately seek out the most likely mislabeled instances from T for expert annotators to examine and re-annotate. When applying a classifier to classify the instances in the corresponding data subset, we get the probability about how likely one instance belongs to a class. The top m instances with the highest probabilities belonging to some class but conflicting preliminary labels are selected as the most likely errors for annotators to fix. During the re-annotation process we keep the old labels hidden to prevent that information from

biasing annotators' decisions. Similarly, we keep the probability scores hidden while annotating.

This process is done with multiple iterations of training, sampling, and re-annotating. We maintain the re-annotated instances in S_r to avoid annotating the same instance multiple times. After each round of annotation, we compare the old labels to the new labels to measure the degree of impact this process is having on the dataset. We stop re-annotating on the Ith round after we decide that the reward for an additional round of annotation is too low to justify.

4 Feature Weighting Methods

Building the classifier C that allows the most likely mislabeled instances to be selected and annotated is the essence of the active learning approach. There are two main goals of developing this classifier: (1) accurately predicting the labels of data points and ranking them based on prediction confidence, so that the most likely errors can be effectively identified; (2) requiring less time on training, so that the saved time can be spent on correcting more labeling errors. Thus we aim to build a classifier that is both accurate and time efficient.

Labeling noise affects the classification accuracy. One possible reason is that some effective features that should be given high weights are inhibited in the training phase due to the labeling errors. For example, emoticon ":D" is a good indicator for emotion *happy*, however, if by mistake many instances containing this emoticon are not correctly labeled as *happy*, this class-specific feature would be underestimated during training. Following this idea, we develop computationally cheap feature weighting techniques to counteract such effect by boosting the weight of discriminative features, so that they would not be subdued and the instances with such features would have higher chance to be correctly classified.

Specifically, we propose a non-linear distribution spreading algorithm for feature weighting. This algorithm first utilizes Delta IDF to weigh the features, and then non-linearly spreads out the distribution of features' Delta IDF scores to exaggerate the weight of discriminative features. We first introduce Delta-IDF technique, and then describe our algorithm of distribution spreading. Since we focus on n-gram features, we use the words *feature* and *term* interchangeably in this paper.

4.1 Delta IDF Weighting Scheme

Different from the commonly used TF (term frequency) or TF.IDF (term frequency.inverse document frequency) weighting schemes, Delta IDF treats the positive and negative training instances as two separate corpora, and weighs the terms by how biased they are to one corpus. The more biased a term is to one class, the higher (absolute value of) weight it will get. Delta IDF boosts the importance of terms that tend to be class-specific in the dataset, since they are usually effective features in distinguishing one class from another.

Each training instance (e.g., a document) is represented as a feature vector: $x_i = (w_{1,i}, ..., w_{|V|,i})$, where each dimension in the vector corresponds to a n-gram term in vocabulary $V = \{t_1, ..., t_{|V|}\}$, $|V|$ is the number of unique terms, and $w_{j,i} (1 \leq j \leq |V|)$ is the weight of term t_j in instance x_i. Delta IDF (Martineau and Finin, 2009) assigns score Δ_idf_j to term t_j in V as:

$$\Delta\_idf_j = \log \frac{(N+1)(P_j+1)}{(N_j+1)(P+1)} \quad (1)$$

where P (or N) is the number of positively (or negatively) labeled training instances, P_j (or N_j) is the number of positively (or negatively) labeled training instances with term t_j. Simple add-one smoothing is used to smooth low frequency terms and prevent dividing by zero when a term appears in only one corpus. We calculate the Delta IDF score of every term in V, and get the Delta IDF weight vector $\Delta = (\Delta\_idf_1, ..., \Delta\_idf_{|V|})$ for all terms.

When the dataset is imblanced, to avoid building a biased model, we down sample the majority class before calculating the Delta IDF score and then use the a bias balancing procedure to balance the Delta IDF weight vector. This procedure first divides the Delta IDF weight vector to two vectors, one of which contains all the features with positive scores, and the other of which contains all the features with negative scores. It then applies L2 normalization to each of the two vectors, and add them together to create the final vector.

For each instance, we can calculate the TF.Delta-IDF score as its weight:

$$w_{j,i} = tf_{j,i} \times \Delta\_idf_j \quad (2)$$

where $tf_{j,i}$ is the number of times term t_j occurs in document x_i, and Δ_idf_j is the Delta IDF score of t_j.

4.2 A Non-linear Distribution Spreading Algorithm

Delta IDF technique boosts the weight of features with strong discriminative power. The model's ability to discriminate at the feature level can be further enhanced by leveraging the distribution of feature weights across multiple classes, e.g., multiple emotion categories *funny*, *happy*, *sad*, *exciting*, *boring*, etc.. The distinction of multiple classes can be used to further force feature bias scores apart to improve the identification of class-specific features in the presence of labeling errors.

Let L be a set of target classes, and $|L|$ be the number of classes in L. For each class $l \in L$, we create a binary labeled dataset $\hat{D}^l$. Let V^l be the vocabulary of dataset $\hat{D}^l$, V be the vocabulary of all datasets, and $|V|$ is the number of unique terms in V. Using Formula (1) and dataset $\hat{D}^l$, we get the Delta IDF weight vector for each class l: $\Delta^l = (\Delta\_idf_1^l, ..., \Delta\_idf_{|V|}^l)$. Note that $\Delta\_idf_j^l = 0$ for any term $t_j \in V - V^l$. For a class u, we calculate the spreading score $spread_j^u$ of each feature $t_j \in V$ using a non-linear distribution spreading formula as following (where s is the configurable spread parameter):

$$spread_j^u = \Delta\_idf_j^u \times \frac{\sum_{l \in L-u} |\Delta\_idf_j^u - \Delta\_idf_j^l|^s}{|L| - 1} \quad (3)$$

For any term $t_j \in V$, we can get its Delta IDF score on a class l. The distribution of Delta IDF scores of t_j on all classes in L is represented as $\delta_j = \{\Delta\_idf_j^1, ..., \Delta\_idf_j^{|L|}\}$.

The mechanism of Formula (3) is to non-linearly spread out the distribution, so that the importance of class-specific features can be further boosted to counteract the effect of noisy labels. Specifically, according to Formula (3), a high (absolute value of) spread score indicates that the Delta IDF score of that term on that class is high and deviates greatly from the scores on other classes. In other words, our algorithm assigns high spread score (absolute value) to a term on a class for which the term has strong discriminative power and very specific to that class compared with to other classes. When the dataset is imbalanced, we apply the similar bias balancing procedure as described in Section 4.1 to the spreading model.

While these feature weighting models can be used to score and rank instances for data cleaning, better classification and regression models can be built by using the feature weights generated by these models as a pre-weight on the data points for other machine learning algorithms.

5 Experiments

We conduct experiments on a Twitter dataset that contains tweets about TV shows and movies. The goal is to extract consumers' emotional reactions to multimedia content, which has broad commercial applications including targeted advertising, intelligent search, and recommendation. To create the dataset, we collected 2 billion unique tweets using Twitter API queries for a list of known TV shows and movies on IMDB. Spam tweets were filtered out using a set of heuristics and manually crafted rules. From the set of 2 billion tweets we randomly selected a small subset of 100K tweets about the 60 most highly mentioned TV shows and movies in the dataset. Tweets were randomly sampled for each show using the round robin algorithm. Duplicates were not allowed. This samples an equal number of tweets for each show. We then sent these tweets to Amazon Mechanical Turk for annotation.

We defined our own set of emotions to annotate. The widely accepted emotion taxonomies, including Ekmans Basic Emotions (Ekman, 1999), Russells Circumplex model (Russell and Barrett, 1999), and Plutchiks emotion wheel (Plutchik, 2001), did not fit well for TV shows and Movies. For example, the emotion expressed by laughter is a very important emotion for TV shows and movies, but this emotion is not covered by the taxonomies listed above. After browsing through the raw dataset, reviewing the literature on emotion analysis, and considering the TV and movie problem domain, we decided to focus on eight emotions: *funny*, *happy*, *sad*, *exciting*, *boring*, *angry*, *fear*, and *heartwarming*.

Emotion annotation is a non-trivial task that is typically time-consuming, expensive and error-prone. This task is difficult because: (1) There are multiple emotions to annotate. In this work, we annotate eight different emotions. (2) Emotion expressions could be subtle and ambiguous and thus are easy to miss when labeling quickly. (3) The dataset is very imbalanced, which increases the problem of confirmation bias. As minority classes, emotional tweets can be easily missed because the last X tweets are all not emotional, and the annota-

tors do not expect the next one to be either. Due to these reasons, there is a lack of sufficient and high quality labeled data for emotion research. Some researchers have studied harnessing Twitter hashtags to automatically create an emotion annotated dataset (Wang et al., 2012).

In order to evaluate our approach in real world scenarios, instead of creating a high quality annotated dataset and then introducing artificial noise, we followed the common practice of crowdsoucing, and collected emotion annotations through Amazon Mechanical Turk (AMT). This AMT annotated dataset was used as the low quality dataset $\hat{D}$ in our evaluation. After that, the same dataset was annotated independently by a group of expert annotators to create the ground truth. We evaluate the proposed approach on two factors, the effectiveness of the models for emotion classification, and the improvement of annotation quality provided by the active learning procedure. We first describe the AMT annotation and ground truth annotation, and then discuss the baselines and experimental results.

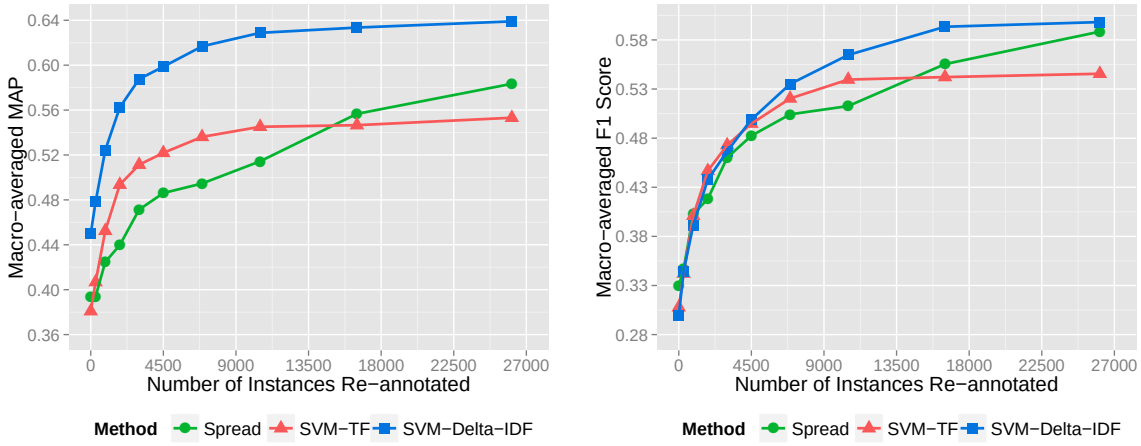
Amazon Mechanical Turk Annotation: we posted the set of 100K tweets to the workers on AMT for emotion annotation. We defined a set of annotation guidelines, which specified rules and examples to help annotators determine when to tag a tweet with an emotion. We applied substantial quality control to our AMT workers to improve the initial quality of annotation following the common practice of crowdsourcing. Each tweet was annotated by at least two workers. We used a series of tests to identify bad workers. These tests include (1) identifying workers with poor pairwise agreement, (2) identifying workers with poor performance on English language annotation, (3) identifying workers that were annotating at unrealistic speeds, (4) identifying workers with near random annotation distributions, and (5) identifying workers that annotate each tweet for a given TV show the same (or nearly the same) way. We manually inspected any worker with low performance on any of these tests before we made a final decision about using any of their annotations.

For further quality control, we also gathered additional annotations from additional workers for tweets where only one out of two workers identified an emotion. After these quality control steps we defined minimum emotion annotation thresholds to determine and assign preliminary emotion labels to tweets. Note that some tweets were discarded as mixed examples for each emotion based upon thresholds for how many times they were tagged, and it resulted in different number of tweets in each emotion dataset. See Table 1 for the statistics of the annotations collected from AMT.

Ground Truth Annotation: After we obtained the annotated dataset from AMT, we posted the same dataset (without the labels) to a group of expert annotators. The experts followed the same annotation guidelines, and each tweet was labeled by at least two experts. When there was a disagreement between two experts, they discussed to reach an agreement or gathered additional opinion from another expert to decide the label of a tweet. We used this annotated dataset as ground truth. See Table 2 for the statistics of the ground truth annotations. Compared with the ground truth, many emotion bearing tweets were missed by the AMT annotators, despite the quality control we applied. It demonstrates the challenge of annotation by crowdsourcing. The imbalanced class distribution

[1]The total number of tweets is lower than the AMT dataset because the experts removed some off-topic tweets.

[2]Expert annotators had a Kappa agreement score of 0.639 before meeting to resolve their differences.



(a) Macro-Averaged MAP

(b) Macro-Averaged F1 Score

Figure 1: Performance comparison of mislabeled instance selection methods. Classifiers become more accurate as more instances are re-annotated. Spread achieves comparable performance with SVMs in terms of both MAP and F1 Score.

aggravates the confirmation bias – the minority class examples are especially easy to miss when labeling quickly due to their rare presence in the dataset.

Evaluation Metric: We evaluated the results with both Mean Average Precision (MAP) and F1 Score. Average Precision (AP) is the average of the algorithm's precision at every position in the confidence ranked list of results where a true emotional document has been identified. Thus, AP places extra emphasis on getting the front of the list correct. MAP is the mean of the average precision scores for each ranked list. This is highly desirable for many practical application such as intelligent search, recommendation, and target advertising where users almost never see results that are not at the top of the list. F1 is a widely-used measure of classification accuracy.

Methods: We evaluated the overall performance relative to the common SVM bag of words approach that can be ubiquitously found in text mining literature. We implemented the following four classification methods:

- **Delta-IDF**: Takes the dot product of the Delta IDF weight vector (Formula 1) with the document's term frequency vector.

- **Spread**: Takes the dot product of the distribution spread weight vector (Formula 3) with the document's term frequency vector. For all the experiments, we used spread parameter $s = 2$.

- **SVM-TF**: Uses a bag of words SVM with term frequency weights.

- **SVM-Delta-IDF**: Uses a bag of words SVM classification with TF.Delta-IDF weights (Formula 2) in the feature vectors before training or testing an SVM.

We employed each method to build the active learner C described in Algorithm 1. We used standard bag of *unigram* and *bigram* words representation and *topic-based fold cross validation*. Since in real world applications people are primarily concerned with how well the algorithm will work for new TV shows or movies that may not be included in the training data, we defined a test fold for each TV show or movie in our labeled data set. Each test fold corresponded to a training fold containing all the labeled data from all the other TV shows and movies. We call it topic-based fold cross validation.

We built the SVM classifiers using LIBLINEAR (Fan et al., 2008) and applied its L2-regularized support vector regression model. Based on the dot product or SVM regression scores, we ranked the tweets by how strongly they express the emotion. We selected the top m tweets with the highest dot product or regression scores but conflicting preliminary AMT labels as the suspected mislabeled instances for re-annotation, just as described in Algorithm 1. For the experimental purpose, the re-annotation was done by assigning the ground truth labels to the selected instances. Since the dataset is highly imbalanced, we applied the *under-sampling strategy* when training the classifiers.

Figure 1 compares the performance of different approaches in each iteration after a certain number of potentially mislabeled instances are re-

annotated. The X axis shows the total number of data points that have been examined for each emotion so far till the current iteration (i.e., 300, 900, 1800, 3000, 4500, 6900, 10500, 16500, and 26100). We reported both the macro-averaged MAP (Figure 1a) and the macro-averaged F1 Score (Figure 1b) on eight emotions as the overall performance of three competitive methods – Spread, SVM-Delta-IDF and SVM-TF. We have also conducted experiments using Delta-IDF, but its performance is low and not comparable with the other three methods.

Generally, Figure 1 shows consistent performance gains as more labels are corrected during active learning. In comparison, SVM-Delta-IDF significantly outperforms SVM-TF with respect to both MAP and F1 Score. SVM-TF achieves higher MAP and F1 Score than Spread at the first few iterations, but then it is beat by Spread after 16,500 tweets had been selected and re-annotated till the eighth iteration. Overall, at the end of the active learning process, Spread outperforms SVM-TF by 3.03% the MAP score (and by 4.29% the F1 score), and SVM-Delta-IDF outperforms SVM-TF by 8.59% the MAP score (and by 5.26% the F1 score). Spread achieves a F1 Score of 58.84%, which is quite competitive compared to 59.82% achieved by SVM-Delta-IDF, though SVM-Delta-IDF outperforms Spread with respect to MAP.

Spread and Delta-IDF are superior with respect to the time efficiency. Figure 2 shows the average training time of the four methods on eight emotions. The time spent training SVM-TF classifiers is twice that of SVM-Delta-IDF classifiers, 12 times that of Spread classifiers, and 31 times that of Delta-IDF classifiers. In our experiments, on average, it took 258.8 seconds to train a SVM-TF classifier for one emotion. In comparison, the average training time of a Spread classifier was only 21.4 seconds, and it required almost no parameter tuning. In total, our method Spread saved up to $(258.8 - 21.4) * 9 * 8 = 17092.8$ seconds (4.75 hours) over nine iterations of active learning for all the eight emotions. This is enough time to re-annotate thousands of data points.

The other important quantity to measure is annotation quality. One measure of improvement for annotation quality is the number of mislabeled instances that can be fixed after a certain number of active learning iterations. Better methods can fix more labels with fewer iterations.

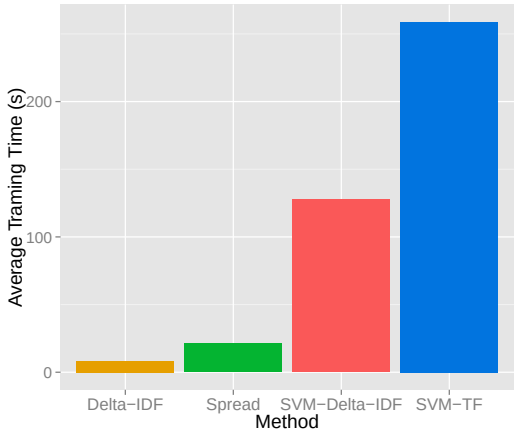


Figure 2: Average training time on eight emotions. Spread requires only one-twelfth of the time spent to training an SVM-TF classifier. Note that the time spent tuning the SVM's parameters has not been included, but is considerable. Compared with such computationally expensive methods, Spread is more appropriate for use with active learning.

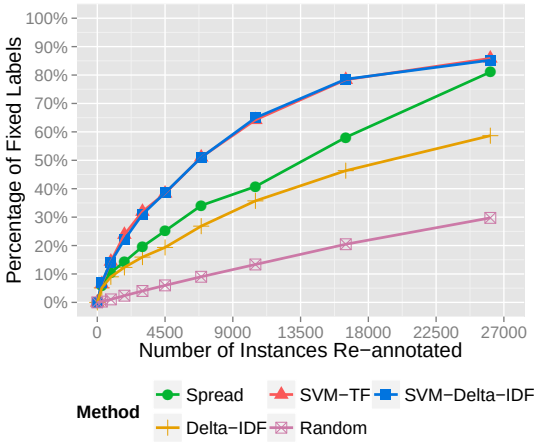

Figure 3: Accumulated average percentage of fixed labels on eight emotions. Spreading the feature weights reduces the number of data points that must be examined in order to correct the mislabeled instances. SVMs require slightly fewer points but take far longer to build.

Besides the four methods, we also implemented a random baseline (Random) which randomly selected the specified number of instances for re-annotation in each round. We compared the improved dataset with the final ground truth at the end of each round to monitor the progress. Figure 3 reports the accumulated average percentage of corrected labels on all emotions in each iteration of the active learning process.

According to the figure, SVM-Delta-IDF and SVM-TF are the most advantageous methods, followed by Spread and Delta-IDF. After the last iteration, SVM-Delta-IDF, SVM-TF, Spread and Delta-IDF has fixed 85.23%, 85.85%, 81.05% and 58.66% of the labels, respectively, all of which significantly outperform the Random baseline (29.74%).

6 Conclusion

In this paper, we explored an active learning approach to improve data annotation quality for classification tasks. Instead of training the active learner using computationally expensive techniques (e.g., SVM-TF), we used a novel non-linear distribution spreading algorithm. This algorithm first weighs the features using the Delta-IDF technique, and then non-linearly spreads out the distribution of the feature scores to enhance the model's ability to discriminate at the feature level. The evaluation shows that our algorithm has the following advantages: (1) It intelligently ordered the data points for annotators to annotate the most likely errors first. The accuracy was at least comparable with computationally expensive baselines (e.g. SVM-TF). (2) The algorithm trained and ran much faster than SVM-TF, allowing annotators to finish more annotations than competitors. (3) The annotation process improved the dataset quality by positively impacting the accuracy of classifiers that were built upon it.

Abstract

An individual's words often reveal their political ideology. Existing automated techniques to identify ideology from text focus on bags of words or wordlists, ignoring syntax. Taking inspiration from recent work in sentiment analysis that successfully models the compositional aspect of language, we apply a recursive neural network (RNN) framework to the task of identifying the political position evinced by a sentence. To show the importance of modeling subsentential elements, we crowdsource political annotations at a phrase and sentence level. Our model outperforms existing models on our newly annotated dataset and an existing dataset.

1 Introduction

Many of the issues discussed by politicians and the media are so nuanced that even word choice entails choosing an ideological position. For example, what liberals call the "estate tax" conservatives call the "death tax"; there are no ideologically neutral alternatives (Lakoff, 2002). While objectivity remains an important principle of journalistic professionalism, scholars and watchdog groups claim that the media are biased (Groseclose and Milyo, 2005; Gentzkow and Shapiro, 2010; Niven, 2003), backing up their assertions by publishing examples of obviously biased articles on their websites. Whether or not it reflects an underlying lack of objectivity, quantitative changes in the popular framing of an issue over time—favoring one ideologically-based position over another—can have a substantial effect on the evolution of policy (Dardis et al., 2008).

Manually identifying ideological bias in political text, especially in the age of big data, is an impractical and expensive process. Moreover, bias may be localized to a small portion of a document, undetectable by coarse-grained methods. In this paper, we examine the problem of detecting ideological bias on the sentence level. We say a sentence contains *ideological bias* if its author's political position (here *liberal* or *conservative*, in the sense of U.S. politics) is evident from the text.

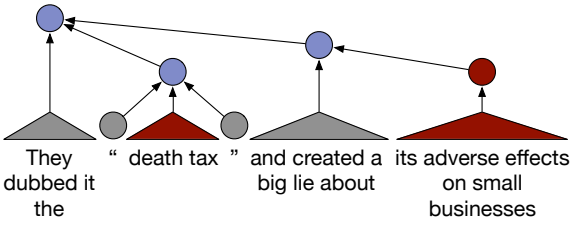

Figure 1: An example of compositionality in ideological bias detection (red → conservative, blue → liberal, gray → neutral) in which modifier phrases and punctuation cause polarity switches at higher levels of the parse tree.

Ideological bias is difficult to detect, even for humans—the task relies not only on political knowledge but also on the annotator's ability to pick up on subtle elements of language use. For example, the sentence in Figure 1 includes phrases typically associated with conservatives, such as "small businesses" and "death tax". When we take more of the structure into account, however, we find that scare quotes and a negative propositional attitude (*a lie about X*) yield an evident liberal bias.

Existing approaches toward bias detection have not gone far beyond "bag of words" classifiers, thus ignoring richer linguistic context of this kind and often operating at the level of whole documents. In contrast, recent work in sentiment analysis has used deep learning to discover compositional effects (Socher et al., 2011b; Socher et al., 2013b).

Building from those insights, we introduce a recursive neural network (RNN) to detect ideological bias on the sentence level. This model requires

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1113–1122,
Baltimore, Maryland, USA, June 23-25 2014.

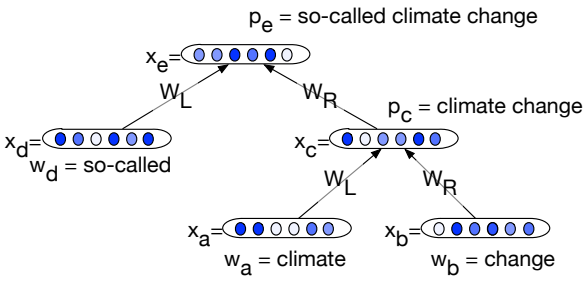

Figure 2: An example RNN for the phrase "so-called climate change". Two d-dimensional word vectors (here, $d = 6$) are composed to generate a phrase vector of the same dimensionality, which can then be recursively used to generate vectors at higher-level nodes.

richer data than currently available, so we develop a new political ideology dataset annotated at the phrase level. With this new dataset we show that RNNs not only label sentences well but also improve further when given additional phrase-level annotations. RNNs are quantitatively more effective than existing methods that use syntactic and semantic features separately, and we also illustrate how our model correctly identifies ideological bias in complex syntactic constructions.

2 Recursive Neural Networks

Recursive neural networks (RNNs) are machine learning models that capture syntactic and semantic composition. They have achieved state-of-the-art performance on a variety of sentence-level NLP tasks, including sentiment analysis, paraphrase detection, and parsing (Socher et al., 2011a; Hermann and Blunsom, 2013). RNN models represent a shift from previous research on ideological bias detection in that they do not rely on hand-made lexicons, dictionaries, or rule sets. In this section, we describe a supervised RNN model for bias detection and highlight differences from previous work in training procedure and initialization.

2.1 Model Description

By taking into account the hierarchical nature of language, RNNs can model *semantic composition*, which is the principle that a phrase's meaning is a combination of the meaning of the words within that phrase and the syntax that combines those words. While semantic composition does not apply universally (e.g., sarcasm and idioms), most language follows this principle. Since most ideological bias becomes identifiable only at higher levels of sentence trees (as verified by our annotation, Figure 4), models relying primarily on word-level distributional statistics are not desirable for our problem.

The basic idea behind the standard RNN model is that each word w in a sentence is associated with a vector representation $x_w \in \mathbb{R}^d$. Based on a parse tree, these words form phrases p (Figure 2). Each of these phrases also has an associated vector $x_p \in \mathbb{R}^d$ of the same dimension as the word vectors. These phrase vectors should represent the meaning of the phrases composed of individual words. As phrases themselves merge into complete sentences, the underlying vector representation is trained to retain the sentence's whole meaning.

The challenge is to describe how vectors combine to form complete representations. If two words w_a and w_b merge to form phrase p, we posit that the phrase-level vector is

$$x_p = f(W_L \cdot x_a + W_R \cdot x_b + b_1), \qquad (1)$$

where W_L and W_R are $d \times d$ left and right composition matrices shared across all nodes in the tree, b_1 is a bias term, and f is a nonlinear activation function such as $\tanh$. The word-level vectors x_a and x_b come from a $d \times V$ dimensional word embedding matrix W_e, where V is the size of the vocabulary.

We are interested in learning representations that can distinguish political polarities given labeled data. If an element of this vector space, x_d, represents a sentence with liberal bias, its vector should be distinct from the vector x_r of a conservative-leaning sentence.

Supervised RNNs achieve this distinction by applying a regression that takes the node's vector x_p as input and produces a prediction $\hat{y}_p$. This is a softmax layer

$$\hat{y}_d = \text{softmax}(W_{cat} \cdot x_p + b_2), \qquad (2)$$

where the softmax function is

$$\text{softmax}(q) = \frac{\exp q}{\sum_{j=1}^{k} \exp q_j} \qquad (3)$$

and W_{cat} is a $k \times d$ matrix for a dataset with k-dimensional labels.

We want the predictions of the softmax layer to match our annotated data; the discrepancy between categorical predictions and annotations is measured

through the cross-entropy loss. We optimize the model parameters to minimize the cross-entropy loss over all sentences in the corpus. The cross-entropy loss of a single sentence is the sum over the true labels y_i in the sentence,

$$\ell(\hat{y}_s) = \sum_{p=1}^{k} y_p * log(\hat{y}_p). \quad (4)$$

This induces a supervised objective function over all sentences: a regularized sum over all node losses normalized by the number of nodes N in the training set,

$$C = \frac{1}{N} \sum_{i}^{N} \ell(pred_i) + \frac{\lambda}{2} \|\theta\|^2. \quad (5)$$

We use L-BFGS with parameter averaging (Hashimoto et al., 2013) to optimize the model parameters $\theta = (W_L, W_R, W_{cat}, W_e, b_1, b_2)$. The gradient of the objective, shown in Eq. (6), is computed using backpropagation through structure (Goller and Kuchler, 1996),

$$\frac{\partial C}{\partial \theta} = \frac{1}{N} \sum_{i}^{N} \frac{\partial \ell(\hat{y}_i)}{\partial \theta} + \lambda\theta. \quad (6)$$

2.2 Initialization

When initializing our model, we have two choices: we can initialize all of our parameters randomly or provide the model some prior knowledge. As we see in Section 4, these choices have a significant effect on final performance.

Random The most straightforward choice is to initialize the word embedding matrix W_e and composition matrices W_L and W_R randomly such that without any training, representations for words and phrases are arbitrarily projected into the vector space.

word2vec The other alternative is to initialize the word embedding matrix W_e with values that reflect the meanings of the associated word types. This improves the performance of RNN models over random initializations (Collobert and Weston, 2008; Socher et al., 2011a). We initialize our model with 300-dimensional *word2vec* toolkit vectors generated by a continuous skip-gram model trained on around 100 billion words from the Google News corpus (Mikolov et al., 2013).

The word2vec embeddings have linear relationships (e.g., the closest vectors to the average of "green" and "energy" include phrases such as "renewable energy", "eco-friendly", and "efficient lightbulbs"). To preserve these relationships as phrases are formed in our sentences, we initialize our left and right composition matrices such that parent vector p is computed by taking the average of children a and b ($W_L = W_R = 0.5\mathbb{I}_{d\times d}$). This initialization of the composition matrices has previously been effective for parsing (Socher et al., 2013a).

3 Datasets

We performed initial experiments on a dataset of Congressional debates that has annotations on the author level for partisanship, not ideology. While the two terms are highly correlated (e.g., a member of the Republican party likely agrees with conservative stances on most issues), they are not identical. For example, a moderate Republican might agree with the liberal position on increased gun control but take conservative positions on other issues. To avoid conflating partisanship and ideology we create a new dataset annotated for ideological bias on the sentence and phrase level. In this section we describe our initial dataset (Convote) and explain the procedure we followed for creating our new dataset (IBC).[1]

3.1 Convote

The Convote dataset (Thomas et al., 2006) consists of US Congressional floor debate transcripts from 2005 in which all speakers have been labeled with their political party (Democrat, Republican, or independent). We propagate party labels down from the speaker to all of their individual sentences and map from party label to ideology label (Democrat → liberal, Republican → conservative). This is an expedient choice; in future work we plan to make use of work in political science characterizing candidates' ideological positions empirically based on their behavior (Carroll et al., 2009).

While the Convote dataset has seen widespread use for document-level political classification, we are unaware of similar efforts at the sentence level.

3.1.1 Biased Sentence Selection

The strong correlation between US political parties and political ideologies (Democrats with liberal, Republicans with conservative) lends confidence that this dataset contains a rich mix of ideological

[1] Available at `http://cs.umd.edu/~miyyer/ibc`

statements. However, the raw Convote dataset contains a low percentage of sentences with explicit ideological bias.[2] We therefore use the features in Yano et al. (2010), which correlate with political bias, to select sentences to annotate that have a higher likelihood of containing bias. Their features come from the Linguistic Inquiry and Word Count lexicon (LIWC) (Pennebaker et al., 2001), as well as from lists of "sticky bigrams" (Brown et al., 1992) strongly associated with one party or another (e.g., "illegal aliens" implies conservative, "universal healthcare" implies liberal).

We first extract the subset of sentences that contains any words in the LIWC categories of Negative Emotion, Positive Emotion, Causation, Anger, and Kill verbs.[3] After computing a list of the top 100 sticky bigrams for each category, ranked by log-likelihood ratio, and selecting another subset from the original data that included only sentences containing at least one sticky bigram, we take the union of the two subsets. Finally, we balance the resulting dataset so that it contains an equal number of sentences from Democrats and Republicans, leaving us with a total of 7,816 sentences.

3.2 Ideological Books

In addition to Convote, we use the Ideological Books Corpus (IBC) developed by Gross et al. (2013). This is a collection of books and magazine articles written between 2008 and 2012 by authors with well-known political leanings. Each document in the IBC has been manually labeled with coarse-grained ideologies (right, left, and center) as well as fine-grained ideologies (e.g., religious-right, libertarian-right) by political science experts.

There are over a million sentences in the IBC, most of which have no noticeable political bias. Therefore we use the filtering procedure outlined in Section 3.1.1 to obtain a subset of 55,932 sentences. Compared to our final Convote dataset, an even larger percentage of the IBC sentences exhibit no noticeable political bias.[4] Because our goal is to distinguish between liberal and conservative bias, instead of the more general task of classifying sentences as "neutral" or "biased", we filter the dataset further using DUALIST (Settles, 2011), an active learning tool, to reduce the proportion of neutral sentences in our dataset. To train the DUALIST classifier, we manually assigned class labels of "neutral" or "biased" to 200 sentences, and selected typical partisan unigrams to represent the "biased" class. DUALIST labels 11,555 sentences as politically biased, 5,434 of which come from conservative authors and 6,121 of which come from liberal authors.

3.2.1 Annotating the IBC

For purposes of annotation, we define the task of political ideology detection as identifying, if possible, the political position of a given sentence's author, where position is either *liberal* or *conservative*.[5] We used the Crowdflower crowdsourcing platform (crowdflower.com), which has previously been used for subsentential sentiment annotation (Sayeed et al., 2012), to obtain human annotations of the filtered IBC dataset for political bias on both the sentence and phrase level. While members of the Crowdflower workforce are certainly not experts in political science, our simple task and the ubiquity of political bias allows us to acquire useful annotations.

Crowdflower Task First, we parse the filtered IBC sentences using the Stanford constituency parser (Socher et al., 2013a). Because of the expense of labeling every node in a sentence, we only label one path in each sentence. The process for selecting paths is as follows: first, if any paths contain one of the top-ten partisan unigrams,[6] we select the longest such path; otherwise, we select the path with the most open class constituencies (NP, VP, ADJP). The root node of a sentence is always included in a path.

Our task is shown in Figure 3. Open class constituencies are revealed to the worker incrementally, starting with the NP, VP, or ADJP furthest from the root and progressing up the tree. We choose this design to prevent workers from changing their lower-level phrase annotations after reading the full sentence.

[2] Many sentences in Convote are variations on "I think this is a good/bad bill", and there is also substantial parliamentary boilerplate language.

[3] While Kill verbs are not a category in LIWC, Yano et al. (2010) adopted it from Greene and Resnik (2009) and showed it to be a useful predictor of political bias. It includes words such as "slaughter" and "starve".

[4] This difference can be mainly attributed to a historical topics in the IBC (e.g., the Crusades, American Civil War). In Convote, every sentence is part of a debate about 2005 political policy.

[5] This is a simplification, as the ideological hierarchy in IBC makes clear.

[6] The words that the multinomial naïve Bayes classifier in DUALIST marked as highest probability given a polarity: market, abortion, economy, rich, liberal, tea, economic, taxes, gun, abortion

Filtering the Workforce To ensure our annotators have a basic understanding of US politics, we restrict workers to US IP addresses and require workers manually annotate one node from 60 different "gold " paths annotated by the authors. We select these nodes such that the associated phrase is either obviously biased or obviously neutral. Workers must correctly annotate at least six of eight gold paths before they are granted access to the full task. In addition, workers must maintain 75% accuracy on gold paths that randomly appear alongside normal paths. Gold paths dramatically improve the quality of our workforce: 60% of contributors passed the initial quiz (the 40% that failed were barred from working on the task), while only 10% of workers who passed the quiz were kicked out for mislabeling subsequent gold paths.

Annotation Results Workers receive the following instructions:

> Each task on this page contains a set of phrases from a single sentence. For each phrase, decide whether or not the author favors a political position to the left (*Liberal*) or right (*Conservative*) of center.
>
> - If the phrase is indicative of a position to the left of center, please choose *Liberal*.
> - If the phrase is indicative of a position to the right of center, please choose *Conservative*.
> - If you feel like the phrase indicates some position to the left or right of the political center, but you're not sure which direction, please mark *Not neutral, but I'm unsure of which direction*.
> - If the phrase is not indicative of a position to the left or right of center, please mark *Neutral*.

We had workers annotate 7,000 randomly selected paths from the filtered IBC dataset, with half of the paths coming from conservative authors and the other half from liberal authors, as annotated by Gross et al. (2013). Three workers annotated each path in the dataset, and we paid $0.03 per sentence. Since identifying political bias is a relatively difficult and subjective task, we include all sentences where at least two workers agree on a label for the root node in our final dataset, except when that label is "Not neutral, but I'm unsure of which direction". We only keep phrase-level annotations where at least two workers agree on the label: 70.4% of all annotated nodes fit this definition of agreement. All unannotated nodes receive the label of their closest annotated ancestor. Since the root of each sentence is always annotated, this strategy ensures that every node in the tree has a label. Our final balanced IBC dataset consists of 3,412 sentences (4,062 before balancing and removing neutral sentences) with a total of 13,640 annotated nodes. Of these sentences, 543 switch polarity (liberal → conservative or vice versa) on an annotated path.

Figure 3: Example political ideology annotation task showing incremental reveal of progressively longer phrases.

While we initially wanted to incorporate neutral labels into our model, we observed that lower-level phrases are almost always neutral while full sentences are much more likely to be biased (Figure 4). Due to this discrepancy, the objective function in Eq. (5) was minimized by making neutral predictions for almost every node in the dataset.

4 Experiments

In this section we describe our experimental framework. We discuss strong baselines that use lexical and syntactic information (including framing-specific features from previous work) as well as multiple RNN configurations. Each of these models have the same task: to predict sentence-level ideology labels for sentences in a test set. To account for label imbalance, we subsample the data so that there are an equal number of labels and report accuracy over this balanced dataset.

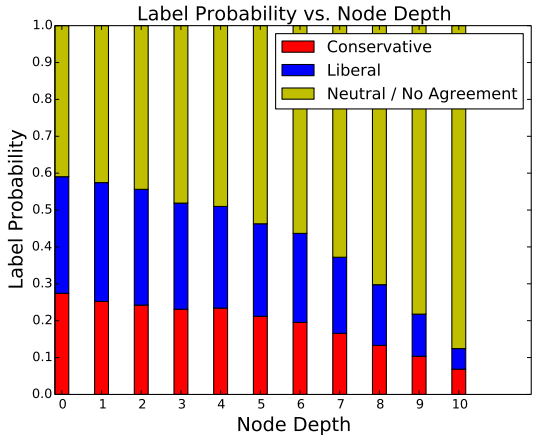

Figure 4: Proportion of liberal, conservative, and neutral annotations with respect to node depth (distance from root). As we get farther from the root of the tree, nodes are more likely to be neutral.

4.1 Baselines

- The **RANDOM** baseline chooses a label at random from {*liberal*, *conservative*}.
- **LR1**, our most basic logistic regression baseline, uses only bag of words (*BoW*) features.
- **LR2** uses only *BoW* features. However, **LR2** also includes phrase-level annotations as separate training instances.[7]
- **LR3** uses *BoW* features as well as syntactic pseudo-word features from Greene & Resnik (2009). These features from dependency relations specify properties of verbs (e.g., transitivity or nominalization).[8]
- **LR-(W2V)** is a logistic regression model trained on the average of the pretrained word embeddings for each sentence (Section 2.2).

The **LR-(W2V)** baseline allows us to compare against a strong lexical representation that encodes syntactic and semantic information without the RNN tree structure. (**LR1**, **LR2**) offer a comparison to simple bag of words models, while the **LR3** baseline contrasts traditional syntactic features with those learned by RNN models.

4.2 RNN Models

For RNN models, we generate a feature vector for every node in the tree. Equation 1 allows us to percolate the representations to the root of the tree. We generate the final instance representation by concatenating the root vector and the average of all other vectors (Socher et al., 2011b). We train an L_2-regularized logistic regression model over these concatenated vectors to obtain final accuracy numbers on the sentence level.

To analyze the effects of initialization and phrase-level annotations, we report results for three different RNN settings. All three models were implemented as described in Section 2 with the nonlinearity f set to the normalized $\tanh$ function,

$$f(v) = \frac{\tanh(v)}{\|\tanh(v)\|}. \quad (7)$$

We perform 10-fold cross-validation on the training data to find the best RNN hyperparameters.[9]

We report results for RNN models with the following configurations:

- **RNN1** initializes all parameters randomly and uses only sentence-level labels for training.
- **RNN1-(W2V)** uses the word2vec initialization described in Section 2.2 but is also trained on only sentence-level labels.
- **RNN2-(W2V)** is initialized using word2vec embeddings and also includes annotated phrase labels in its training. For this model, we also introduce a hyperparameter β that weights the error at annotated nodes $(1-\beta)$ higher than the error at unannotated nodes (β); since we have more confidence in the annotated labels, we want them to contribute more towards the objective function.

Model	Convote	IBC
RANDOM	50%	50%
LR1	64.7%	62.1%
LR2	–	61.9%
LR3	66.9%	62.6%
LR-(W2V)	66.6%	63.7%
RNN1	69.4%	66.2%
RNN1-(W2V)	**70.2%**	67.1%
RNN2-(W2V)	–	**69.3%**

Table 1: Sentence-level bias detection accuracy. The RNN framework, adding phrase-level data, and initializing with word2vec all improve performance over logistic regression baselines. The **LR2** and **RNN2-(W2V)** models were not trained on Convote since it lacks phrase annotations.

[7] The Convote dataset was not annotated on the phrase level, so we only provide a result for the IBC dataset.

[8] We do not include phrase-level annotations in the **LR3** feature set because the pseudo-word features can only be computed from full sentence parses.

[9] $[\lambda_{W_e}$ =1e-6, λ_W =1e-4, $\lambda_{W_{cat}}$ =1e-3, $\beta = 0.3]$

For all RNN models, we set the word vector dimension d to 300 to facilitate direct comparison against the **LR-(W2V)** baseline.[10]

5 Where Compositionality Helps Detect Ideological Bias

In this section, we examine the RNN models to see why they improve over our baselines. We also give examples of sentences that are correctly classified by our best RNN model but incorrectly classified by all of the baselines. Finally, we investigate sentence constructions that our model cannot handle and offer possible explanations for these errors.

Experimental Results Table 1 shows the RNN models outperforming the bag-of-words baselines as well as the word2vec baseline on both datasets. The increased accuracy suggests that the trained RNNs are capable of detecting bias polarity switches at higher levels in parse trees. While phrase-level annotations do not improve baseline performance, the RNN model significantly benefits from these annotations because the phrases are themselves derived from nodes in the network structure. In particular, the phrase annotations allow our best model to detect bias accurately in complex sentences that the baseline models cannot handle.

Initializing the RNN W_e matrix with word2vec embeddings improves accuracy over randomly initialization by 1%. This is similar to improvements from pretrained vectors from neural language models (Socher et al., 2011b).

We obtain better results on Convote than on IBC with both bag-of-words and RNN models. This result was unexpected since the Convote labels are noisier than the annotated IBC labels; however, there are three possible explanations for the discrepancy. First, Convote has twice as many sentences as IBC, and the extra training data might help the model more than IBC's better-quality labels. Second, since the sentences in Convote were originally spoken, they are almost half as short (21.3 words per sentence) as those in the IBC (42.2 words per sentence). Finally, some information is lost at every propagation step, so RNNs are able to model the shorter sentences in Convote more effectively than the longer IBC sentences.

Qualitative Analysis As in previous work (Socher et al., 2011b), we visualize the learned vector space by listing the most probable n-grams for each political affiliation in Table 2. As expected, conservatives emphasize values such as freedom and religion while disparaging excess government spending and their liberal opposition. Meanwhile, liberals inveigh against the gap between the rich and the poor while expressing concern for minority groups and the working class.

Our best model is able to accurately model the compositional effects of bias in sentences with complex syntactic structures. The first three sentences in Figure 5 were correctly classified by our best model (**RNN2-(W2V)**) and incorrectly classified by all of the baselines. Figures 5A and C show traditional conservative phrases, "free market ideology" and "huge amounts of taxpayer money", that switch polarities higher up in the tree when combined with phrases such as "made worse by" and "saved by". Figure 5B shows an example of a bias polarity switch in the opposite direction: the sentence negatively portrays supporters of nationalized health care, which our model picks up on.

Our model often makes errors when polarity switches occur at nodes that are high up in the tree. In Figure 5D, "be used as an instrument to achieve charitable or social ends" reflects a liberal ideology, which the model predicts correctly. However, our model is unable to detect the polarity switch when this phrase is negated with "should not". Since many different issues are discussed in the IBC, it is likely that our dataset has too few examples of some of these issues for the model to adequately learn the appropriate ideological positions, and more training data would resolve many of these errors.

6 Related Work

A growing NLP subfield detects private states such as opinions, sentiment, and beliefs (Wilson et al., 2005; Pang and Lee, 2008) from text. In general, work in this category tends to combine traditional surface lexical modeling (e.g., bag-of-words) with hand-designed syntactic features or lexicons. Here we review the most salient literature related to the present paper.

6.1 Automatic Ideology Detection

Most previous work on ideology detection ignores the syntactic structure of the language in use in favor of familiar bag-of-words representations for

[10] Using smaller vector sizes ($d \in \{50, 100\}$, as in previous work) does not significantly change accuracy.

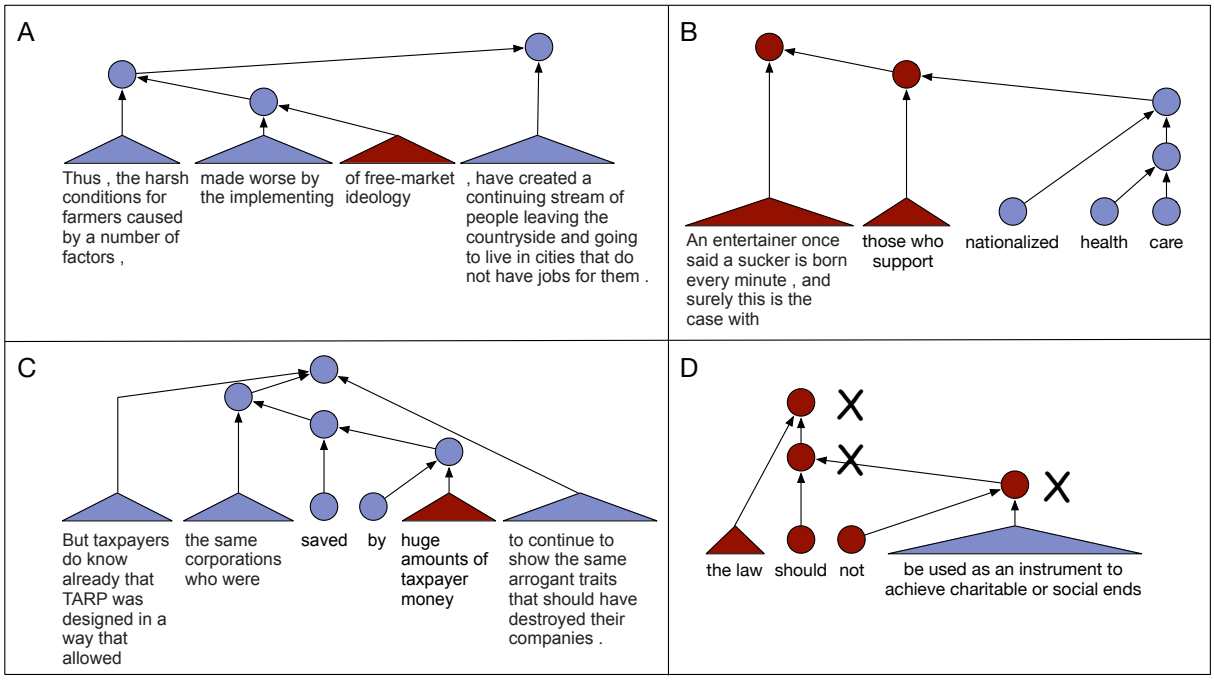

Figure 5: Predictions by **RNN2-(W2V)** on four sentences from the IBC. Node color is the true label (red for conservative, blue for liberal), and an "X" next to a node means the model's prediction was wrong. In *A* and *C*, the model accurately detects conservative-to-liberal polarity switches, while in *B* it correctly predicts the liberal-to-conservative switch. In *D*, negation confuses our model.

the sake of simplicity. For example, Gentzkow and Shapiro (2010) derive a "slant index" to rate the ideological leaning of newspapers. A newspaper's slant index is governed by the frequency of use of partisan collocations of 2-3 tokens. Similarly, authors have relied on simple models of language when leveraging inferred ideological positions. E.g., Gerrish and Blei (2011) predict the voting patterns of Congress members based on bag-of-words representations of bills and inferred political leanings of those members.

Recently, Sim et al. (2013) have proposed a model to infer mixtures of ideological positions in documents, applied to understanding the evolution of ideological rhetoric used by political candidates during the campaign cycle. They use an HMM-based model, defining the states as a set of fine-grained political ideologies, and rely on a closed set of lexical bigram features associated with each ideology, inferred from a manually labeled ideological books corpus. Although it takes elements of discourse structure into account (capturing the"burstiness" of ideological terminology usage), their model explicitly ignores intrasentential contextual influences of the kind seen in Figure 1. Other approaches on the document level use topic models to analyze bias in news articles, blogs, and political speeches (Ahmed and Xing, 2010; Lin et al., 2008; Nguyen et al., 2013).

6.2 Subjectivity Detection

Detecting subjective language, which conveys opinion or speculation, is a related NLP problem. While sentences lacking subjective language may contain ideological bias (e.g., the topic of the sentence), highly-opinionated sentences likely have obvious ideological leanings. In addition, sentiment and subjectivity analysis offers methodological approaches that can be applied to automatic bias detection.

Wiebe et al. (2004) show that low-frequency words and some collocations are a good indicators of subjectivity. More recently, Recasens et al. (2013) detect biased words in sentences using indicator features for bias cues such as hedges and factive verbs in addition to standard bag-of-words and part-of-speech features. They show that this type of linguistic information dramatically improves performance over several standard baselines.

Greene and Resnik (2009) also emphasize the connection between syntactic and semantic relationships in their work on "implicit sentiment",

n	Most conservative n-grams	Most liberal n-grams
1	Salt, Mexico, housework, speculated, consensus, lawyer, pharmaceuticals, ruthless, deadly, Clinton, redistribution	rich, antipsychotic, malaria, biodiversity, richest, gene, pesticides, desertification, Net, wealthiest, labor, fertilizer, nuclear, HIV
3	prize individual liberty, original liberal idiots, stock market crash, God gives freedom, federal government interference, federal oppression nullification, respect individual liberty, Tea Party patriots, radical Sunni Islamists, Obama stimulus programs	rich and poor,"corporate greed", super rich pay, carrying the rich, corporate interest groups, young women workers, the very rich, for the rich, by the rich, soaking the rich, getting rich often, great and rich, the working poor, corporate income tax, the poor migrants
5	spending on popular government programs, bailouts and unfunded government promises, North America from external threats, government regulations place on businesses, strong Church of Christ convictions, radical Islamism and other threats	the rich are really rich, effective forms of worker participation, the pensions of the poor, tax cuts for the rich, the ecological services of biodiversity, poor children and pregnant women, vacation time for overtime pay
7	government intervention helped make the Depression Great, by God in His image and likeness, producing wealth instead of stunting capital creation, the traditional American values of limited government, trillions of dollars to overseas oil producers, its troubled assets to federal sugar daddies, Obama and his party as racialist fanatics	African Americans and other disproportionately poor groups; the growing gap between rich and poor; the Bush tax cuts for the rich; public outrage at corporate and societal greed; sexually transmitted diseases , most notably AIDS; organize unions or fight for better conditions, the biggest hope for health care reform

Table 2: Highest probability n-grams for conservative and liberal ideologies, as predicted by the **RNN2-(W2V)** model.

which refers to sentiment carried by sentence structure and not word choice. They use syntactic dependency relation features combined with lexical information to achieve then state-of-the-art performance on standard sentiment analysis datasets. However, these syntactic features are only computed for a thresholded list of domain-specific verbs. This work extends their insight of modeling sentiment as an interaction between syntax and semantics to ideological bias.

Future Work There are a few obvious directions in which this work can be expanded. First, we can consider more nuanced political ideologies beyond *liberal* and *conservative*. We show that it is possible to detect ideological bias given this binary problem; however, a finer-grained study that also includes neutral annotations may reveal more subtle distinctions between ideologies. While acquiring data with obscure political biases from the IBC or Convote is unfeasible, we can apply a similar analysis to social media (e.g., Twitter or Facebook updates) to discover how many different ideologies propagate in these networks.

Another direction is to implement more sophisticated RNN models (along with more training data) for bias detection. We attempted to apply syntactically-untied RNNs (Socher et al., 2013a) to our data with the idea that associating separate matrices for phrasal categories would improve representations at high-level nodes. While there were too many parameters for this model to work well here, other variations might prove successful, especially with more data. Finally, combining sentence-level and document-level models might improve bias detection at both levels.

7 Conclusion

In this paper we apply recursive neural networks to political ideology detection, a problem where previous work relies heavily on bag-of-words models and hand-designed lexica. We show that our approach detects bias more accurately than existing methods on two different datasets. In addition, we describe an approach to crowdsourcing ideological bias annotations. We use this approach to create a new dataset from the IBC, which is labeled at both the sentence and phrase level.

A Unified Model for Soft Linguistic Reordering Constraints in Statistical Machine Translation

Abstract

This paper explores a simple and effective unified framework for incorporating soft linguistic reordering constraints into a hierarchical phrase-based translation system: 1) a syntactic reordering model that explores reorderings for context free grammar rules; and 2) a semantic reordering model that focuses on the reordering of predicate-argument structures. We develop novel features based on both models and use them as soft constraints to guide the translation process. Experiments on Chinese-English translation show that the reordering approach can significantly improve a state-of-the-art hierarchical phrase-based translation system. However, the gain achieved by the semantic reordering model is limited in the presence of the syntactic reordering model, and we therefore provide a detailed analysis of the behavior differences between the two.

1 Introduction

Reordering models in statistical machine translation (SMT) model the word order difference when translating from one language to another. The popular distortion or lexicalized reordering models in phrase-based SMT make good local predictions by focusing on reordering on word level, while the synchronous context free grammars in hierarchical phrase-based (HPB) translation models are capable of handling non-local reordering on the translation phrase level. However, reordering, especially without any help of external knowledge, remains a great challenge because an accurate reordering is usually beyond these word level or translation phrase level reordering models' ability. In addition, often these translation models fail to respect linguistically-motivated syntax and semantics. As a result, they tend to produce translations containing both syntactic and semantic reordering confusions. In this paper our goal is to take advantage of syntactic and semantic parsing to improve translation quality. Rather than introducing reordering models on either the word level or the translation phrase level, we propose a unified approach to modeling reordering on the linguistic unit level, e.g., syntactic constituents and semantic roles. The reordering unit falls into multiple granularities, from single words to more complex constituents and semantic roles, and often crosses translation phrases. To show the effectiveness of our reordering models, we integrate both syntactic constituent reordering models and semantic role reordering models into a state-of-the-art HPB system (Chiang, 2007; Dyer et al., 2010). We further contrast it with a stronger baseline, already including fine-grained soft syntactic constraint features (Marton and Resnik, 2008; Chiang et al., 2008). The general ideas, however, are applicable to other translation models, e.g., phrase-based model, as well.

Our syntactic constituent reordering model considers context free grammar (CFG) rules in the source language and predicts the reordering of their elements on the target side, using word alignment information. Due to the fact that a constituent, especially a long one, usually maps into multiple discontinuous blocks in the target language, there is more than one way to describe the monotonicity or swapping patterns; we therefore design two reordering models: one is based on the leftmost aligned target word and the other based on the rightmost target word.

While recently there has also been some encouraging work on incorporating semantic structure (or, more specifically, predicate-argument structure: PAS) reordering in SMT, it is still an open question whether semantic structure reordering

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1123–1133,
Baltimore, Maryland, USA, June 23-25 2014.

strongly overlaps with syntactic structure reordering, since the semantic structure is closely tied to syntax. To this end, we employ the same reordering framework as syntactic constituent reordering and focus on semantic roles in a PAS. We then analyze the differences between the syntactic and semantic features.

The contributions of this paper include the following:

- We introduce novel soft reordering constraints, using syntactic constituents or semantic roles, composed over word alignment information in translation rules used during decoding time;
- We introduce a unified framework to incorporate syntactic and semantic reordering constraints;
- We provide a detailed analysis providing insight into why the semantic reordering model is significantly less effective when syntactic reordering features are also present.

The rest of the paper is organized as follows. Section 2 provides an overview of HPB translation model. Section 3 describes the details of our unified reordering models. Section 4 gives our experimental results and Section 5 discusses the behavior difference between syntactic constituent reordering and semantic role reordering. Section 6 reviews related work and, finally Section 7 concludes the paper.

2 HPB Translation Model: an Overview

In HPB models (Chiang, 2007), synchronous rules take the form $X \rightarrow \langle \gamma, \alpha, \sim \rangle$, where X is the non-terminal symbol, γ and α are strings of lexical items and non-terminals in the source and target side, respectively, and $\sim$ indicates the one-to-one correspondence between non-terminals in γ and α. Each such rule is associated with a set of translation model features $\{\phi_i\}$, such as phrase translation probability $p(\alpha \mid \gamma)$ and its inverse $p(\gamma \mid \alpha)$, the lexical translation probability $p_{lex}(\alpha \mid \gamma)$ and its inverse $p_{lex}(\gamma \mid \alpha)$, and a rule penalty that affects preference for longer or shorter derivations. Two other widely used features are a target language model feature and a target word penalty.

Given a derivation d, its translation log-probability is estimated as:

$$\log P(d) \propto \sum_i \lambda_i \phi_i(d) \quad (1)$$

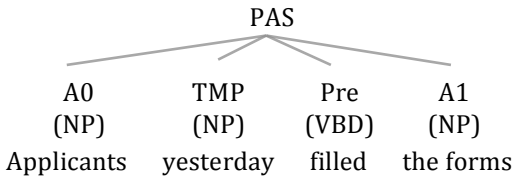

Figure 1: Example of predicate-argument structure.

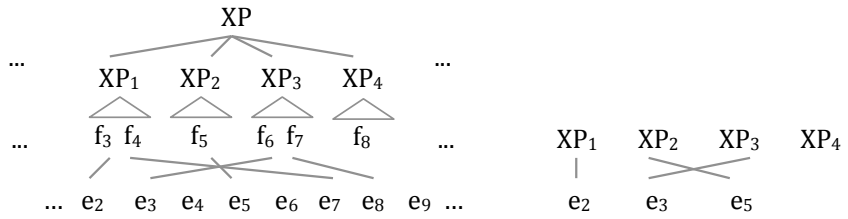
where λ_i is the corresponding weight of feature ϕ_i. See (Chiang, 2007) for more details.

3 Unified Linguistic Reordering Models

As mentioned earlier, the linguistic reordering unit is the syntactic constituent for syntactic reordering, and the semantic role for semantic reordering. The syntactic reordering model takes a CFG rule (e.g., VP $\rightarrow$ VP PP PP) and models the reordering of the constituents on the left hand side by examining their translation or visit order according to the target language. For the semantic reordering model, it takes a PAS and models its reordering on the target side. Figure 1 shows an example of a PAS where the predicate (Pre) has two core arguments (A0 and A1) and one adjunct (TMP). Note that we refer all core arguments, adjuncts, and predicates as semantic roles; thus we say the PAS in Figure 1 has 4 roles. According to the annotation principles in (Chinese) PropBank (Palmer et al., 2005; Xue and Palmer, 2009), all the roles in a PAS map to a corresponding constituent in the parse tree, and these constituents (e.g., NPs and VBD in Figure 1) do not overlap with each other.

Next, we use a CFG rule to describe our syntactic reordering model. Treating the two forms of reorderings in a unified way, the semantic reordering model is obtainable by regarding a PAS as a CFG rule and considering a semantic role as a constituent.

Because the translation of a source constituent might result in multiple discontinuous blocks, there can be several ways to describe or group the reordering patterns. Therefore, we design two general constituent reordering sub-models. One is based on the leftmost aligned word (leftmost reordering model) and the other is based on the rightmost aligned word (rightmost reordering model), as follows. Figure 2 shows the modeling steps for the leftmost reordering model. Figure 2(a) is an example of a CFG rule in the source



(a) a CFG rule and its alignment (b) leftmost aligned target words

(c) visit order

XP1	XP2	XP3	XP4
DM	DS	M	

(d) reordering types

Figure 2: Modeling process illustration for leftmost reordering model.

parse tree and its word alignment links to the target language. Note that constituent XP_4, which covers word f_8, has no alignment. Then for each XP_i, we find the leftmost target word which is aligned to a source word covered by XP_i. Figure 2(b) shows that the leftmost target words for XP_1, XP_2, and XP_3 are e_2, e_5, and e_3, respectively, while XP_4 has no aligned target word. Then we get visit order $V = \{v_i\}$ for $\{XP_i\}$ in the transformation from Figure 2(b) to Figure 2(c), with the following strategies for special cases:

- if the first constituent XP_1 is unaligned, we add a NULL word at the beginning of the target side and link XP_1 to the NULL word;
- if a constituent XP_i $(i > 1)$ is unaligned, we add a link to the target word which is aligned to XP_{i-1}, e.g., XP_4 will be linked to e_3; and
- if k constituents $XP_{m_1} \dots XP_{m_k}$ $(m_1 < \dots < m_k)$ are linked to the same target word, then $v_{m_i} = v_{m_{i+1}} - 1$, e.g., since XP_3 and XP_4 are both linked to e_3, then $v_3 = v_4 - 1$.

Finally Figure 2(d) converts the visit order $V = \{v_1, \dots v_n\}$ into a sequence of leftmost reordering types $LRT = \{lrt_1, \dots, lrt_{n-1}\}$. For every two adjacent constituents XP_i and XP_{i+1} with corresponding visit order v_i and v_{i+1}, their reordering could be one of the following:

- **Monotone (M)** if $v_{i+1} = v_i + 1$;
- **Discontinuous Monotone (DM)** if $v_{i+1} > v_i + 1$;
- **Swap (S)** if $v_{i+1} = v_i - 1$;
- **Discontinuous Swap (DS)** if $v_{i+1} < v_i - 1$.

Up to this point, we have generated a sequence of leftmost reordering types $LRT = \{lrt_1, \dots, lrt_{n-1}\}$ for a given CFG rule *cfg*: $XP \rightarrow XP_1 \dots XP_n$. The leftmost reordering model takes the following form:

$$score_{lrt}(cfg) = P_l(lrt_1, \dots, lrt_{n-1} \mid \psi(cfg)) \quad (2)$$

where $\psi(cfg)$ indicates the surrounding context of the CFG. By assuming that any two reordering types in $LRT = \{lrt_1, \dots, lrt_{n-1}\}$ are independent of each other, we reformulate Eq. 2 into:

$$score_{lrt}(cfg) = \prod_{i=1}^{n-1} P_l(lrt_i \mid \psi(cfg)) \quad (3)$$

Similarly, the sequence of rightmost reordering types *RRT* can be decided for a CFG rule $XP \rightarrow XP_1 \dots XP_n$.

Accordingly, for a PAS *pas*: $PAS \rightarrow R_1 \dots R_n$, we can obtain its sequences of leftmost and rightmost reordering types by using the same way described above.

3.1 Probability Estimation

In order to predict either the leftmost or rightmost reordering type for two adjacent constituents, we use a maximum entropy classifier to estimate the probability of the reordering type $rt \in \{M, DM, S, DS\}$ as follows:

$$P(rt \mid \psi(cfg)) = \frac{exp\left(\sum_k \theta_k f_k(rt, \psi(cfg))\right)}{\sum_{rt'} exp\left(\sum_k \theta_k f_i(rt', \psi(cfg))\right)} \quad (4)$$

where f_k are binary features, θ_k are the weights of these features. Most of our features f_k are syntax-based. For XP_i and XP_{i+1} in *cfg*, the features

#Index	Feature
cf1	$\mathcal{L}(XP_i)$ & $\mathcal{L}(XP_{i+1})$ & $\mathcal{L}(XP)$
cf2	for each XP_j $(j < i)$ $\mathcal{L}(XP_i)$ & $\mathcal{L}(XP_{i+1})$ & $\mathcal{L}(XP)$ & $\mathcal{L}(XP_j)$
cf3	for each XP_j $(j > i+1)$ $\mathcal{L}(XP_i)$ & $\mathcal{L}(XP_{i+1})$ & $\mathcal{L}(XP)$ & $\mathcal{L}(XP_j)$
cf4	$\mathcal{L}(XP_i)$ & $\mathcal{L}(XP_{i+1})$ & $\mathcal{P}(XP_i)$
cf5	$\mathcal{L}(XP_i)$ & $\mathcal{L}(XP_{i+1})$ & $\mathcal{H}(XP_i)$
cf6	$\mathcal{L}(XP_i)$ & $\mathcal{L}(XP_{i+1})$ & $\mathcal{P}(XP_{i+1})$
cf7	$\mathcal{L}(XP_i)$ & $\mathcal{L}(XP_{i+1})$ & $\mathcal{H}(XP_{i+1})$
cf8	$\mathcal{L}(XP_i)$ & $\mathcal{L}(XP_{i+1})$ & $\mathcal{S}(XP_i)$
cf9	$\mathcal{L}(XP_i)$ & $\mathcal{L}(XP_{i+1})$ & $\mathcal{S}(XP_{i+1})$
cf10	$\mathcal{L}(XP_i)$ & $\mathcal{L}(XP)$
cf11	$\mathcal{L}(XP_{i+1})$ & $\mathcal{L}(XP)$

Table 1: Features adopted in the syntactic leftmost and rightmost reordering models. $\mathcal{L}(XP)$ returns the syntactic category of *XP*, e.g., NP, VP, PP etc.; $\mathcal{H}(XP)$ returns the head word of XP; $\mathcal{P}(XP)$ returns the POS tagger of the head word; $\mathcal{S}(XP)$ returns the translation status of *XP* on the target language: *un.* if it is untranslated; *cont.* if it is a continuous block; and *discont.* if it maps into multiple discontinuous blocks.

are aimed to examine which of them should be translated first. Therefore, most features share two common components: the syntactic categories of XP_i and XP_{i+1}. Table 1 shows the features used in syntactic leftmost and rightmost reordering models. Note that we use the same features for both.

Although the semantic reordering model is structured in precisely the same way, we use different feature sets to predict the reordering between two semantic roles. Given the two adjacent roles R_i and R_{i+1} in a PAS *pas*, Table 2 shows the features that are used in the semantic leftmost and rightmost reordering models.

3.2 Integrating into the HPB Model

For models with syntactic reordering, we add two new features (i.e., one for the leftmost reordering model and the other for the rightmost reordering model) into the log-linear translation model in Eq. 1. Unlike the conventional phrase and lexical translation features, whose values are phrase pair-determined and thus can be calculated offline, the value of the reordering features can only be obtained during decoding time, and requires word alignment information as well. Before we present the algorithm integrating the reordering models, we define the following functions by assuming XP_i and XP_{i+1} are the constituent pair of interest in CFG rule *cfg*, H is the translation hypothesis and a is its word alignment:

#Index	Feature
rf1	$\mathcal{R}(R_i)$ & $\mathcal{R}(R_{i+1})$ & $\mathcal{P}(pas)$ $\mathcal{R}(R_i)$ & $\mathcal{R}(R_{i+1})$
rf2	for each R_j $(j < i)$ $\mathcal{R}(R_i)$ & $\mathcal{R}(R_{i+1})$ & $\mathcal{R}(R_j)$ & $\mathcal{P}(pas)$ $\mathcal{R}(R_i)$ & $\mathcal{R}(R_{i+1})$ & $\mathcal{R}(R_j)$
rf3	for each R_j $(j > i+1)$ $\mathcal{R}(R_i)$ & $\mathcal{R}(R_{i+1})$ & $\mathcal{R}(R_j)$ & $\mathcal{P}(pas)$ $\mathcal{R}(R_i)$ & $\mathcal{R}(R_{i+1})$ & $\mathcal{R}(R_j)$
rf4	$\mathcal{R}(R_i)$ & $\mathcal{R}(R_{i+1})$ & $\mathcal{P}(R_i)$
rf5	$\mathcal{R}(R_i)$ & $\mathcal{R}(R_{i+1})$ & $\mathcal{H}(R_i)$
rf6	$\mathcal{R}(R_i)$ & $\mathcal{R}(R_{i+1})$ & $\mathcal{L}(R_i)$
rf7	$\mathcal{R}(R_i)$ & $\mathcal{R}(R_{i+1})$ & $\mathcal{P}(R_{i+1})$
rf8	$\mathcal{R}(R_i)$ & $\mathcal{R}(R_{i+1})$ & $\mathcal{H}(R_{i+1})$
rf9	$\mathcal{R}(R_i)$ & $\mathcal{R}(R_{i+1})$ & $\mathcal{L}(R_{i+1})$
rf10	$\mathcal{R}(R_i)$ & $\mathcal{R}(R_{i+1})$ & $\mathcal{S}(R_i)$
rf11	$\mathcal{R}(R_i)$ & $\mathcal{R}(R_{i+1})$ & $\mathcal{S}(R_{i+1})$
rf12	$\mathcal{R}(R_i)$ & $\mathcal{P}(pas)$ $\mathcal{R}(R_i)$
rf13	$\mathcal{R}(R_{i+1})$ & $\mathcal{P}(pas)$ $\mathcal{R}(R_{i+1})$

Table 2: Features adopted in the semantic leftmost and rightmost reordering models. $\mathcal{P}(pas)$ returns the predicate content of *pas*; $\mathcal{R}(R)$ returns the role type of *R*, e.g., *Pred, A0, TMP,* etc. For features rf1, rf2, rf3, rf12 and rf13, we include another version which excludes the predicate content $\mathcal{P}(pas)$ for reasons of sparsity.

- $\mathcal{F}_1(w_1, w_2, XP)$: returns *true* if constituent *XP* is within the span from word w_1 to w_2; otherwise returns *false*.
- $\mathcal{F}_2(H, cfg, XP_i, XP_{i+1})$ returns *true* if the reordering of the pair $\langle XP_i, XP_{i+1}\rangle$ in rule *cfg* has not been calculated yet; otherwise returns *false*.
- $\mathcal{F}_3(H, a, XP_i, XP_{i+1})$ returns the leftmost and rightmost reordering types for the constituent pair $\langle XP_i, XP_{i+1}\rangle$, given alignment a, according to Section 3.
- $\mathcal{F}_4(rt, cfg, XP_i, XP_{i+1})$ returns the probability of leftmost reordering type rt for the constituent pair $\langle XP_i, XP_{i+1}\rangle$ in rule *cfg*.
- $\mathcal{F}_5(rt, cfg, XP_i, XP_{i+1})$ returns the probability of rightmost reordering type rt for the constituent pair $\langle XP_i, XP_{i+1}\rangle$ in rule *cfg*.

Algorithm 1 integrates the syntactic leftmost and rightmost reordering models into a CKY-style decoder whenever a new hypothesis is generated. Given a hypothesis H with its alignment a, it traverses all CFG rules in the parse tree and sees if two adjacent constituents are conditioned to trigger the reordering models (lines 2-4). For each pair of constituents, it first extracts its leftmost and rightmost reordering types (line 6) and then gets their respective probabilities returned by the maximum entropy classifiers defined in Section 3.1

Algorithm 1: Integrating the syntactic reordering models into a CKY-style decoder

Input: Sentence f in the source language
Parse tree t of f
All CFG rules $\{cfg\}$ in t
Hypothesis H spanning from word w_1 to w_2
Alignment a of H
Output: Log-Probabilities of the syntactic leftmost and rightmost reordering models

1. set $l\_prob = r_prob = 0.0$
2. **foreach** *cfg* in $\{cfg\}$
3. **foreach** pair XP_i and XP_{i+1} in *cfg*
4. **if** $\mathcal{F}_1\,(w_1,\, w_2,\, XP_i)$ = *false* or $\mathcal{F}_1\,(w_1,\, w_2,\, XP_{i+1})$ = *false* or $\mathcal{F}_2\,(H,\, cfg,\, XP_i,\, XP_{i+1})$ = *false*
5. **continue**
6. $(l\_type, r\_type) = \mathcal{F}_3\,(H,\, a,\, XP_i,\, XP_{i+1})$
7. $l\_prob \mathrel{+}= \log \mathcal{F}_4\,(l\_type, cfg, XP_i, XP_{i+1})$
8. $r\_prob \mathrel{+}= \log \mathcal{F}_5\,(r\_type, cfg, XP_i, XP_{i+1})$
9. **return** $(l\_prob,\, r\_prob)$

(lines 7-8). Then the algorithm returns two log-probabilities of the syntactic reordering models. Note that Function $\mathcal{F}_1$ returns true if hypothesis H fully covers, or fully contains, constituent XP_i, regardless of the reordering type of XP_i. Do not confuse any parsing tag XP_i with the nameless variables X_i in Hiero or cdec rules.

For the semantic reordering models, we also add two new features into the log-linear translation model. To get the two semantic reordering model feature values, we simply use Algorithm 1 and its associated functions from $\mathcal{F}_1$ to $\mathcal{F}_5$ replacing a CFG rule *cfg* with a PAS *pas*, and a constituent XP_i with a semantic role R_i. Algorithm 1 therefore permits a unified treatment of syntactic and PAS-based reordering, even though it is expressed in terms of syntactic reordering here for ease of presentation.

4 Experiments

We have presented our unified approach to incorporating syntactic and semantic soft reordering constraints in an HPB system. In this section, we test its effectiveness in Chinese-English translation.

4.1 Experimental Settings

For training we use 1.6M sentence pairs of the non-UN and non-HK Hansards portions of NIST MT training corpora, segmented with the Stanford segmenter (Tseng et al., 2005). The English data is lowercased, tokenized and aligned with GIZA++ (Och and Ney, 2000) to obtain bidirectional alignments, which are symmetrized using the *grow-diag-final-and* method (Koehn et al., 2003). We train a 4-gram LM on the English side of the corpus with 600M additional words from non-NYT and non-LAT, randomly selected portions of the Gigaword v4 corpus, using modified Kneser-Ney smoothing (Chen and Goodman, 1996). We use the HPB decoder cdec (Dyer et al., 2010), with Mr. Mira (Eidelman et al., 2013), which is a k-best variant of MIRA (Chiang et al., 2008), to tune the parameters of the system.

We use NIST MT 06 dataset (1664 sentence pairs) for tuning, and NIST MT 03, 05, and 08 datasets (919, 1082, and 1357 sentence pairs, respectively) for evaluation.[1] We use BLEU (Papineni et al., 2002) for both tuning and evaluation.

To obtain syntactic parse trees and semantic roles on the tuning and test datasets, we first parse the source sentences with the Berkeley Parser (Petrov and Klein, 2007), trained on the Chinese Treebank 7.0 (Xue et al., 2005). We then pass the parses to a Chinese semantic role labeler (Li et al., 2010), trained on the Chinese PropBank 3.0 (Xue and Palmer, 2009), to annotate semantic roles for all verbal predicates (part-of-speech tag *VV*, *VE*, or *VC*).

Our basic baseline system employs 19 basic features: a language model feature, 7 translation model features, word penalty, unknown word penalty, the glue rule, date, number and 6 pass-through features. Our stronger baseline employs, in addition, the fine-grained syntactic soft constraint features of Marton and Resnik (2008), hereafter MR08. The syntactic soft constraint features include both MR08 exact-matching and cross-boundary constraints (denoted *XP=* and *XP+*). Since the syntactic parses of the tuning and test data contain 29 types of constituent labels and 35 types of POS tags, we have 29 types of *XP+* features and 64 types of *XP=* features.

4.2 Model Training

To train the syntactic and semantic reordering models, we use a gold alignment dataset.[2] It contains 7,870 sentences with 191,364 Chinese words and 261,399 English words. We first run syn-

[1] http://www.itl.nist.gov/iad/mig//tests/mt

[2] This dataset includes LDC2006E86, and newswire parts of LDC2012T16, LDC2012T20, LDC2012T24, and LDC2013T05. Indeed, the reordering models can also be trained on the MT training data with its automatic alignment. However, our preliminary experiments showed that the reordering models trained on gold alignment yielded higher improvement.

Reordering Type	Syntactic		Semantic	
	l-m	r-m	l-m	r-m
M	73.5	80.6	63.8	67.9
DM	3.9	3.3	14.0	12.0
S	19.5	13.2	13.1	10.7
DS	3.2	3.0	9.1	9.5
#instance	199,234		66,757	

Table 3: Reordering type distribution over the reordering model's training data. Hereafter, l-m and r-m are for leftmost and rightmost, respectively.

tactic parsing and semantic role labeling on the Chinese sentences, then train the models by using MaxEnt toolkit with L1 regularizer (Tsuruoka et al., 2009).[3] Table 3 shows the reordering type distribution over the training data. Interestingly, about 17% of the syntactic instances and 16% of the semantic instances differ in their leftmost and rightmost reordering types, indicating that the leftmost/rightmost distinction is informative. We also see that the number of semantic instances is about 1/3 of that of syntactic instances, but the entropy of the semantic reordering classes is higher, indicating the reordering of semantic roles is harder than that of syntactic constituents.

A deeper examination of the reordering model's training data reveals that some constituent pairs and semantic role pairs have a preference for a specific reordering type (monotone or swap). In order to understand how well the MR08 system respects their reordering preference, we use the gold alignment dataset LDC2006E86, in which the source sentences are from the Chinese Treebank, and thus both the gold parse trees and gold predicate-argument structures are available. Table 4 presents examples comparing the reordering distribution between gold alignment and the output of the MR08 system. For example, the first row shows that based on the gold alignment, for $\langle PP,VP \rangle$, 16% are in monotone and 76% are in swap reordering. However, our MR08 system outputs 46% of them in monotone and and 50% in swap reordering. Hence, the reordering accuracy for $\langle PP,VP \rangle$ is 54%. Table 4 also shows that the semantic reordering between core arguments and predicates (e.g., $\langle Pred, A1 \rangle$, $\langle A0, Pred \rangle$) has a less ambiguous pattern than that between adjuncts and other roles (e.g., $\langle LOC,Pred \rangle$, $\langle A0,TMP \rangle$), indicating the higher reordering flexibility of adjuncts.

Table 4: Examples of the reordering distribution (%) of gold alignment and the MR08 system output. For simplicity, we only focus on *(M)onotone* and *(S)wap* based on leftmost reordering.

4.3 Translation Experiment Results

Our first group of experiments investigates whether the syntactic reordering models are able to improve translation quality in terms of BLEU. To this end, we respectively add our syntactic reordering models into both the baseline and MR08 systems. The effect is shown in the rows of "+ syn-reorder" in Table 5. From the table, we have the following two observations.

- Although the HPB model is capable of handling non-local phrase reordering using synchronous context free grammars, both our syntactic leftmost reordering model and rightmost model are still able to achieve improvement over both the baseline and MR08. This suggests that our syntactic reordering features interact well with the MR08 syntactic soft constraints: the XP+ and XP= features focus on a single constituent each, while our reordering features focus on a pair of constituents each.

- There is no clear indication of whether the leftmost reordering model works better than the other. In addition, integrating both the leftmost and rightmost reordering models has limited improvement over a single reordering model.

Our second group of experiments is to validate the semantic reordering models. Results are

System		Tuning	Test

Table 5: System performance in BLEU scores. ‡/†: significant over baseline or MR08 at 0.01 / 0.05, respectively, as tested by bootstrap resampling (Koehn, 2004)

shown in the rows of "+ sem-reorder" in Table 5. Here we observe:

- The semantic reordering models also achieve significant gain of 0.8 BLEU on average over the baseline system, demonstrating the effectiveness of PAS-based reordering. However, the gain diminishes to 0.3 BLEU on the MR08 system.
- The syntactic reordering models outperform the semantic reordering models on both the baseline and MR08 systems.

Finally, we integrate both the syntactic and semantic reordering models into the final system. The two models collectively achieve a gain of up to 1.4 BLEU over the baseline and 1.0 BLEU over MR08 on average, which is shown in the rows of "+syn+sem" in Table 5.

5 Discussion

The trend of the results, summarized as performance gain over the baseline and MR08 systems averaged over all test sets, is presented in Table 6. The syntactic reordering models outperform the semantic reordering models, and the gain achieved by the semantic reordering models is limited in the presence of the MR08 syntactic features. In this section, we look at MR08 system and the systems improving it to explore the behavior differences between the two reordering models.

Coverage analysis: Our statistics show that syntactic reordering features (either leftmost or rightmost) are called 24 times per sentence on average. This is compared to only 9 times per sentence for semantic reordering features. This is not surprising since the semantic reordering features are exclusively attached to predicates, and the span set of the semantic roles is a strict subset of the span set of the syntactic constituents; only 22% of syntactic constituents are semantic roles. On average, a sentences has 4 PASs and each PAS contains 3 semantic roles. Of all the semantic role pairs, 44% are in the same CFG rules, indicating that this part of semantic reordering has overlap with syntactic reordering. Therefore, the PAS model has fewer opportunities to influence reordering.

System	Baseline	MR08
+syn-reorder	1.2	0.9
+sem-reorder	0.8	0.3
+ both	1.4	1.0

Table 6: Performance gain in BLEU over baseline and MR08 systems averaged over all test sets.

Reordering accuracy analysis: The reordering type distribution on the reordering model training data in Table 3 suggests that semantic reordering is more difficult than syntactic reordering. To validate this conjecture on our translation test data, we compare the reordering performance among the MR08 system, the improved systems and the maximum entropy classifiers. For the test set, we have four reference translations. We run GIZA++ on the data combination of our translation training data and test data to get the alignment for the test data and each reference translation. Once we have the (semi-)gold alignment, we compute the gold reordering types between two adjacent syntactic constituents or semantic roles. Then we evaluate the automatic reordering outputs generated from both our translation systems and maximum entropy classifiers. Table 7 shows the accuracy averaged over the four gold reordering sets (the four reference translations). It shows that 1) as expected, our classifiers do worse on the harder semantic reordering prediction than syntactic reordering prediction; 2) thanks to the high accuracy obtained by the maxent classifiers, integrating either the syntactic or the semantic reordering constraints results in better reordering performance from both syntactic and semantic perspectives; 3) in terms of the mutual impact, the syntactic reordering models help improving semantic reordering more than the semantic reordering

System	Syntactic		Semantic	
	l-m	r-m	l-m	r-m
MR08	75.0	78.0	66.3	68.5
+syn-reorder	78.4	80.9	69.0	70.2
+sem-reorder	76.0	78.8	70.7	72.7
+both	78.6	81.7	70.6	72.1
Maxent Classifier	80.7	85.6	70.9	73.5

Table 7: Reordering accuracy on four gold sets.

System	Syntactic		Semantic	
	l-m	r-m	l-m	r-m
+syn-reorder	1.2	1.2	-	-
+sem-reorder	-	-	0.7	0.9
+both	1.2	1.0	0.5	0.4

Table 8: Reordering feature weights.

models help improving syntactic reordering; and 4) the rightmost models have a learnability advantage over the leftmost models, achieving higher accuracy across the board.

Feature weight analysis: Table 8 shows the syntactic and semantic reordering feature weights. It shows that the semantic feature weights decrease in the presence of the syntactic features, indicating that the decoder learns to trust semantic features less in the presence of the more accurate syntactic features. This is consistent with our observation that semantic reordering is harder than syntactic reordering, as seen in Tables 3 and 7.

Potential improvement analysis: Table 7 also shows that our current maximum entropy classifiers have room for improvement, especially for semantic reordering. In order to explore the error propagation from the classifiers themselves and explore the upper bound for improvement from the reordering models, we perform an "oracle" study, letting the classifiers be aware of the "gold" reordering type between two syntactic constituents or two semantic roles, and returning a higher probability for the gold reordering type and a smaller one for the others (i.e., we set 0.9 for the gold reordering type, and let the other non-gold three types share 0.1). Again, to get the gold reordering type, we run GIZA++ to get the alignment for tuning/test source sentences and each of four reference translations. We report the averaged performance by using the gold reordering type extracted from the four reference translations. Table 9 compares the performance between the non-oracle and oracle settings. We clearly see that using gold syntactic reordering types significantly improves the performance (e.g., 34.9 vs. 33.4 on average) and there is still some room for improvement by building a better maximum entropy classifiers (e.g., 34.9 vs. 34.3). To our surprise, however, the improvement achieved by gold semantic reordering types is still small (e.g., 33.9 vs. 33.4), suggesting that the potential improvement of semantic reordering models is much more limited. And we again see that the improvement achieved by semantic reordering models is limited in the presence of the syntactic reordering models.

	System	MT 03	MT 05	MT 08	Avg.
Non-Oracle	MR08	37.4	34.2	28.7	33.4
	+syn-reorder	38.2	35.3	29.5	34.3
	+sem-reorder	37.6	34.7	28.8	33.7
	+ both	38.4	35.2	29.5	34.4
Oracle	+syn-reorder	39.2	35.9	29.6	34.9
	+sem-reorder	37.9	34.8	28.9	33.9
	+ both	39.1	36.0	29.8	35.0

6 Related Work

Syntax-based reordering: Some previous work pre-ordered words in the source sentences, so that the word order of source and target sentences is similar. The reordering rules were either manually designed (Collins et al., 2005; Wang et al., 2007; Xu et al., 2009; Lee et al., 2010) or automatically learned (Xia and McCord, 2004; Genzel, 2010; Visweswariah et al., 2010; Khalilov and Sima'an, 2011; Lerner and Petrov, 2013), using syntactic parses. Li et al. (2007) focused on finding the n-best pre-ordered source sentences by predicting the reordering of sibling constituents, while Yang et al. (2012) obtained word order by using a reranking approach to reposition nodes in syntactic parse trees. Both are close to our work; however, our model generates reordering features that are integrated into the log-linear translation model during decoding.

Another approach in previous work added soft constraints as weighted features in the SMT decoder to reward good reorderings and penalize bad ones. Marton and Resnik (2008) employed soft syntactic constraints with weighted binary features and no MaxEnt model. They did not explicitly target reordering (beyond applying constraints on HPB rules). Although employing linguistically motivated labels in SCFG is capable of capturing constituent reorderings (Chiang, 2010; Mylon-

akis and Sima'an, 2011), the rules are sparser than SCFG with nameless non-terminals (i.e., *X*s) and soft constraints. Ge (2010) presented a syntax-driven maximum entropy reordering model that predicted the source word translation order. Gao et al. (2011) employed dependency trees to predict the translation order of a word and its head word. Huang et al. (2013) predicted the translation order of two source words.[4] Our work, which shares this approach, differs from their work primarily in that our syntactic reordering models are based on the constituent level, rather than the word level.

Semantics-based reordering: Semantics-based reordering has also seen an increase in activity recently. In the pre-ordering approach, Wu et al. (2011) automatically learned pre-ordering rules from PAS. In the soft constraint or reordering model approach, Liu and Gildea (2010) modeled the reordering/deletion of source-side semantic roles in a tree-to-string translation model. Xiong et al. (2012) and Li et al. (2013) predicted the translation order between either two arguments or an argument and its predicate. Instead of decomposing a PAS into individual units, Zhai et al. (2013) constructed a classifier for each source side PAS. Finally in the post-processing approach category, Wu and Fung (2009) performed semantic role labeling on translation output and reordered arguments to maximize the cross-lingual match of the semantic frames between the source sentence and the target translation. To our knowledge, their semantic reordering models were PAS-specific. In contrast, our model is universal and can be easily adopted to model the reordering of other linguistic units (e.g., syntactic constituents). Moreover, we have studied the effectiveness of the semantic reordering model in different scenarios.

Non-syntax-based reorderings in HPB: Recently we have also seen work on lexicalized reordering models without syntactic information in HPB (Setiawan et al., 2009; Huck et al., 2013; Nguyen and Vogel, 2013). The non-syntax-based reordering approach models the reordering of translation words/phrases while the syntax-based approach models the reordering of syntactic constituents. Although there are overlaps between translation phrases and syntactic constituents, it is reasonable to think that the two reordering approaches can work together well and even complement each other, as the linguistic patterns they capture differ substantially. Setiawan et al. (2013) modeled the orientation decisions between anchors and two neighboring multi-unit chunks which might cross phrase or rule boundaries. Last, we also note that recent work on non-syntax-based reorderings in (flat) phrase-based models (Cherry, 2013; Feng et al., 2013) can also be potentially adopted to hpb models.

[4]Note that they obtained the translation order of source word pairs by predicting the reordering of adjacent constituents, which was quite close to our work.

7 Conclusion and Future Work

In this paper, we have presented a unified reordering framework to incorporate soft linguistic constraints (of syntactic or semantic nature) into the HPB translation model. The syntactic reordering models take CFG rules and model their reordering on the target side, while the semantic reordering models work with PAS. Experiments on Chinese-English translation show that the reordering approach can significantly improve a state-of-the-art hierarchical phrase-based translation system. We have also discussed the differences between the two linguistic reordering models.

There are many directions in which this work can be continued. First, the syntactic reordering model can be extended to model reordering among constituents that cross CFG rules. Second, although we do not see obvious gain from the semantic reordering model when the syntactic model is adopted, it might be beneficial to further jointly consider the two reordering models, focusing on where each one does well. Third, to better examine the overlap or synergy between our approach and the non-syntax-based reordering approach, we will conduct direct comparisons and combinations with the latter.

Are Two Heads Better than One? Crowdsourced Translation via a Two-Step Collaboration of Non-Professional Translators and Editors

Abstract

Crowdsourcing is a viable mechanism for creating training data for machine translation. It provides a low cost, fast turnaround way of processing large volumes of data. However, when compared to professional translation, naive collection of translations from non-professionals yields low-quality results. Careful quality control is necessary for crowdsourcing to work well. In this paper, we examine the challenges of a two-step collaboration process with translation and post-editing by non-professionals. We develop graph-based ranking models that automatically select the best output from multiple redundant versions of translations and edits, and improves translation quality closer to professionals.

1 Introduction

Statistical machine translation (SMT) systems are trained using bilingual sentence-aligned parallel corpora. Theoretically, SMT can be applied to any language pair, but in practice it produces the state-of-art results only for language pairs with ample training data, like English-Arabic, English-Chinese, French-English, etc. SMT gets stuck in a severe bottleneck for many minority or 'low resource' languages with insufficient data. This drastically limits which languages SMT can be successfully applied to. Because of this, collecting parallel corpora for minor languages has become an interesting research challenge. There are various options for creating training data for new language pairs. Past approaches have examined harvesting translated documents from the web (Resnik and Smith, 2003; Uszkoreit et al., 2010; Smith et al., 2013), or discovering parallel fragments from comparable corpora (Munteanu and Marcu, 2005; Abdul-Rauf and Schwenk, 2009; Smith et al., 2010). Until relatively recently, little consideration has been given to creating parallel data from scratch. This is because the cost of hiring professional translators is prohibitively high. For instance, Germann (2001) hoped to hire professional translators to create a modest sized 100,000 word Tamil-English parallel corpus, but were stymied by the costs and the difficulty of finding good translators for a short-term commitment.

Recently, crowdsourcing has opened the possibility of translating large amounts of text at low cost using non-professional translators. Facebook localized its web site into different languages using volunteers (TechCrunch, 2008). DuoLingo turns translation into an educational game, and translates web content using its language learners (von Ahn, 2013).

Rather than relying on volunteers or gamification, NLP research into crowdsourcing translation has focused on hiring workers on the Amazon Mechanical Turk (MTurk) platform (Callison-Burch, 2009). This setup presents unique challenges, since it typically involves non-professional translators whose language skills are varied, and since it sometimes involves participants who try to cheat to get the small financial reward (Zaidan and Callison-Burch, 2011). A natural approach for trying to shore up the skills of weak bilinguals is to pair them with a native speaker of the target language to edit their translations. We review relevant research from NLP and human-computer interaction (HCI) on collaborative translation processes in Section 2. To sort good translations from bad, researchers often solicit multiple, redundant translations and then build models to try to predict which translations are the best, or which translators tend to produce the highest quality translations.

The contributions of this paper are:

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1134–1144,
Baltimore, Maryland, USA, June 23-25 2014.

- An analysis of the difficulties posed by a two-step collaboration between editors and translators in Mechanical Turk-style crowdsourcing environments. Editors vary in quality, and poor editing can be difficult to detect.

- A new graph-based algorithm for selecting the best translation among multiple translations of the same input. This method takes into account the collaborative relationship between the translators and the editors.

2 Related work

In the HCI community, several researchers have proposed protocols for collaborative translation efforts (Morita and Ishida, 2009b; Morita and Ishida, 2009a; Hu, 2009; Hu et al., 2010). These have focused on an iterative collaboration between monolingual speakers of the two languages, facilitated with a machine translation system. These studies are similar to ours in that they rely on native speakers' understanding of the target language to correct the disfluencies in poor translations. In our setup the poor translations are produced by bilingual individuals who are weak in the target language, and in their experiments the translations are the output of a machine translation system.[1]

Another significant difference is that the HCI studies assume cooperative participants. For instance, Hu et al. (2010) recruited volunteers from the International Children's Digital Library (Hourcade et al., 2003) who were all well intentioned and participated out a sense of altruism and to build a good reputation among the other volunteer translators at `childrenslibrary.org`. Our setup uses anonymous crowd workers hired on Mechanical Turk, whose motivation to participate is financial. Bernstein et al. (2010) characterized the problems with hiring editors via MTurk for a word processing application. Workers were either lazy (meaning they made only minimal edits) or overly zealous (meaning they made many unnecessary edits). Bernstein et al. (2010) addressed this problem with a three step find-fix-verify process. In the first step, workers click on one word or phrase that needed to be corrected. In the next step, a separate group of workers proposed corrections to problematic regions that had been identified by multiple workers in the first pass. In the final step, other workers would validate whether the proposed corrections were good.

Most NLP research into crowdsourcing has focused on Mechanical Turk, following pioneering work by Snow et al. (2008) who showed that the platform was a viable way of collecting data for a wide variety of NLP tasks at low cost and in large volumes. They further showed that non-expert annotations are similar to expert annotations when many non-expert labelings for the same input are aggregated, through simple voting or through weighting votes based on how closely non-experts matched experts on a small amount of calibration data. MTurk has subsequently been widely adopted by the NLP community and used for an extensive range of speech and language applications (Callison-Burch and Dredze, 2010).

Although hiring professional translators to create bilingual training data for machine translation systems has been deemed infeasible, Mechanical Turk has provided a low cost way of creating large volumes of translations (Callison-Burch, 2009; Ambati and Vogel, 2010). For instance, Zbib et al. (2012; Zbib et al. (2013) translated 1.5 million words of Levine Arabic and Egyptian Arabic, and showed that a statistical translation system trained on the dialect data outperformed a system trained on 100 times more MSA data. Post et al. (2012) used MTurk to create parallel corpora for six Indian languages for less than $0.01 per word. MTurk workers translated more than half a million words worth of Malayalam in less than a week. Several researchers have examined the use of active learning to further reduce the cost of translation (Ambati et al., 2010; Ambati, 2012; Bloodgood and Callison-Burch, 2010). Crowdsourcing allowed real studies to be conducted whereas most past active learning were simulated. Pavlick et al. (2014) conducted a large-scale demographic study of the languages spoken by workers on MTurk by translating 10,000 words in each of 100 languages. Chen and Dolan (2012) examined the steps necessary to build a persistent multilingual workforce on MTurk.

This paper is most closely related to previous work by Zaidan and Callison-Burch (2011), who showed that non-professional translators could approach the level of professional translators. They solicited multiple redundant translations from dif-

[1] A variety of HCI and NLP studies have confirmed the efficacy of monolingual or bilingual individuals post-editing of machine translation output (Callison-Burch, 2005; Koehn, 2010; Green et al., 2013). Past NLP work has also examined automatic post-editing(Knight and Chander, 1994).

Urdu translator:
According to the territory's people the pamphlets from the Taaliban had been read in the announcements in all the mosques of the Northern Wazeerastan.
English post-editor:
According to locals, the pamphlet released by the Taliban was read out on the loudspeakers of all the mosques in North Waziristan.
LDC professional:
According to the local people, the Taliban's pamphlet was read over the loudspeakers of all mosques in North Waziristan.

Table 1: Different versions of translations.

ferent Turkers for a collection of Urdu sentences that had been previously professionally translated by the Linguistics Data Consortium. They built a model to try to predict on a sentence-by-sentence and Turker-by-Turker which was the best translation or translator. They also hired US-based Turkers to edit the translations, since the translators were largely based in Pakistan and exhibited errors that are characteristic of speakers of English as a language. Zaidan and Callison-Burch (2011) observed only modest improvements when incorporating these edited translation into their model. We attempt to analyze why this is, and we proposed a new model to try to better leverage their data.

3 Crowdsourcing Translation

Setup We conduct our experiments using the data collected by Zaidan and Callison-Burch (2011). This data set consists 1,792 Urdu sentences from a variety of news and online sources, each paired with English translations provided by non-professional translators on Mechanical Turk.

Each Urdu sentence was translated redundantly by 3 distinct translators, and each translation was edited by 3 separate (native English-speaking) editors to correct for grammatical and stylistic errors. In total, this gives us 12 non-professional English candidate sentences (3 unedited, 9 edited) per original Urdu sentence. 52 different Turkers took part in the translation task, each translating 138 sentences on average. In the editing task, 320 Turkers participated, averaging 56 sentences each. For comparison, the data also includes 4 different reference translations for each source sentence, produced by professional translators.

Table 1 gives an example of an unedited translation, an edited translation, and a professional translation for the same sentence. The translations provided by translators on MTurk are generally done conscientiously, preserving the meaning of the source sentence, but typically contain simple mistakes like misspellings, typos, and awkward word choice. English-speaking editors, despite having no knowledge of the source language, are able to fix these errors. In this work, we show that the collaboration design of two heads– non-professional Urdu translators and non-professional English editors– yields better translated output than would either one working in isolation, and can better approximate the quality of professional translators.

Analysis We know from inspection that translations seem to improve with editing (Table 1). Given the data from MTurk, we explore whether this is the case in general: Do all translations improve with editing? To what extent does the individual translator and the individual editor effect the quality of the final sentence?

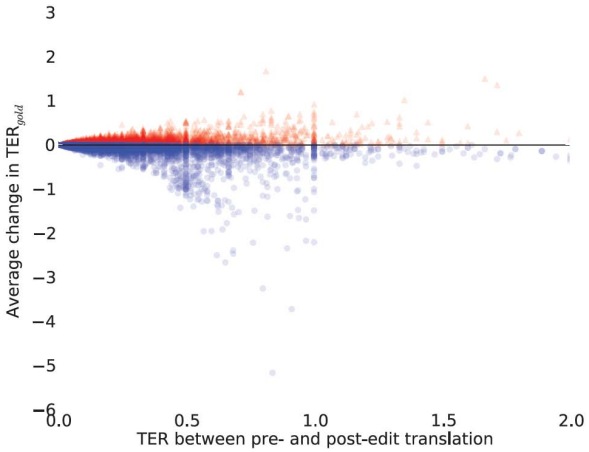

Figure 1: Relationship between editor aggressiveness and effectiveness. Each point represents an editor/translation pair. Aggressiveness (x-axis) is measured as the TER between the pre-edit and post-edit version of the translation, and effectiveness (y-axis) is measured as the average amount by which the editing reduces the translation's TER$_{gold}$. While many editors make only a few changes, those who make many changes can bring the translation substantially closer to professional quality.

We use *translation edit rate* (TER) as a measure of translation similarity. TER represents the amount of change necessary to transform one sentence into another, so a low TER means the two

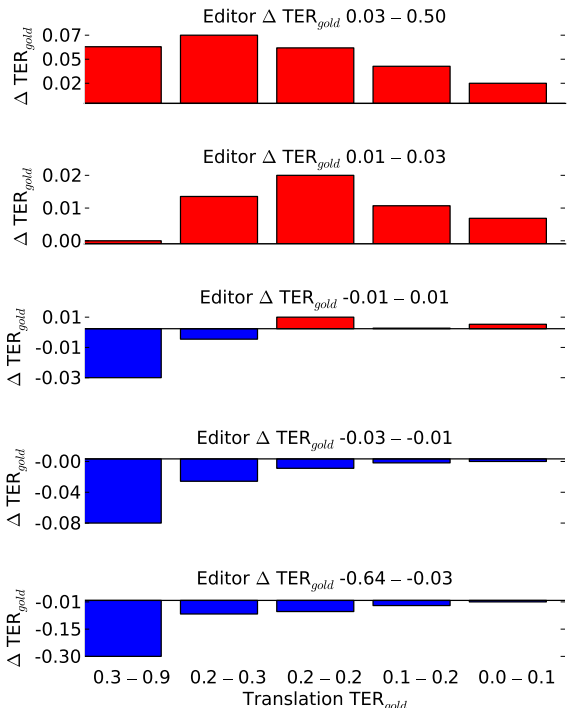

Figure 2: Effect of editing on translations of varying quality. Rows reflect bins of editors, with the worse editors (those whose changes result in increased TER$_{gold}$) on the top and the most effective editors (those whose changes result in the largest reduction in TER$_{gold}$) on the bottom. Bars reflect bins of translations, with the highest TER$_{gold}$ translations on the left, and the lowest on the right. We can see from the consistently negative Δ TER$_{gold}$ in the bottom row that good editors are able to improve both good and bad translations.

sentences are very similar. To capture the quality ("professionalness") of a translation, we take the average TER of the translation against each of our gold translations. That is, we define TER$_{gold}$ of translation t as

$$TER_{gold} = \frac{1}{4}\sum_{i=1}^{4} TER(gold_i, t) \qquad (1)$$

where a lower TER$_{gold}$ is indicative of a higher quality (more professional-sounding) translation.

We first look at editors along two dimensions: their aggressiveness and their effectiveness. Some editors may be very aggressive (they make many changes to the original translation) but still be ineffective (they fail to bring the quality of the translation closer to that of a professional). We measure aggressiveness by looking at the TER between the pre- and post-edited versions of each editor's translations; higher TER implies more aggressive editing. To measure effectiveness, we look at the change in TER$_{gold}$ that results from the editing; negative ΔTER$_{gold}$ means the editor effectively improved the quality of the translation, while positive ΔTER$_{gold}$ means the editing actually brought the translation further from our gold standard.

Figure 1 shows the relationship between these two qualities for individual editor/translation pairs. We see that while most translations require only a few edits, there are a large number of translations which improve substantially after heavy editing. This trend conforms to our intuition that editing is most useful when the translation has much room for improvement, and opens the question of whether good editors can offer improvements to translations of all qualities.

To address this question, we split our translations into 5 bins, based on their TER$_{gold}$. We also split our editors into 5 bins, based on their effectiveness (i.e. the average amount by which their editing reduces TER$_{gold}$). Figure 2 shows the degree to which editors at each level are able to improve the translations from each bin. We see that good editors are able to make improvements to translations of all qualities, but that good editing has the greatest impact on lower quality translations. This result suggests that finding good editor/translator pairs, rather than good editors and good translators in isolation, should produce the best translations overall. Figure 3 gives an example of how an initially medium-quality translation, when combined with good editing, produces a better result than the higher-quality translation paired with mediocre editing.

4 Problem Formulation

The problem definition of the crowdsourcing translation task is straightforward: given a set of candidate translations for a source sentence, we want to choose the best output translation.

This output translation is the result of the combined translation and editing stages. Therefore, our method operates over a heterogeneous network that includes translators and post-editors as well as the translated sentences that they produce. We frame the problem as follows. We form two graphs: the first graph (G_T) represents Turkers (translator/editor pairs) as nodes; the second graph (G_C) represents candidate translated and

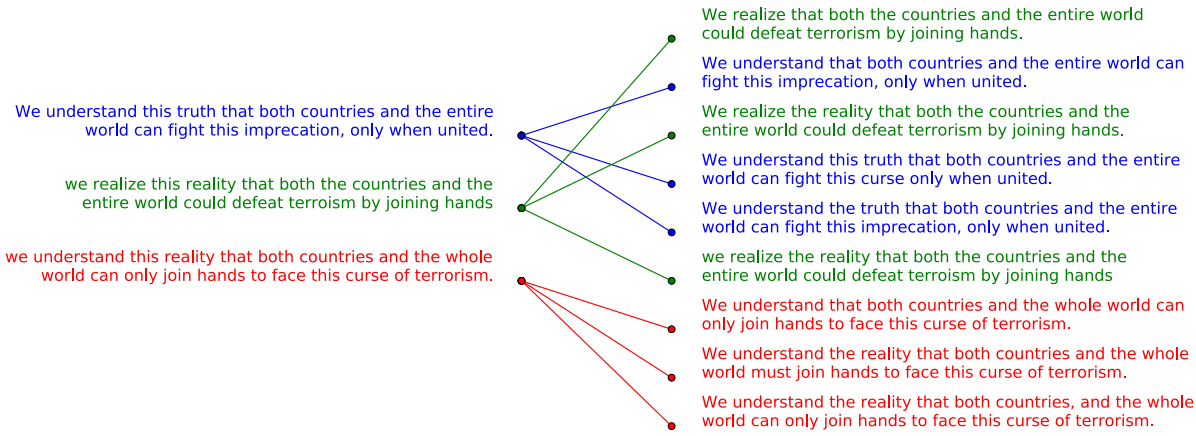

Figure 3: Three alternative translations (left) and the edited versions of each (right). Each edit on the right was produced by a different editor. Order reflects the TER_{gold} of each translation, with the lowest TER_{gold} on the top. Some translators receive low TER_{gold} scores due to superficial errors, which can be easily improved through editing. In the above example, the middle-ranked translation (green) becomes the best translation after being revised by a good editor.

post-edited sentences (henceforth "candidates") as nodes. These two graphs, G_T and G_C are combined as subgraphs of a third graph (G_{TC}). Edges in G_{TC} connect author pairs (nodes in G_T) to the candidate that they produced (nodes in G_C). Together, G_T, G_C, and G_{TC} define a co-ranking problem (Yan et al., 2012a; Yan et al., 2011b; Yan et al., 2012b) with linkage establishment (Yan et al., 2011a; Yan et al., 2012c), which we define formally as follows.

Let G denote the heterogeneous graph with nodes V and edges E. Let $G = (V,E) = (V_T, V_C, E_T, E_C, E_{TC})$. G is divided into three subgraphs, G_T, G_C, and G_{TC}. $G_C = (V_C, E_C)$ is a weighted undirected graph representing the candidates and their lexical relationships to one another. Let V_C denote a collection of translated and edited candidates, and E_C the lexical similarity between the candidates (see Section 4.3 for details). $G_T = (V_T, E_T)$ is a weighted undirected graph representing collaborations between Turkers. V_T is the set of translator/editor pairs. Edges E_T connect translator/editor pairs in V_T which share a translator and/or editor. Each collaboration (i.e. each node in V_T) produces a candidate (i.e. a node in V_C). $G_{TC} = (V_{TC}, E_{TC})$ is an unweighted bipartite graph that ties G_T and G_C together and represents "authorship". The graph G consists of nodes $V_{TC} = V_T \cup V_C$ and edges E_{TC} connecting each candidate with its authoring translator/post-editor pair. The three sub-networks (G_T, G_C, and G_{TC}) are illustrated in Figure 4.

4.1 Inter-Graph Ranking

The framework includes three random walks, one on G_T, one on G_C and one on G_{TC}. A random walk on a graph is a Markov chain, its states being the vertices of the graph. It can be described by a stochastic square matrix, where the dimension is the number of vertices in the graph, and the entries describe the transition probabilities from one vertex to the next. The mutual reinforcement framework couples the two random walks on G_T and G_C that rank candidates and Turkers in isolation. The ranking method allows us to obtain a global ranking by taking into account the intra-/inter-component dependencies. In the following sections, we describe how we obtain the rankings on G_T and G_C, and then move on to discuss how the two are coupled.

Our algorithm aims to capture the following intuitions. A candidate is important if 1) it is similar to many of the other proposed candidates and 2) it is authored by better qualified translators and/or post-editors. Analogously, a translator/editor pair is believed to be better qualified if 1) the editor is collaborating with a good translator and vice versa and 2) the pair has authored important candidates. This ranking schema is actually a reinforced process across the heterogeneous graphs. We use two vectors $\mathbf{c} = [\pi(c)]_{|c|\times 1}$ and $\mathbf{t} = [\pi(t)]_{|t|\times 1}$ to denote the saliency scores $\pi(.)$ of candidates and Turker pairs. The above-mentioned intuitions can be formulated as follows:

- **Homogeneity.** We use adjacency matrix

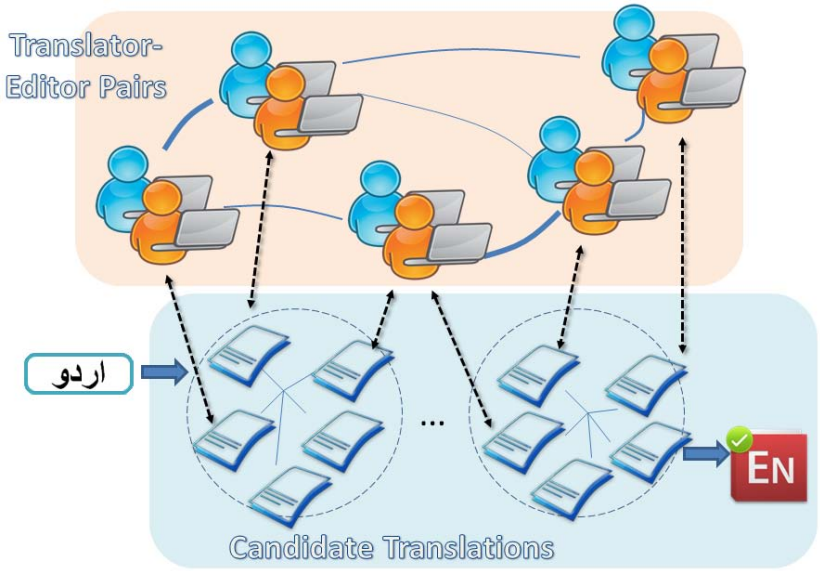

Figure 4: 2-step collaborative crowdsourcing translation model based on graph ranking framework including three sub-networks. The undirected links between users denotes *translation-editing* collaboration. The undirected links between candidate translations indicate lexical similarity between candidates. A bipartite graph ties candidate and Turker networks together by authorship (to make the figure clearer, some linkage is omitted). A dashed circle indicates the group of candidate translations for a single source sentence to translate.

$[M]_{|\mathbf{c}|\times|\mathbf{c}|}$ to describe the homogeneous affinity between candidates and $[N]_{|\mathbf{t}|\times|\mathbf{t}|}$ to describe the affinity between Turkers.

$$\mathbf{c} \propto M^T\mathbf{c}, \qquad \mathbf{t} \propto N^T\mathbf{t} \tag{2}$$

where $c = |V_C|$ is the number of vertices in the candidate graph and $t = |V_T|$ is the number of vertices in the Turker graph. The adjacency matrix $[M]$ denotes the transition probabilities between candidates, and analogously matrix $[N]$ denotes the affinity between Turker collaboration pairs.

• **Heterogeneity.** We use an adjacency matrix $[\hat{W}]_{|\mathbf{c}|\times|\mathbf{t}|}$ and $[\bar{W}]_{|\mathbf{t}|\times|\mathbf{c}|}$ to describe the authorship between the output candidate and the producer Turker pair from both of the candidate-to-Turker and Turker-to-candidate perspectives.

$$\mathbf{c} \propto \hat{W}^T\mathbf{t}, \qquad \mathbf{t} \propto \bar{W}^T\mathbf{c} \tag{3}$$

All affinity matrices will be defined in the next section. By fusing the above equations, we can have the following iterative calculation in matrix forms. For numerical computation of the saliency scores, the initial scores of all sentences and Turkers are set to 1 and the following two steps are alternated until convergence to select the best candidate.

Step 1: compute the saliency scores of candidates, and then normalize using ℓ-1 norm.

$$\begin{aligned}\mathbf{c}^{(n)} &= (1-\lambda)M^T\mathbf{c}^{(n-1)} + \lambda\hat{W}\mathbf{t}^{(n-1)} \\ \mathbf{c}^{(n)} &= \mathbf{c}^{(n)}/||\mathbf{c}^{(n)}||_1\end{aligned} \tag{4}$$

Step 2: compute the saliency scores of Turker pairs, and then normalize using ℓ-1 norm.

$$\begin{aligned}\mathbf{t}^{(n)} &= (1-\lambda)N^T\mathbf{t}^{(n-1)} + \lambda\bar{W}\mathbf{c}^{(n-1)} \\ \mathbf{t}^{(n)} &= \mathbf{t}^{(n)}/||\mathbf{t}^{(n)}||_1\end{aligned} \tag{5}$$

where λ specifies the relative contributions to the saliency score trade-off between the homogeneous affinity and the heterogeneous affinity. In order to guarantee the convergence of the iterative form, we must force the transition matrix to be stochastic and irreducible. To this end, we must make the $\mathbf{c}$ and $\mathbf{t}$ *column stochastic* (Langville and Meyer, 2004). $\mathbf{c}$ and $\mathbf{t}$ are therefore normalized after each iteration of Equation (4) and (5).

4.2 Intra-Graph Ranking

The standard PageRank algorithm starts from an arbitrary node and randomly selects to either follow a random out-going edge (considering the weighted transition matrix) or to jump to a random node (treating all nodes with equal probability).

In a simple random walk, it is assumed that all nodes in the transitional matrix are equi-probable before the walk starts. Then **c** and **t** are calculated as:

$$\mathbf{c} = \mu M^T \mathbf{c} + (1-\mu)\frac{\mathbf{1}}{|V_C|} \quad (6)$$

and

$$\mathbf{t} = \mu N^T \mathbf{t} + (1-\mu)\frac{\mathbf{1}}{|V_T|} \quad (7)$$

where **1** is a vector with all elements equaling to 1 and the size is correspondent to the size of V_C or V_T. μ is the damping factor usually set to 0.85, as in the PageRank algorithm.

4.3 Affinity Matrix Establishment

We introduce the affinity matrix calculation, including homogeneous affinity (i.e., M, N) and heterogeneous affinity (i.e., $\hat{W}, \bar{W}$).

As discussed, we model the collection of candidates as a weighted undirected graph, G_C, in which nodes in the graph represent candidate sentences and edges represent lexical relatedness. We define an edge's weight to be the cosine similarity between the candidates represented by the nodes that it connects. The adjacency matrix M describes such a graph, with each entry corresponding to the weight of an edge.

$$\begin{aligned} \mathcal{F}(c_i, c_j) &= \frac{c_i \cdot c_j}{||c_i||||c_j||} \\ M_{ij} &= \frac{\mathcal{F}(c_i, c_j)}{\sum_k \mathcal{F}(c_i, c_k)} \end{aligned} \quad (8)$$

where $\mathcal{F}(.)$ is the cosine similarity and c is a term vector corresponding to a candidate. We treat a candidate as a short document and weight each term with *tf.idf* (Manning et al., 2008), where *tf* is the term frequency and *idf* is the inverse document frequency.

The Turker graph, G_T, is an undirected graph whose edges represent "collaboration." Formally, let t_i and t_j be two translator/editor pairs; we say that pair t_i "collaborates with" pair t_j (and therefore, there is an edge between t_i and t_j) if t_i and t_j share either a translator or an editor (or share both a translator and an editor). Let the function $\mathcal{I}(t_i, t_j)$ denote the number of "collaborations" ($\#col$) between t_i and t_j.

$$\mathcal{I}(t_i, t_j) = \begin{cases} \#col & (e_{ij} \in E_T) \\ 0 & \text{otherwise} \end{cases}, \quad (9)$$

Then the adjacency matrix N is then defined as

$$N_{ij} = \frac{\mathcal{I}(t_i, t_j)}{\sum_k \mathcal{I}(t_i, t_k)} \quad (10)$$

In the bipartite candidate-Turker graph G_{TC}, the entry $E_{TC}(i, j)$ is an indicator function denoting whether the candidate c_i is generated by t_j:

$$\mathcal{A}(c_i, t_j) = \begin{cases} 1 & (e_{ij} \in E_{TC}) \\ 0 & \text{otherwise} \end{cases} \quad (11)$$

Through E_{TC} we define the weight matrices $\bar{W}_{ij}$ and $\hat{W}_{ij}$, containing the conditional probabilities of transitions from c_i to t_j and vice versa:

$$\begin{aligned} \bar{W}_{ij} &= \frac{\mathcal{A}(c_i, t_j)}{\sum_k \mathcal{A}(c_i, t_k)}, \\ \hat{W}_{ij} &= \frac{\mathcal{A}(c_i, t_j)}{\sum_k \mathcal{A}(c_k, t_j)} \end{aligned} \quad (12)$$

5 Evaluation

We are interested in testing our random walk method, which incorporates information from both the candidate translations and from the Turkers. We want to test two versions of our proposed collaborative co-ranking method: 1) based on the unedited translations only and 2) based on the edited sentences after translator/editor collaborations.

Metric Since we have four professional translation sets, we can calculate the Bilingual Evaluation Understudy (BLEU) score (Papineni et al., 2002) for one professional translator (P1) using the other three (P2,3,4) as a reference set. We repeat the process four times, scoring each professional translator against the others, to calculate the expected range of professional quality translation. In the following sections, we evaluate each of our methods by calculating BLEU scores against the same four sets of three reference translations. Therefore, each number reported in our experimental results is an average of four numbers, corresponding to the four possible ways of choosing 3 of the 4 reference sets. This allows us to compare the BLEU score achieved by our methods against the BLEU scores achievable by professional translators.

Baselines As a naive baseline, we choose one candidate translation at random for each input Urdu sentence. To establish an upper bound for our methods, and to determine if there exist high-quality Turker translations at all, we compute four

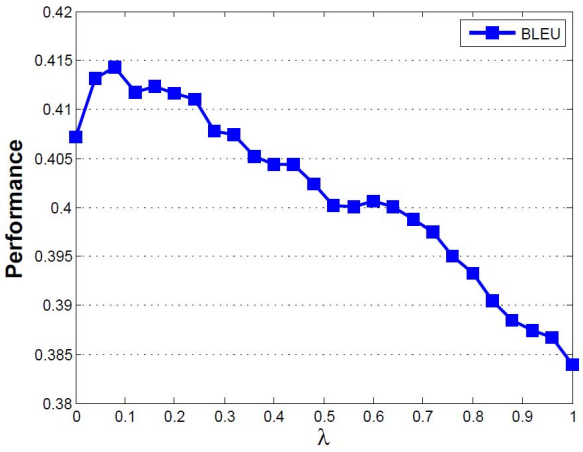

Figure 5: Effect of candidate-Turker coupling (λ) on BLEU score.

oracle scores. The first oracle operates at the segment level on the sentences produced by translators only: for each source segment, we choose from the translations the one that scores highest (in terms of BLEU) against the reference sentences. The second oracle is applied similarly, but chooses from the candidates produced by the collaboration of translator/post-editor pairs. The third oracle operates at the worker level: for each source segment, we choose from the translations the one provided by the worker whose translations (over all sentences) score the highest on average. The fourth oracle also operates at the worker level, but selects from sentences produced by translator/post-editor collaborations. These oracle methods represent ideal solutions under our scenario. We also examine two voting-inspired methods. The first method selects the translation with the minimum average TER (Snover et al., 2006) against the other translations; intuitively, this would represent the "consensus" translation. The second method selects the translation generated by the Turker who, on average, provides translations with the minimum average TER.

Results A summary of our results in given in Table 2. As expected, random selection yields bad performance, with a BLEU score of 30.52. The oracles indicate that there is usually an acceptable translation from the Turkers for any given sentence. Since the oracles select from a small group of only 4 translations per source segment, they are not overly optimistic, and rather reflect the true potential of the collected translations. On average, the reference translations give a score of 42.38. To put this in perspective, the output of a state-of-the-art machine translation system (the syntax-based variant of Joshua) achieves a score of 26.91, which is reported in (Zaidan and Callison-Burch, 2011). The approach which selects the translations with the minimum average TER (Snover et al., 2006) against the other three translations (the "consensus" translation) achieves BLEU scores of 35.78.

Using the raw translations without post-editing, our graph-based ranking method achieves a BLEU score of 38.89, compared to Zaidan and Callison-Burch (2011)' s reported score of 28.13, which they achieved using a linear feature-based classification. Their linear classifier achieved a reported score of 39.06[2] when combining information from both translators and editors. In contrast, our proposed graph-based ranking framework achieves a score of 41.43 when using the same information. This boost in BLEU score confirms our intuition that the hidden collaboration networks between candidate translations and transltor/editor pairs are indeed useful.

Parameter Tuning There are two parameters in our experimental setups: μ controls the probability of starting a new random walk and λ controls the coupling between the candidate and Turker subgraphs. We set the damping factor μ to 0.85, following the standard PageRank paradigm. In order to determine a value for λ, we used the average BLEU, computed against the professional refer-

[2]Note that the data we used in our experiments are slightly different, by discarding nearly 100 NULL sentences in the raw data. We do not re-implement this baseline but report the results from the paper directly. According to our experiments, most of the results generated by baselines and oracles are very close to the previously reported values.

Plain ranking	38.89
w/o collaboration	38.88
Shared translator	41.38
Shared post-editor	41.29
Shared Turker	**41.43**

Table 3: Variations of all component settings.

ence translations, as a tuning metric. We experimented with values of λ ranging from 0 to 1, with a step size of 0.05 (Figure 5). Small λ values place little emphasis on the candidate/Turker coupling, whereas larger values rely more heavily on the co-ranking. Overall, we observed better performance with values within the range of 0.05-0.15. This suggests that both sources of information– the candidate itself and its authors– are important for the crowdsourcing translation task. In all of our reported results, we used the $\lambda = 0.1$.

Analysis We examine the relative contribution of each component of our approach on the overall performance. We first examine the centroid-based ranking on the candidate sub-graph (G_C) alone to see the effect of voting among translated sentences; we denote this strategy as *plain ranking*. Then we incorporate the standard random walk on the Turker graph (G_T) to include the structural information but without yet including any collaboration information; that is, we incorporate information from G_T and G_C without including edges linking the two together. The co-ranking paradigm is exactly the same as the framework described in Section 3.2, but with simplified structures.

Finally, we examine the two-step collaboration based candidate-Turker graph using several variations on edge establishment. As before, the nodes are the translator/post-editor working pairs. We investigate three settings in which 1) edges connect two nodes when they share only a translator, 2) edges connect two nodes when they share only a post-editor, and 3) edges connect two nodes when they share either a translator or a post-editor. These results are summarized in Table 3.

Interestingly, we observe that when modeling the linkage between the collaboration pairs, connecting Turker pairs which share either a translator or the post-editor achieves better performance than connecting pairs that share only translators or connecting pairs which share only editors. This result supports the intuition that a denser collaboration matrix will help propagate saliency to good translators/post-editors and hence provides better predictions for candidate quality.

6 Conclusion

We have proposed an algorithm for using a two-step collaboration between non-professional translators and post-editors to obtain professional-quality translations. Our method, based on a co-ranking model, selects the best crowdsourced translation from a set of candidates, and is capable of selecting translations which near professional quality.

Crowdsourcing can play a pivotal role in future efforts to create parallel translation datasets. In addition to its benefits of cost and scalability, crowdsourcing provides access to languages that currently fall outside the scope of statistical machine translation research. In future work on crowdsourced translation, further benefits in quality improvement and cost reduction could stem from 1) building ground truth data sets based on high-quality Turkers' translations and 2) identifying when sufficient data has been collected for a given input, to avoid soliciting unnecessary redundant translations.

Abstract

We introduce a novel approach for building language models based on a systematic, recursive exploration of skip n-gram models which are interpolated using modified Kneser-Ney smoothing. Our approach generalizes language models as it contains the classical interpolation with lower order models as a special case. In this paper we motivate, formalize and present our approach. In an extensive empirical experiment over English text corpora we demonstrate that our generalized language models lead to a substantial reduction of perplexity between 3.1% and 12.7% in comparison to traditional language models using modified Kneser-Ney smoothing. Furthermore, we investigate the behaviour over three other languages and a domain specific corpus where we observed consistent improvements. Finally, we also show that the strength of our approach lies in its ability to cope in particular with sparse training data. Using a very small training data set of only 736 KB text we yield improvements of even 25.7% reduction of perplexity.

1 Introduction motivation

Language Models are a probabilistic approach for predicting the occurrence of a sequence of words. They are used in many applications, e.g. word prediction (Bickel et al., 2005), speech recognition (Rabiner and Juang, 1993), machine translation (Brown et al., 1990), or spelling correction (Mays et al., 1991). The task language models attempt to solve is the estimation of a probability of a given sequence of words $w_1^l = w_1, \ldots, w_l$. The probability $P(w_1^l)$ of this sequence can be broken down into a product of conditional probabilities:

$$\begin{aligned} P(w_1^l) =& P(w_1) \cdot P(w_2|w_1) \cdot \ldots \cdot P(w_l|w_1 \cdots w_{l-1}) \\ =& \prod_{i=1}^{l} P(w_i|w_1 \cdots w_{i-1}) \end{aligned} \quad (1)$$

Because of combinatorial explosion and data sparsity, it is very difficult to reliably estimate the probabilities that are conditioned on a longer subsequence. Therefore, by making a Markov assumption the true probability of a word sequence is only approximated by restricting conditional probabilities to depend only on a local context w_{i-n+1}^{i-1} of $n-1$ preceding words rather than the full sequence w_1^{i-1}. The challenge in the construction of language models is to provide reliable estimators for the conditional probabilities. While the estimators can be learnt—using, e.g., a maximum likelihood estimator over n-grams obtained from training data—the obtained values are not very reliable for events which may have been observed only a few times or not at all in the training data.

Smoothing is a standard technique to overcome this data sparsity problem. Various smoothing approaches have been developed and applied in the context of language models. Chen and Goodman (Chen and Goodman, 1999) introduced modified Kneser-Ney Smoothing, which up to now has been considered the state-of-the-art method for language modelling over the last 15 years. Modified Kneser-Ney Smoothing is an interpolating method which combines the estimated conditional probabilities $P(w_i|w_{i-n+1}^{i-1})$ recursively with lower order models involving a shorter local context w_{i-n+2}^{i-1} and their estimate for $P(w_i|w_{i-n+2}^{i-1})$. The motivation for using lower order models is that shorter contexts may be observed more often and, thus, suffer less from data sparsity. However, a single rare word towards the end of the local context will always cause the context to be observed rarely in the training data and hence will lead to an unreliable estimation.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1145–1154,
Baltimore, Maryland, USA, June 23-25 2014.

Because of Zipfian word distributions, most words occur very rarely and hence their true probability of occurrence may be estimated only very poorly. One word that appears at the end of a local context w_{i-n+1}^{i-1} and for which only a poor approximation exists may adversely affect the conditional probabilities in language models of all lengths — leading to severe errors even for smoothed language models. Thus, the idea motivating our approach is to involve several lower order models which systematically leave out one position in the context (one may think of replacing the affected word in the context with a wildcard) instead of shortening the sequence only by one word at the beginning.

This concept of introducing gaps in n-grams is referred to as skip n-grams (Ney et al., 1994; Huang et al., 1993). Among other techniques, skip n-grams have also been considered as an approach to overcome problems of data sparsity (Goodman, 2001). However, to best of our knowledge, language models making use of skip n-grams models have never been investigated to their full extent and over different levels of lower order models. Our approach differs as we consider all possible combinations of gaps in a local context and interpolate the higher order model with all possible lower order models derived from adding gaps in all different ways.

In this paper we make the following contributions:

1. We provide a framework for using modified Kneser-Ney smoothing in combination with a systematic exploration of lower order models based on skip n-grams.

2. We show how our novel approach can indeed easily be interpreted as a generalized version of the current state-of-the-art language models.

3. We present a large scale empirical analysis of our generalized language models on eight data sets spanning four different languages, namely, a wikipedia-based text corpus and the JRC-Acquis corpus of legislative texts.

4. We empirically observe that introducing skip n-gram models may reduce perplexity by 12.7% compared to the current state-of-the-art using modified Kneser-Ney models on large data sets. Using small training data sets we observe even higher reductions of perplexity of up to 25.6%.

The rest of the paper is organized as follows. We start with reviewing related work in Section 2. We will then introduce our generalized language models in Section 3. After explaining the evaluation methodology and introducing the data sets in Section 4 we will present the results of our evaluation in Section 5. In Section 6 we discuss why a generalized language model performs better than a standard language model. Finally, in Section 7 we summarize our findings and conclude with an overview of further interesting research challenges in the field of generalized language models.

2 Related Work

Work related to our generalized language model approach can be divided in two categories: various smoothing techniques for language models and approaches making use of skip n-grams.

Smoothing techniques for language models have a long history. Their aim is to overcome data sparsity and provide more reliable estimators—in particular for rare events. The Good Turing estimator (Good, 1953), deleted interpolation (Jelinek and Mercer, 1980), Katz backoff (Katz, 1987) and Kneser-Ney smoothing (Kneser and Ney, 1995) are just some of the approaches to be mentioned. Common strategies of these approaches are to either backoff to lower order models when a higher order model lacks sufficient training data for good estimation, to interpolate between higher and lower order models or to interpolate with a prior distribution. Furthermore, the estimation of the amount of unseen events from rare events aims to find the right weights for interpolation as well as for discounting probability mass from unreliable estimators and to retain it for unseen events.

The state of the art is a modified version of Kneser-Ney smoothing introduced in (Chen and Goodman, 1999). The modified version implements a recursive interpolation with lower order models, making use of different discount values for more or less frequently observed events. This variation has been compared to other smoothing techniques on various corpora and has shown to outperform competing approaches. We will review modified Kneser-Ney smoothing in Section 2.1 in more detail as we reuse some ideas to define our generalized language model.

Smoothing techniques which do not rely on using lower order models involve clustering (Brown et al., 1992; Ney et al., 1994), i.e. grouping together similar words to form classes of words, as well as skip n-grams (Ney et al., 1994; Huang et al., 1993). Yet other approaches make use of permutations of the word order in n-grams (Schukat-Talamazzini et al., 1995; Goodman, 2001).

Skip n-grams are typically used to incorporate long distance relations between words. Introducing the possibility of gaps between the words in an n-gram allows for capturing word relations beyond the level of n consecutive words without an exponential increase in the parameter space. However, with their restriction on a subsequence of words, skip n-grams are also used as a technique to overcome data sparsity (Goodman, 2001). In related work different terminology and different definitions have been used to describe skip n-grams. Variations modify the number of words which can be skipped between elements in an n-gram as well as the manner in which the skipped words are determined (e.g. fixed patterns (Goodman, 2001) or functional words (Gao and Suzuki, 2005)).

The impact of various extensions and smoothing techniques for language models is investigated in (Goodman, 2001; Goodman, 2000). In particular, the authors compared Kneser-Ney smoothing, Katz backoff smoothing, caching, clustering, inclusion of higher order n-grams, sentence mixture and skip n-grams. They also evaluated combinations of techniques, for instance, using skip n-gram models in combination with Kneser-Ney smoothing. The experiments in this case followed two paths: (1) interpolating a 5-gram model with lower order distribution introducing a single gap and (2) interpolating higher order models with skip n-grams which retained only combinations of two words. Goodman reported on small data sets and in the best case a moderate improvement of cross entropy in the range of 0.02 to 0.04.

In (Guthrie et al., 2006), the authors investigated the increase of observed word combinations when including skips in n-grams. The conclusion was that using skip n-grams is often more effective for increasing the number of observations than increasing the corpus size. This observation aligns well with our experiments.

2.1 Review of Modified Kneser-Ney Smoothing

We briefly recall modified Kneser-Ney Smoothing as presented in (Chen and Goodman, 1999). Modified Kneser-Ney implements smoothing by interpolating between higher and lower order n-gram language models. The highest order distribution is interpolated with lower order distribution as follows:

$$P_{\text{MKN}}(w_i|w_{i-n+1}^{i-1}) = \frac{\max\{c(w_{i-n+1}^{i}) - D(c(w_{i-n+1}^{i})), 0\}}{c(w_{i-n+1}^{i-1})} + \gamma_{high}(w_{i-n+1}^{i-1})\hat{P}_{\text{MKN}}(w_i|w_{i-n+2}^{i-1}) \quad (2)$$

where $c(w_{i-n+1}^{i})$ provides the frequency count that sequence w_{i-n+1}^{i} occurs in training data, D is a discount value (which depends on the frequency of the sequence) and γ_{high} depends on D and is the interpolation factor to mix in the lower order distribution[1]. Essentially, interpolation with a lower order model corresponds to leaving out the first word in the considered sequence. The lower order models are computed differently using the notion of continuation counts rather than absolute counts:

$$\hat{P}_{\text{MKN}}(w_i|(w_{i-n+1}^{i-1})) = \frac{\max\{N_{1+}(\bullet w_{i-n+1}^{i}) - D(c(w_{i-n+1}^{i})), 0\}}{N_{1+}(\bullet w_{i-n+1}^{i-1}\bullet)} + \gamma_{mid}(w_{i-n+1}^{i-1})\hat{P}_{\text{MKN}}(w_i|w_{i-n+2}^{i-1})) \quad (3)$$

where the continuation counts are defined as $N_{1+}(\bullet w_{i-n+1}^{i}) = |\{w_{i-n} : c(w_{i-n}^{i}) > 0\}|$, i.e. the number of different words which precede the sequence w_{i-n+1}^{i}. The term γ_{mid} is again an interpolation factor which depends on the discounted probability mass D in the first term of the formula.

3 Generalized Language Models

3.1 Notation for Skip n-gram with k Skips

We express skip n-grams using an operator notation. The operator ∂_i applied to an n-gram removes the word at the i-th position. For instance: $\partial_3 w_1 w_2 w_3 w_4 = w_1 w_2 \_ w_4$, where $\_$ is used as wildcard placeholder to indicate a removed word. The wildcard operator allows for

[1] The factors γ and D are quite technical and lengthy. As they do not play a significant role for understanding our novel approach we refer to Appendix A for details.

larger number of matches. For instance, when $c(w_1 w_2 w_{3a} w_4) = x$ and $c(w_1 w_2 w_{3b} w_4) = y$ then $c(w_1 w_2 \_ w4) \geq x + y$ since at least the two sequences $w_1 w_2 w_{3a} w_4$ and $w_1 w_2 w_{3b} w_4$ match the sequence $w_1 w_2 \_ w_4$. In order to align with standard language models the skip operator applied to the first word of a sequence will remove the word instead of introducing a wildcard. In particular the equation $\partial_1 w_{i-n+1}^i = w_{i-n+2}^i$ holds where the right hand side is the subsequence of w_{i-n+1}^i omitting the first word. We can thus formulate the interpolation step of modified Kneser-Ney smoothing using our notation as $\hat{P}_{\text{MKN}}(w_i|w_{i-n+2}^{i-1}) = \hat{P}_{\text{MKN}}(w_i|\partial_1 w_{i-n+1}^{i-1})$.

Thus, our skip n-grams correspond to n-grams of which we only use k words, after having applied the skip operators $\partial_{i_1} \dots \partial_{i_{n-k}}$

3.2 Generalized Language Model

Interpolation with lower order models is motivated by the problem of data sparsity in higher order models. However, lower order models omit only the first word in the local context, which might not necessarily be the cause for the overall n-gram to be rare. This is the motivation for our generalized language models to not only interpolate with one lower order model, where the first word in a sequence is omitted, but also with all other skip n-gram models, where one word is left out. Combining this idea with modified Kneser-Ney smoothing leads to a formula similar to (2).

$$P_{\text{GLM}}(w_i|w_{i-n+1}^{i-1}) = \frac{\max\{c(w_{i-n+1}^i) - D(c(w_{i-n+1}^i)), 0\}}{c(w_{i-n+1}^{i-1})} + \gamma_{high}(w_{i-n+1}^{i-1}) \sum_{j=1}^{n-1} \frac{1}{n-1} \hat{P}_{\text{GLM}}(w_i|\partial_j w_{i-n+1}^{i-1}) \quad (4)$$

The difference between formula (2) and formula (4) is the way in which lower order models are interpolated.

Note, the sum over all possible positions in the context w_{i-n+1}^{i-1} for which we can skip a word and the according lower order models $P_{\text{GLM}}(w_i|\partial_j(w_{i-n+1}^{i-1}))$. We give all lower order models the same weight $\frac{1}{n-1}$.

The same principle is recursively applied in the lower order models in which some words of the full n-gram are already skipped. As in modified Kneser-Ney smoothing we use continuation counts for the lower order models, incorporating the skip operator also for these counts. Incorporating this directly into modified Kneser-Ney smoothing leads in the second highest model to:

$$\hat{P}_{\text{GLM}}(w_i|\partial_j(w_{i-n+1}^{i-1})) = \frac{\max\{N_{1+}(\partial_j(w_{i-n}^i)) - D(c(\partial_j(w_{i-n+1}^i))), 0\}}{N_{1+}(\partial_j(w_{i-n+1}^{i-1})\bullet)} + \gamma_{mid}(\partial_j(w_{i-n+1}^{i-1})) \sum_{\substack{k=1 \\ k \neq j}}^{n-1} \frac{1}{n-2} \hat{P}_{\text{GLM}}(w_i|\partial_j \partial_k(w_{i-n+1}^{i-1})) \quad (5)$$

Given that we skip words at different positions, we have to extend the notion of the count function and the continuation counts. The count function applied to a skip n-gram is given by $c(\partial_j(w_{i-n}^i)) = \sum_{w_j} c(w_{i-n}^i)$, i.e. we aggregate the count information over all words which fill the gap in the n-gram. Regarding the continuation counts we define:

$$N_{1+}(\partial_j(w_{i-n}^i)) = |\{w_{i-n+j-1} : c(w_{i-n}^i) > 0\}| \quad (6)$$

$$N_{1+}(\partial_j(w_{i-n}^{i-1})\bullet) = |\{(w_{i-n+j-1}, w_i) : c(w_{i-n}^i) > 0\}| \quad (7)$$

As lowest order model we use—just as done for traditional modified Kneser-Ney (Chen and Goodman, 1999)—a unigram model interpolated with a uniform distribution for unseen words.

The overall process is depicted in Figure 1, illustrating how the higher level models are recursively smoothed with several lower order ones.

4 Experimental Setup and Data Sets

To evaluate the quality of our generalized language models we empirically compare their ability to explain sequences of words. To this end we use text corpora, split them into test and training data, build language models as well as generalized language models over the training data and apply them on the test data. We employ established metrics, such as cross entropy and perplexity. In the following we explain the details of our experimental setup.

4.1 Data Sets

For evaluation purposes we employed eight different data sets. The data sets cover different domains and languages. As languages we considered English (*en*), German (*de*), French (*fr*), and Italian (*it*). As general domain data set we used the full collection of articles from Wikipedia (*wiki*) in the corresponding languages. The download dates of the dumps are displayed in Table 1.

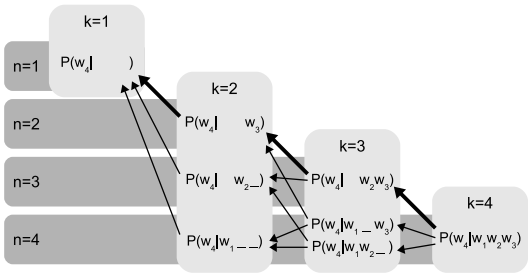

Figure 1: Interpolation of models of different order and using skip patterns. The value of n indicates the length of the raw n-grams necessary for computing the model, the value of k indicates the number of words actually used in the model. The wild card symbol _ marks skipped words in an n-gram. The arrows indicate how a higher order model is interpolated with lower order models which skips one word. The bold arrows correspond to interpolation of models in traditional modified Kneser-Ney smoothing. The lighter arrows illustrate the additional interpolations introduced by our generalized language models.

JRC-fr	35.8	0.46
wiki-it	193	3.09
JRC-it	34.4	0.47

Table 2: Word statistics and size of of evaluation corpora

The data sets come in the form of structured text corpora which we cleaned from markup and tokenized to generate word sequences. We filtered the word tokens by removing all character sequences which did not contain any letter, digit or common punctuation marks. Eventually, the word token sequences were split into word sequences of length n which provided the basis for the training and test sets for all algorithms. Note that we did not perform case-folding nor did we apply stemming algorithms to normalize the word forms. Also, we did our evaluation using case sensitive training and test data. Additionally, we kept all tokens for named entities such as names of persons or places.

4.2 Evaluation Methodology

All data sets have been randomly split into a training and a test set on a sentence level. The training sets consist of 80% of the sentences, which have been used to derive n-grams, skip n-grams and corresponding continuation counts for values of n between 1 and 5. Note that we have trained a prediction model for each data set individually. From the remaining 20% of the sequences we have randomly sampled a separate set of $100,000$ sequences of 5 words each. These test sequences have also been shortened to sequences of length 3, and 4 and provide a basis to conduct our final experiments to evaluate the performance of the different algorithms.

We learnt the generalized language models on the same split of the training corpus as the standard language model using modified Kneser-Ney smoothing and we also used the same set of test sequences for a direct comparison. To ensure rigour and openness of research the data set for training as well as the test sequences and the entire source code is open source. [2] [3] [4] We compared the probabilities of our language model implementation (which is a subset of the generalized language model) using KN as well as MKN smoothing with the Kyoto Language Model Toolkit [5]. Since we got the same results for small n and small data sets we believe that our implementation is correct.

In a second experiment we have investigated the impact of the size of the training data set. The wikipedia corpus consists of 1.7 bn. words.

[2] http://west.uni-koblenz.de/Research

[3] https://github.com/renepickhardt/generalized-language-modeling-toolkit

[4] http://glm.rene-pickhardt.de

[5] http://www.phontron.com/kylm/

Thus, the 80% split for training consists of 1.3 bn. words. We have iteratively created smaller training sets by decreasing the split factor by an order of magnitude. So we created 8% / 92% and 0.8% / 99.2% split, and so on. We have stopped at the $0.008\%/99.992\%$ split as the training data set in this case consisted of less words than our 100k test sequences which we still randomly sampled from the test data of each split. Then we trained a generalized language model as well as a standard language model with modified Kneser-Ney smoothing on each of these samples of the training data. Again we have evaluated these language models on the same random sample of $100,000$ sequences as mentioned above.

4.3 Evaluation Metrics

As evaluation metric we use *perplexity*: a standard measure in the field of language models (Manning and Schütze, 1999). First we calculate the *cross entropy* of a trained language model given a test set using

$$H(P_{\texttt{alg}}) = -\sum_{s \in T} P_{\texttt{MLE}}(s) \cdot \log_2 P_{\texttt{alg}}(s) \quad (8)$$

Where $P_{\texttt{alg}}$ will be replaced by the probability estimates provided by our generalized language models and the estimates of a language model using modified Kneser-Ney smoothing. $P_{\texttt{MLE}}$, instead, is a maximum likelihood estimator of the test sequence to occur in the test corpus. Finally, T is the set of test sequences. The perplexity is defined as:

$$\textit{Perplexity}(P_{\texttt{alg}}) = 2^{H(P_{\texttt{alg}})} \quad (9)$$

Lower perplexity values indicate better results.

5 Results

5.1 Baseline

As a baseline for our generalized language model (GLM) we have trained standard language models using modified Kneser-Ney Smoothing (MKN). These models have been trained for model lengths 3 to 5. For unigram and bigram models MKN and GLM are identical.

5.2 Evaluation Experiments

The perplexity values for all data sets and various model orders can be seen in Table 3. In this table we also present the relative reduction of perplexity in comparison to the baseline.

Table 3: Absolute perplexity values and relative reduction of perplexity from MKN to GLM on all data sets for models of order 3 to 5

As we can see, the GLM clearly outperforms the baseline for all model lengths and data sets. In general we see a larger improvement in performance for models of higher orders ($n = 5$). The gain for 3-gram models, instead, is negligible. For German texts the increase in performance is the highest (12.7%) for a model of order 5. We also note that GLMs seem to work better on broad domain text rather than special purpose text as the reduction on the wiki corpora is constantly higher than the reduction of perplexity on the JRC corpora.

We made consistent observations in our second experiment where we iteratively shrank the size of the training data set. We calculated the relative reduction in perplexity from MKN to GLM

for various model lengths and the different sizes of the training data. The results for the English Wikipedia data set are illustrated in Figure 2.

We see that the GLM performs particularly well on small training data. As the size of the training data set becomes smaller (even smaller than the evaluation data), the GLM achieves a reduction of perplexity of up to 25.7% compared to language models with modified Kneser-Ney smoothing on the same data set. The absolute perplexity values for this experiment are presented in Table 4.

	model length		
Experiments	$n=3$	$n=4$	$n=5$

Table 4: Absolute perplexity values and relative reduction of perplexity from MKN to GLM on shrunk training data sets for the English Wikipedia for models of order 3 to 5

Our theory as well as the results so far suggest that the GLM performs particularly well on sparse training data. This conjecture has been investigated in a last experiment. For each model length we have split the test data of the largest English Wikipedia corpus into two disjoint evaluation data sets. The data set *unseen* consists of all test sequences which have never been observed in the training data. The set *observed* consists only of test sequences which have been observed at least once in the training data. Again we have calculated the perplexity of each set. For reference, also the values of the complete test data set are shown in Table 5.

	model length		
Experiments	$n=3$	$n=4$	$n=5$
$\text{MKN}^{\text{complete}}$	586.9	404	307.3
$\text{GLM}^{\text{complete}}$	**571.6**	**378.1**	**275**
rel. change	2.6%	6.5%	10.5%
$\text{MKN}^{\text{unseen}}$	14696.8	2199.8	846.1
$\text{GLM}^{\text{unseen}}$	**13058.7**	**1902.4**	**714.4**
rel. change	11.2%	13.5%	15.6%
$\text{MKN}^{\text{observed}}$	**220.2**	**88.0**	**43.4**
$\text{GLM}^{\text{observed}}$	220.6	88.3	43.5
rel. change	-0.16%	-0.28%	-0.15%

Table 5: Absolute perplexity values and relative reduction of perplexity from MKN to GLM for the complete and split test file into observed and unseen sequences for models of order 3 to 5. The data set is the largest English Wikipedia corpus.

As expected we see the overall perplexity values rise for the *unseen* test case and decline for the *observed* test case. More interestingly we see that the relative reduction of perplexity of the GLM over MKN increases from 10.5% to 15.6% on the *unseen* test case. This indicates that the superior performance of the GLM on small training corpora and for higher order models indeed comes from its good performance properties with regard to sparse training data. It also confirms that our motivation to produce lower order n-grams by omitting not only the first word of the local context but systematically all words has been fruitful. However, we also see that for the *observed* sequences the GLM performs slightly worse than MKN. For the observed cases we find the relative change to be negligible.

6 Discussion

In our experiments we have observed an improvement of our generalized language models over classical language models using Kneser-Ney smoothing. The improvements have been observed for different languages, different domains as well as different sizes of the training data. In the experiments we have also seen that the GLM performs well in particular for small training data sets and sparse data, encouraging our initial motivation. This feature of the GLM is of particular value, as data sparsity becomes a more and more immanent problem for higher values of n. This known fact is underlined also by the statis-

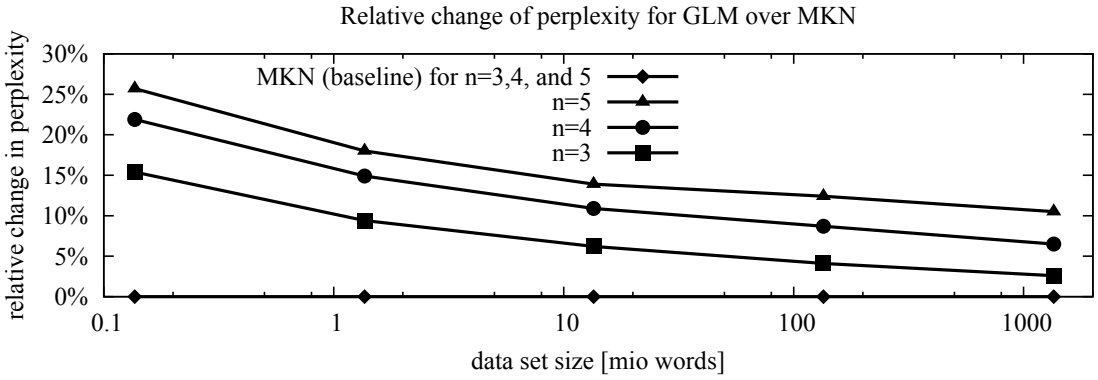

Figure 2: Variation of the size of the training data on 100k test sequences on the English Wikipedia data set with different model lengths for GLM.

tics shown in Table 6. The fraction of total n-grams which appear only once in our Wikipedia corpus increases for higher values of n. However, for the same value of n the skip n-grams are less rare. Our generalized language models leverage this additional information to obtain more reliable estimates for the probability of word sequences.

w_1^n	**total**	**unique**
w_1	0.5%	64.0%
$w_1 w_2$	5.1%	68.2%
$w_1 \_ w_3$	8.0%	79.9%
$w_1 \_\_ w_4$	9.6%	72.1%
$w_1 \_\_\_ w_5$	10.1%	72.7%
$w_1 w_2 w_3$	21.1%	77.5%
$w_1 \_ w_3 w_4$	28.2%	80.4%
$w_1 w_2 \_ w_4$	28.2%	80.7%
$w_1 \_\_ w_4 w_5$	31.7%	81.9%
$w_1 \_ w_3 \_ w_5$	35.3%	83.0%
$w_1 w_2 \_\_ w_5$	31.5%	82.2%
$w_1 w_2 w_3 w_4$	44.7%	85.4%
$w_1 \_ w_3 w_4 w_5$	52.7%	87.6%
$w_1 w_2 \_ w_4 w_5$	52.6%	88.0%
$w_1 w_2 w_3 \_ w_5$	52.3%	87.7%
$w_1 w_2 w_3 w_4 w_5$	64.4%	90.7%

Table 6: Percentage of generalized n-grams which occur only once in the English Wikipedia corpus. Total means a percentage relative to the total amount of sequences. Unique means a percentage relative to the amount of unique sequences of this pattern in the data set.

Beyond the general improvements there is an additional path for benefitting from generalized language models. As it is possible to better leverage the information in smaller and sparse data sets, we can build smaller models of competitive performance. For instance, when looking at Table 4 we observe the 3-gram MKN approach on the full training data set to achieve a perplexity of 586.9. This model has been trained on 7 GB of text and the resulting model has a size of 15 GB and 742 Mio. entries for the count and continuation count values. Looking for a GLM with comparable but better performance we see that the 5-gram model trained on 1% of the training data has a perplexity of 528.7. This GLM model has a size of 9.5 GB and contains only 427 Mio. entries. So, using a far smaller set of training data we can build a smaller model which still demonstrates a competitive performance.

7 Conclusion and Future Work

7.1 Conclusion

We have introduced a novel generalized language model as the systematic combination of skip n-grams and modified Kneser-Ney smoothing. The main strength of our approach is the combination of a simple and elegant idea with an an empirically convincing result. Mathematically one can see that the GLM includes the standard language model with modified Kneser-Ney smoothing as a sub model and is consequently a real generalization.

In an empirical evaluation, we have demonstrated that for higher orders the GLM outperforms MKN for all test cases. The relative improvement in perplexity is up to 12.7% for large data sets. GLMs also performs particularly well on small and sparse sets of training data. On a very

small training data set we observed a reduction of perplexity by 25.7%. Our experiments underline that the generalized language models overcome in particular the weaknesses of modified Kneser-Ney smoothing on sparse training data.

7.2 Future work

A desirable extension of our current definition of GLMs will be the combination of different lower lower order models in our generalized language model using different weights for each model. Such weights can be used to model the statistical reliability of the different lower order models. The value of the weights would have to be chosen according to the probability or counts of the respective skip n-grams.

Another important step that has not been considered yet is compressing and indexing of generalized language models to improve the performance of the computation and be able to store them in main memory. Regarding the scalability of the approach to very large data sets we intend to apply the Map Reduce techniques from (Heafield et al., 2013) to our generalized language models in order to have a more scalable calculation.

This will open the path also to another interesting experiment. Goodman (Goodman, 2001) observed that increasing the length of n-grams in combination with modified Kneser-Ney smoothing did not lead to improvements for values of n beyond 7. We believe that our generalized language models could still benefit from such an increase. They suffer less from the sparsity of long n-grams and can overcome this sparsity when interpolating with the lower order skip n-grams while benefiting from the larger context.

Finally, it would be interesting to see how applications of language models—like next word prediction, machine translation, speech recognition, text classification, spelling correction, e.g.—benefit from the better performance of generalized language models.

A Discount Values and Weights in Modified Kneser Ney

The discount value $D(c)$ used in formula (2) is defined as (Chen and Goodman, 1999):

$$D(c) = \begin{cases} 0 & \text{if } c = 0 \\ D_1 & \text{if } c = 1 \\ D_2 & \text{if } c = 2 \\ D_{3+} & \text{if } c > 2 \end{cases} \tag{10}$$

The discounting values D_1, D_2, and D_{3+} are defined as (Chen and Goodman, 1998)

$$D_1 = 1 - 2Y\frac{n_2}{n_1} \tag{11a}$$

$$D_2 = 2 - 3Y\frac{n_3}{n_2} \tag{11b}$$

$$D_{3+} = 3 - 4Y\frac{n_4}{n_3} \tag{11c}$$

with $Y = \frac{n_1}{n_1+n_2}$ and n_i is the total number of n-grams which appear exactly i times in the training data. The weight $\gamma_{high}(w_{i-n+1}^{i-1})$ is defined as:

$$\gamma_{high}(w_{i-n+1}^{i-1}) = \frac{D_1 N_1(w_{i-n+1}^{i-1}\bullet) + D_2 N_2(w_{i-n+1}^{i-1}\bullet) + D_{3+} N_{3+}(w_{i-n+1}^{i-1}\bullet)}{c(w_{i-n+1}^{i-1})} \tag{12}$$

And the weight $\gamma_{mid}(w_{i-n+1}^{i-1})$ is defined as:

$$\gamma_{mid}(w_{i-n+1}^{i-1}) = \frac{D_1 N_1(w_{i-n+1}^{i-1}\bullet) + D_2 N_2(w_{i-n+1}^{i-1}\bullet) + D_{3+} N_{3+}(w_{i-n+1}^{i-1}\bullet)}{N_{1+}(\bullet w_{i-n+1}^{i-1}\bullet)} \tag{13}$$

where $N_1(w_{i-n+1}^{i-1}\bullet)$, $N_2(w_{i-n+1}^{i-1}\bullet)$, and $N_{3+}(w_{i-n+1}^{i-1}\bullet)$ are analogously defined to $N_{1+}(w_{i-n+1}^{i-1}\bullet)$.

A Semiparametric Gaussian Copula Regression Model for Predicting Financial Risks from Earnings Calls

Abstract

Earnings call summarizes the financial performance of a company, and it is an important indicator of the future financial risks of the company. We quantitatively study how earnings calls are correlated with the financial risks, with a special focus on the financial crisis of 2009. In particular, we perform a text regression task: given the transcript of an earnings call, we predict the volatility of stock prices from the week after the call is made. We propose the use of *copula*: a powerful statistical framework that separately models the uniform marginals and their complex multivariate stochastic dependencies, while not requiring any prior assumptions on the distributions of the covariate and the dependent variable. By performing *probability integral transform*, our approach moves beyond the standard count-based bag-of-words models in NLP, and improves previous work on text regression by incorporating the correlation among local features in the form of semiparametric Gaussian copula. In experiments, we show that our model significantly outperforms strong linear and non-linear discriminative baselines on three datasets under various settings.

1 Introduction

Predicting the risks of publicly listed companies is of great interests not only to the traders and analysts on the Wall Street, but also virtually anyone who has investments in the market (Kogan et al., 2009). Traditionally, analysts focus on quantitative modeling of historical trading data. Today, even though earnings calls transcripts are abundantly available, their distinctive communicative practices (Camiciottoli, 2010), and correlations with the financial risks, in particular, future stock performances (Price et al., 2012), are not well studied in the past.

Earnings calls are conference calls where a listed company discusses the financial performance. Typically, a earnings call contains two parts: the senior executives first report the operational outcomes, as well as the current financial performance, and then discuss their perspectives on the future of the company. The second part of the teleconference includes a question answering session where the floor will be open to investors, analysts, and other parties for inquiries. The question we ask is that, even though each earnings call has distinct styles, as well as different speakers and mixed formats, can we use earnings calls to predict the financial risks of the company in the limited future?

Given a piece of earnings call transcript, we investigate a semiparametric approach for automatic prediction of future financial risk[1]. To do this, we formulate the problem as a text regression task, and use a Gaussian copula with probability integral transform to model the uniform marginals and their dependencies. Copula models (Schweizer and Sklar, 1983; Nelsen, 1999) are often used by statisticians (Genest and Favre, 2007; Liu et al., 2012; Masarotto and Varin, 2012) and economists (Chen and Fan, 2006) to study the bivariate and multivariate stochastic dependency among random variables, but they are very new to the machine learning (Ghahramani et al., 2012; Han et al., 2012; Xiang and Neville, 2013; Lopez-paz et al., 2013) and related communities (Eickhoff et al., 2013). To the best of our knowledge, even though the term "copula" is named for the resemblance to grammatical copulas in linguistics, copula models have not been explored in the NLP community. To evaluate the performance of our approach, we compare with a standard squared loss linear regression baseline, as well as strong baselines such as linear and non-linear support

[1] In this work, the risk is defined as the measured volatility of stock prices from the week following the earnings call teleconference. See details in Section 5.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1155–1165,
Baltimore, Maryland, USA, June 23-25 2014.

vector machines (SVMs) that are widely used in text regression tasks. By varying different experimental settings on three datasets concerning different periods of the Great Recession from 2006-2013, we empirically show that our approach significantly outperforms the baselines by a wide margin. Our main contributions are:

- We are among the first to formally study transcripts of earnings calls to predict financial risks.
- We propose a novel semiparametric Gaussian copula model for text regression.
- Our results significantly outperform standard linear regression and strong SVM baselines.
- By varying the number of dimensions of the covariates and the size of the training data, we show that the improvements over the baselines are robust across different parameter settings on three datasets.

In the next section, we outline related work in modeling financial reports and text regression. In Section 3, the details of the semiparametric copula model are introduced. We then describe the dataset and dependent variable in this study, and the experiments are shown in Section 6. We discuss the results and findings in Section 7 and then conclude in Section 8.

2 Related Work

Fung et al. (2003) are among the first to study SVM and text mining methods in the market prediction domain, where they align financial news articles with multiple time series to simulate the 33 stocks in the Hong Kong Hang Seng Index. However, text regression in the financial domain have not been explored until recently. Kogan et al. (2009) model the SEC-mandated annual reports, and performs linear SVM regression with ϵ-insensitive loss function to predict the measured volatility. Another recent study (Wang et al., 2013) uses exactly the same max-margin regression technique, but with a different focus on the financial sentiment. Using the same dataset, Tsai and Wang (2013) reformulate the regression problem as a text ranking problem. Note that all these regression studies above investigate the SEC-mandated annual reports, which are very different from the earnings calls in many aspects such as length, format, vocabulary, and genre. Most recently, Xie et al. (2013) have proposed the use of frame-level semantic features to understand financial news, but they treat the stock movement prediction problem as a binary classification task. Broadly speaking, our work is also aligned to recent studies that make use of social media data to predict the stock market (Bollen et al., 2011; Zhang et al., 2011).

Despite our financial domain, our approach is more relevant to text regression. Traditional discriminative models, such as linear regression and linear SVM, have been very popular in various text regression tasks, such as predicting movie revenues from reviews (Joshi et al., 2010), understanding the geographic lexical variation (Eisenstein et al., 2010), and predicting food prices from menus (Chahuneau et al., 2012). The advantage of these models is that the estimation of the parameters is often simple, the results are easy to interpret, and the approach often yields strong performances. While these approaches have merits, they suffer from the problem of not explicitly modeling the correlations and interactions among random variables, which in some sense, corresponding to the impractical assumption of independent and identically distributed (i.i.d) of the data. For example, when bag-of-word-unigrams are present in the feature space, it is easier if one does not explicitly model the stochastic dependencies among the words, even though doing so might hurt the predictive power, while the variance from the correlations among the random variables is not explained.

3 Copula Models for Text Regression

In NLP, many statistical machine learning methods that capture the dependencies among random variables, including topic models (Blei et al., 2003; Lafferty and Blei, 2005; Wang et al., 2012), always have to make assumptions with the underlying distributions of the random variables, and make use of informative priors. This might be rather restricting the expressiveness of the model in some sense (Reisinger et al., 2010). On the other hand, once such assumptions are removed, another problem arises — they might be prone to errors, and suffer from the overfitting issue. Therefore, coping with the tradeoff between expressiveness and overfitting, seems to be rather important in statistical approaches that capture stochastic dependency.

Our proposed semiparametric copula regression model takes a different perspective. On one hand, copula models (Nelsen, 1999) seek to explicitly model the dependency of random variables by separating the marginals and their correlations. On the other hand, it does not make use of any as-

sumptions on the distributions of the random variables, yet, the copula model is still expressive. This nice property essentially allows us to fuse distinctive lexical, syntactic, and semantic feature sets naturally into a single compact model.

From an information-theoretic point of view (Shannon, 1948), various problems in text analytics can be formulated as estimating the probability mass/density functions of tokens in text. In NLP, many of the probabilistic text models work in the discrete space (Church and Gale, 1995; Blei et al., 2003), but our model is different: since the text features are sparse, we first perform kernel density estimates to smooth out the zeroing items, and then calculate the empirical cumulative distribution function (CDF) of the random variables. By doing this, we are essentially performing *probability integral transform*— an important statistical technique that moves beyond the count-based bag-of-words feature space to marginal cumulative density functions space. Last but not least, by using a parametric copula, in our case, the Gaussian copula, we reduce the computational cost from fully nonparametric methods, and explicitly model the correlations among the covariate and the dependent variable.

In this section, we first briefly look at the theoretical foundations of copulas, including the Sklar's theorem. Then we describe the proposed semiparametric Gaussian copula text regression model. The algorithmic implementation of our approach is introduced at the end of this section.

3.1 The Theory of Copula

In the statistics literature, copula is widely known as a family of distribution function. The idea behind copula theory is that the cumulative distribution function (CDF) of a random vector can be represented in the form of uniform marginal cumulative distribution functions, and a copula that connects these marginal CDFs, which describes the correlations among the input random variables. However, in order to have a valid multivariate distribution function regardless of n-dimensional covariates, not every function can be used as a copula function. The central idea behind copula, therefore, can be summarize by the Sklar's theorem and the corollary.

Theorem 1 (Sklar's Theorem (1959)) *Let F be the joint cumulative distribution function of n random variables $X_1, X_2, ..., X_n$. Let the corresponding marginal cumulative distribution functions of the random variable be $F_1(x_1), F_2(x_2), ..., F_n(x_n)$. Then, if the marginal functions are continuous, there exists a unique copula C, such that*

$$F(x_1, ..., x_n) = C[F_1(x_1), ..., F_n(x_n)]. \quad (1)$$

Furthermore, if the distributions are continuous, the multivariate dependency structure and the marginals might be separated, and the copula can be considered independent of the marginals (Joe, 1997; Parsa and Klugman, 2011). Therefore, the copula does not have requirements on the marginal distributions, and any arbitrary marginals can be combined and their dependency structure can be modeled using the copula. The inverse of Sklar's Theorem is also true in the following:

Corollary 1 *If there exists a copula $C : (0,1)^n$ and marginal cumulative distribution functions $F_1(x_1), F_2(x_2), ..., F_n(x_n)$, then $C[F_1(x_1), ..., F_n(x_n)]$ defines a multivariate cumulative distribution function.*

3.2 Semiparametric Gaussian Copula Models

The Non-Parametric Estimation

We formulate the copula regression model as follows. Assume we have n random variables of text features $X_1, X_2, ..., X_n$. The problem is that text features are sparse, so we need to perform nonparametric kernel density estimation to smooth out the distribution of each variable. Let $f_1, f_2, ..., f_n$ be the unknown density, we are interested in deriving the shape of these functions. Assume we have m samples, the kernel density estimator can be defined as:

$$\hat{f}_h(x) = \frac{1}{m}\sum_{i=1}^{m} K_h(x - x_i) \quad (2)$$

$$= \frac{1}{mh}\sum_{i=1}^{m} K\left(\frac{x - x_i}{h}\right) \quad (3)$$

Here, $K(\cdot)$ is the kernel function, where in our case, we use the Box kernel[2] $K(z)$:

$$K(z) = \frac{1}{2}, |z| \leq 1, \quad (4)$$

$$= 0, |z| > 1. \quad (5)$$

Comparing to the Gaussian kernel and other kernels, the Box kernel is simple, and computationally inexpensive. The parameter h is the bandwidth for smoothing[3].

[2] It is also known as the original Parzen windows (Parzen, 1962).

[3] In our implementation, we use the default h of the Box kernel in the *ksdensity* function in Matlab.

Now, we can derive the empirical cumulative distribution functions $\hat{F}_{X_1}(\hat{f}_1(X_1)), \hat{F}_{X_2}(\hat{f}_2(X_2)), ..., \hat{F}_{X_n}(\hat{f}_n(X_n))$ of the smoothed covariates, as well as the dependent variable y and its CDF $\hat{F}_y(\hat{f}(y))$. The empirical cumulative distribution functions are defined as:

$$\hat{F}(\nu) = \frac{1}{m}\sum_{i=1}^{m}\mathbf{I}\{x_i \leq \nu\} \tag{6}$$

where $\mathbf{I}\{\cdot\}$ is the indicator function, and ν indicates the current value that we are evaluating. Note that the above step is also known as *probability integral transform* (Diebold et al., 1997), which allows us to convert any given continuous distribution to random variables having a uniform distribution. This is of crucial importance to modeling text data: instead of using the classic bag-of-words representation that uses raw counts, we are now working with uniform marginal CDFs, which helps coping with the overfitting issue due to noise and data sparsity.

The Parametric Copula Estimation

Now that we have obtained the marginals, and then the joint distribution can be constructed by applying the copula function that models the stochastic dependencies among marginal CDFs:

$$\hat{F}(\hat{f}_1(X_1), ..., \hat{f}_1(X_n), \hat{f}(y)) \tag{7}$$
$$= C[\hat{F}_{X_1}(\hat{f}_1(X_1)), ..., \hat{F}_{X_n}(\hat{f}_n(X_n)), \hat{F}_y(\hat{f}_y(y))] \tag{8}$$

In this work, we apply the parametric Gaussian copula to model the correlations among the text features and the label. Assume x_i is the smoothed version of random variable X_i, and y is the smoothed label, we have:

$$F(x_1, ..., x_n, y) \tag{9}$$
$$= \Phi_\Sigma\Big(\Phi^{-1}[F_{x_1}(x_1)], ..., , \Phi^{-1}[F_{x_n}(x_n)], \Phi^{-1}[F_y(y)]\Big) \tag{10}$$

where Φ_Σ is the joint cumulative distribution function of a multivariate Gaussian with zero mean and Σ variance. Φ^{-1} is the inverse CDF of a standard Gaussian. In this parametric part of the model, the parameter estimation boils down to the problem of learning the covariance matrix Σ of this Gaussian copula. In this work, we perform standard maximum likelihood estimation for the Σ matrix.

To calibrate the Σ matrix, we make use of the power of randomness: using the initial Σ from MLE, we generate random samples from the Gaussian copula, and then concatenate previously generated joint of Gaussian inverse marginal CDFs with the newly generated random copula numbers, and re-estimate using MLE to derive the final adjusted Σ. Note that the final Σ matrix has to be symmetric and positive definite.

Computational Complexity

One important question regarding the proposed semiparametric Gaussian copula model is the corresponding computational complexity. This boils down to the estimation of the $\hat{\Sigma}$ matrix (Liu et al., 2012): one only needs to calculate the correlation coefficients of $n(n-1)/2$ pairs of random variables. Christensen (2005) shows that sorting and balanced binary trees can be used to calculate the correlation coefficients with complexity of $O(n \log n)$. Therefore, the computational complexity of MLE for the proposed model is $O(n \log n)$.

Efficient Approximate Inference

In this regression task, in order to perform exact inference of the conditional probability distribution $p(F_y(y)|F_{x_1}(x_1), ..., F_{x_n}(x_n))$, one needs to solve the mean response $\hat{\mathbf{E}}(F_y(y)|F_{x_1}(x_1), ..., F_{x_1}(x_1))$ from a joint distribution of high-dimensional Gaussian copula.

Assume in the simple bivariate case of Gaussian copula regression, the covariance matrix Σ is:

$$\Sigma = \begin{bmatrix} \Sigma_{11} & \Sigma_{12} \\ & \Sigma_{22} \end{bmatrix}$$

We can easily derive the conditional density that can be used to calculate the expected value of the CDF of the label:

$$C(F_y(y)|F_{x_1}(x_1); \Sigma) = \frac{1}{|\Sigma_{22} - \Sigma_{12}^T\Sigma_{11}^{-1}\Sigma_{12}|^{\frac{1}{2}}}$$
$$\exp\left(-\frac{1}{2}\delta^T\Big([\Sigma_{22} - \Sigma_{12}^T\Sigma_{11}^{-1}\Sigma_{12}]^{-1} - \mathbf{I}\Big)\delta\right) \tag{11}$$

where $\delta = \Phi^{-1}[F_y(y)] - \Sigma_{12}^T\Sigma_{11}^{-1}\Phi^{-1}[F_{x_1}(x_1)]$.

Unfortunately, the exact inference can be intractable in the multivariate case, and approximate inference, such as Markov Chain Monte Carlo sampling (Gelfand and Smith, 1990; Pitt et al., 2006) is often used for posterior inference. In this work, we propose an efficient sampling method to derive y given the text features — we sample $F_y(y)$ s.t. it maximizes the joint high-dimensional Gaussian copula density:

$$\hat{F_y(y)} \approx \underset{F_y(y)\in(0,1)}{\arg\max} \frac{1}{\sqrt{\det\Sigma}} \exp\left(-\frac{1}{2}\Delta^T \cdot (\Sigma^{-1} - \mathbf{I}) \cdot \Delta\right) \tag{12}$$

where

$$\Delta = \begin{pmatrix} \Phi^{-1}(F_{x_1}(x_1)) \\ \vdots \\ \Phi^{-1}(F_{x_n}(x_n)) \\ \Phi^{-1}(F_y(y)) \end{pmatrix}$$

Again, the reason why we perform approximated inference is that: exact inference in the high-dimensional Gaussian copula density is nontrivial, and might not have analytical solutions, but approximate inference using maximum density sampling from the Gaussian copula significantly relaxes the complexity of inference. Finally, to derive $\hat{y}$, the last step is to compute the inverse CDF of $\hat{F_y}(y)$.

3.3 Algorithmic Implementation

The algorithmic implementation of our semiparametric Gaussian copula text regression model is shown in Algorithm 1. Basically, the algorithm can be decomposed into four parts:

- Perform nonparametric Box kernel density estimates of the covariates and the dependent variable for smoothing.
- Calculate the empirical cumulative distribution functions of the smoothed random variables.
- Estimate the parameters (covariance Σ) of the Gaussian copula.
- Infer the predicted value of the dependent variable by sampling the Gaussian copula probability density function.

4 Datasets

We use three datasets[4] of transcribed quarterly earnings calls from the U.S. stock market, focusing on the period of the Great Recession.

The *pre-2009* dataset consists of earnings calls from the period of 2006-2008, which includes calls from the beginning of economic downturn, the outbreak of the subprime mortgage crisis, and the epidemic of collapses of large financial institutions. The *2009* dataset contains earnings calls from the year of 2009, which is a period where the credit crisis spreads globally, and the Dow Jones Industrial Average hit the lowest since the beginning of the millennium. The *post-2009* dataset includes earnings calls from the period of 2010 to 2013, which concerns the recovery of global economy. The detailed statistics is shown in Table 1.

[4]http://www.cs.cmu.edu/~yww/data/earningscalls.zip

Algorithm 1 A Semi-parametric Gaussian Copula Model Based Text Regression Algorithm

Given:
(1) training data $(X^{(tr)}, \vec{y}^{(tr)})$;
(2) testing data $(X^{(te)}, \vec{y}^{(te)})$;

Learning:
for $i = 1 \rightarrow n$ dimensions **do**
  $X_i^{(tr)'} \leftarrow BoxKDE(X_i^{(tr)}, X_i^{(tr)})$;
  $U_i^{(tr)} \leftarrow EmpiricalCDF(X_i^{(tr)'})$;
  $X_i^{(te)'} \leftarrow BoxKDE(X_i^{(tr)}, X_i^{(te)})$;
  $U_i^{(te)} \leftarrow EmpiricalCDF(X_i^{(te)'})$;
end for
$y^{(tr)'} \leftarrow BoxKDE(y^{(tr)}, y^{(tr)})$;
$v^{(tr)} \leftarrow EmpiricalCDF(y^{(tr)'})$;
$Z^{(tr)} \leftarrow GaussianInverseCDF([U^{(tr)}\ v^{(tr)}])$;
$\hat{\Sigma} \leftarrow CorrelationCoefficients(Z^{(tr)})$;
$r \leftarrow MultiVariateGaussianRandNum(0, \hat{\Sigma}, n)$;
$Z^{(tr)'} = GaussianCDF(r)$;
$\hat{\Sigma} \leftarrow CorrelationCoefficients([Z^{(tr)}\ Z^{(tr)'}])$;

Inference:
for $j = 1 \rightarrow m$ instances **do**
  $\max_j \leftarrow 0$;
  $\hat{Y}' = 0$;
  for $k = 0.01 \rightarrow 1$ **do**
    $Z^{(te)} \leftarrow GaussianInverseCDF([U^{(te)}\ k])$;
    $p_j = \frac{MultiVariateGaussianPDF(Z^{(te)}, \hat{\Sigma})}{\prod_n GaussianPDF(Z^{(te)})}$;
    if $p_j \geq \max_j$ **then**
      $\max_j = p_j$;
      $\hat{Y}' = k$;
    end if
  end for
end for
$\hat{y} \leftarrow InverseCDF(\vec{y}^{(tr)}, \hat{Y}')$;

Dataset	#Calls	#Companies	#Types	#Tokens
Pre-2009	3694	2746	371.5K	28.7M
2009	3474	2178	346.2K	26.4M
Post-2009	3726	2107	377.4K	28.6M

Table 1: Statistics of three datasets. *Types: unique words. Tokens: word tokens.*

Note that unlike the standard news corpora in NLP or the SEC-mandated financial report, Transcripts of earnings call is a very special genre of text. For example, the length of WSJ documents is typically one to three hundreds (Harman, 1995), but the averaged document length of our three earnings calls datasets is 7677. Depending on the amount of interactions in the question answering session, the complexities of the calls vary. This mixed form of formal statement and informal speech brought difficulties to machine learning algorithms.

5 Measuring Financial Risks

Volatility is an important measure of the financial risk, and in this work, we focus on predicting the future volatility following the earnings teleconfer-

ence call. For each earning call, we have a week of stock prices of the company after the day on which the earnings call is made. The *Return* of Day t is:

$$r_t = \frac{x_t}{x_{t-1}} - 1 \tag{13}$$

where x_t represents the share price of Day t, and the *Measured Stock Volatility* from Day t to $t + \tau$:

$$y_{(t,t+\tau)} = \sqrt{\frac{\sum_{i=0}^{\tau}(r_{t+i} - \bar{r})^2}{\tau}} \tag{14}$$

Using the stock prices, we can use the equations above to calculate the measured stock volatility after the earnings call, which is the standard measure of risks in finance, and the dependent variable y of our predictive task.

6 Experiments

6.1 Experimental Setup

In all experiments throughout this section, we use 80-20 train/test splits on all three datasets.

Feature sets:

We have extracted lexical, named entity, syntactic, and frame-semantics features, most of which have been shown to perform well in previous work (Xie et al., 2013). We use the unigrams and bigrams to represent lexical features, and the Stanford part-of-speech tagger (Toutanova et al., 2003) to extract the lexicalized named entity and part-of-speech features. A probabilistic frame-semantics parser, SEMAFOR (Das et al., 2010), is used to provide the FrameNet-style frame-level semantic annotations. For each of the five sets, we collect the top-100 most frequent features, and end up with a total of 500 features.

Baselines:

The baselines are standard squared-loss linear regression, linear kernel SVM, and non-linear (Gaussian) kernel SVM. They are all standard algorithms in regression problems, and have been shown to have outstanding performances in many recent text regression (Kogan et al., 2009; Chahuneau et al., 2012; Xie et al., 2013; Wang et al., 2013; Tsai and Wang, 2013). We use the Statistical Toolbox's linear regression implementation in Matlab, and LibSVM (Chang and Lin, 2011) for training and testing the SVM models. The hyperparameter C in linear SVM, and the γ and C hyperparameters in Gaussian SVM are tuned on the training set using 10-fold cross-validation. Note that since the kernel density estimation in the proposed copula model is nonparametric, and we only need to learn the Σ in the Gaussian copula, there is no hyperparameters that need to be tuned.

Evaluation Metrics:

Spearman's correlation (Hogg and Craig, 1994) and Kendall's tau (Kendall, 1938) have been widely used in many regression problems in NLP (Albrecht and Hwa, 2007; Yogatama et al., 2011; Wang et al., 2013; Tsai and Wang, 2013), and here we use them to measure the quality of predicted values $\hat{\mathbf{y}}$ by comparing to the vector of ground truth $\mathbf{y}$. In contrast to Pearson's correlation, Spearman's correlation has no assumptions on the relationship of the two measured variables. Kendall's tau is a nonparametric statistical metric that have shown to be inexpensive, robust, and representation independent (Lapata, 2006). We also use paired two-tailed t-test to measure the statistical significance between the best and the second best approaches.

6.2 Comparing to Various Baselines

In the first experiment, we compare the proposed semiparametric Gaussian copula regression model to three baselines on three datasets with all features. The detailed results are shown in Table 2. On the *pre-2009* dataset, we see that the linear regression and linear SVM perform reasonably well, but the Gaussian kernel SVM performs less well, probably due to overfitting. The copula model outperformed all three baselines by a wide margin on this dataset with both metrics. Similar performances are also obtained in the *2009* dataset, where the result of linear SVM baseline falls behind. On the *post-2009* dataset, none of results from the linear and non-linear SVM models can match up with the linear regression model, but our proposed copula model still improves over all baselines by a large margin. Comparing to second-best approaches, all improvements obtained by the copula model are statistically significant.

6.3 Varying the Amount of Training Data

To understand the learning curve of our proposed copula regression model, we use the 25%, 50%, 75% subsets from the training data, and evaluate all four models. Figure 1 shows the evaluation results. From the experiments on the *pre-2009* dataset, we see that when the amount of training data is small (25%), both SVM models have obtained very impressive results. This is not surprising at all, because as max-margin models, soft-margin SVM only needs a handful of examples that come with nonvanishing coefficients (support vectors) to find a reasonable margin. When in-

Method	Pre-2009		2009		Post-2009	
	Spearman	Kendall	Spearman	Kendall	Spearman	Kendall
linear regression:	0.377	0.259	0.367	0.252	0.314	0.216
linear SVM:	0.364	0.249	0.242	0.167	0.132	0.091
Gaussian SVM:	0.305	0.207	0.280	0.192	0.152	0.104
Gaussian copula:	**0.425***	**0.315***	**0.422***	**0.310***	**0.375***	**0.282***

Table 2: Comparing the learning algorithms on three datasets with all features. The best result is highlighted in **bold**. * indicates $p < .001$ comparing to the second best result.

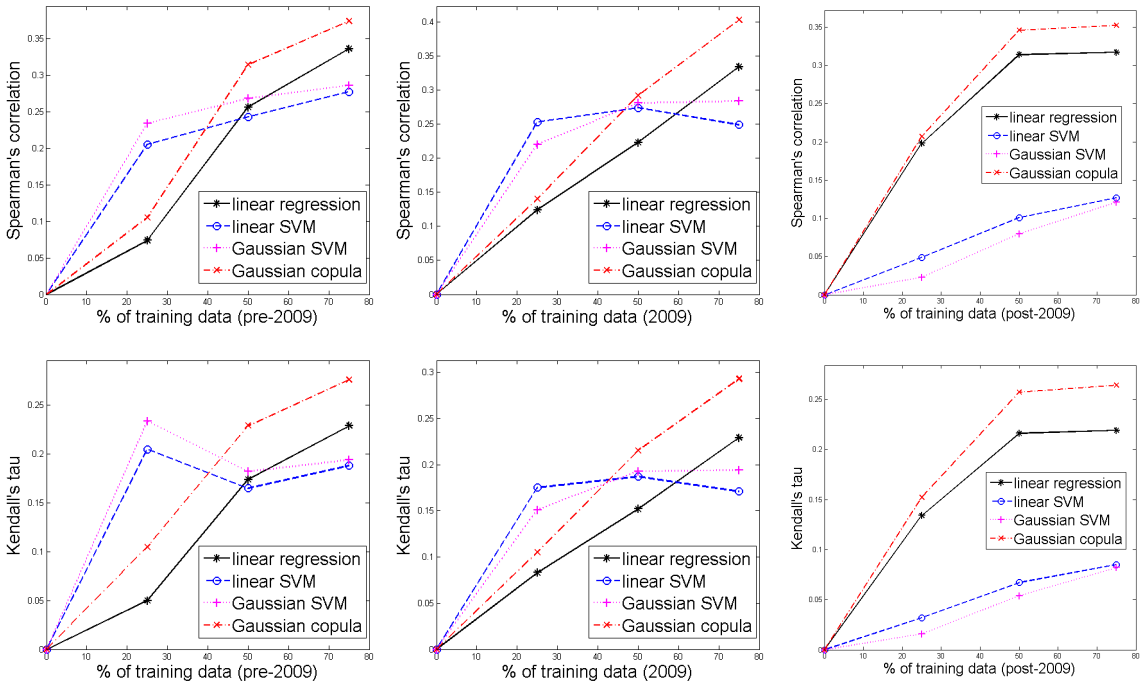

Figure 1: Varying the amount of training data. Left column: pre-2009 dataset. Middle column: 2009 dataset. Right column: post-2009 dataset. Top row: Spearman's correlation. Bottom row: Kendall's tau.

creasing the amount of training data to 50%, we do see the proposed copula model catches up quickly, and lead all baseline methods undoubtably at 75% training data. On the *2009* dataset, we observe very similar patterns. Interestingly, the proposed copula regression model has dominated all methods for both metrics throughout all proportions of the "post-2009" earnings calls dataset, where instead of financial crisis, the economic recovery is the main theme. In contrast to the previous two datasets, both linear and non-linear SVMs fail to reach reasonable performances on this dataset.

6.4 Varying the Amount of Features

Finally, we investigate the robustness of the proposed semiparametric Gaussian copula regression model by varying the amount of features in the covariate space. To do this, we sample equal amount of features from each feature set, and concatenate them into a feature vector. When increasing the amount of total features from 100 to 400, the results are shown in Figure 2. On the *pre-2009* dataset, we see that the gaps between the best-perform copula model and the second-best linear regression model are consistent throughout all feature sizes. On the *2009* dataset, we see that the performance of Gaussian copula is aligned with the linear regression model in terms of Spearman's correlation, where the former seems to perform better in terms of Kendall's tau. Both linear and non-linear SVM models do not have any advantages over the proposed approach. On the *post-2009* dataset that concerns economic growth and recovery, the boundaries among all methods are very clear. The Spearman's correlation for both SVM baselines is less than 0.15 throughout all settings, but copula model is able to achieve 0.4 when using 400 features. The improvements of copula

model over squared loss linear regression model are increasing, when working with larger feature spaces.

6.5 Qualitative Analysis

Like linear classifiers, by "opening the hood" to the Gaussian copula regression model, one can examine features that exhibit high correlations with the dependent variable. Table 3 shows the top features that are positively correlated with the future stock volatility in the three datasets. On the top features from the "pre-2009" dataset, which primarily (82%) includes calls from 2008, we can clearly observe that the word "2008" has strong correlation with the financial risks. Interestingly, the phrase "third quarter" and its variations, not only play an important role in the model, but also highly correlated to the timeline of the financial crisis: the Q3 of 2008 is a critical period in the recession, where Lehman Brothers falls on the Sept. 15 of 2008, filing $613 billion of debt — the biggest bankruptcy in U.S. history (Mamudi, 2008). This huge panic soon broke out in various financial institutions in the Wall Street. On the top features from "2009" dataset, again, we see the word "2008" is still prominent in predicting financial risks, indicating the hardship and extended impacts from the center of the economic crisis. After examining the transcripts, we found sentences like: "*...our specialty lighting business that we discontinued in the fourth quarter of 2008...*", "*...the exception of fourth quarter revenue which was $100,000 below our guidance target...*", and "*...to address changing economic conditions and their impact on our operations, in the fourth quarter we took the painful but prudent step of decreasing our headcount by about 5%...*", showing the crucial role that Q4 of 2008 plays in 2009 earnings calls. Interestingly, after the 2008-2009 crisis, in the recovery period, we have observed new words like "revenue", indicating the "back-to-normal" trend of financial environment, and new features that predict financial volatility.

7 Discussions

In the experimental section, we notice that the proposed semiparametric Gaussian copula model has obtained promising results in various setups on three datasets in this text regression task. The

main questions we ask are: how is the proposed model different from standard text regression/classification models? What are the advantages of copula-based models, and what makes it perform so well?

One advantage we see from the copula model is that it does not require any assumptions on the marginal distributions. For example, in latent Dirichlet allocation (Blei et al., 2003), the topic proportion of a document is always drawn from a $Dirichlet(\alpha)$ distribution. This is rather restricted, because the possible shapes from a $K-1$ simplex of Dirichlet is always limited in some sense. In our copula model, instead of using some priors, we just calculate the empirical cumulative distribution function of the random variables, and model the correlation among them. This is extremely practical, because in many natural language processing tasks, we often have to deal with features that are extracted from many different domains and signals. By applying the *Probability Integral Transform* to raw features in the copula model, we essentially avoid comparing apples and oranges in the feature space, which is a common problem in bag-of-features models in NLP.

The second hypothesis is about the semiparametirc parameterization, which contains the nonparametric kernel density estimation and the parametric Gaussian copula regression components. The benefit of a semiparametric model is that here we are not interested in performing completely nonparametric estimations, where the infinite dimensional parameters might bring intractability. In contrast, by considering the semiparametric case, we not only obtain some expressiveness from the nonparametric models, but also reduce the complexity of the task: we are only interested in the finite-dimensional components Σ in the Gaussian copula with $O(n \log n)$ complexity, which is not as computationally difficult as the completely nonparametric cases. Also, by modeling the marginals and their correlations seperately, our approach is cleaner, easy-to-understand, and allows us to have more flexibility to model the uncertainty of data. Our pilot experiment also aligns with our hypothesis: when not performing the kernel density estimation part for smoothing out the marginal distributions, the performances dropped significantly when sparser features are included.

The third advantage we observe is the power of modeling the covariance of the random variables. Traditionally, in statistics, independent and identically distributed (i.i.d) assumptions among the instances and the random variables are often used in various models, such that the correlations among the instances or the variables are often ignored. However, this might not be practical at all: in image processing, the "cloud" pixel of a pixel showing the blue sky of a picture are more likelihood to co-occur in the same picture; in natural language processing, the word "mythical" is more likely to co-occur with the word "unicorn", rather than the word "popcorn". Therefore, by modeling the correlations among marginal CDFs, the copula model has gained the insights on the dependency structures of the random variables, and thus, the performance of the regression task is boosted.

In the future, we plan to apply the proposed approach to large datasets where millions of features and millions of instances are involved. Currently we have not experienced the difficulty when estimating the Gaussian copula model, but parallel methods might be needed to speedup learning when significantly more marginal CDFs are involved. The second issue is about overfitting. We see that when features are rather noisy, we might need to investigate regularized copula models to avoid this. Finally, we plan to extend the proposed approach to text classification and structured prediction problems in NLP.

8 Conclusion

In this work, we have demonstrated that the more complex quarterly earnings calls can also be used to predict the measured volatility of the stocks in the limited future. We propose a novel semiparametric Gausian copula regression approach that models the dependency structure of the language in the earnings calls. Unlike traditional bag-of-features models that work discrete features from various signals, we perform kernel density estimation to smooth out the distribution, and use probability integral transform to work with CDFs that are uniform. The copula model deals with marginal CDFs and the correlation among them separately, in a cleaner manner that is also flexible to parameterize. Focusing on the three financial crisis related datasets, the proposed model significantly outperform the standard linear regression method in statistics and strong discriminative support vector regression baselines. By varying the size of the training data and the dimensionality of the covariates, we have demonstrated that our proposed model is relatively robust across different parameter settings.

Abstract

Topic models, an unsupervised technique for inferring translation domains improve machine translation quality. However, previous work uses only the source language and completely ignores the target language, which can disambiguate domains. We propose new polylingual tree-based topic models to extract domain knowledge that considers both source and target languages and derive three different inference schemes. We evaluate our model on a Chinese to English translation task and obtain up to 1.2 BLEU improvement over strong baselines.

1 Introduction

Probabilistic topic models (Blei and Lafferty, 2009), exemplified by *latent Dirichlet allocation* (Blei et al., 2003, LDA), are one of the most popular statistical frameworks for navigating large unannotated document collections. Topic models discover—without any supervision—the primary themes presented in a dataset: the namesake topics.

Topic models have two primary applications: to aid human exploration of corpora (Chang et al., 2009) or serve as a low-dimensional representation for downstream applications. We focus on the second application, which has been fruitful for computer vision (Li Fei-Fei and Perona, 2005), computational biology (Perina et al., 2010), and information retrieval (Kataria et al., 2011).

In particular, we use topic models to aid *statistical machine translation* (Koehn, 2009, SMT). Modern machine translation systems use millions of examples of translations to learn translation rules. These systems work best when the training corpus has consistent genre, register, and topic. Systems that are robust to systematic variation in the training set are said to exhibit *domain adaptation*.

† indicates equal contributions.

As we review in Section 2, topic models are a promising solution for automatically discovering domains in machine translation corpora. However, past work either relies solely on monolingual source-side models (Eidelman et al., 2012; Hasler et al., 2012; Su et al., 2012), or limited modeling of the target side (Xiao et al., 2012). In contrast, machine translation uses inherently multilingual data: an SMT system must translate a phrase or sentence from a *source* language to a different *target* language, so existing applications of topic models (Eidelman et al., 2012) are wilfully ignoring available information on the target side that could aid domain discovery.

This is not for a lack of multilingual topic models. Topic models bridge the chasm between languages using document connections (Mimno et al., 2009), dictionaries (Boyd-Graber and Resnik, 2010), and word alignments (Zhao and Xing, 2006). In Section 2, we review these models for discovering topics in multilingual datasets and discuss how they can improve SMT.

However, no models combine multiple bridges between languages. In Section 3, we create a model—the polylingual tree-based topic models (ptLDA)—that uses information from both external dictionaries and document alignments simultaneously. In Section 4, we derive both MCMC and variational inference for this new topic model.

In Section 5, we evaluate our model on the task of SMT using aligned datasets. We show that ptLDA offers better domain adaptation than other topic models for machine translation. Finally, in Section 6, we show how these topic models improve SMT with detailed examples.

2 Topic Models for Machine Translation

Before considering past approaches using topic models to improve SMT, we briefly review lexical weighting and domain adaptation for SMT.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1166–1176,
Baltimore, Maryland, USA, June 23-25 2014.

2.1 Statistical Machine Translation

Statistical machine translation casts machine translation as a probabilistic process (Koehn, 2009). For a parallel corpus of aligned source and target sentences $(\mathcal{F}, \mathcal{E})$, a phrase $\bar{f} \in \mathcal{F}$ is translated to a phrase $\bar{e} \in \mathcal{E}$ according to a distribution $p_w(\bar{e}|\bar{f})$. One popular method to estimate the probability $p_w(\bar{e}|\bar{f})$ is via lexical weighting features.

Lexical Weighting In phrase-based SMT, lexical weighting features estimate the phrase pair quality by combining lexical translation probabilities of words in a phrase (Koehn et al., 2003). Lexical conditional probabilities $p(e|f)$ are maximum likelihood estimates from relative lexical frequencies $c(f,e)/\sum_e c(f,e)$, where $c(f,e)$ is the count of observing lexical pair (f,e) in the training dataset. The phrase pair probabilities $p_w(\bar{e}|\bar{f})$ are the normalized product of lexical probabilities of the aligned word pairs within that phrase pair (Koehn et al., 2003). In Section 2.2, we create topic-specific lexical weighting features.

Cross-Domain SMT A SMT system is usually trained on documents with the same genre (e.g., sports, business) from a similar style (e.g., newswire, blog-posts). These are called *domains*. Translations within one domain are better than translations across domains since they vary dramatically in their word choices and style. A correct translation in one domain may be inappropriate in another domain. For example, "潜水" in a newspaper usually means "underwater diving". On social media, it means a non-contributing "lurker".

Domain Adaptation for SMT Training a SMT system using diverse data requires *domain adaptation*. Early efforts focus on building separate models (Foster and Kuhn, 2007) and adding features (Matsoukas et al., 2009) to model domain information. Chiang et al. (2011) combine these approaches by directly optimizing genre and collection features by computing separate translation tables for each domain.

However, these approaches treat domains as hand-labeled, constant, and known *a priori*. This setup is at best expensive and at worst infeasible for large data. Topic models provide a solution where domains can be automatically induced from raw data: treat each topic as a domain.[1]

[1]Henceforth we will use the term "topic" and "domain" interchangeably: "topic" to refer to the concept in topic models and "domain" to refer to SMT corpora.

2.2 Inducing Domains with Topic Models

Topic models take the number of topics K and a collection of documents as input, where each document is a bag of words. They output two distributions: a distribution over topics for each document d; and a distribution over words for each topic. If each topic defines a SMT domain, the document's topic distribution is a soft domain assignment for that document.

Given the soft domain assignments, Eidelman et al. (2012) extract lexical weighting features conditioned on the topics, optimizing feature weights using the *Margin Infused Relaxed Algorithm* (Crammer et al., 2006, MIRA). The topics come from source documents *only* and create topic-specific lexical weights from the per-document topic distribution $p(k \mid d)$. The lexical probability conditioned on the topic is expected count $e_k(e,f)$ of a word translation pair under topic k,

$$\hat{c}_k(e,f) = \textstyle\sum_d p(k|d) c_d(e,f), \qquad (1)$$

where $c_d(\bullet)$ is the number of occurrences of the word pair in document d. The lexical probability conditioned on topic k is the unsmoothed probability estimate of those expected counts

$$p_w(e|f;k) = \tfrac{\hat{c}_k(e,f)}{\sum_e \hat{c}_k(e,f)}, \qquad (2)$$

from which we can compute the phrase pair probabilities $p_w(\bar{e}|\bar{f};k)$ by multiplying the lexical probabilities and normalizing as in Koehn et al. (2003).

For a test document d, the document topic distribution $p(k \mid d)$ is inferred based on the topics learned from training data. The feature value of a phrase pair $(\bar{e}, \bar{f})$ is

$$f_k(\bar{e}|\bar{f}) = -\log\left\{p_w(\bar{e}|\bar{f};k) \cdot p(k|d)\right\}, \qquad (3)$$

a combination of the topic dependent lexical weight and the topic distribution of the document, from which we extract the phrase. Eidelman et al. (2012) compute the resulting model score by combining these features in a linear model with other standard SMT features and optimizing the weights.

Conceptually, this approach is just reweighting examples. The probability of a topic given a document is never zero. Every translation observed in the training set will contribute to $p_k(e|f)$; many of the expected counts, however, will be less than one. This obviates the explicit smoothing used in other domain adaptation systems (Chiang et al., 2011).

We adopt this framework in its entirety. Our contribution are topics that capture *multilingual* information and thus better capture the domains in the parallel corpus.

2.3 Beyond Vanilla Topic Models

Eidelman et al. (2012) ignore a wealth of information that could improve topic models and help machine translation. Namely, they only use monolingual data from the source language, ignoring all target-language data and available lexical semantic resources between source and target languages.

Different complement each other to reduce ambiguity. For example, "木马" in a Chinese document can be either "hobbyhorse" in a children's topic, or "Trojan virus" in a technology topic. A short Chinese context obscures the true topic. However, these terms are unambiguous in English, revealing the true topic.

While vanilla topic models (LDA) can only be applied to monolingual data, there are a number of topic models for parallel corpora: Zhao and Xing (2006) assume aligned word pairs share same topics; Mimno et al. (2009) connect different languages through comparable documents. These models take advantage of word or document *alignment information* and infer more robust topics from the aligned dataset.

On the other hand, *lexical information* can induce topics from multilingual corpora. For instance, orthographic similarity connects words with the same meaning in related languages (Boyd-Graber and Blei, 2009), and dictionaries are a more general source of information on which words share meaning (Boyd-Graber and Resnik, 2010).

These two approaches are not mutually exclusive, however; they reveal different connections across languages. In the next section, we combine these two approaches into a polylingual tree-based topic model.

3 Polylingual Tree-based Topic Models

In this section, we bring existing tree-based topic models (Boyd-Graber et al., 2007, tLDA) and polylingual topic models (Mimno et al., 2009, pLDA) together and create the polylingual tree-based topic model (ptLDA) that incorporates both word-level correlations and document-level alignment information.

Word-level Correlations Tree-based topic models incorporate the correlations between words by encouraging words that appear together in a **concept** to have similar probabilities given a topic. These concepts can come from WordNet (Boyd-Graber and Resnik, 2010), domain experts (Andrzejewski et al., 2009), or user constrains (Hu et al., 2013). When we gather concepts from bilingual resources, these concepts can connect different languages. For example, if a bilingual dictionary defines "电脑" as "computer", we combine these words in a concept.

We organize the vocabulary in a tree structure based on these concepts (Figure 1): words in the same concept share a common parent node, and then that concept becomes one of many children of the root node. Words that are not in any concept—**uncorrelated words**—are directly connected to the root node. We call this structure the **tree prior**.

When this tree serves as a prior for topic models, words in the same concept are correlated in topics. For example, if "电脑" has high probability in a topic, so will "computer", since they share the same parent node. With the tree priors, each topic is no longer a distribution over word types, instead, it is a distribution over paths, and each path is associated with a word type. The same word could appear in multiple paths, and each path represents a unique sense of this word.

Document-level Alignments Lexical resources connect languages and help guide the topics. However, these resources are sometimes brittle and may not cover the whole vocabulary. Aligned document pairs provide a more corpus-specific, flexible association across languages.

Polylingual topic models (Mimno et al., 2009) assume that the aligned documents in different languages share the same topic distribution and each language has a unique topic distribution over its word types. This level of connection between languages is flexible: instead of requiring the exact matching on words and sentences, only a coarse document alignment is necessary, as long as the documents discuss the same topics.

Combine Words and Documents We propose polylingual tree-based topic models (ptLDA), which connect information across different languages by incorporating both word correlation (as in tLDA) and document alignment information (as in pLDA). We initially assume a given tree structure, deferring the tree's provenance to the end of this section.

Generative Process As in LDA, each word token is associated with a topic. However, tree-based topic models introduce an additional step of selecting a concept in a topic responsible for generating each word token. This is represented by a path $y_{d,n}$ through the topic's tree.

The probability of a path in a topic depends on the transition probabilities in a topic. Each concept i in topic k has a distribution over its children nodes is governed by a Dirichlet prior: $\pi_{k,i} \sim \text{Dir}(\beta_i)$. Each path ends in a word (i.e., a leaf node) and the probability of a path is the product of all of the transitions between topics it traverses. Topics have correlations over words because the Dirichlet parameters can encode positive or negative correlations (Andrzejewski et al., 2009).

With these correlated in topics in hand, the generation of documents are very similar to LDA. For every document d, we first sample a distribution over topics θ_d from a Dirichlet prior $\text{Dir}(\alpha)$. For every token in the documents, we first sample a topic z_{dn} from the multinomial distribution θ_d, and then sample a path y_{dn} along the tree according to the transition distributions specified by topic z_{dn}. Because every path y_{dn} leads to a word w_{dn} in language l_{dn}, we append the sampled word w_{dn} to document $d_{l_{dn}}$. Aligned documents have words in both languages; monolingual documents only have words in a single language.

The full generative process is:

for topic $k \in 1, \cdots, K$ **do**
  for each internal node n_i **do**
    draw a distribution $\pi_{ki} \sim \text{Dir}(\beta_i)$
for document set $d \in 1, \cdots, D$ **do**
  draw a distribution $\theta_d \sim \text{Dir}(\alpha)$
  for each word in documents d **do**
    choose a topic $z_{dn} \sim \text{Mult}(\theta_d)$
    sample a path y_{dn} with probability $\prod_{(i,j) \in y_{dn}} \pi_{z_{dn},i,j}$
    y_{dn} leads to word w_{dn} in language l_{dn}
    append token w_{dn} to document $d_{l_{dn}}$

If we use a flat symmetric Dirichlet prior instead of the tree prior, we recover pLDA; and if all documents are monolingual (i.e., with distinct distributions over topics θ), we recover tLDA. ptLDA connects different languages on both the word level (using the word correlations) and the document level (using the document alignments). We compare these models' machine translation performance in Section 5.

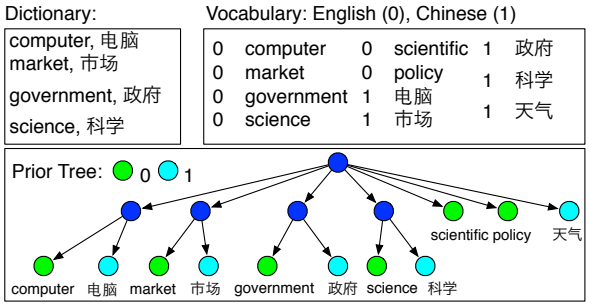

Figure 1: An example of constructing a prior tree from a bilingual dictionary: word pairs with the same meaning but in different languages are concepts; we create a common parent node to group words in a concept, and then connect to the root; uncorrelated words are connected to the root directly. Each topic uses this tree structure as a prior.

Build Prior Tree Structures One remaining question is the source of the word-level connections across languages for the tree prior. We consider two resources to build trees that correlate words across languages. The first are a multilingual dictionaries (*dict*), which match words with the same meaning in different languages together. These relations between words are used as the concepts in the prior tree (Figure 1).

In addition, we extract the word alignments from aligned sentences in a parallel corpus. The word pairs define concepts for the prior tree (*align*). We use both resources for our models (denoted as ptLDA-*dict* and ptLDA-*align*) in our experiments (Section 5) and show that they yield comparable performance in SMT.

4 Inference

Inference of probabilistic models discovers the posterior distribution over latent variables. For a collection of D documents, each of which contains N_d number of words, the latent variables of ptLDA are: transition distributions $\boldsymbol{\pi}_{ki}$ for every topic k and internal node i in the prior tree structure; multinomial distributions over topics $\boldsymbol{\theta}_d$ for every document d; topic assignments z_{dn} and path y_{dn} for the n^{th} word w_{dn} in document d. The joint distribution of polylingual tree-based topic models is

$$p(\boldsymbol{w}, \boldsymbol{z}, \boldsymbol{y}, \boldsymbol{\theta}, \boldsymbol{\pi}; \alpha, \beta) = \prod_k \prod_i p(\boldsymbol{\pi}_{ki}|\beta_i) \cdot \prod_d p(\boldsymbol{\theta}_d|\alpha) \cdot \prod_d \prod_n p(z_{dn}|\boldsymbol{\theta}_d) \cdot \prod_d \prod_n \big(p(y_{dn}|z_{dn}, \boldsymbol{\pi}) p(w_{dn}|y_{dn})\big). \quad (4)$$

Exact inference is intractable, so we turn to ap-

proximate posterior inference to discover the latent variables that best explain our data. Two widely used approximation approaches are *Markov chain Monte Carlo* (Neal, 2000, MCMC) and *variational Bayesian inference* (Blei et al., 2003, VB). Both frameworks produce good approximations of the posterior mode (Asuncion et al., 2009). In addition, Mimno et al. (2012) propose hybrid inference that takes advantage of parallelizable variational inference for global variables (Wolfe et al., 2008) while enjoying the sparse, efficient updates for local variables (Neal, 1993). In the rest of this section, we discuss all three methods in turn.

We explore multiple inference schemes because while all of these methods optimize likelihood because they might give different results on the translation task.

4.1 Markov Chain Monte Carlo Inference

We use a collapsed Gibbs sampler for tree-based topic models to sample the path y_{dn} and topic assignment z_{dn} for word w_{dn},

$$\begin{aligned} p(z_{dn} = k, y_{dn} = s | \neg \boldsymbol{z}_{dn}, \neg \boldsymbol{y}_{dn}, \boldsymbol{w}; \alpha, \boldsymbol{\beta}) \\ \propto \mathbb{I}\left[\Omega(s) = w_{dn}\right] \cdot \frac{N_{k|d} + \alpha}{\sum_{k'} (N_{k'|d} + \alpha)} \\ \cdot \prod_{i \to j \in s} \frac{N_{i \to j|k} + \beta_{i \to j}}{\sum_{j'} (N_{i \to j'|k} + \beta_{i \to j'})}, \end{aligned}$$

where $\Omega(s)$ represents the word that path s leads to, $N_{k|d}$ is the number of tokens assigned to topic k in document d and $N_{i \to j|k}$ is the number of times edge $i \to j$ in the tree assigned to topic k, excluding the topic assignment z_{dn} and its path y_{dn} of current token w_{dn}. In practice, we sample the latent variables using efficient sparse updates (Yao et al., 2009; Hu and Boyd-Graber, 2012).

4.2 Variational Bayesian Inference

Variational Bayesian inference approximates the posterior distribution with a simplified *variational distribution* q over the latent variables: document topic proportions θ, transition probabilities π, topic assignments z, and path assignments y.

Variational distributions typically assume a mean-field distribution over these latent variables, removing all dependencies between the latent variables. We follow this assumption for the transition probabilities $q(\boldsymbol{\pi} \mid \boldsymbol{\lambda})$ and the document topic proportions $q(\boldsymbol{\theta} \mid \boldsymbol{\gamma})$; both are variational Dirichlet distributions. However, due to the tight coupling between the path and topic variables, we must model this joint distribution as one multinomial, $q(\boldsymbol{z}, \boldsymbol{y} \mid \boldsymbol{\phi})$. If word token w_{dn} has K topics and S paths, it has a $K * S$ length variational multinomial ϕ_{dnks}, which represents the probability that the word takes path s in topic k. The complete variational distribution is

$$\begin{aligned} q(\boldsymbol{\theta}, \boldsymbol{\pi}, \boldsymbol{z}, \boldsymbol{y} | \boldsymbol{\gamma}, \boldsymbol{\lambda}, \boldsymbol{\phi}) = \textstyle\prod_d q(\boldsymbol{\theta}_d | \boldsymbol{\gamma}_d) \cdot \\ \textstyle\prod_k \prod_i q(\boldsymbol{\pi}_{ki} | \lambda_{ki}) \cdot \prod_d \prod_n q(z_{dn}, y_{dn} | \boldsymbol{\phi}_{dn}). \end{aligned} \tag{5}$$

Our goal is to find the variational distribution q that is closest to the true posterior, as measured by the *Kullback-Leibler* (KL) divergence between the true posterior p and variational distribution q. This induces an "evidence lower bound" (ELBO, $\mathcal{L}$) as a function of a variational distribution q: $\mathcal{L} =$

$$\begin{aligned} &\mathbb{E}_q[\log p(\boldsymbol{w}, \boldsymbol{z}, \boldsymbol{y}, \boldsymbol{\theta}, \boldsymbol{\pi})] - \mathbb{E}_q[\log q(\boldsymbol{\theta}, \boldsymbol{\pi}, \boldsymbol{z}, \boldsymbol{y})] \\ &= \textstyle\sum_k \sum_i \mathbb{E}_q[\log p(\boldsymbol{\pi}_{ki} | \beta_i)] \\ &+ \textstyle\sum_d \mathbb{E}_q[\log p(\boldsymbol{\theta}_d | \alpha)] \\ &+ \textstyle\sum_d \sum_n \mathbb{E}_q[\log p(z_{dn}, y_{dn} | \boldsymbol{\theta}_d, \boldsymbol{\pi}) p(w_{dn} | y_{dn})] \\ &+ \mathbb{H}[q(\boldsymbol{\theta})] + \mathbb{H}[q(\boldsymbol{\pi})] + \mathbb{H}[q(\boldsymbol{z}, \boldsymbol{y})], \end{aligned} \tag{6}$$

where $\mathbb{H}[\bullet]$ represents the entropy of a distribution. Optimizing $\mathcal{L}$ using coordinate descent provides the following updates:

$$\begin{aligned} \phi_{dnkt} &\propto \exp\{\Psi(\gamma_{dk}) - \Psi(\textstyle\sum_k \gamma_{dk}) \\ &\quad + \textstyle\sum_{i \to j \in s} \left(\Psi(\lambda_{k,i \to j}) - \Psi(\sum_{j'} \lambda_{k,i \to j'})\right)\}; \end{aligned} \tag{7}$$

$$\gamma_{dk} = \alpha_k + \textstyle\sum_n \sum_{s \in \Omega^{-1}(w_{dn})} \phi_{dnkt}; \tag{8}$$

$$\begin{aligned} \lambda_{k,i \to j} &= \beta_{i \to j} \\ &\quad + \textstyle\sum_d \sum_n \sum_{s \in \Omega'(w_{dn})} \phi_{dnkt} \mathbb{I}\left[i \to j \in s\right]; \end{aligned} \tag{9}$$

where $\Omega'(w_{dn})$ is the set of all paths that lead to word w_{dn} in the tree, and t represents one particular path in this set. $\mathbb{I}\left[i \to j \in s\right]$ is the indicator of whether path s contains an edge from node i to j.

4.3 Hybrid Stochastic Inference

Given the complementary strengths of MCMC and VB, and following hybrid inference proposed by Mimno et al. (2012), we also derive hybrid inference for ptLDA.

The transition distributions $\boldsymbol{\pi}$ are treated identically as in variational inference. We posit a variational Dirichlet distribution $\boldsymbol{\lambda}$ and choose the one that minimizes the KL divergence between the true posterior and the variational distribution.

For topic $\boldsymbol{z}$ and path $\boldsymbol{y}$, instead of variational updates, we use a Gibbs sampler within a document. We sample z_{dn} and y_{dn} conditioned on the topic

and path assignments of all other document tokens, based on the variational expectation of $\boldsymbol{\pi}$,

$$q(z_{dn} = k, y_{dn} = s | \neg \boldsymbol{z}_{dn}, \neg \boldsymbol{y}_{dn}; \boldsymbol{w}) \propto \quad (10)$$
$$(\alpha + \textstyle\sum_{m \neq n} \mathbb{I}\left[z_{dm} = k\right])$$
$$\cdot \exp\{\mathbb{E}_q[\log p(y_{dn}|z_{dn}, \boldsymbol{\pi}) p(w_{dn}|y_{dn})]\}.$$

This equation embodies how this is a hybrid algorithm: the first term resembles the Gibbs sampling term encoding how much a document prefers a topic, while the second term encodes the expectation under the variational distribution of how much a path is preferred by this topic,

$$\mathbb{E}_q[\log p(y_{dn}|z_{dn}, \boldsymbol{\pi}) p(w_{dn}|y_{dn})] = \mathbb{I}_{[\Omega(y_{dn}) = w_{dn}]}$$
$$\cdot \textstyle\sum_{i \to j \in y_{dn}} \mathbb{E}_q[\log \lambda_{z_{dn}, i \to j}].$$

For every document, we sweep over all its tokens and resample their topic z_{dn} and path y_{dn} conditioned on all the other tokens' topic and path assignments $\neg \boldsymbol{z}_{dn}$ and $\neg \boldsymbol{y}_{dn}$. To avoid bias, we discard the first B burn-in sweeps and take the following M samples. We then use the empirical average of these samples update the global variational parameter $q(\boldsymbol{\pi}|\boldsymbol{\lambda})$ based on how many times we sampled these paths

$$\lambda_{k, i \to j} = \tfrac{1}{M} \textstyle\sum_d \sum_n \sum_{s \in \Omega^{-1}(w_{dn})} \big(\mathbb{I}\left[i \to j \in s\right]$$
$$\cdot \mathbb{I}\left[z_{dn} = k, y_{dn} = s\right]\big) + \beta_{i \to j}. \quad (11)$$

For our experiments, we use the recommended settings $B = 5$ and $M = 5$ from Mimno et al. (2012).

5 Experiments

We evaluate our new topic model, ptLDA, and existing topic models—LDA, pLDA, and tLDA—on their ability to induce domains for machine translation and the resulting performance of the translations on standard machine translation metrics.

Dataset and SMT Pipeline We use the NIST MT Chinese-English parallel corpus (NIST), excluding non-UN and non-HK Hansards portions as our training dataset. It contains 1.6M sentence pairs, with 40.4M Chinese tokens and 44.4M English tokens. We replicate the SMT pipeline of Eidelman et al. (2012): word segmentation (Tseng et al., 2005), align (Och and Ney, 2003), and symmetrize (Koehn et al., 2003) the data. We train a modified Kneser-Ney trigram language model on English (Chen and Goodman, 1996). We use CDEC (Dyer et al., 2010) for decoding, and MIRA (Crammer et al., 2006) for parameter training. To optimize SMT system, we tune the parameters on NIST MT06, and report results on three test sets: MT02, MT03 and MT05.[2]

Topic Models Configuration We compare our polylingual tree-based topic model (ptLDA) against tree-based topic models (tLDA), polylingual topic models (pLDA) and vanilla topic models (LDA).[3] We also examine different inference algorithms—Gibbs sampling (**gibbs**), variational inference (**variational**) and hybrid approach (**variational-hybrid**)—on the effects of SMT performance. In all experiments, we set the per-document Dirichlet parameter $\alpha = 0.01$ and the number of topics to 10, as used in Eidelman et al. (2012).

Resources for Prior Tree To build the tree for tLDA and ptLDA, we extract the word correlations from a Chinese-English bilingual dictionary (Denisowski, 1997).[4] We filter the dictionary using the NIST vocabulary, and keep entries mapping single Chinese and single English words. The prior tree has about 1000 word pairs (*dict*).

We also extract the bidirectional word alignments between Chinese and English using GIZA++ (Och and Ney, 2003). We then remove the word pairs appearing more than 50K times or fewer than 500 times and construct a second prior tree with about 2500 word pairs (*align*).

We apply both trees to tLDA and ptLDA, denoted as tLDA-*dict*, tLDA-*align*, ptLDA-*dict*, and ptLDA-*align*. However, tLDA-*align* and ptLDA-*align* do worse than tLDA-*dict* and ptLDA-*dict*, so we omit tLDA-*align* in the results.

Domain Adaptation using Topic Models We examine the effectiveness of using topic models for domain adaptation on standard SMT evaluation metrics—BLEU (Papineni et al., 2002) and TER (Snover et al., 2006). We report the results on three different test sets (Figure 2), and all SMT results are averaged over five runs.

We refer to the SMT model without domain adaptation as **baseline**.[5] LDA marginally improves machine translation (less than half a BLEU point).

[2] The NIST datasets contain 878, 919, 1082 and 1664 sentences for MT02, MT03, MT05 and MT06 respectively.

[3] For Gibbs sampling, we use implementations available in Hu and Boyd-Graber (2012) for tLDA; and Mallet (McCallum, 2002) for LDA and pLDA.

[4] This is a two-level tree structure. However, one could build a more sophisticated tree prior with a hierarchical dictionary such as multilingual WordNet.

[5] Our replication of Eidelman et al. (2012) yields slightly higher baseline performance, but the trend is consistent.

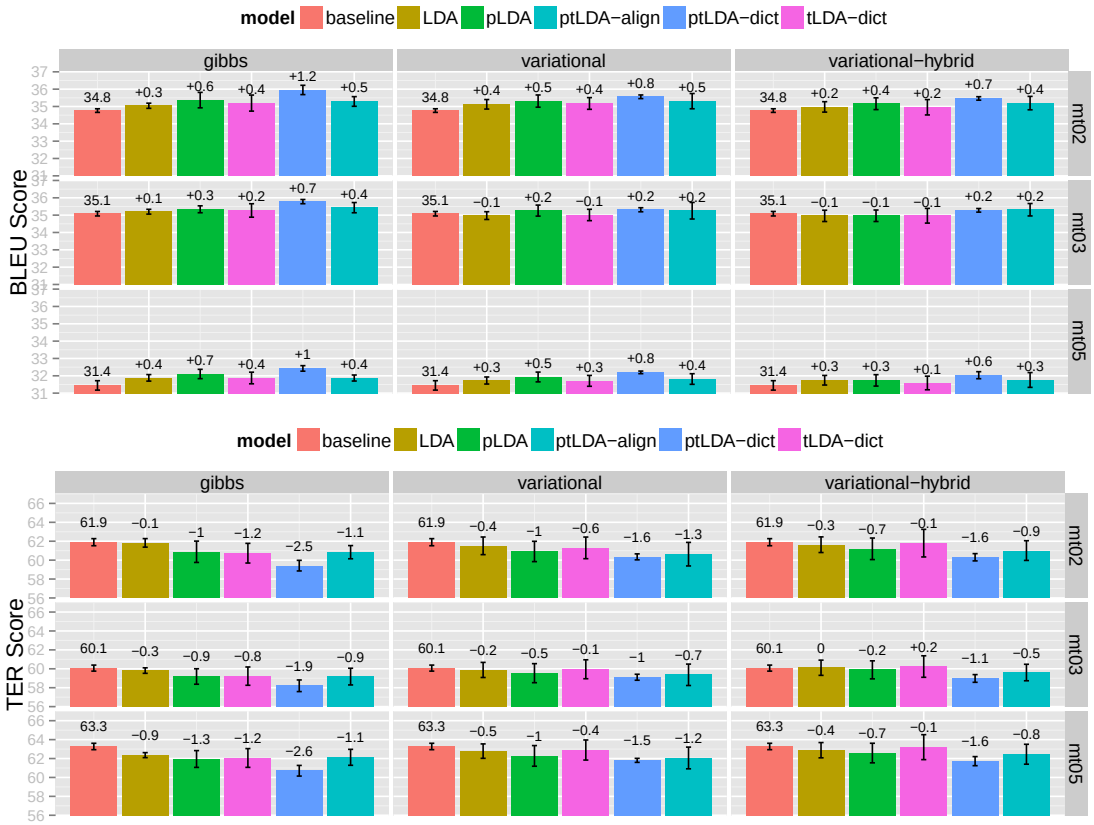

Figure 2: Machine translation performance for different models and inference algorithms against the baseline, on BLEU (top, higher the better) and TER (bottom, lower the better) scores. Our proposed ptLDA performs best. Results are averaged over 5 random runs. For model ptLDA-*dict* with different inference schemes, the BLEU improvement on three test sets is mostly significant with $p = 0.01$, except the results on MT03 using variational and variational-hybrid inferences.

Polylingual topic models pLDA and tree-based topic models tLDA-*dict* are consistently better than LDA, suggesting that incorporating additional bilingual knowledge improves topic models. These improvements are not redundant: our new ptLDA-*dict* model, which has aspects of both models yields the best performance among these approaches—up to a 1.2 BLEU point gain (higher is better), and -2.6 TER improvement (lower is better). The BLEU improvement is significant (Koehn, 2004) at $p = 0.01$,[6] except on MT03 with variational and variational-hybrid inference.

While ptLDA-*align* performs better than **baseline** SMT and LDA, it is worse than ptLDA-*dict*, possibly because of errors in the word alignments, making the tree priors less effective.

Scalability While **gibbs** has better translation scores than **variational** and **variational-hybrid**, it is less scalable to larger datasets. With 1.6M NIST training sentences, **gibbs** takes nearly a week to run 1000 iterations. In contrast, the parallelized **variational** and **variational-hybrid** approaches, which we implement in MapReduce (Dean and Ghemawat, 2004; Wolfe et al., 2008; Zhai et al., 2012), take less than a day to converge.

6 Discussion

In this section, we qualitatively analyze the translation results and investigate how ptLDA and its cousins improve SMT. We also discuss other approaches to improve unsupervised domain adaptation for SMT.

6.1 How do Topic Models Help SMT?

We present two examples of how topic models can improve SMT. The first example shows both LDA and ptLDA improve the **baseline**. The second example shows how LDA introduce biases that mislead SMT and how ptLDA's bilingual constraints correct these mistakes.

Figure 3 shows a sentence about a company

[6] Because we have multiple runs of each topic model (and thus different translation models), we select the run closest to the average BLEU for the translation significance test.

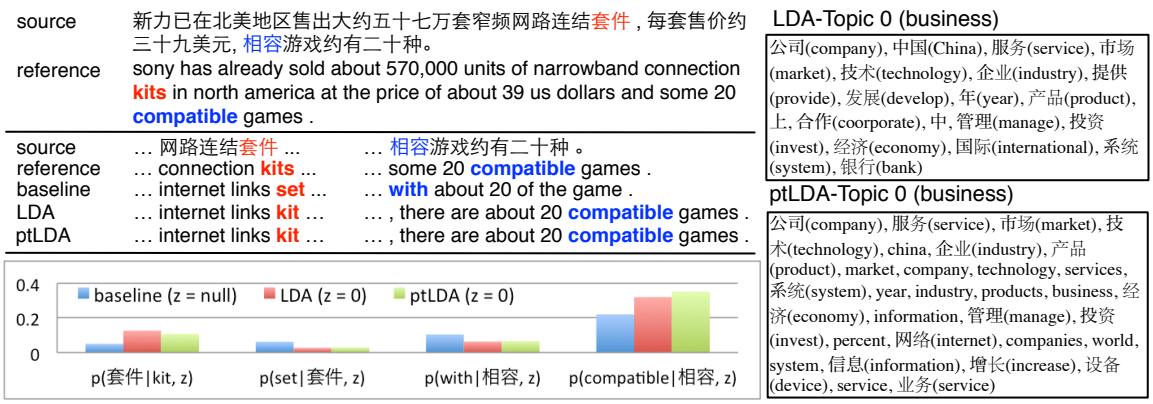

Figure 3: Better SMT result using topic models for domain adaptation. Top row: the source sentence and its reference translation. Middle row: the highlighted translations from different approaches. Bottom row: the change of relevant translation probabilities after incorporating the domain knowledge from LDA and ptLDA. Right: most-probable words of the topic the source sentence is assigned to under LDA (top) and ptLDA (bottom). The Chinese translations are in parenthesis.

introducing new technology gadgets where both LDA and ptLDA improve translations. The **baseline** translates "套件" to "set" (red), and "相容" to "with" (blue), which do not capture the reference meaning of a *add-on device* that works with *compatible* games. Both LDA and ptLDA assign this sentence to a business domain, which makes the translations probabilities shift toward correct translations: the probability of translating "相容" to "compatible" and the probability of translating "套件" to "kit" in the business domain are both significantly larger than without the domain knowledge; and the probabilities of translating "相容" to "with" and the probability of translating "set" to "套件" in the business domain decrease.

The second example (Figure 4) illustrates how ptLDA offers further improvements over LDA. The source sentence discusses foreign affairs. The **baseline** correctly translates the word "影响" to "affect". However, LDA—which only takes monolingual information from the source language—assigns this sentence to economic development. This misleads SMT to lower the probability for the correct translation "affect"; it chooses "impact" instead. In contrast, ptLDA—which incorporates bilingual constraints—successfully labels this sentence as foreign affairs and produces a softer, more nuanced translation that better matches the reference. The translation of "承诺" is very similar, except in this case, both the **baseline** and LDA produce the incorrect translation "the commitment of". This is possible because the probabilities of translating "承诺" to "promised to" and translating "promised to" to "承诺" (the correct translation, in both directions) increase when conditioned on ptLDA's correct topic but decrease when conditioned on LDA's incorrect topic.

6.2 Other Approaches

Other approaches have used topic models for machine translation. Xiao et al. (2012) present a topic similarity model based on LDA that produces a feature that weights grammar rules based on topic compatibility. They also model the source and target side of rules and compare the target similarity during decoding by projecting the target distribution into the source space. Hasler et al. (2012) use the source-side topic assignments from *hidden topic Markov models* (Gruber et al., 2007, HTMM) which models documents as a Markov chain and assign one topic to the whole sentence, instead of a mixture of topics. Su et al. (2012) also apply HTMM to monolingual data and apply the results to machine translation. To our knowledge, however, this is the first work to use *multilingual* topic models for domain adaptation in machine translation.

6.3 Improving Language Models

Topic models capture document-level properties of language, but a critical component of machine translation systems is the language model, which provides local constraints and preferences. Domain adaptation for language models (Bellegarda, 2004; Wood and Teh, 2009) is an important avenue for improving machine translation. Models that simultaneously discover global document themes as well as local, contextual domain-specific informa-

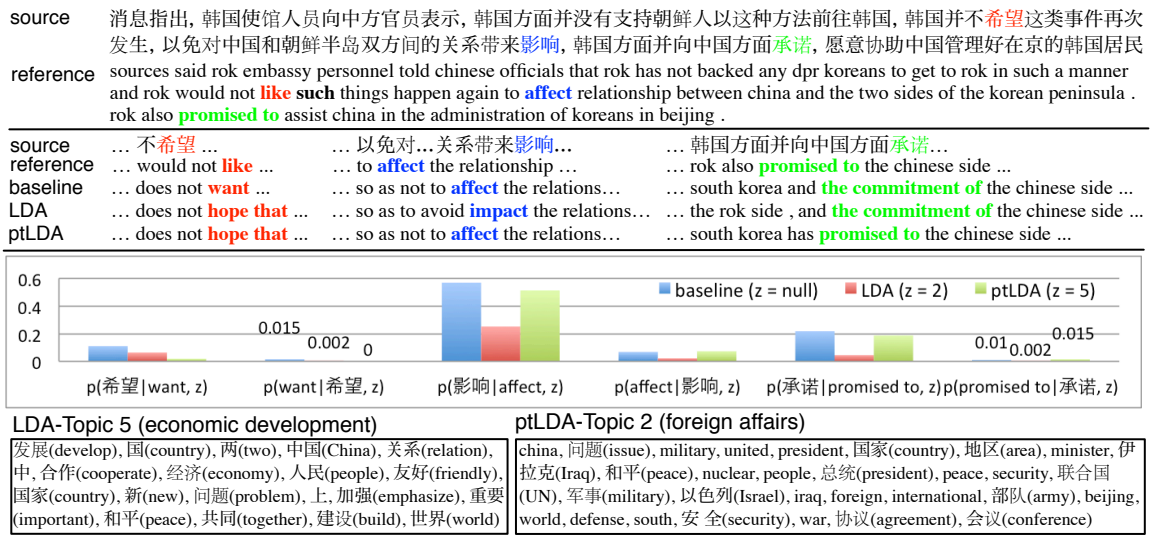

Figure 4: Better SMT result using ptLDA compared to LDA and the baseline. Top row: the source sentence and a reference translation. Second row: the highlighted translations from different models. tion (Wallach, 2006; Boyd-Graber and Blei, 2008) may offer further improvements.

6.4 External Data

The topic models presented here only require weak alignment between documents at the document level. Extending to larger datasets for learning topics is straightforward in principle. For example, ptLDA could learn domains from a much larger corpus like Wikipedia and then apply the extracted domains to machine translation data. However, this presents further challenges, as Wikipedia's domains are not representative of newswire machine translation datasets; a flexible hierarchical topic model (Teh et al., 2006) would better distinguish useful domains from extraneous ones.

7 Conclusion

Topic models generate great interest, but their use in "real world" applications still lags; this is particularly true for multilingual topic models. As topic models become more integrated in commonplace applications, their adoption, understanding, and robustness will improve.

This paper contributes to the deeper integration of topic models into critical applications by presenting a new multilingual topic model, ptLDA, comparing it with other multilingual topic models on a machine translation task, and showing that these topic models improve machine translation. ptLDA models both source and target data to induce domains from both dictionaries and alignments. Further improvement is possible by incorporating topic models deeper in the decoding process and adding domain knowledge to the language model.

Abstract

We explore the extent to which high-resource manual annotations such as treebanks are necessary for the task of semantic role labeling (SRL). We examine how performance changes without syntactic supervision, comparing both *joint* and *pipelined* methods to induce latent syntax. This work highlights a new application of unsupervised grammar induction and demonstrates several approaches to SRL in the absence of supervised syntax. Our best models obtain competitive results in the high-resource setting and state-of-the-art results in the low resource setting, reaching 72.48% F1 averaged across languages. We release our code for this work along with a larger toolkit for specifying arbitrary graphical structure.[1]

1 Introduction

The goal of semantic role labeling (SRL) is to identify predicates and arguments and label their semantic contribution in a sentence. Such labeling defines *who* did *what* to *whom*, *when*, *where* and *how*. For example, in the sentence "The kids ran the marathon", *ran* assigns a role to *kids* to denote that they are the runners; and a role to *marathon* to denote that it is the race course.

Models for SRL have increasingly come to rely on an array of NLP tools (e.g., parsers, lemmatizers) in order to obtain state-of-the-art results (Björkelund et al., 2009; Zhao et al., 2009). Each tool is typically trained on hand-annotated data, thus placing SRL at the end of a very high-resource NLP pipeline. However, richly annotated data such as that provided in parsing treebanks is expensive to produce, and may be tied to specific domains (e.g., newswire). Many languages do not have such supervised resources (*low-resource languages*), which makes exploring SRL cross-linguistically difficult.

The problem of SRL for low-resource languages is an important one to solve, as solutions pave the way for a wide range of applications: Accurate identification of the semantic roles of entities is a critical step for any application sensitive to semantics, from information retrieval to machine translation to question answering.

In this work, we explore models that minimize the need for high-resource supervision. We examine approaches in a **joint** setting where we marginalize over latent syntax to find the optimal semantic role assignment; and a **pipeline** setting where we first induce an unsupervised grammar. We find that the joint approach is a viable alternative for making reasonable semantic role predictions, outperforming the pipeline models. These models can be effectively trained with access to only SRL annotations, and mark a state-of-the-art contribution for low-resource SRL.

To better understand the effect of the low-resource grammars and features used in these models, we further include comparisons with (1) models that use higher-resource versions of the same features; (2) state-of-the-art high resource models; and (3) previous work on low-resource grammar induction. In sum, this paper makes several experimental and modeling contributions, summarized below.

Experimental contributions:

- Comparison of pipeline and joint models for SRL.
- Subtractive experiments that consider the removal of supervised data.
- Analysis of the induced grammars in unsupervised, distantly-supervised, and joint training settings.

[1]http://www.cs.jhu.edu/~mrg/software/

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1177–1187,
Baltimore, Maryland, USA, June 23-25 2014.

Modeling contributions:

- Simpler joint CRF for syntactic and semantic dependency parsing than previously reported.
- New application of unsupervised grammar induction: low-resource SRL.
- Constrained grammar induction using SRL for distant-supervision.
- Use of Brown clusters in place of POS tags for low-resource SRL.

The pipeline models are introduced in § 3.1 and jointly-trained models for syntactic and semantic dependencies (similar in form to Naradowsky et al. (2012)) are introduced in § 3.2. In the pipeline models, we develop a novel approach to unsupervised grammar induction and explore performance using SRL as distant supervision. The joint models use a non-loopy conditional random field (CRF) with a global factor constraining latent syntactic edge variables to form a tree. Efficient exact marginal inference is possible by embedding a dynamic programming algorithm within belief propagation as in Smith and Eisner (2008).

Even at the expense of no dependency path features, the joint models best pipeline-trained models for state-of-the-art performance in the low-resource setting (§ 4.4). When the models have access to observed syntactic trees, they achieve near state-of-the-art accuracy in the high-resource setting on some languages (§ 4.3).

Examining the learning curve of the joint and pipeline models in two languages demonstrates that a small number of labeled SRL examples may be essential for good end-task performance, but that the choice of a good model for grammar induction has an even greater impact.

2 Related Work

Our work builds upon research in both semantic role labeling and unsupervised grammar induction (Klein and Manning, 2004; Spitkovsky et al., 2010a). Previous related approaches to semantic role labeling include joint classification of semantic arguments (Toutanova et al., 2005; Johansson and Nugues, 2008), latent syntax induction (Boxwell et al., 2011; Naradowsky et al., 2012), and feature engineering for SRL (Zhao et al., 2009; Björkelund et al., 2009).

Toutanova et al. (2005) introduced one of the first joint approaches for SRL and demonstrated that a model that scores the full predicate-argument structure of a parse tree could lead to significant error reduction over independent classifiers for each predicate-argument relation.

Johansson and Nugues (2008) and Lluís et al. (2013) extend this idea by coupling predictions of a dependency parser with predictions from a semantic role labeler. In the model from Johansson and Nugues (2008), the outputs from an SRL pipeline are reranked based on the full predicate-argument structure that they form. The candidate set of syntactic-semantic structures is reranked using the probability of the syntactic tree and semantic structure. Lluís et al. (2013) use a joint arc-factored model that predicts full syntactic paths along with predicate-argument structures via dual decomposition.

Boxwell et al. (2011) and Naradowsky et al. (2012) observe that syntax may be treated as latent when a treebank is not available. Boxwell et al. (2011) describe a method for training a semantic role labeler by extracting features from a packed CCG parse chart, where the parse weights are given by a simple ruleset. Naradowsky et al. (2012) marginalize over latent syntactic dependency parses.

Both Boxwell et al. (2011) and Naradowsky et al. (2012) suggest methods for SRL without supervised syntax, however, their features come largely from supervised resources. Even in their lowest resource setting, Boxwell et al. (2011) require an oracle CCG tag dictionary extracted from a treebank. Naradowsky et al. (2012) limit their exploration to a small set of basic features, and included high-resource supervision in the form of lemmas, POS tags, and morphology available from the CoNLL 2009 data.

There has not yet been a comparison of techniques for SRL that do not rely on a syntactic treebank, and no exploration of probabilistic models for unsupervised grammar induction within an SRL pipeline that we have been able to find.

Related work for the unsupervised learning of dependency structures separately from semantic roles primarily comes from Klein and Manning (2004), who introduced the Dependency Model with Valence (DMV). This is a robust generative model that uses a head-outward process over word classes, where heads generate arguments.

Spitkovsky et al. (2010a) show that Viterbi (hard) EM training of the DMV with simple uniform initialization of the model parameters yields higher accuracy models than standard soft-EM

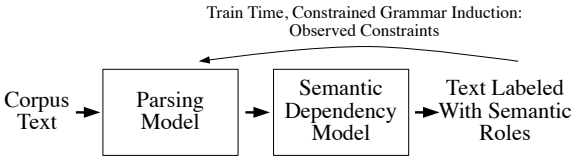

Figure 1: Pipeline approach to SRL. In this simple pipeline, the first stage syntactically parses the corpus, and the second stage predicts semantic predicate-argument structure for each sentence using the labels of the first stage as features. In our *low-resource* pipelines, we assume that the syntactic parser is given no labeled parses—however, it may optionally utilize the semantic parses as distant supervision. Our experiments also consider 'longer' pipelines that include earlier stages: a morphological analyzer, POS tagger, lemmatizer.

training. In Viterbi EM, the E-step finds the maximum likelihood corpus parse given the current model parameters. The M-step then finds the maximum likelihood parameters given the corpus parse. We utilize this approach to produce unsupervised syntactic features for the SRL task.

Grammar induction work has further demonstrated that distant supervision in the form of ACE-style relations (Naseem and Barzilay, 2011) or HTML markup (Spitkovsky et al., 2010b) can lead to considerable gains. Recent work in fully unsupervised dependency parsing has supplanted these methods with even higher accuracies (Spitkovsky et al., 2013) by arranging optimizers into networks that suggest informed restarts based on previously identified local optima. We do not reimplement these approaches within the SRL pipeline here, but provide comparison of these methods against our grammar induction approach in isolation in § 4.5.

In both pipeline and joint models, we use features adapted from state-of-the-art approaches to SRL. This includes Zhao et al. (2009) features, who use feature templates from combinations of word properties, syntactic positions including head and children, and semantic properties; and features from Björkelund et al. (2009), who utilize features on syntactic siblings and the dependency path concatenated with the direction of each edge. Features are described further in § 3.3.

3 Approaches

We consider an array of models, varying:

1. Pipeline vs. joint training (Figures 1 and 2)
2. Types of supervision
3. The objective function at the level of syntax

3.1 Unsupervised Syntax in the Pipeline

Typical SRL systems are trained following a pipeline where the first component is trained on supervised data, and each subsequent component is trained using the 1-best output of the previous components. A typical pipeline consists of a POS tagger, dependency parser, and semantic role labeler. In this section, we introduce pipelines that remove the need for a supervised tagger and parser by training in an unsupervised and distantly supervised fashion.

Brown Clusters We use fully unsupervised Brown clusters (Brown et al., 1992) in place of POS tags. Brown clusters have been used to good effect for various NLP tasks such as named entity recognition (Miller et al., 2004) and dependency parsing (Koo et al., 2008; Spitkovsky et al., 2011).

The clusters are formed by a greedy hierachical clustering algorithm that finds an assignment of words to classes by maximizing the likelihood of the training data under a latent-class bigram model. Each word type is assigned to a fine-grained cluster at a leaf of the hierarchy of clusters. Each cluster can be uniquely identified by the path from the root cluster to that leaf. Representing this path as a bit-string (with 1 indicating a left and 0 indicating a right child) allows a simple coarsening of the clusters by truncating the bit-strings. We train 1000 Brown clusters for each of the CoNLL-2009 languages on Wikipedia text.[2]

Unsupervised Grammar Induction Our first method for grammar induction is *fully unsupervised* Viterbi EM training of the Dependency Model with Valence (DMV) (Klein and Manning, 2004), with uniform initialization of the model parameters. We define the DMV such that it generates sequences of word classes: either POS tags or Brown clusters as in Spitkovsky et al. (2011). The DMV is a simple generative model for projective dependency trees. Children are generated recursively for each node. Conditioned on the parent class, the direction (right or left), and the current valence (first child or not), a coin is flipped to decide whether to generate another child; the distribution over child classes is conditioned on only the parent class and direction.

[2]The Wikipedia text was tokenized for Polyglot (Al-Rfou' et al., 2013): `http://bit.ly/embeddings`

Constrained Grammar Induction Our second method, which we will refer to as DMV+C, induces grammar in a *distantly supervised* fashion by using a constrained parser in the E-step of Viterbi EM. Since the parser is part of a pipeline, we constrain it to respect the downstream SRL annotations during training. At test time, the parser is unconstrained.

Dependency-based semantic role labeling can be described as a simple structured prediction problem: the predicted structure is a labeled directed graph, where nodes correspond to words in the sentence. Each directed edge indicates that there is a predicate-argument relationship between the two words; the parent is the predicate and the child the argument. The label on the edge indicates the type of semantic relationship. Unlike syntactic dependency parsing, the graph is not required to be a tree, nor even a connected graph. Self-loops and crossing arcs are permitted.

The constrained *syntactic* DMV parser treats the semantic graph as observed, and constrains the syntactic parent to be chosen from one of the semantic parents, if there are any. In some cases, imposing this constraint would not permit *any* projective dependency parses—in this case, we ignore the semantic constraint for that sentence. We parse with the CKY algorithm (Younger, 1967; Aho and Ullman, 1972) by utilizing a PCFG corresponding to the DMV (Cohn et al., 2010). Each chart cell allows only non-terminals compatible with the constrained sets. This can be viewed as a variation of Pereira and Schabes (1992).

Semantic Dependency Model As described above, semantic role labeling can be cast as a structured prediction problem where the structure is a labeled semantic dependency graph. We define a conditional random field (CRF) (Lafferty et al., 2001) for this task. Because each word in a sentence may be in a semantic relationship with any other word (including itself), a sentence of length n has n^2 possible edges. We define a single L+1-ary variable for each edge, whose value can be any of L semantic labels or a special label indicating there is no predicate-argument relationship between the two words. In this way, we jointly perform *identification* (determining whether a semantic relationship exists) and *classification* (determining the semantic label). This use of an L+1-ary variable is in contrast to the model of Naradowsky et al. (2012), which used a more complex set of binary variables and required a constraint factor permitting AT-MOST-ONE. We include one unary factor for each variable.

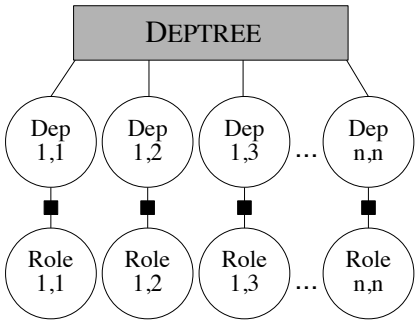

Figure 2: Factor graph for the joint syntactic/semantic dependency parsing model.

We optionally include additional variables that perform word sense disambiguation for each predicate. Each has a unary factor and is completely disconnected from the semantic edge (similar to Naradowsky et al. (2012)). These variables range over all the predicate senses observed in the training data for the *lemma* of that predicate.

3.2 Joint Syntactic and Semantic Parsing Model

In Section 3.1, we introduced pipeline-trained models for SRL, which used grammar induction to predict unlabeled syntactic parses. In this section, we define a simple model for joint syntactic and semantic dependency parsing.

This model extends the CRF model in Section 3.1 to include the projective syntactic dependency parse for a sentence. This is done by including an additional n^2 binary variables that indicate whether or not a directed syntactic dependency edge exists between a pair of words in the sentence. Unlike the semantic dependencies, these syntactic variables must be coupled so that they produce a projective dependency parse; this requires an additional global constraint factor to ensure that this is the case (Smith and Eisner, 2008). The constraint factor touches all n^2 syntactic-edge variables, and multiplies in 1.0 if they form a projective dependency parse, and 0.0 otherwise. We couple each syntactic edge variable to its semantic edge variable with a binary factor. Figure 2 shows the factor graph for this joint model.

Note that our factor graph does not contain any loops, thereby permitting efficient exact marginal inference just as in Naradowsky et al. (2012). We

Property		Possible values
1	word form	all word forms
2	lower case word form	all lower-case forms
3	5-char word form prefixes	all 5-char form prefixes

train our CRF models by maximizing conditional log-likelihood using stochastic gradient descent with an adaptive learning rate (AdaGrad) (Duchi et al., 2011) over mini-batches.

The unary and binary factors are defined with exponential family potentials. In the next section, we consider binary features of the observations (the sentence and labels from previous pipeline stages) which are conjoined with the state of the variables in the factor.

3.3 Features for CRF Models

Our feature design stems from two key ideas. First, for SRL, it has been observed that feature bigrams (the concatenation of simple features such as a predicate's POS tag and an argument's word) are important for state-of-the-art (Zhao et al., 2009; Björkelund et al., 2009). Second, for syntactic dependency parsing, combining Brown cluster features with word forms or POS tags yields high accuracy even with little training data (Koo et al., 2008).

We create binary indicator features for each model using feature templates. Our feature template definitions build from those used by the top performing systems in the CoNLL-2009 Shared Task, Zhao et al. (2009) and Björkelund et al. (2009) and from features in syntactic dependency parsing (McDonald et al., 2005; Koo et al., 2008).

Template	Possible values
relative position	*before, after, on*
distance, continuity	$\mathbb{Z}^+$
binned distance	$>$ 2, 5, 10, 20, 30, or 40
geneological relationship	*parent, child, ancestor, descendant*
path-grams	*the_NN_went*

Table 3: Additional standalone templates.

Template Creation Feature templates are defined over triples of $\langle$property, positions, order$\rangle$. **Properties**, listed in Table 1, are extracted from word **positions** within the sentence, shown in Table 2. Single positions for a word w_i include its syntactic parent, its leftmost farthest child (leftFarChild), its rightmost nearest sibling (rightNearSib), etc. Following Zhao et al. (2009), we include the notion of verb and noun supports and sections of the dependency path. Also following Zhao et al. (2009), properties from a set of positions can be put together in three possible **orders**: as the given sequence, as a sorted list of unique strings, and removing all duplicated neighbored strings. We consider both template unigrams and bigrams, combining two templates in sequence.

Additional templates we include are the relative position (Björkelund et al., 2009), geneological relationship, distance (Zhao et al., 2009), and binned distance (Koo et al., 2008) between two words in the path. From Lluís et al. (2013), we use $1, 2, 3$-gram path features of words/POS tags (path-grams), and the number of non-consecutive token pairs in a predicate-argument path (continuity).

3.4 Feature Selection

Constructing all feature template unigrams and bigrams would yield an unwieldy number of features. We therefore determine the top N template bigrams for a dataset and factor a according to an information gain measure (Martins et al., 2011):

$$IG_{a,m} = \sum_{f \in T_m} \sum_{x_a} p(f, x_a) \log_2 \frac{p(f, x_a)}{p(f)p(x_a)}$$

where T_m is the mth feature template, f is a particular instantiation of that template, and x_a is an assignment to the variables in factor a. The probabilities are empirical estimates computed from the training data. This is simply the mutual information of the feature template instantiation with the variable assignment.

This filtering approach was treated as a simple baseline in Martins et al. (2011) to contrast with increasingly popular gradient based regularization approaches. Unlike the gradient based ap-

proaches, this filtering approach easily scales to many features since we can decompose the memory usage over feature templates.

As an additional speedup, we reduce the dimensionality of our feature space to 1 million for each clique using a common trick referred to as *feature hashing* (Weinberger et al., 2009): we map each feature instantiation to an integer using a hash function[3] modulo the desired dimentionality.

4 Experiments

We are interested in the effects of varied supervision using pipeline and joint training for SRL. To compare to prior work (i.e., submissions to the CoNLL-2009 Shared Task), we also consider the joint task of semantic role labeling *and* predicate sense disambiguation. Our experiments are subtractive, beginning with all supervision available and then successively removing (a) dependency syntax, (b) morphological features, (c) POS tags, and (d) lemmas. Dependency syntax is the most expensive and difficult to obtain of these various forms of supervision. We explore the importance of both the labels and structure, and what quantity of supervision is useful.

4.1 Data

The CoNLL-2009 Shared Task (Hajič et al., 2009) dataset contains POS tags, lemmas, morphological features, syntactic dependencies, predicate senses, and semantic roles annotations for 7 languages: Catalan, Chinese, Czech, English, German, Japanese,[4] Spanish. The CoNLL-2005 and -2008 Shared Task datasets provide English SRL annotation, and for cross dataset comparability we consider only verbal predicates (more details in § 4.4). To compare with prior approaches that use semantic supervision for grammar induction, we utilize Section 23 of the WSJ portion of the Penn Treebank (Marcus et al., 1993).

4.2 Feature Template Sets

Our primary feature set $\mathbf{IG}_C$ consists of 127 template unigrams that emphasize coarse properties (i.e., properties 7, 9, and 11 in Table 1). We also explore the 31 template unigrams[5] $\mathbf{IG}_B$ described by Björkelund et al. (2009). Each of IG_C and IG_B also include 32 template bigrams selected by information gain on 1000 sentences—we select a different set of template bigrams for each dataset.

We compare against the language-specific feature sets detailed in the literature on high-resource top-performing SRL systems: From Björkelund et al. (2009), these are feature sets for German, English, Spanish and Chinese, obtained by weeks of forward selection ($\mathbf{B}_{de,en,es,zh}$); and from Zhao et al. (2009), these are features for Catalan $\mathbf{Z}_{ca}$.[6]

4.3 High-resource SRL

We first compare our models trained as a pipeline, using all available supervision (syntax, morphology, POS tags, lemmas) from the CoNLL-2009 data. Table 4(a) shows the results of our model with gold syntax and a richer feature set than that of Naradowsky et al. (2012), which only looked at whether a syntactic dependency edge was present. This highlights an important advantage of the pipeline trained model: the features can consider any part of the syntax (e.g., arbitrary subtrees), whereas the joint model is limited to those features over which it can efficiently marginalize (e.g., short dependency paths). This holds true even in the pipeline setting where no syntactic supervision is available.

Table 4(b) contrasts our high-resource results for the task of SRL and sense disambiguation with the top systems in the CoNLL-2009 Shared Task, giving further insight into the performance of the simple information gain feature selection technique. With supervised syntax, our simple information gain feature selection technique (§ 3.4) performs admirably. However, the original unigram Björkelund features ($\text{B}_{de,en,es,zh}$), which were tuned for a high-resource model, obtain higher F1 than our information gain set using the same features in unigram and bigram templates (IG_B). This suggests that further work on feature selection may improve the results. We find that IG_B obtain *higher* F1 than the original Björkelund feature sets ($\text{B}_{de,en,es,zh}$) in the low-resource pipeline setting with constrained grammar induction (DMV+C).

[3] To reduce hash collisions, We use MurmurHash v3 `https://code.google.com/p/smhasher`.

[4] We do not report results on Japanese as that data was only made freely available to researchers that competed in CoNLL 2009.

[5] Because we do not include a binary factor between predicate sense and semantic role, we do not include sense as a feature for argument prediction.

[6] This covers all CoNLL languages but Czech, where feature sets were not made publicly available in either work. In Czech, we disallowed template bigrams involving path-grams.

	SRL Approach	Feature Set	Dep. Parser	Avg.	ca	cs	de	en	es	zh

Table 5: F1 for SRL approaches (without sense disambiguation) in matched and mismatched train/test settings for CoNLL 2005 span and 2008 head supervision. We contrast low-resource (☐) and high-resource settings (☑), where latter uses a treebank. See § 4.4 for caveats to this comparison.

4.4 Low-Resource SRL

CoNLL-2009 Table 4(c) includes results for our low-resource approaches and Naradowsky et al. (2012) on predicting semantic roles as well as sense. In the low-resource setting of the CoNLL-2009 Shared task without syntactic supervision, our joint model (Joint) with marginalized syntax obtains state-of-the-art results with features IG_C described in § 4.2. This model outperforms prior work (Naradowsky et al., 2012) and our pipeline model (Pipeline) with contrained (DMV+C) and unconstrained grammar induction (DMV) trained on brown clusters (bc).

In the low-resource setting, training and decoding times for the pipeline and joint methods are similar as computation time tends to be dominated by feature extraction.

These results begin to answer a key research question in this work: The joint models outperform the pipeline models in the low-resource setting. This holds even when using the same feature selection process. Further, the best-performing low-resource features found in this work are those based on coarse feature templates and selected by information gain. Templates for these features generalize well to the high-resource setting. However, analysis of the induced grammars in the pipeline setting suggests that the book is not closed on the issue. We return to this in § 4.5.

CoNLL-2008, -2005 To finish out comparisons with state-of-the-art SRL, we contrast our approach with that of Boxwell et al. (2011), who evaluate on SRL in isolation (without sense disambiguation, as in CoNLL-2009). They report results on Prop-CCGbank (Boxwell and White, 2008), which uses the same training/testing splits as the CoNLL-2005 Shared Task. Their results are therefore loosely[7] comparable to results on the CoNLL-2005 dataset, which we can compare here.

There is an additional complication in comparing SRL approaches directly: The CoNLL-2005 dataset defines arguments as *spans* instead of

[7]The comparison is imperfect for two reasons: first, the CCGBank contains only 99.44% of the original PTB sentences (Hockenmaier and Steedman, 2007); second, because PropBank was annotated over CFGs, after converting to CCG only 99.977% of the argument spans were exact matches (Boxwell and White, 2008). However, this comparison was adopted by Boxwell et al. (2011), so we use it here.

heads, which runs counter to our head-based syntactic representation. This creates a mismatched train/test scenario: we must train our model to predict argument *heads*, but then test on our models ability to predict argument *spans*.[8] We therefore train our models on the CoNLL-2008 argument heads,[9] and post-process and convert from heads to spans using the conversion algorithm available from Johansson and Nugues (2008).[10] The heads are either from an MBR tree or an oracle tree. This gives Boxwell et al. (2011) the advantage, since our syntactic dependency parses are optimized to pick out semantic argument heads, not spans.

Table 5 presents our results. Boxwell et al. (2011) (B'11) uses additional supervision in the form of a CCG tag dictionary derived from supervised data with (tdc) and without (tc) a cutoff. Our model does very poorly on the '05 span-based evaluation because the constituent bracketing of the marginalized trees are inaccurate. This is elucidated by instead evaluating on the oracle spans, where our F1 scores are higher than Boxwell et al. (2011). We also contrast with relavant high-resource methods with span/head conversions from Johansson and Nugues (2008): Punyakanok et al. (2008) (PRY'08) and Johansson and Nugues (2008) (JN'08).

Subtractive Study In our subsequent experiments, we study the effectiveness of our models as the available supervision is decreased. We incrementally remove dependency syntax, morphological features, POS tags, then lemmas. For these experiments, we utilize the coarse-grained feature set (IG_C), which includes Brown clusters.

Across languages, we find the largest drop in F1 when we remove POS tags; and we find a gain in F1 when we remove lemmas. This indicates that lemmas, which are a high-resource annotation, may not provide a significant benefit for this task. The effect of removing morphological features is different across languages, with little change in performance for Catalan and Spanish, but a drop in performance for German. This may reflect a difference between the languages, or may reflect the difference between the annotation of the languages: both the Catalan and Spanish data originated from the Ancora project,[11] while the German data came from another source.

Figure 3 contains the learning curve for SRL supervision in our lowest resource setting for two example languages, Catalan and German. This shows how F1 of SRL changes as we adjust the number of training examples. We find that the joint training approach to grammar induction yields consistently higher SRL performance than its distantly supervised counterpart.

Rem	#FT	ca	de	es
–	127+32	74.46	72.62	74.23
Dep	40+32	67.43	64.24	67.18
Mor	30+32	67.84	59.78	66.94
POS	23+32	64.40	54.68	62.71
Lem	21+32	64.85	54.89	63.80

Table 6: Subtractive experiments. Each row contains the F1 for SRL only (without sense disambiguation) where the supervision type of that row and all above it have been removed. Removed supervision types (Rem) are: syntactic dependencies (*Dep*), morphology (*Mor*), POS tags (*POS*), and lemmas (*Lem*). #FT indicates the number of feature templates used (unigrams+bigrams).

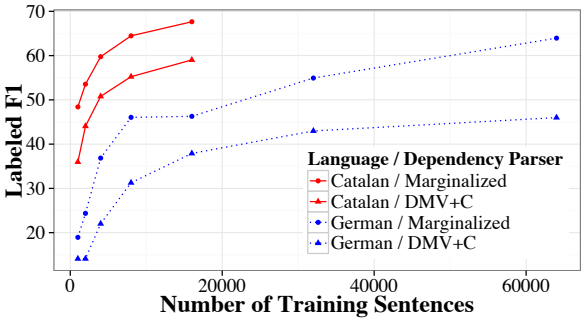

Figure 3: Learning curve for semantic dependency supervision in Catalan and German. F1 of SRL only (without sense disambiguation) shown as the number of training sentences is increased.

4.5 Analysis of Grammar Induction

Table 7 shows grammar induction accuracy in low-resource settings. We find that the gap between the supervised parser and the unsupervised methods is quite large, despite the reasonable accuracy both methods achieve for the SRL end task.

[8] We were unable to obtain the system output of Boxwell et al. (2011) in order to convert their spans to dependencies and evaluate the other mismatched train/test setting.

[9] CoNLL-2005, -2008, and -2009 were derived from PropBank and share the same source text; -2008 and -2009 use argument heads.

[10] Specifically, we use their Algorithm 2, which produces the span dominated by each argument, with special handling of the case when the argument head dominates that of the predicate. Also following Johansson and Nugues (2008), we recover the '05 sentences missing from the '08 evaluation set.

Marginal, IG_B	50.2	52.4	43.4	41.3	52.6	55.2	56.2

Table 7: Unlabeled directed dependency accuracy on CoNLL'09 test set in low-resource settings. DMV models are trained on either POS tags (pos) or Brown clusters (bc). *Indicates the supervised parser outputs provided by the CoNLL'09 Shared Task.

	WSJ^{∞}	Distant Supervision
SAJM'10	44.8	none
SAJ'13	**64.4**	none
SJA'10	50.4	HTML
NB'11	59.4	ACE05
DMV (bc)	24.8	none
DMV+C (bc)	44.8	SRL
Marginalized, IG_C	48.8	SRL
Marginalized, IG_B	58.9	SRL

Table 8: Comparison of grammar induction approaches. We contrast the DMV trained with Viterbi EM+uniform initialization (DMV), our constrained DMV (DMV+C), and our model's MBR decoding of latent syntax (Marginalized) with other recent work: Spitkovsky et al. (2010a) (SAJM'10), Spitkovsky et al. (2010b) (SJA'10), Naseem and Barzilay (2011) (NB'11), and the CS model of Spitkovsky et al. (2013) (SAJ'13).

This suggests that refining the low-resource grammar induction methods may lead to gains in SRL.

Interestingly, the marginalized grammars best the DMV grammar induction method; however, this difference is less pronounced when the DMV is constrained using SRL labels as distant supervision. This could indicate that a better model for grammar induction would result in better performance for SRL. We therefore turn to an analysis of other approaches to grammar induction in Table 8, evaluated on the Penn Treebank. We contrast with methods using distant supervision (Naseem and Barzilay, 2011; Spitkovsky et al., 2010b) and fully unsupervised dependency parsing (Spitkovsky et al., 2013). Following prior work, we exclude punctuation from evaluation and convert the constituency trees to dependencies.[12]

The approach from Spitkovsky et al. (2013) (SAJ'13) outperforms all other approaches, including our marginalized settings. We therefore may be able to achieve further gains in the pipeline model by considering better models of latent syntax, or better search techniques that break out of local optima. Similarly, improving the non-convex optimization of our latent-variable CRF (Marginalized) may offer further gains.

5 Discussion and Future Work

We have compared various approaches for low-resource semantic role labeling at the state-of-the-art level. We find that we can outperform prior work in the low-resource setting by coupling the selection of feature templates based on information gain with a joint model that marginalizes over latent syntax.

We utilize unlabeled data in both generative and discriminative models for dependency syntax and in generative word clustering. Our discriminative joint models treat latent syntax as a structured-feature to be optimized for the end-task of SRL, while our other grammar induction techniques optimize for unlabeled data likelihood—optionally with distant supervision. We observe that careful use of these unlabeled data resources can improve performance on the end task.

Our subtractive experiments suggest that lemma annotations, a high-resource annotation, may not provide a large benefit for SRL. Our grammar induction analysis indicates that relatively low accuracy can still result in reasonable SRL predictions; still, the models do not outperform those that use supervised syntax, and we aim to explore how well the pipeline models in particular improve when we apply higher accuracy unsupervised grammar induction techniques.

We have utilized well studied datasets in order to best understand the quality of our models relative to prior work. In future work, we hope to explore the effectiveness of our approaches on truly low resource settings by using crowdsourcing to develop semantic role datasets in other languages and domains.

Acknowledgments We thank Richard Johansson, Dennis Mehay, and Stephen Boxwell for help with data. We also thank Jason Naradowsky, Jason Eisner, and anonymous reviewers for comments on the paper.

[12]Naseem and Barzilay (2011) and our results use the Penn converter (Pierre and Heiki-Jaan, 2007). Spitkovsky et al. (2010b; 2013) use Collins (1999) head percolation rules.

Abstract

We present an approach to training a joint syntactic and semantic parser that combines syntactic training information from CCGbank with semantic training information from a knowledge base via distant supervision. The trained parser produces a full syntactic parse of any sentence, while simultaneously producing logical forms for portions of the sentence that have a semantic representation within the parser's predicate vocabulary. We demonstrate our approach by training a parser whose semantic representation contains 130 predicates from the NELL ontology. A semantic evaluation demonstrates that this parser produces logical forms better than both comparable prior work and a pipelined syntax-then-semantics approach. A syntactic evaluation on CCGbank demonstrates that the parser's dependency F-score is within 2.5% of state-of-the-art.

1 Introduction

Integrating syntactic parsing with semantics has long been a goal of natural language processing and is expected to improve both syntactic and semantic processing. For example, semantics could help predict the differing prepositional phrase attachments in "I caught the butterfly with the net" and "I caught the butterfly with the spots." A joint analysis could also avoid propagating syntactic parsing errors into semantic processing, thereby improving performance.

We suggest that a large populated knowledge base should play a key role in syntactic and semantic parsing: in training the parser, in resolving syntactic ambiguities when the trained parser is applied to new text, and in its output semantic representation. Using semantic information from the knowledge base at training and test time will ideally improve the parser's ability to solve difficult syntactic parsing problems, as in the examples above. A semantic representation tied to a knowledge base allows for powerful inference operations – such as identifying the possible entity referents of a noun phrase – that cannot be performed with shallower representations (e.g., frame semantics (Baker et al., 1998) or a direct conversion of syntax to logic (Bos, 2005)).

This paper presents an approach to training a joint syntactic and semantic parser using a large background knowledge base. Our parser produces a full syntactic parse of every sentence, and furthermore produces logical forms for portions of the sentence that have a semantic representation within the parser's predicate vocabulary. For example, given a phrase like "my favorite town in California," our parser will assign a logical form like $\lambda x.\text{CITY}(x) \wedge \text{LOCATEDIN}(x, \text{CALIFORNIA})$ to the "town in California" portion. Additionally, the parser uses predicate and entity type information during parsing to select a syntactic parse.

Our parser is trained by combining a syntactic parsing task with a distantly-supervised relation extraction task. Syntactic information is provided by CCGbank, a conversion of the Penn Treebank into the CCG formalism (Hockenmaier and Steedman, 2002a). Semantics are learned by training the parser to extract knowledge base relation instances from a corpus of unlabeled sentences, in a distantly-supervised training regime. This approach uses the knowledge base to avoid expensive manual labeling of individual sentence semantics. By optimizing the parser to perform both tasks simultaneously, we train a parser that produces accurate syntactic and semantic analyses.

We demonstrate our approach by training a joint syntactic and semantic parser, which we call ASP. ASP produces a full syntactic analysis of every sentence while simultaneously producing logical forms containing any of 61 category and 69 re-

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1188–1198,

lation predicates from NELL. Experiments with ASP demonstrate that jointly analyzing syntax and semantics improves semantic parsing performance over comparable prior work and a pipelined syntax-then-semantics approach. ASP's syntactic parsing performance is within 2.5% of state-of-the-art; however, we also find that incorporating semantic information reduces syntactic parsing accuracy by $\sim 0.5\%$.

2 Prior Work

This paper combines two lines of prior work: broad coverage syntactic parsing with CCG and semantic parsing.

Broad coverage syntactic parsing with CCG has produced both resources and successful parsers. These parsers are trained and evaluated using CCGbank (Hockenmaier and Steedman, 2002a), an automatic conversion of the Penn Treebank into the CCG formalism. Several broad coverage parsers have been trained using this resource (Hockenmaier and Steedman, 2002b; Hockenmaier, 2003b). The parsing model in this paper is loosely based on C&C (Clark and Curran, 2007b; Clark and Curran, 2007a), a discriminative log-linear model for statistical parsing. Some work has also attempted to automatically derive logical meaning representations directly from syntactic CCG parses (Bos, 2005; Lewis and Steedman, 2013). However, these approaches to semantics do not ground the text to beliefs in a knowledge base.

Meanwhile, work on semantic parsing has focused on producing semantic parsers for answering simple natural language questions (Zelle and Mooney, 1996; Ge and Mooney, 2005; Wong and Mooney, 2006; Wong and Mooney, 2007; Lu et al., 2008; Kate and Mooney, 2006; Zettlemoyer and Collins, 2005; Kwiatkowski et al., 2011). This line of work has typically used a corpus of sentences with annotated logical forms to train the parser. Recent work has relaxed the requisite supervision conditions (Clarke et al., 2010; Liang et al., 2011), but has still focused on simple questions. Finally, some work has looked at applying semantic parsing to answer queries against large knowledge bases, such as YAGO (Yahya et al., 2012) and Freebase (Cai and Yates, 2013b; Cai and Yates, 2013a; Kwiatkowski et al., 2013; Berant et al., 2013). Although this work considers a larger number (thousands) of predicates than we do, none of these systems are capable of parsing open-domain text. Our approach is most closely related to the distantly-supervised approach of Krishnamurthy and Mitchell (2012).

The parser presented in this paper can be viewed as a combination of both a broad coverage syntactic parser and a semantic parser trained using distant supervision. Combining these two lines of work has synergistic effects – for example, our parser is capable of semantically analyzing conjunctions and relative clauses based on the syntactic annotation of these categories in CCGbank. This synergy gives our parser a richer semantic representation than previous work, while simultaneously enabling broad coverage.

3 Parser Design

This section describes the Combinatory Categorial Grammar (CCG) parsing model used by ASP. The input to the parser is a part-of-speech tagged sentence, and the output is a syntactic CCG parse tree, along with zero or more logical forms representing the semantics of subspans of the sentence. These logical forms are constructed using category and relation predicates from a broad coverage knowledge base. The parser also outputs a collection of dependency structures summarizing the sentence's predicate-argument structure. Figure 1 illustrates ASP's input/output specification.

3.1 Knowledge Base

The parser uses category and relation predicates from a broad coverage knowledge base both to construct logical forms and to parametrize the parsing model. The knowledge base is assumed to have two kinds of ontological structure: a generalization/subsumption hierarchy and argument type constraints. This paper uses NELL's ontology (Carlson et al., 2010), which, for example, specifies that the category ORGANIZATION is a generalization of SPORTSTEAM, and that both arguments to the LOCATEDIN relation must have type LOCATION. These type constraints are enforced during parsing. Throughout this paper, predicate names are shown in SMALLCAPS.

3.2 Syntax

ASP uses a lexicalized and semantically-typed Combinatory Categorial Grammar (CCG) (Steedman, 1996). Most grammatical information in CCG is encoded in a lexicon Λ, containing entries such as:

		Head				Argument			
word	POS	semantic type	index	syntactic category	arg. num.	word	POS	semantic type	index
that	WDT	—	1	$(N_1\backslash N_1)/(S\backslash NP_1)_2$	1	area	NN	LOCATION	0
that	WDT	—	1	$(N_1\backslash N_1)/(S\backslash NP_1)_2$	2	includes	VBZ	LOCATEDIN^{-1}	2
includes	VBZ	LOCATEDIN^{-1}	2	$(S[\text{dcl}]\backslash NP_1)/NP_2$	1	area	NN	LOCATION	0
includes	VBZ	LOCATEDIN^{-1}	2	$(S[\text{dcl}]\backslash NP_1)/NP_2$	2	ENTITY:CITY	NNP	CITY	4
beautiful	JJ	—	3	N_1/N_1	1	ENTITY:CITY	NNP	CITY	4

Figure 1: Example input and output for ASP. Given a POS-tagged sentence, the parser produces a CCG syntactic tree and logical form (top), and a collection of dependency structures (bottom).

person := N : PERSON : $\lambda x.\text{PERSON}(x)$

London := N : CITY : $\lambda x.\text{M}(x, \text{“london”}, \text{CITY})$

great := N_1/N_1 : — : $\lambda f.\lambda x.f(x)$

bought := $(S[\text{dcl}]\backslash NP_1)/NP_2$: ACQUIRED : $\lambda f.\lambda g.\exists x, y.f(y) \wedge g(x) \wedge \text{ACQUIRED}(x, y)$

Each lexicon entry maps a word to a syntactic category, semantic type, and logical form. CCG has two kinds of syntactic categories: atomic and functional. Atomic categories include N for noun and S for sentence. Functional categories are functions constructed recursively from atomic categories; these categories are denoted using slashes to separate the category's argument type from its return type. The argument type appears on the right side of the slash, and the return type on the left. The direction of slash determines where the argument must appear – / means an argument on the right, and \ means an argument on the left.

Syntactic categories in ASP are annotated with two additional kinds of information. First, atomic categories may have associated syntactic features given in square brackets. These features are used in CCGbank to distinguish variants of atomic syntactic categories, e.g., $S[\text{dcl}]$ denotes a declarative sentence. Second, each category is annotated with head and dependency information using subscripts. These subscripts are used to populate predicate-argument dependencies (described below), and to pass head information using unification. For example, the head of the parse in Figure 1 is "area," due to the coindexing of the argument and return categories in the category $N_1\backslash N_1$.

In addition to the syntactic category, each lexicon entry has a semantic type and a logical form. The semantic type is a category or relation predicate that concisely represents the word's semantics. The semantic type is used to enforce type constraints during parsing and to include semantics in the parser's parametrization. The logical form gives the full semantics of the word in lambda calculus. The parser also allows lexicon entries with the semantic type "—", representing words whose semantics cannot be expressed using predicates from the ontology.

Parsing in CCG combines adjacent categories using a small number of combinators, such as function application:

$$X/Y : f \quad Y : g \implies X : f(g)$$
$$Y : g \quad X\backslash Y : f \implies X : f(g)$$

The first rule states that the category X/Y can be applied to the category Y, returning category X, and that the logical form f is applied to g to produce the logical form for the returned category. Head words and semantic types are also propagated to the returned category based on the annotated head-passing markup.

3.3 Dependency Structures

Parsing a sentence produces a collection of dependency structures which summarize the predicate-argument structure of the sentence. Dependency structures are 10-tuples, of the form:

< head word, head POS, head semantic type, head word index, head word syntactic category, argument number, argument word, argument POS, argument semantic type, argument word index >

A dependency structure captures a relationship between a head word and its argument. During parsing, whenever a subscripted argument of a syntactic category is filled, a dependency structure

is created between the head of the applied function and its argument. For example, in Figure 1, the first application fills argument 1 of "beautiful" with "London," creating a dependency structure.

3.4 Logical Forms

ASP performs a best-effort semantic analysis of every parsed sentence, producing logical forms for subspans of the sentence when possible. Logical forms are designed so that the meaning of a sentence is a universally- and existentially-quantified conjunction of predicates with partially shared arguments. This representation allows the parser to produce semantic analyses for a reasonable subset of language, including prepositions, verbs, nouns, relative clauses, and conjunctions.

Figure 1 shows a representative sample of a logical form produced by ASP. Generally, the parser produces a lambda calculus statement with several existentially-quantified variables ranging over entities in the knowledge base. The only exception to this rule is conjunctions, which are represented using a scoped universal quantifier over the conjoined predicates. Entity mentions appear in logical forms via a special mention predicate, M, instead of as database constants. For example, "London" appears as $\text{M}(x, \text{"london"}, \text{CITY})$, instead of as a constant like LONDON. The meaning of this mention predicate is that x is an entity which can be called "london" and belongs to the CITY category. This representation propagates uncertainty about entity references into the logical form where background knowledge can be used for disambiguation. For example, "London, England" is assigned a logical form that disambiguates "London" to a "London" located in "England."[1]

Lexicon entries without a semantic type are automatically assigned logical forms based on their head passing markup. For example, in Figure 1, the adjective "beautiful" is assigned $\lambda f.f$. This approach allows a logical form to be derived for most sentences, but (somewhat counterintuitively) can lose interesting logical forms from constituent subspans. For example, the preposition "in" has syntactic category $(N_1 \backslash N_1)/N_2$, which results in the logical form $\lambda f.\lambda g.g$. This logical form discards any information present in the argument f. We avoid this problem by extracting a logical form from every subtree of the CCG parse.

[1] Specifically, $\lambda x.\exists y.\text{CITYLOCATEDINCOUNTRY}(x, y) \wedge \text{M}(x, \text{"london"}, \text{CITY}) \wedge \text{M}(y, \text{"england"}, \text{COUNTRY})$

3.5 Parametrization

The parser Γ is trained as a discriminative linear model of the following form:

$$\Gamma(\ell, d, t|s; \theta) \quad = \quad \theta^T \phi(d, t, s)$$

Given a parameter vector θ and a sentence s, the parser produces a score for a syntactic parse tree t, a collection of dependency structures d and a logical form ℓ. The score depends on features of the parse produced by the feature function ϕ.

ϕ contains four classes of features: lexicon features, combinator features, dependency features and dependency distance features (Table 1). These features are based on those of C&C (Clark and Curran, 2007b), modified to include semantic types. The features are designed to share syntactic information about a word across its distinct semantic realizations in order to transfer syntactic information from CCGbank to semantic parsing.

The parser also includes a hard type-checking constraint to ensure that logical forms are well-typed. This constraint states that dependency structures with a head semantic type only accept arguments that (1) have a semantic type, and (2) are within the domain/range of the head type.

4 Parameter Estimation

This section describes the training procedure for ASP. Training is performed by minimizing a joint objective function combining a syntactic parsing task and a distantly-supervised relation extraction task. The input training data includes:

1. A collection L of sentences s_i with annotated syntactic trees t_i (e.g., CCGbank).
2. A corpus of sentences S (e.g., Wikipedia).
3. A knowledge base K (e.g., NELL), containing relation instances $r(e_1, e_2) \in K$.
4. A CCG lexicon Λ (see Section 5.2).

Given these resources, the algorithm described in this section produces parameters θ for a semantic parser. Our parameter estimation procedure constructs a joint objective function $O(\theta)$ that decomposes into syntactic and semantic components: $O(\theta) = O_{\text{syn}}(\theta) + O_{\text{sem}}(\theta)$. The syntactic component O_{syn} is a standard syntactic parsing objective constructed using the syntactic resource L. The semantic component O_{sem} is a distantly-supervised relation extraction task based on the semantic constraint from Krishnamurthy and Mitchell (2012). These components are described in more detail in the following sections.

Lexicon features: word, POS $:= X : t : \ell$

Word/syntactic category	word, X
POS/syntactic category	POS, X
Word semantics	word, X, t

Combinator features: $X\ Y \rightarrow Z$ or $X \rightarrow Z$

Binary combinator indicator	$X\ Y \rightarrow Z$
Unary combinator indicator	$X \rightarrow Z$
Root syntactic category	Z

Dependency Features: $< h_w, h_p, h_t, h_i, s, n, a_w, a_p, a_t, a_i >$

Predicate-Argument Indicator	$< h_w, —, h_t, —, s, n, a_w, —, a_t, — >$
Word-Word Indicator	$< h_w, —, —, —, s, n, a_w, —, —, — >$
Predicate-POS Indicator	$< h_w, —, h_t, —, s, n, —, a_p, —, — >$
Word-POS Indicator	$< h_w, —, —, —, s, n, —, a_p, —, — >$
POS-Argument Indicator	$< —, h_p, —, —, s, n, a_w, —, a_t, — >$
POS-Word Indicator	$< —, h_p, —, —, s, n, a_w, —, —, — >$
POS-POS Indicator	$< —, h_p, —, —, s, n, —, a_p, —, — >$

Dependency Distance Features:

Token distance	$h_w, h_t, —, s, n, d$	d = Number of tokens between h_i and a_i: 0, 1, 2 or more.
Token distance word backoff	$h_w, —, s, n, d$	d = Number of tokens between h_i and a_i: 0, 1, 2 or more.
Token distance POS backoff	$—, —, h_p, s, n, d$	d = Number of tokens between h_i and a_i: 0, 1, 2 or more.

(The above distance features are repeated using the number of intervening verbs and punctuation marks.)

Table 1: Listing of parser feature templates used in the feature function ϕ. Each feature template represents a class of indicator features that fire during parsing when lexicon entries are used, combinators are applied, or dependency structures are instantiated.

4.1 Syntactic Objective

The syntactic objective is the structured perceptron objective instantiated for a syntactic parsing task. This objective encourages the parser to accurately reproduce the syntactic parses in the annotated corpus $L = \{(s_i, t_i)\}_{i=1}^n$:

$$O_{\text{syn}}(\theta) = \sum_{i=1}^{n} | \max_{\hat{\ell},\hat{d},\hat{t}} \Gamma(\hat{\ell}, \hat{d}, \hat{t} | s_i; \theta) - \max_{\ell^*, d^*} \Gamma(\ell^*, d^*, t_i | s_i; \theta) |_+$$

The first term in the above expression represents the best CCG parse of the sentence s_i according to the current model. The second term is the best parse of s_i whose syntactic tree equals the true syntactic tree t_i. In the above equation $|\cdot|_+$ denotes the positive part of the expression. Minimizing this objective therefore finds parameters θ that reproduce the annotated syntactic trees.

4.2 Semantic Objective

The semantic objective corresponds to a distantly-supervised relation extraction task that constrains the logical forms produced by the semantic parser. Distant supervision is provided by the following constraint: every relation instance $r(e_1, e_2) \in K$ must be expressed by at least one sentence in $\mathbf{S}_{(e_1,e_2)}$, the set of sentences that mention both e_1 and e_2 (Hoffmann et al., 2011). If this constraint is empirically true and sufficiently constrains the parser's logical forms, then optimizing the semantic objective produces an accurate semantic parser.

A training example in the semantic objective consists of the set of sentences mentioning a pair of entities, $\mathbf{S}_{(e_1,e_2)} = \{s_1, s_2, ...\}$, paired with a binary vector representing the set of relations that the two entities participate in, $\mathbf{y}_{(e_1,e_2)}$. The distant supervision constraint Ψ forces the logical forms predicted for the sentences to entail the relations in $\mathbf{y}_{(e_1,e_2)}$. Ψ is a deterministic OR constraint that checks whether each logical form entails the relation instance $r(e_1, e_2)$, deterministically setting $y_r = 1$ if any logical form entails the instance and $y_r = 0$ otherwise.

Let $(\boldsymbol{\ell}, \boldsymbol{d}, \mathbf{t})$ represent a collection of semantic parses for the sentences $\mathbf{S} = \mathbf{S}_{(e_1,e_2)}$. Let $\Gamma(\boldsymbol{\ell}, \boldsymbol{d}, \mathbf{t} | \mathbf{S}; \theta) = \sum_{i=1}^{|\mathbf{S}|} \Gamma(\ell_i, d_i, t_i | s_i; \theta)$ represent the total weight assigned by the parser to a collection of parses for the sentences $\mathbf{S}$. For the pair of entities (e_1, e_2), the semantic objective is:

$$O_{\text{sem}}(\theta) = | \max_{\hat{\boldsymbol{\ell}},\hat{\boldsymbol{d}},\hat{\mathbf{t}}} \Gamma(\hat{\boldsymbol{\ell}}, \hat{\boldsymbol{d}}, \hat{\mathbf{t}} | \mathbf{S}; \theta) - \max_{\boldsymbol{\ell}^*, \boldsymbol{d}^*, \mathbf{t}^*} \big(\Psi(\mathbf{y}_{(e_1,e_2)}, \boldsymbol{\ell}^*, \boldsymbol{d}^*, \mathbf{t}^*) + \Gamma(\boldsymbol{\ell}^*, \boldsymbol{d}^*, \mathbf{t}^* | \mathbf{S}; \theta)\big) |_+$$

4.3 Optimization

Training minimizes the joint objective using the structured perceptron algorithm, which can be viewed as the stochastic subgradient method (Ratliff et al., 2006) applied to the objective $O(\theta)$. We initialize the parameters to zero, i.e., $\theta^0 = 0$. On each iteration, we sample either a syntactic example (s_i, t_i) or a semantic example $(\mathbf{S}_{(e_1,e_2)}, \mathbf{y}_{(e_1,e_2)})$. If a syntactic example is sampled, we apply the following parameter update:

$$\begin{aligned} \hat{\ell}, \hat{d}, \hat{t} &\leftarrow \arg\max_{\ell,d,t} \Gamma(\ell, d, t | s_i; \theta^t) \\ \ell^*, d^* &\leftarrow \arg\max_{\ell,d} \Gamma(\ell, d, t_i | s_i; \theta^t) \\ \theta^{t+1} &\leftarrow \theta^t + \phi(d^*, t_i, s_i) - \phi(\hat{d}, \hat{t}, s_i) \end{aligned}$$

This update moves the parameters toward the features of the best parse with the correct syntactic derivation, $\phi(d^*, t_i, s_i)$. If a semantic example is

	Labeled Dependencies			Unlabeled Dependencies			
	P	R	F	P	R	F	Coverage
ASP	85.58	85.31	85.44	91.75	91.46	91.60	99.63
ASP-SYN	86.06	85.84	85.95	92.13	91.89	92.01	99.63
C&C (Clark and Curran, 2007b)	88.34	86.96	87.64	93.74	92.28	93.00	99.63
(Hockenmaier, 2003a)	84.3	84.6	84.4	91.8	92.2	92.0	99.83

Table 2: Syntactic parsing results for Section 23 of CCGbank. Parser performance is measured using precision (P), recall (R) and F-measure (F) of labeled and unlabeled dependencies.

sampled, we instead apply the following update:

$$\hat{\boldsymbol{\ell}}, \hat{\boldsymbol{d}}, \hat{\mathbf{t}} \leftarrow \arg\max_{\boldsymbol{\ell}, \boldsymbol{d}, \mathbf{t}} \Gamma(\boldsymbol{\ell}, \boldsymbol{d}, \mathbf{t} | \mathbf{S}_{(e_1,e_2)}; \theta^t)$$

$$\boldsymbol{\ell}^*, \boldsymbol{d}^*, \mathbf{t}^* \leftarrow \arg\max_{\boldsymbol{\ell}, \boldsymbol{d}, \mathbf{t}} \Gamma(\boldsymbol{\ell}, \boldsymbol{d}, \mathbf{t} | \mathbf{S}_{(e_1,e_2)}; \theta^t) + \Psi(\mathbf{y}_{(e_1,e_2)}, \boldsymbol{\ell}, \boldsymbol{d}, \mathbf{t})$$

$$\theta^{t+1} \leftarrow \theta^t + \phi(\boldsymbol{d}^*, \mathbf{t}^*, \mathbf{S}_{(e_1,e_2)}) - \phi(\hat{\boldsymbol{d}}, \hat{\mathbf{t}}, \mathbf{S}_{(e_1,e_2)})$$

This update moves the parameters toward the features of the best set of parses that satisfy the distant supervision constraint. Training outputs the average of each iteration's parameters, $\bar{\theta} = \frac{1}{n} \sum_{t=1}^{n} \theta^t$. In practice, we train the parser by performing a single pass over the examples in the data set.

All of the maximizations above can be performed exactly using a CKY-style chart parsing algorithm, except for the last one. This maximization is intractable due to the coupling between logical forms in $\boldsymbol{\ell}$ caused by enforcing the distant supervision constraint. We approximate this maximization in two steps. First, we perform a beam search to produce a list of candidate parses for each sentence $s \in \mathbf{S}_{(e_1,e_2)}$. We then extract relation instances from each parse and apply the greedy inference algorithm from Hoffmann et al., (2011) to identify the best set of parses that satisfy the distant supervision constraint. The procedure skips any examples with sentences that cannot be parsed (due to beam search failures) or where the distant supervision constraint cannot be satisfied.

5 Experiments

The experiments below evaluate ASP's syntactic and semantic parsing ability. The parser is trained on CCGbank and a corpus of Wikipedia sentences, using NELL's predicate vocabulary. The syntactic analyses of the trained parser are evaluated against CCGbank, and its logical forms are evaluated on an information extraction task and against an annotated test set of Wikipedia sentences.

5.1 Data Sets

The data sets for the evaluation consist of CCGbank, a corpus of dependency-parsed Wikipedia sentences, and a logical knowledge base derived from NELL and Freebase. Sections 02-21 of CCGbank were used for training, Section 00 for validation, and Section 23 for the final results. The knowledge base's predicate vocabulary is taken from NELL, and its instances are taken from Freebase using a manually-constructed mapping between Freebase and NELL. Using Freebase relation instances produces cleaner training data than NELL's automatically-extracted instances.

Using the relation instances and Wikipedia sentences, we constructed a data set for distantly-supervised relation extraction. We identified mentions of entities in each sentence using simple string matching, then aggregated these sentences by entity pair. 20% of the entity pairs were set aside for validation. In the remaining training data, we downsampled entity pairs that did not participate in at least one relation. We further eliminated sentences containing more than 30 tokens. The resulting training corpus contains 25k entity pairs (half of which participate in a relation), 41k sentences, and 71 distinct relation predicates.

5.2 Grammar Construction

The grammar for ASP contains the annotated lexicon entries and grammar rules in Sections 02-21 of CCGbank, and additional semantic entries produced using a set of dependency parse heuristics.

The lexicon Λ contains all words that occur at least 20 times in CCGbank. Rare words are replaced by their part of speech. The head passing and dependency markup was generated using the rules of the C&C parser (Clark and Curran, 2007b). These lexicon entries are also annotated with logical forms capturing their head passing relationship. For example, the adjective category N_1/N_1 is annotated with the logical form $\lambda f.f.$ These entries are all assigned semantic type —.

We augment this lexicon with additional entries

Sentence	Extracted Logical Form
St. John, a Mexican-American born in San Francisco, California, her family comes from Zacatecas, Mexico.	$\lambda x.\exists y, z.\text{M}(x, \text{“st. john”}) \wedge \text{M}(y, \text{“san francisco”}) \wedge \text{PERSONBORNINLOCATION}(x, y) \wedge \text{CITYLOCATEDINSTATE}(y, z) \wedge \text{M}(z, \text{“california”})$
The capital and largest city of Laos is Vientiane and other major cities include Luang Prabang, Savannakhet and Pakse.	$\exists x, y.\text{M}(x, \text{“vientiane”}) \wedge \text{CITY}(x) \wedge \text{CITYCAPITALOFCOUNTRY}(x, y) \wedge \text{M}(y, \text{“laos”})$
Gellar next played a lead role in James Toback 's critically unsuccessful independent “Harvard Man” (2001), where she played the daughter of a mobster.	$\lambda x.\exists y.\text{M}(y, \text{“james toback”}) \wedge \text{DIRECTORDIRECTEDMOVIE}(y, x) \wedge \text{M}(x, \text{“harvard man”})$

Figure 2: Logical forms produced by ASP for sentences in the information extraction corpus. Each logical form is extracted from the underlined sentence portion.

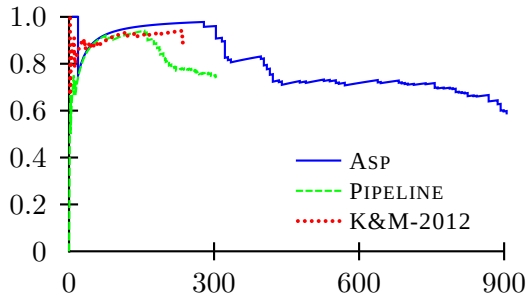

Figure 3: Logical form precision as a function of the expected number of correct extracted logical forms. ASP extracts more correct logical forms because it jointly analyzes syntax and semantics.

mapping words to logical forms with NELL predicates. These entries are instantiated using a set of dependency parse patterns, listed in an online appendix.[2] These patterns are applied to the training corpus, heuristically identifying verbs, prepositions, and possessives that express relations, and nouns that express categories. The patterns also include special cases for forms of “to be.” This process generates ∼4000 entries (not counting entity names), representing 69 relations and 61 categories from NELL. Section 3.2 shows several lexicon entries generated by this process.

The parser's combinators include function application, composition, and crossed composition, as well as several binary and unary type-changing rules that occur in CCGbank. All combinators were restricted to only apply to categories that combine in Sections 02-21. Finally, the grammar includes a number of heuristically-instantiated binary rules of the form , $N \rightarrow N\backslash N$ that instantiate a relation between adjacent nouns. These rules capture appositives and some other constructions.

5.3 Supertagging

Parsing in practice can be slow because the parser's lexicalized grammar permits a large number of parses for a sentence. We improve parser performance by performing *supertagging* (Bangalore and Joshi, 1999; Clark and Curran, 2004). We trained a logistic regression classifier to predict the syntactic category of each token in a sentence from features of the surrounding tokens and POS tags. Subsequent parsing is restricted to only consider categories whose probability is within a factor of α of the highest-scoring category. The parser uses a backoff strategy, first attempting to parse with the supertags from $\alpha = 0.01$, backing off to $\alpha = 0.001$ if the initial parsing attempt fails.

5.4 Syntactic Evaluation

The syntactic evaluation measures ASP's ability to reproduce the predicate-argument dependencies in CCGbank. As in previous work, our evaluation uses *labeled* and *unlabeled* dependencies. Labeled dependencies are dependency structures with both words and semantic types removed, leaving two word indexes, a syntactic category, and an argument number. Unlabeled dependencies further eliminate the syntactic category and argument number, leaving a pair of word indexes. Performance is measured using precision, recall, and F-measure against the annotated dependency structures in CCGbank. Precision is the fraction of predicted dependencies which are in CCGbank, recall is the fraction of CCGbank dependencies produced by the parser, and F-measure is the harmonic mean of precision and recall.

For comparison, we also trained a syntactic version of our parser, ASP-SYN, using only the CCGbank lexicon and grammar. Comparing against this parser lets us measure the effect of the relation extraction task on syntactic parsing.

Table 2 shows the results of our evaluation. For comparison, we include results for two existing syntactic CCG parsers: C&C, the current state-of-the-art CCG parser (Clark and Curran, 2007b), and the next best system (Hockenmaier, 2003a). Both ASP and ASP-SYN perform reasonably well, within 2.5% of the performance of C&C at the same coverage level. However, ASP-

[2] http://rtw.ml.cmu.edu/acl2014_asp/

	Logical Form Accuracy	Extraction Precision	Extraction Recall
ASP	0.28	0.90	0.32
K&M-2012	0.14	1.00	0.06
PIPELINE	0.2	0.63	0.17

Table 3: Logical form accuracy and extraction precision/recall on the annotated test set. The high extraction recall for ASP shows that it produces more complete logical forms than either baseline.

SYN outperforms ASP by around 0.5%, suggesting that ASP's additional semantic knowledge slightly hurts syntactic parsing performance. This performance loss appears to be largely due to poor entity mention detection, as we found that not using entity mention lexicon entries at test time improves ASP's labeled and unlabeled F-scores by 0.3% on Section 00. The knowledge base contains many infrequently-mentioned entities with common names; these entities contribute incorrect semantic type information that confuses the parser.

5.5 Semantic Evaluation

We performed two semantic evaluations to better understand ASP's ability to construct logical forms. The first evaluation emphasizes precision over recall, and the second evaluation accurately measures recall using a manually labeled test set.

5.5.1 Baselines

For comparison, we also trained two baseline models. The first baseline, PIPELINE, is a pipelined syntax-then-semantics approach designed to mimic Boxer (Bos, 2005). This baseline first syntactically parses each sentence using ASP-SYN, then produces a semantic analysis by assigning a logical form to each word. We train this baseline using the semantic objective (Section 4.2) while holding fixed the syntactic parse of each sentence. Note that, unlike Boxer, this baseline learns which logical form to assign each word, and its logical forms contain NELL predicates.

The second baseline, K&M-2012, is the approach of Krishnamurthy and Mitchell (2012), representing the state-of-the-art in distantly-supervised semantic parsing. This approach trains a semantic parser by combining distant semantic supervision with syntactic supervision from dependency parses. The best performing variant of this system also uses dependency parses at test time to constrain the interpretation of test sentences – hence, this system also uses a pipelined syntax-then-semantics approach. To improve comparability, we reimplemented this approach using our parsing model, which has richer features than were used in their paper.

5.5.2 Information Extraction Evaluation

The information extraction evaluation uses each system to extract logical forms from a large corpus of sentences, then measures the fraction of extracted logical forms that are correct. The test set consists of 8.5k sentences sampled from the held-out Wikipedia sentences. Each system was run on this data set, extracting all logical forms from each sentence that entailed at least one category or relation instance. We ranked these extractions using the parser's inside chart score, then manually annotated a sample of 250 logical forms from each system for correctness. Logical forms were marked correct if all category and relation instances entailed by the logical form were expressed by the sentence. Note that a correct logical form need not entail all of the relations expressed by the sentence, reflecting an emphasis on precision over recall. Figure 2 shows some example logical forms produced by ASP in the evaluation.

The annotated sample of logical forms allows us to estimate precision for each system as a function of the number of correct extractions (Figure 3). The number of correct extractions is directly proportional to recall, and was estimated from the total number of extractions and precision at each rank in the sample. All three systems initially have high precision, implying that their extracted logical forms express facts found in the sentence. However, ASP produces 3 times more correct logical forms than either baseline because it jointly analyzes syntax and semantics. The baselines suffer from reduced recall because they depend on receiving an accurate syntactic parse as input; syntactic parsing errors cause these systems to fail.

Examining the incorrect logical forms produced by ASP reveals that incorrect mention detection is by far the most common source of mistakes. Approximately 50% of errors are caused by marking common nouns as entity mentions (e.g., marking "coin" as a COMPANY). These errors occur because the knowledge base contains many infrequently mentioned entities with relatively common names. Another 30% of errors are caused by assigning an incorrect type to a common proper noun (e.g, marking "Bolivia" as a CITY). This analysis suggests that performing entity linking before parsing could significantly reduce errors.

Sentence: *De Niro and Joe Pesci in "Goodfellas"* offered a virtuoso display of the director's bravura cinematic technique and reestablished, enhanced, and consolidated his reputation.
Annotation:
LF: $\lambda x.\forall p \in \{\lambda d.\text{M}(d, \text{“de niro”}), \lambda j.\text{M}(j, \text{“joe pesci”})\} \exists y.p(x) \wedge \text{STARREDINMOVIE}(x, y) \wedge \text{M}(y, \text{“goodfellas”})$
Instances: STARREDINMOVIE(de niro, goodfellas), STARREDINMOVIE(joe pesci, goodfellas)
Prediction:
LF: $\lambda x.\forall p \in \{\lambda d.\text{M}(d, \text{“de niro”}), \lambda j.\text{M}(j, \text{“joe pesci”})\} \exists y.p(x) \wedge \text{STARREDINMOVIE}(x, y) \wedge \text{M}(y, \text{“goodfellas”})$
Instances: STARREDINMOVIE(de niro, goodfellas), STARREDINMOVIE(joe pesci, goodfellas)
Logical form accuracy: 1 / 1 **Extraction Precision:** 2 / 2 **Extraction Recall:** 2 / 2

Sentence: In addition to the University of Illinois, *Champaign is also home to Parkland College*.
Annotation:
LF: $\exists c, p.\text{M}(c, \text{“champaign”}) \wedge \text{CITY}(c) \wedge \text{M}(p, \text{“parkland college”}) \wedge \text{UNIVERSITYINCITY}(p, c)$
Instances: CITY(champaign), UNIVERSITYINCITY(parkland college, champaign)
Prediction:
LF 1: $\lambda x.\exists y\text{M}(y, \text{“illinois”}) \wedge \text{M}(x, \text{“university”}) \wedge \text{CITYLOCATEDINSTATE}(x, y)$
LF 2: $\exists c, p.\text{M}(c, \text{“champaign”}) \wedge \text{CITY}(c) \wedge \text{M}(p, \text{“parkland college”}) \wedge \text{UNIVERSITYINCITY}(p, c)$
Instances: CITY(champaign), UNIVERSITYINCITY(parkland college, champaign),
CITYLOCATEDINSTATE(university, illinois)
Logical form accuracy: 1 / 1 **Extraction Precision:** 2 / 3 **Extraction Recall:** 2 / 2

Figure 4: Two test examples with ASP's predictions and error calculations. The annotated logical forms are for the italicized sentence spans, while the extracted logical forms are for the underlined spans.

5.5.3 Annotated Sentence Evaluation

A limitation of the previous evaluation is that it does not measure the completeness of predicted logical forms, nor estimate what portion of sentences are left unanalyzed. We conducted a second evaluation to measure these quantities.

The data for this evaluation consists of sentences annotated with logical forms for subspans. We manually annotated Wikipedia sentences from the held-out set with logical forms for the largest subspans for which a logical form existed. To avoid trivial cases, we only annotated logical forms containing at least one category or relation predicate and at least one mention. We also chose not to annotate mentions of entities that are not in the knowledge base, as no system would be able to correctly identify them. The corpus contains 97 sentences with 100 annotated logical forms.

We measured performance using two metrics: logical form accuracy, and extraction precision/recall. Logical form accuracy examines the predicted logical form for the smallest subspan of the sentence containing the annotated span, and marks this prediction correct if it exactly matches the annotation. A limitation of this metric is that it does not assign partial credit to logical forms that are close to, but do not exactly match, the annotation. The extraction metric assigns partial credit by computing the precision and recall of the category and relation instances entailed by the predicted logical form, using those entailed by the annotated logical form as the gold standard. Figure 4 shows the computation of both error metrics on two examples from the test corpus.

Table 3 shows the results of the annotated sentence evaluation. ASP outperforms both baselines in logical form accuracy and extraction recall, suggesting that it produces more complete analyses than either baseline. The extraction precision of 90% suggests that ASP rarely extracts incorrect information. Precision is higher in this evaluation because every sentence in the data set has at least one correct extraction.

6 Discussion

We present an approach to training a joint syntactic and semantic parser. Our parser ASP produces a full syntactic parse of any sentence, while simultaneously producing logical forms for sentence spans that have a semantic representation within its predicate vocabulary. The parser is trained by jointly optimizing performance on a syntactic parsing task and a distantly-supervised relation extraction task. Experimental results demonstrate that jointly analyzing syntax and semantics triples the number of extracted logical forms over approaches that first analyze syntax, then semantics. However, we also find that incorporating semantics slightly reduces syntactic parsing performance. Poor entity mention detection is a major source of error in both cases, suggesting that future work should consider integrating entity linking with joint syntactic and semantic parsing.

Abstract

Semantic hierarchy construction aims to build structures of concepts linked by hypernym–hyponym ("is-a") relations. A major challenge for this task is the automatic discovery of such relations. This paper proposes a novel and effective method for the construction of semantic hierarchies based on word embeddings, which can be used to measure the semantic relationship between words. We identify whether a candidate word pair has hypernym–hyponym relation by using the word-embedding-based semantic projections between words and their hypernyms. Our result, an F-score of 73.74%, outperforms the state-of-the-art methods on a manually labeled test dataset. Moreover, combining our method with a previous manually-built hierarchy extension method can further improve F-score to 80.29%.

1 Introduction

Semantic hierarchies are natural ways to organize knowledge. They are the main components of ontologies or semantic thesauri (Miller, 1995; Suchanek et al., 2008). In the WordNet hierarchy, senses are organized according to the "is-a" relations. For example, "dog" and "canine" are connected by a directed edge. Here, "canine" is called a hypernym of "dog." Conversely, "dog" is a hyponym of "canine." As key sources of knowledge, semantic thesauri and ontologies can support many natural language processing applications. However, these semantic resources are limited in its scope and domain, and their manual construction is knowledge intensive and time consuming. Therefore, many researchers have attempted to automatically extract semantic relations or to construct taxonomies.

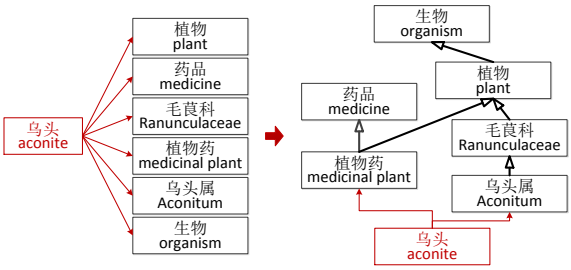

Figure 1: An example of semantic hierarchy construction.

A major challenge for this task is the automatic discovery of hypernym-hyponym relations. Fu et al. (2013) propose a distant supervision method to extract hypernyms for entities from multiple sources. The output of their model is a list of hypernyms for a given enity (left panel, Figure 1). However, there usually also exists hypernym–hyponym relations among these hypernyms. For instance, "植物 (plant)" and "毛茛科 (Ranunculaceae)" are both hypernyms of the entity "乌头 (aconit)," and "植物 (plant)" is also a hypernym of "毛茛科 (Ranunculaceae)." Given a list of hypernyms of an entity, our goal in the present work is to construct a semantic hierarchy of these hypernyms (right panel, Figure 1).[1]

Some previous works extend and refine manually-built semantic hierarchies by using other resources (e.g., Wikipedia) (Suchanek et al., 2008). However, the coverage is limited by the scope of the resources. Several other works relied heavily on lexical patterns, which would suffer from deficiency because such patterns can only cover a small proportion of complex linguistic circumstances (Hearst, 1992; Snow et al., 2005).

[1]In this study, we focus on Chinese semantic hierarchy construction. The proposed method can be easily adapted to other languages.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1199–1209,
Baltimore, Maryland, USA, June 23-25 2014.

Besides, distributional similarity methods (Kotlerman et al., 2010; Lenci and Benotto, 2012) are based on the assumption that a term can only be used in contexts where its hypernyms can be used and that a term might be used in any contexts where its hyponyms are used. However, it is not always rational. Our previous method based on web mining (Fu et al., 2013) works well for hypernym extraction of entity names, but it is unsuitable for semantic hierarchy construction which involves many words with broad semantics. Moreover, all of these methods do not use the word semantics effectively.

This paper proposes a novel approach for semantic hierarchy construction based on word embeddings. Word embeddings, also known as distributed word representations, typically represent words with dense, low-dimensional and real-valued vectors. Word embeddings have been empirically shown to preserve linguistic regularities, such as the semantic relationship between words (Mikolov et al., 2013b). For example, $v(\texttt{king}) - v(\texttt{queen}) \approx v(\texttt{man}) - v(\texttt{woman})$, where $v(w)$ is the embedding of the word w. We observe that a similar property also applies to the hypernym–hyponym relationship (Section 3.3), which is the main inspiration of the present study.

However, we further observe that hypernym–hyponym relations are more complicated than a single offset can represent. To address this challenge, we propose a more sophisticated and general method — learning a linear projection which maps words to their hypernyms (Section 3.3.1). Furthermore, we propose a piecewise linear projection method based on relation clustering to better model hypernym–hyponym relations (Section 3.3.2). Subsequently, we identify whether an unknown word pair is a hypernym–hyponym relation using the projections (Section 3.4). To the best of our knowledge, we are the first to apply word embeddings to this task.

For evaluation, we manually annotate a dataset containing 418 Chinese entities and their hypernym hierarchies, which is the first dataset for this task as far as we know. The experimental results show that our method achieves an F-score of 73.74% which significantly outperforms the previous state-of-the-art methods. Moreover, combining our method with the manually-built hierarchy extension method proposed by Suchanek et al. (2008) can further improve F-score to 80.29%.

2 Background

As main components of ontologies, semantic hierarchies have been studied by many researchers. Some have established concept hierarchies based on manually-built semantic resources such as WordNet (Miller, 1995). Such hierarchies have good structures and high accuracy, but their coverage is limited to fine-grained concepts (e.g., "Ranunculaceae" is not included in WordNet.). We have made similar obsevation that about a half of hypernym–hyponym relations are absent in a Chinese semantic thesaurus. Therefore, a broader range of resources is needed to supplement the manually built resources. In the construction of the famous ontology YAGO, Suchanek et al. (2008) link the categories in Wikipedia onto WordNet. However, the coverage is still limited by the scope of Wikipedia.

Several other methods are based on lexical patterns. They use manually or automatically constructed lexical patterns to mine hypernym–hyponym relations from text corpora. A hierarchy can then be built based on these pairwise relations. The pioneer work by Hearst (1992) has found out that linking two noun phrases (NPs) via certain lexical constructions often implies hypernym relations. For example, NP_1 is a hypernym of NP_2 in the lexical pattern "such NP_1 as NP_2." Snow et al. (2005) propose to automatically extract large numbers of lexico-syntactic patterns and subsequently detect hypernym relations from a large newswire corpus. Their method relies on accurate syntactic parsers, and the quality of the automatically extracted patterns is difficult to guarantee. Generally speaking, these pattern-based methods often suffer from low recall or precision because of the coverage or the quality of the patterns.

The distributional methods assume that the contexts of hypernyms are broader than the ones of their hyponyms. For distributional similarity computing, each word is represented as a semantic vector composed of the pointwise mutual information (PMI) with its contexts. Kotlerman et al. (2010) design a directional distributional measure to infer hypernym–hyponym relations based on the standard IR Average Precision evaluation measure. Lenci and Benotto (2012) propose another measure focusing on the contexts that hypernyms do not share with their hyponyms. However, broader semantics may not always infer broader contexts. For example, for terms "Obama' and

"American people", it is hard to say whose contexts are broader.

Our previous work (Fu et al., 2013) applies a web mining method to discover the hypernyms of Chinese entities from multiple sources. We assume that the hypernyms of an entity co-occur with it frequently. It works well for named entities. But for class names (e.g., singers in Hong Kong, tropical fruits) with wider range of meanings, this assumption may fail.

In this paper, we aim to identify hypernym–hyponym relations using word embeddings, which have been shown to preserve good properties for capturing semantic relationship between words.

3 Method

In this section, we first define the task formally. Then we elaborate on our proposed method composed of three major steps, namely, word embedding training, projection learning, and hypernym–hyponym relation identification.

3.1 Task Definition

Given a list of hypernyms of an entity, our goal is to construct a semantic hierarchy on it (Figure 1). We represent the hierarchy as a directed graph G, in which the nodes denote the words, and the edges denote the hypernym–hyponym relations. Hypernym-hyponym relations are *asymmetric* and *transitive* when words are unambiguous:

- $\forall x, y \in L : x \xrightarrow{H} y \Rightarrow \neg(y \xrightarrow{H} x)$
- $\forall x, y, z \in L : (x \xrightarrow{H} z \wedge z \xrightarrow{H} y) \Rightarrow x \xrightarrow{H} y$

Here, L denotes the list of hypernyms. x, y and z denote the hypernyms in L. We use $\xrightarrow{H}$ to represent a hypernym–hyponym relation in this paper. Actually, x, y and z are unambiguous as the hypernyms of a certain entity. Therefore, G should be a directed acyclic graph (DAG).

3.2 Word Embedding Training

Various models for learning word embeddings have been proposed, including neural net language models (Bengio et al., 2003; Mnih and Hinton, 2008; Mikolov et al., 2013b) and spectral models (Dhillon et al., 2011). More recently, Mikolov et al. (2013a) propose two log-linear models, namely the *Skip-gram* and *CBOW* model, to efficiently induce word embeddings. These two models can be trained very efficiently on a large-scale corpus because of their low time complexity.

No.	Examples
1	v(虾) − v(对虾) ≈ v(鱼) − v(金鱼) v(shrimp) − v(prawn) ≈ v(fish) − v(gold fish)
2	v(工人) − v(木匠) ≈ v(演员) − v(小丑) v(laborer) − v(carpenter) ≈ v(actor) − v(clown)
3	v(工人) − v(木匠) $\not\approx$ v(鱼) − v(金鱼) v(laborer) − v(carpenter) $\not\approx$ v(fish) − v(gold fish)

Table 1: Embedding offsets on a sample of hypernym–hyponym word pairs.

Additionally, their experiment results have shown that the *Skip-gram* model performs best in identifying semantic relationship among words. Therefore, we employ the *Skip-gram* model for estimating word embeddings in this study.

The *Skip-gram* model adopts log-linear classifiers to predict context words given the current word $\mathbf{w}(t)$ as input. First, $\mathbf{w}(t)$ is projected to its embedding. Then, log-linear classifiers are employed, taking the embedding as input and predict $\mathbf{w}(t)$'s context words within a certain range, e.g. k words in the left and k words in the right. After maximizing the log-likelihood over the entire dataset using stochastic gradient descent (SGD), the embeddings are learned.

3.3 Projection Learning

Mikolov et al. (2013b) observe that word embeddings preserve interesting linguistic regularities, capturing a considerable amount of syntactic/semantic relations. Looking at the well-known example: $v(\texttt{king}) - v(\texttt{queen}) \approx v(\texttt{man}) - v(\texttt{woman})$, it indicates that the embedding offsets indeed represent the shared semantic relation between the two word pairs.

We observe that the same property also applies to some hypernym–hyponym relations. As a preliminary experiment, we compute the embedding offsets between some randomly sampled hypernym–hyponym word pairs and measure their similarities. The results are shown in Table 1.

The first two examples imply that a word can also be mapped to its hypernym by utilizing word embedding offsets. However, the offset from "carpenter" to "laborer" is distant from the one from "gold fish" to "fish," indicating that hypernym–hyponym relations should be more complicated than a single vector offset can represent. To verify this hypothesis, we compute the embedding offsets over all hypernym–

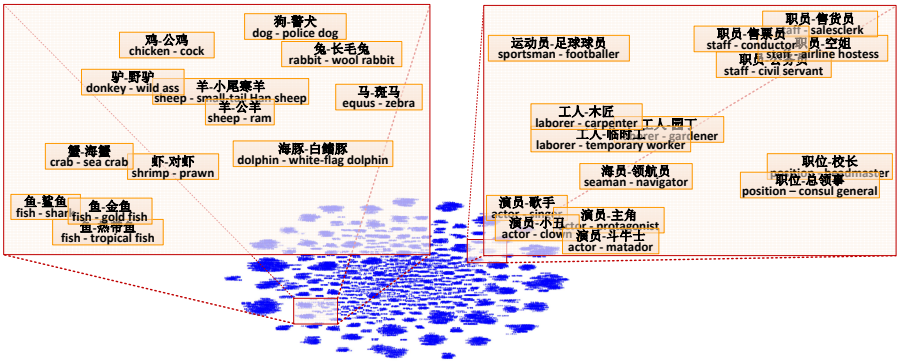

Figure 2: Clusters of the vector offsets in training data. The figure shows that the vector offsets distribute in some clusters. The left cluster shows some hypernym–hyponym relations about animals. The right one shows some relations about people's occupations.

hyponym word pairs in our training data and visualize them.[2] Figure 2 shows that the relations are adequately distributed in the clusters, which implies that hypernym–hyponym relations indeed can be decomposed into more fine-grained relations. Moreover, the relations about animals are spatially close, but separate from the relations about people's occupations.

To address this challenge, we propose to learn the hypernym–hyponym relations using projection matrices.

3.3.1 A Uniform Linear Projection

Intuitively, we assume that all words can be projected to their hypernyms based on a uniform transition matrix. That is, given a word x and its hypernym y, there exists a matrix Φ so that $y = \Phi x$. For simplicity, we use the same symbols as the words to represent the embedding vectors. Obtaining a consistent exact Φ for the projection of all hypernym–hyponym pairs is difficult. Instead, we can learn an approximate Φ using Equation 1 on the training data, which minimizes the mean-squared error:

$$\Phi^* = \arg\min_{\Phi} \frac{1}{N} \sum_{(x,y)} \| \Phi x - y \|^2 \qquad (1)$$

where N is the number of (x, y) word pairs in the training data. This is a typical linear regression problem. The only difference is that our predictions are multi-dimensional vectors instead of scalar values. We use SGD for optimization.

[2]Principal Component Analysis (PCA) is applied for dimensionality reduction.

3.3.2 Piecewise Linear Projections

A uniform linear projection may still be underrepresentative for fitting all of the hypernym–hyponym word pairs, because the relations are rather diverse, as shown in Figure 2. To better model the various kinds of hypernym–hyponym relations, we apply the idea of piecewise linear regression (Ritzema, 1994) in this study.

Specifically, the input space is first segmented into several regions. That is, all word pairs (x, y) in the training data are first clustered into several groups, where word pairs in each group are expected to exhibit similar hypernym–hyponym relations. Each word pair (x, y) is represented with their vector offsets: $y - x$ for clustering. The reasons are twofold: (1) Mikolov's work has shown that the vector offsets imply a certain level of semantic relationship. (2) The vector offsets distribute in clusters well, and the word pairs which are close indeed represent similar relations, as shown in Figure 2.

Then we learn a separate projection for each cluster, respectively (Equation 2).

$$\Phi_k^* = \arg\min_{\Phi_k} \frac{1}{N_k} \sum_{(x,y)\in C_k} \| \Phi_k x - y \|^2 \qquad (2)$$

where N_k is the amount of word pairs in the k^{th} cluster C_k.

We use the k-means algorithm for clustering, where k is tuned on a development dataset.

3.3.3 Training Data

To learn the projection matrices, we extract training data from a Chinese semantic thesaurus, Tongyi Cilin (Extended) (CilinE for short) which

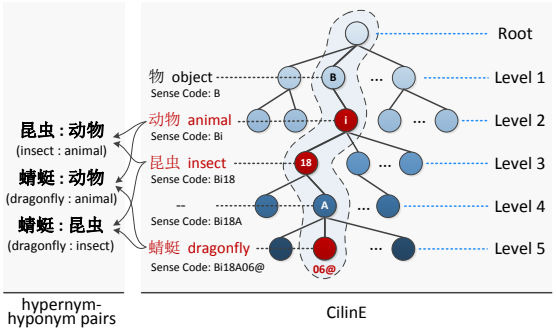

Figure 3: Hierarchy of CilinE and an Example of Training Data Generation

contains 100,093 words (Che et al., 2010).[3] CilinE is organized as a hierarchy of five levels, in which the words are linked by hypernym–hyponym relations (right panel, Figure 3). Each word in CilinE has one or more sense codes (some words are polysemous) that indicate its position in the hierarchy.

The senses of words in the first level, such as "物 (`object`)" and "时间 (`time`)," are very general. The fourth level only has sense codes without real words. Therefore, we extract words in the second, third and fifth levels to constitute hypernym–hyponym pairs (left panel, Figure 3).

Note that mapping one hyponym to multiple hypernyms with the same projection (Φx is unique) is difficult. Therefore, the pairs with the same hyponym but different hypernyms are expected to be clustered into separate groups. Figure 3 shows that the word "`dragonfly`" in the fifth level has two hypernyms: "`insect`" in the third level and "`animal`" in the second level. Hence the relations `dragonfly` $\xrightarrow{H}$ `insect` and `dragonfly` $\xrightarrow{H}$ `animal` should fall into different clusters.

In our implementation, we apply this constraint by simply dividing the training data into two categories, namely, *direct* and *indirect*. Hypernym-hyponym word pair (x, y) is classified into the *direct* category, only if there doesn't exist another word z in the training data, which is a hypernym of x and a hyponym of y. Otherwise, (x, y) is classified into the *indirect* category. Then, data in these two categories are clustered separately.

[3] `www.ltp-cloud.com/download/`

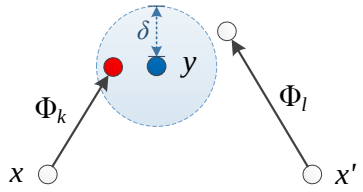

Figure 4: In this example, $\Phi_k x$ is located in the circle with center y and radius δ. So y is considered as a hypernym of x. Conversely, y is not a hypernym of x'.

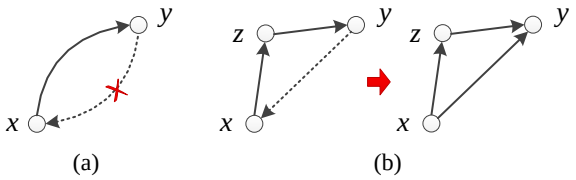

Figure 5: (a) If $d(\Phi_j y, x) > d(\Phi_k x, y)$, we remove the path from y to x; (b) if $d(\Phi_j y, x) > d(\Phi_k x, z)$ and $d(\Phi_j y, x) > d(\Phi_i z, y)$, we reverse the path from y to x.

3.4 Hypernym-hyponym Relation Identification

Upon obtaining the clusters of training data and the corresponding projections, we can identify whether two words have a hypernym–hyponym relation. Given two words x and y, we find cluster C_k whose center is closest to the offset $y - x$, and obtain the corresponding projection Φ_k. For y to be considered a hypernym of x, one of the two conditions below must hold.

Condition 1: The projection Φ_k puts $\Phi_k x$ close enough to y (Figure 4). Formally, the euclidean distance between $\Phi_k x$ and y: $d(\Phi_k x, y)$ must be less than a threshold δ.

$$d(\Phi_k x, y) = \| \Phi_k x - y \|^2 < \delta \qquad (3)$$

Condition 2: There exists another word z satisfying $x \xrightarrow{H} z$ and $z \xrightarrow{H} y$. In this case, we use the transitivity of hypernym–hyponym relations.

Besides, the final hierarchy should be a DAG as discussed in Section 3.1. However, the projection method cannot guarantee that theoretically, because the projections are learned from pairwise hypernym–hyponym relations without the whole hierarchy structure. All pairwise hypernym–hyponym relation identification methods would suffer from this problem actually. It is an interesting problem how to construct a globally opti-

mal semantic hierarchy conforming to the form of a DAG. But this is not the focus of this paper. So if some conflicts occur, that is, a relation circle exists, we remove or reverse the weakest path heuristically (Figure 5). If a circle has only two nodes, we remove the weakest path. If a circle has more than two nodes, we reverse the weakest path to form an *indirect* hypernym–hyponym relation.

4 Experimental Setup

4.1 Experimental Data

In this work, we learn word embeddings from a Chinese encyclopedia corpus named Baidubaike[4], which contains about 30 million sentences (about 780 million words). The Chinese segmentation is provided by the open-source Chinese language processing platform LTP[5] (Che et al., 2010). Then, we employ the *Skip-gram* method (Section 3.2) to train word embeddings. Finally we obtain the embedding vectors of 0.56 million words.

The training data for projection learning is collected from CilinE (Section 3.3.3). We obtain 15,247 word pairs of hypernym–hyponym relations (9,288 for *direct* relations and 5,959 for *indirect* relations).

For evaluation, we collect the hypernyms for 418 entities, which are selected randomly from Baidubaike, following Fu et al. (2013). We then ask two annotators to manually label the semantic hierarchies of the correct hypernyms. The final data set contains 655 unique hypernyms and 1,391 hypernym–hyponym relations among them. We randomly split the labeled data into 1/5 for development and 4/5 for testing (Table 2). The hierarchies are represented as relations of pairwise words. We measure the inter-annotator agreement using the kappa coefficient (Siegel and Castellan Jr, 1988). The kappa value is 0.96, which indicates a good strength of agreement.

4.2 Evaluation Metrics

We use precision, recall, and F-score as our metrics to evaluate the performances of the methods.

Since hypernym–hyponym relations and its reverse (hyponym–hypernym) have one-to-one correspondence, their performances are equal. For simplicity, we only report the performance of the former in the experiments.

[4]Baidubaike (baike.baidu.com) is one of the largest Chinese encyclopedias containing more than 7.05 million entries as of September, 2013.

[5]www.ltp-cloud.com/demo/

Relation	# of word pairs	
	Dev.	Test
hypernym–hyponym	312	1,079
hyponym–hypernym*	312	1,079
unrelated	1,044	3,250
Total	1,668	5,408

Table 2: The evaluation data. *Since hypernym–hyponym relations and hyponym–hypernym relations have one-to-one correspondence, their numbers are the same.

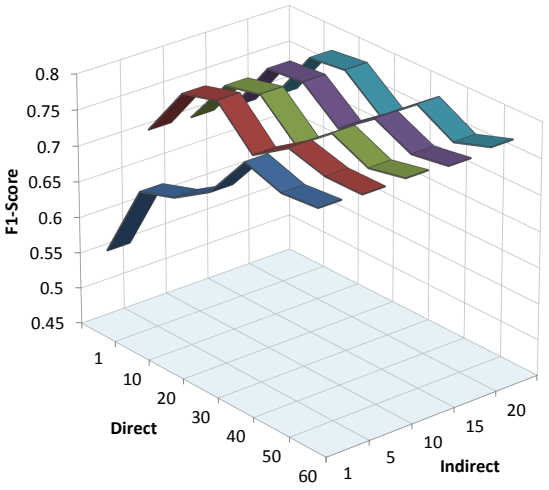

Figure 6: Performance on development data w.r.t. cluster size.

5 Results and Analysis

5.1 Varying the Amount of Clusters

We first evaluate the effect of different number of clusters based on the development data. We vary the numbers of the clusters both for the *direct* and *indirect* training word pairs.

As shown in Figure 6, the performance of clustering is better than non-clustering (when the cluster number is 1), thus providing evidences that learning piecewise projections based on clustering is reasonable. We finally set the numbers of the clusters of *direct* and *indirect* to 20 and 5, respectively, where the best performances are achieved on the development data.

5.2 Comparison with Previous Work

In this section, we compare the proposed method with previous methods, including manually-built hierarchy extension, pairwise relation extraction

	P(%)	R(%)	F(%)
$M_{Wiki+CilinE}$	92.41	60.61	73.20
$M_{Pattern}$	97.47	21.41	35.11
M_{Snow}	60.88	25.67	36.11
$M_{balApinc}$	54.96	53.38	54.16
M_{invCL}	49.63	62.84	55.46
M_{Fu}	87.40	48.19	62.13
M_{Emb}	80.54	67.99	**73.74**
$M_{Emb+CilinE}$	80.59	72.42	76.29
$M_{Emb+Wiki+CilinE}$	79.78	80.81	**80.29**

Table 3: Comparison of the proposed method with existing methods in the test set.

Pattern	Translation
w 是[一个|一种] h	w is a [a kind of] h
w [、] 等 h	w[,] and other h
h [，] 叫[做] w	h[,] called w
h [，] [像]如 w	h[,] such as w
h [，] 特别是 w	h[,] especially w

Table 4: Chinese Hearst-style lexical patterns. The contents in square brackets are omissible.

based on patterns, word distributions, and web mining (Section 2). Results are shown in Table 3.

5.2.1 Overall Comparison

$M_{Wiki+CilinE}$ refers to the manually-built hierarchy extension method of Suchanek et al. (2008). In our experiment, we use the category taxonomy of Chinese Wikipedia[6] to extend CilinE. Table 3 shows that this method achieves a high precision but also a low recall, mainly because of the limited scope of Wikipedia.

$M_{Pattern}$ refers to the pattern-based method of Hearst (1992). We extract hypernym–hyponym relations in the Baidubaike corpus, which is also used to train word embeddings (Section 4.1). We use the Chinese Hearst-style patterns (Table 4) proposed by Fu et al. (2013), in which w represents a word, and h represents one of its hypernyms. The result shows that only a small part of the hypernyms can be extracted based on these patterns because only a few hypernym relations are expressed in these fixed patterns, and many are expressed in highly flexible manners.

In the same corpus, we apply the method M_{Snow} originally proposed by Snow et al. (2005). The same training data for projections learning from CilinE (Section 3.3.3) is used as seed hypernym–hyponym pairs. Lexico-syntactic patterns are extracted from the Baidubaike corpus by using the seeds. We then develop a logistic regression classifier based on the patterns to recognize hypernym–hyponym relations. This method relies on an accurate syntactic parser, and the quality of the automatically extracted patterns is difficult to guarantee.

We re-implement two previous distributional methods $M_{balApinc}$ (Kotlerman et al., 2010) and M_{invCL} (Lenci and Benotto, 2012) in the Baidubaike corpus. Each word is represented as a feature vector in which each dimension is the PMI value of the word and its context words. We compute a score for each word pair and apply a threshold to identify whether it is a hypernym–hyponym relation.

M_{Fu} refers to our previous web mining method (Fu et al., 2013). This method mines hypernyms of a given word w from multiple sources and returns a ranked list of the hypernyms. We select the hypernyms with scores over a threshold of each word in the test set for evaluation. This method assumes that frequent co-occurrence of a noun or noun phrase n in multiple sources with w indicate possibility of n being a hypernym of w. The results presented in Fu et al. (2013) show that the method works well when w is an entity, but not when w is a word with a common semantic concept. The main reason may be that there are relatively more introductory pages about entities than about common words in the Web.

M_{Emb} is the proposed method based on word embeddings. Table 3 shows that the proposed method achieves a better recall and F-score than all of the previous methods do. It can significantly ($p < 0.01$) improve the F-score over the state-of-the-art method $M_{Wiki+CilinE}$.

M_{Emb} and M_{CilinE} can also be combined. The combination strategy is to simply merge all positive results from the two methods together, and then to infer new relations based on the transitivity of hypernym–hyponym relations. The F-score is further improved from 73.74% to 76.29%. Note that, the combined method achieves a 4.43% recall improvement over M_{Emb}, but the precision is almost unchanged. The reason is that the inference based on the relations identified automatically may lead to error propagation. For example, the relation $x \xrightarrow{H} y$ is incorrectly identified by M_{Emb}.

[6] dumps.wikimedia.org/zhwiki/20131205/

	P(%)	R(%)	F(%)
$M_{Wiki+CilinE}$	80.39	19.29	31.12
$M_{Emb+CilinE}$	71.16	52.80	60.62
$M_{Emb+Wiki+CilinE}$	69.13	61.65	**65.17**

Table 5: Performance on the out-of-CilinE data in the test set.

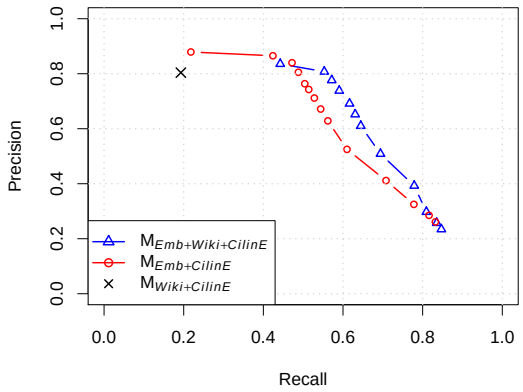

Figure 7: Precision-Recall curves on the out-of-CilinE data in the test set.

When the relation $y \xrightarrow{H} z$ from M_{CilinE} is added, it will cause a new incorrect relation $x \xrightarrow{H} z$.

Combining M_{Emb} with $M_{Wiki+CilinE}$ achieves a 7% F-score improvement over the best baseline $M_{Wiki+CilinE}$. Therefore, the proposed method is complementary to the manually-built hierarchy extension method (Suchanek et al., 2008).

5.2.2 Comparison on the Out-of-CilinE Data

We are greatly interested in the practical performance of the proposed method on the hypernym–hyponym relations outside of CilinE. We say a word pair is outside of CilinE, as long as there is one word in the pair not existing in CilinE. In our test data, about 62% word pairs are outside of CilinE. Table 5 shows the performances of the best baseline method and our method on the out-of-CilinE data. The method exploiting the taxonomy in Wikipedia, $M_{Wiki+CilinE}$, achieves the highest precision but has a low recall. By contrast, our method can discover more hypernym–hyponym relations with some loss of precision, thereby achieving a more than 29% F-score improvement. The combination of these two methods achieves a further 4.5% F-score improvement over $M_{Emb+CilinE}$. Generally speaking, the proposed method greatly improves the recall but damages the precision.

Actually, we can get different precisions and recalls by adjusting the threshold δ (Equation 3). Figure 7 shows that $M_{Emb+CilinE}$ achieves a higher precision than $M_{Wiki+CilinE}$ when their recalls are the same. When they achieve the same precision, the recall of $M_{Emb+CilinE}$ is higher.

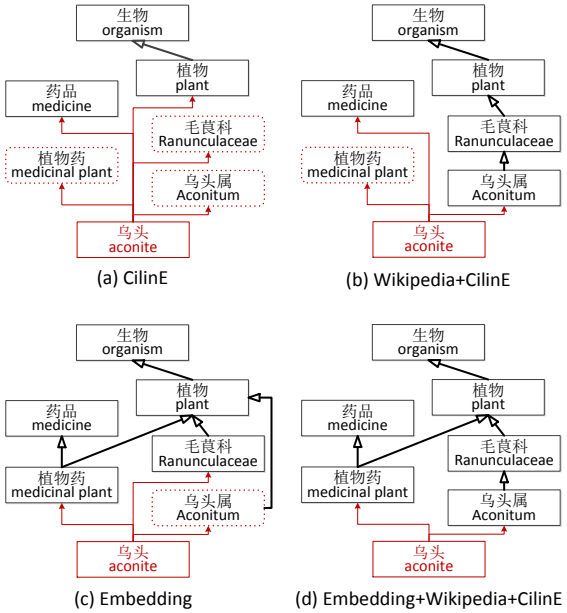

Figure 8: An example for error analysis. The red paths refer to the relations between the named entity and its hypernyms extracted using the web mining method (Fu et al., 2013). The black paths with hollow arrows denote the relations identified by the different methods. The boxes with dotted borders refer to the concepts which are not linked to correct positions.

5.3 Error Analysis and Discussion

We analyze error cases after experiments. Some cases are shown in Figure 8. We can see that there is only one general relation "植物 (plant)" $\xrightarrow{H}$ "生物 (organism)" existing in CilinE. Some fine-grained relations exist in Wikipedia, but the coverage is limited. Our method based on word embeddings can discover more hypernym–hyponym relations than the previous methods can. When we combine the methods together, we get the correct hierarchy.

Figure 8 shows that our method loses the relation "乌头属 (Aconitum)" $\xrightarrow{H}$ "毛茛科 (Ranunculaceae)." It is because they are very semantically similar (their cosine similarity is 0.9038). Their representations are so close to each other in the embedding space that we have not find projections suitable for these pairs. The

error statistics show that when the cosine similarities of word pairs are greater than 0.8, the recall is only 9.5%. This kind of error accounted for about 10.9% among all the errors in our test set. One possible solution may be adding more data of this kind to the training set.

6 Related Work

In addition to the works mentioned in Section 2, we introduce another set of related studies in this section.

Evans (2004), Ortega-Mendoza et al. (2007), and Sang (2007) consider web data as a large corpus and use search engines to identify hypernyms based on the lexical patterns of Hearst (1992). However, the low quality of the sentences in the search results negatively influence the precision of hypernym extraction.

Following the method for discovering patterns automatically (Snow et al., 2005), McNamee et al. (2008) apply the same method to extract hypernyms of entities in order to improve the performance of a question answering system. Ritter et al. (2009) propose a method based on patterns to find hypernyms on arbitrary noun phrases. They use a support vector machine classifier to identify the correct hypernyms from the candidates that match the patterns. As our experiments show, pattern-based methods suffer from low recall because of the low coverage of patterns.

Besides Kotlerman et al. (2010) and Lenci and Benotto (2012), other researchers also propose directional distributional similarity methods (Weeds et al., 2004; Geffet and Dagan, 2005; Bhagat et al., 2007; Szpektor et al., 2007; Clarke, 2009). However, their basic assumption that a hyponym can only be used in contexts where its hypernyms can be used and that a hypernym might be used in all of the contexts where its hyponyms are used may not always rational.

Snow et al. (2006) provides a global optimization scheme for extending WordNet, which is different from the above-mentioned pairwise relationships identification methods.

Word embeddings have been successfully applied in many applications, such as in sentiment analysis (Socher et al., 2011b), paraphrase detection (Socher et al., 2011a), chunking, and named entity recognition (Turian et al., 2010; Collobert et al., 2011). These applications mainly utilize the representing power of word embeddings to alleviate the problem of data sparsity. Mikolov et al. (2013a) and Mikolov et al. (2013b) further observe that the semantic relationship of words can be induced by performing simple algebraic operations with word vectors. Their work indicates that word embeddings preserve some interesting linguistic regularities, which might provide support for many applications. In this paper, we improve on their work by learning multiple linear projections in the embedding space, to model hypernym–hyponym relationships within different clusters.

7 Conclusion and Future Work

This paper proposes a novel method for semantic hierarchy construction based on word embeddings, which are trained using a large-scale corpus. Using the word embeddings, we learn the hypernym–hyponym relationship by estimating projection matrices which map words to their hypernyms. Further improvements are made using a cluster-based approach in order to model the more fine-grained relations. Then we propose a few simple criteria to identity whether a new word pair is a hypernym–hyponym relation. Based on the pairwise hypernym–hyponym relations, we build semantic hierarchies automatically.

In our experiments, the proposed method significantly outperforms state-of-the-art methods and achieves the best F1-score of 73.74% on a manually labeled test dataset. Further experiments show that our method is complementary to the previous manually-built hierarchy extension methods.

For future work, we aim to improve word embedding learning under the guidance of hypernym–hyponym relations. By including the hypernym–hyponym relation constraints while training word embeddings, we expect to improve the embeddings such that they become more suitable for this task.

Probabilistic Soft Logic for Semantic Textual Similarity

Islam Beltagy[§] **Katrin Erk**[†] **Raymond Mooney**[§]

Abstract

Probabilistic Soft Logic (PSL) is a recently developed framework for probabilistic logic. We use PSL to combine logical and distributional representations of natural-language meaning, where distributional information is represented in the form of weighted inference rules. We apply this framework to the task of Semantic Textual Similarity (STS) (i.e. judging the semantic similarity of natural-language sentences), and show that PSL gives improved results compared to a previous approach based on Markov Logic Networks (MLNs) and a purely distributional approach.

1 Introduction

When will people say that two sentences are similar? This question is at the heart of the Semantic Textual Similarity task (STS)(Agirre et al., 2012). Certainly, if two sentences contain many of the same words, or many similar words, that is a good indication of sentence similarity. But that can be misleading. A better characterization would be to say that if two sentences use the same or similar words *in the same or similar relations*, then those two sentences will be judged similar.[1] Interestingly, this characterization echoes the principle of compositionality, which states that the meaning of a phrase is uniquely determined by the meaning of its parts and the rules that connect those parts.

Beltagy et al. (2013) proposed a hybrid approach to sentence similarity: They use a very deep representation of sentence meaning, expressed in first-order logic, to capture sentence structure, but combine it with distributional similarity ratings at the word and phrase level. Sentence similarity is then modelled as mutual entailment in a probabilistic logic. This approach is interesting in that it uses a very deep and precise representation of meaning, which can then be relaxed in a controlled fashion using distributional similarity. But the approach faces large hurdles in practice, stemming from efficiency issues with the Markov Logic Networks (MLN) (Richardson and Domingos, 2006) that they use for performing probabilistic logical inference.

In this paper, we use the same combined logic-based and distributional framework as Beltagy et al., (2013) but replace Markov Logic Networks with Probabilistic Soft Logic (PSL) (Kimmig et al., 2012; Bach et al., 2013). PSL is a probabilistic logic framework designed to have efficient inference. Inference in MLNs is theoretically intractable in the general case, and existing approximate inference algorithms are computationally expensive and sometimes inaccurate. Consequently, the MLN approach of Beltagy et al. (2013) was unable to scale to long sentences and was only tested on the relatively short sentences in the Microsoft video description corpus used for STS (Agirre et al., 2012). On the other hand, inference in PSL reduces to a linear programming problem, which is theoretically and practically much more efficient. Empirical results on a range of problems have confirmed that inference in PSL is much more efficient than in MLNs, and frequently more accurate (Kimmig et al., 2012; Bach et al., 2013).

We show how to use PSL for STS, and describe changes to the PSL framework that make it more effective for STS. For evaluation, we test on three STS datasets, and compare our PSL system with the MLN approach of Beltagy et al., (2013) and with distributional-only baselines. Experimental

[1] Mitchell and Lapata (2008) give an amusing example of two sentences that consist of all the same words, but are very different in their meaning: (a) It was not the sales manager who hit the bottle that day, but the office worker with the serious drinking problem. (b) That day the office manager, who was drinking, hit the problem sales worker with a bottle, but it was not serious.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1210–1219,
Baltimore, Maryland, USA, June 23-25 2014.

results demonstrate that, overall, PSL models human similarity judgements more accurately than these alternative approaches, and is significantly faster than MLNs.

The rest of the paper is organized as follows: section 2 presents relevant background material, section 3 explains how we adapted PSL for the STS task, section 4 presents the evaluation, and sections 5 and 6 discuss future work and conclusions, respectively.

2 Background

2.1 Logical Semantics

Logic-based representations of meaning have a long tradition (Montague, 1970; Kamp and Reyle, 1993). They handle many complex semantic phenomena such as relational propositions, logical operators, and quantifiers; however, their binary nature prevents them from capturing the "graded" aspects of meaning in language. Also, it is difficult to construct formal ontologies of properties and relations that have broad coverage, and semantically parsing sentences into logical expressions utilizing such an ontology is very difficult. Consequently, current semantic parsers are mostly restricted to quite limited domains, such as querying a specific database (Kwiatkowski et al., 2013; Berant et al., 2013). In contrast, our system is not limited to any formal ontology and can use a wide-coverage tool for semantic analysis, as discussed below.

2.2 Distributional Semantics

Distributional models (Turney and Pantel, 2010), on the other hand, use statistics on contextual data from large corpora to predict semantic similarity of words and phrases (Landauer and Dumais, 1997; Mitchell and Lapata, 2010). They are relatively easier to build than logical representations, automatically acquire knowledge from "big data," and capture the "graded" nature of linguistic meaning, but do not adequately capture logical structure (Grefenstette, 2013).

Distributional models are motivated by the observation that semantically similar words occur in similar contexts, so words can be represented as vectors in high dimensional spaces generated from the contexts in which they occur (Landauer and Dumais, 1997; Lund and Burgess, 1996). Such models have also been extended to compute vector representations for larger phrases, e.g. by adding the vectors for the individual words (Landauer and Dumais, 1997) or by a component-wise product of word vectors (Mitchell and Lapata, 2008; Mitchell and Lapata, 2010), or more complex methods that compute phrase vectors from word vectors and tensors (Baroni and Zamparelli, 2010; Grefenstette and Sadrzadeh, 2011). We use vector addition (Landauer and Dumais, 1997), and component-wise product (Mitchell and Lapata, 2008) as baselines for STS. Vector addition was previously found to be the best performing simple distributional method for STS (Beltagy et al., 2013).

2.3 Markov Logic Networks

Markov Logic Networks (MLN) (Richardson and Domingos, 2006) are a framework for probabilistic logic that employ weighted formulas in first-order logic to compactly encode complex undirected probabilistic graphical models (i.e., Markov networks). Weighting the rules is a way of softening them compared to hard logical constraints and thereby allowing situations in which not all clauses are satisfied. MLNs define a probability distribution over possible worlds, where a world's probability increases exponentially with the total weight of the logical clauses that it satisfies. A variety of inference methods for MLNs have been developed, however, developing a scalable, general-purpose, accurate inference method for complex MLNs is an open problem. Beltagy et al. (2013) use MLNs to represent the meaning of natural language sentences and judge textual entailment and semantic similarity, but they were unable to scale the approach beyond short sentences due to the complexity of MLN inference.

2.4 Probabilistic Soft Logic

Probabilistic Soft Logic (PSL) is a recently proposed alternative framework for probabilistic logic (Kimmig et al., 2012; Bach et al., 2013). It uses logical representations to compactly define large graphical models with continuous variables, and includes methods for performing efficient probabilistic inference for the resulting models. A key distinguishing feature of PSL is that ground atoms have soft, continuous truth values in the interval [0, 1] rather than binary truth values as used in MLNs and most other probabilistic logics. Given a set of weighted logical formulas, PSL builds a graphical model defining a probability distribution over the continuous space of values of the random variables in the model.

A PSL model is defined using a set of weighted if-then rules in first-order logic, as in the following example:

$$\forall x, y, z.\ friend(x, y) \wedge votesFor(y, z) \rightarrow votesFor(x, z) \mid 0.3 \quad (1)$$

$$\forall x, y, z.\ spouse(x, y) \wedge votesFor(y, z) \rightarrow votesFor(x, z) \mid 0.8 \quad (2)$$

In our notation, we use lower case letters like x, y, z to represent variables and upper case letters for constants. The first rule states that a person is likely to vote for the same person as his/her friend. The second rule encodes the same regularity for a person's spouse. The weights encode the knowledge that a spouse's influence is greater than a friend's in this regard.

In addition, PSL includes *similarity functions*. Similarity functions take two strings or two sets as input and return a truth value in the interval [0, 1] denoting the similarity of the inputs. For example, in our application, we generate inference rules that incorporate the similarity of two predicates. This can be represented in PSL as:

$$\forall x.\ similarity(\text{“}predicate1\text{”}, \text{“}predicate2\text{”}) \wedge predicate1(x) \rightarrow predicate2(x)$$

As mentioned above, each ground atom, a, has a soft truth value in the interval [0, 1], which is denoted by $I(a)$. To compute soft truth values for logical formulas, Lukasiewicz's relaxation of conjunctions($\wedge$), disjunctions($\vee$) and negations($\neg$) are used:

$$I(l_1 \wedge l_1) = max\{0, I(l_1) + I(l_2) - 1\}$$
$$I(l_1 \vee l_1) = min\{I(l_1) + I(l_2), 1\}$$
$$I(\neg l_1) = 1 - I(l_1)$$

Then, a given rule $r \equiv r_{body} \rightarrow r_{head}$, is said to be *satisfied* (i.e. $I(r) = 1$) iff $I(r_{body}) \leq I(r_{head})$. Otherwise, PSL defines a *distance to satisfaction* $d(r)$ which captures how far a rule r is from being satisfied: $d(r) = max\{0, I(r_{body}) - I(r_{head})\}$. For example, assume we have the set of evidence: $I(spouse(B, A)) = 1$, $I(votesFor(A, P)) = 0.9$, $I(votesFor(B, P)) = 0.3$, and that r is the resulting ground instance of rule (2). Then $I(spouse(B, A) \wedge votesFor(A, P)) = max\{0, 1 + 0.9 - 1\} = 0.9$, and $d(r) = max\{0, 0.9 - 0.3\} = 0.6$.

Using *distance to satisfaction*, PSL defines a probability distribution over all possible interpretations I of all ground atoms. The pdf is defined as follows:

$$p(I) = \frac{1}{Z} \exp\left[-\sum_{r \in R} \lambda_r (d(r))^p\right]; \quad (3)$$

$$Z = \int_I \exp\left[-\sum_{r \in R} \lambda_r (d(r))^p\right]$$

where Z is the normalization constant, λ_r is the weight of rule r, R is the set of all rules, and $p \in \{1, 2\}$ provides two different loss functions. For our application, we always use $p = 1$

PSL is primarily designed to support MPE inference (Most Probable Explanation). MPE inference is the task of finding the overall interpretation with the maximum probability given a set of evidence. Intuitively, the interpretation with the highest probability is the interpretation with the lowest distance to satisfaction. In other words, it is the interpretation that tries to satisfy all rules as much as possible. Formally, from equation 3, the most probable interpretation, is the one that minimizes $\sum_{r \in R} \lambda_r (d(r))^p$. In case of $p = 1$, and given that all $d(r)$ are linear equations, then minimizing the sum requires solving a linear program, which, compared to inference in other probabilistic logics such as MLNs, can be done relatively efficiently using well-established techniques. In case $p = 2$, MPE inference can be shown to be a second-order cone program (SOCP) (Kimmig et al., 2012).

2.5 Semantic Textual Similarity

Semantic Textual Similarity (STS) is the task of judging the similarity of a pair of sentences on a scale from 0 to 5, and was recently introduced as a SemEval task (Agirre et al., 2012). Gold standard scores are averaged over multiple human annotations and systems are evaluated using the Pearson correlation between a system's output and gold standard scores. The best performing system in 2012's competition was by Bär et al. (2012), a complex ensemble system that integrates many techniques including string similarity, n-gram overlap, WordNet similarity, vector space similarity and MT evaluation metrics. Two of the datasets we use for evaluation are from the 2012 competition. We did not utilize the new datasets added in the 2013 competition since they did not contain naturally-occurring, full sentences, which is the focus of our work.

2.6 Combining logical and distributional methods using probabilistic logic

There are a few recent attempts to combine logical and distributional representations in order to obtain the advantages of both. Lewis and Steedman (2013) use distributional information to determine word senses, but still produce a strictly logical semantic representation that does not address the "graded" nature of linguistic meaning that is important to measuring semantic similarity.

Garrette et al. (2011) introduced a framework for combining logic and distributional models using probabilistic logic. Distributional similarity between pairs of words is converted into weighted inference rules that are added to the logical representation, and Markov Logic Networks are used to perform probabilistic logical inference.

Beltagy et al. (2013) extended this framework by generating distributional inference rules from phrase similarity and tailoring the system to the STS task. STS is treated as computing the probability of two textual entailments $T \models H$ and $H \models T$, where T and H are the two sentences whose similarity is being judged. These two entailment probabilities are averaged to produce a measure of similarity. The MLN constructed to determine the probability of a given entailment includes the logical forms for both T and H as well as soft inference rules that are constructed from distributional information. Given a similarity score for all pairs of sentences in the dataset, a regressor is trained on the training set to map the system's output to the gold standard scores. The trained regressor is applied to the scores in the test set before calculating Pearson correlation. The regression algorithm used is Additive Regression (Friedman, 2002).

To determine an entailment probability, first, the two sentences are mapped to logical representations using Boxer (Bos, 2008), a tool for wide-coverage semantic analysis that maps a CCG (Combinatory Categorial Grammar) parse into a lexically-based logical form. Boxer uses C&C for CCG parsing (Clark and Curran, 2004).

Distributional semantic knowledge is then encoded as weighted inference rules in the MLN. A rule's weight (w) is a function of the cosine similarity (sim) between its antecedent and consequent. Rules are generated on the fly for each T and H. Let t and h be the lists of all words and phrases in T and H respectively. For all pairs (a, b), where $a \in t, b \in h$, it generates an inference rule: $a \rightarrow b \mid w$, where $w = f(sim(\overrightarrow{a}, \overrightarrow{b}))$. Both a and b can be words or phrases. Phrases are defined in terms of Boxer's output. A phrase is more than one unary atom sharing the same variable like "a little kid" which in logic is $little(K) \wedge kid(K)$. A phrase also can be two unary atoms connected by a relation like "a man is driving" which in logic is $man(M) \wedge agent(D, M) \wedge drive(D)$. The similarity function sim takes two vectors as input. Phrasal vectors are constructed using Vector Addition (Landauer and Dumais, 1997). The set of generated inference rules can be regarded as the knowledge base KB.

Beltagy et al. (2013) found that the logical conjunction in H is very restrictive for the STS task, so they relaxed the conjunction by using an average evidence combiner (Natarajan et al., 2010). The average combiner results in computationally complex inference and only works for short sentences. In case inference breaks or times-out, they back off to a simpler combiner that leads to much faster inference but loses most of the structure of the sentence and is therefore less accurate.

Given T, KB and H from the previous steps, MLN inference is then used to compute $p(H|T, KB)$, which is then used as a measure of the degree to which T entails H.

3 PSL for STS

For several reasons, we believe PSL is a more appropriate probabilistic logic for STS than MLNs. First, it is explicitly designed to support efficient inference, therefore it scales better to longer sentences with more complex logical forms. Second, it was also specifically designed for computing *similarity* between complex structured objects rather than determining probabilistic logical entailment. In fact, the initial version of PSL (Broecheler et al., 2010) was called *Probabilistic Similarity Logic*, based on its use of *similarity functions*. This initial version was shown to be very effective for measuring the similarity of noisy database records and performing *record linkage* (i.e. identifying database entries referring to the same entity, such as bibliographic citations referring to the same paper). Therefore, we have developed an approach that follows that of Beltagy et al. (2013), but replaces Markov Logic with PSL.

This section explains how we formulate the STS

task as a PSL program. PSL does not work very well "out of the box" for STS, mainly because Lukasiewicz's equation for the conjunction is very restrictive. Therefore, we use a different interpretation for conjunction that uses averaging, which requires corresponding changes to the optimization problem and the grounding technique.

3.1 Representation

Given the logical forms for a pair of sentences, a text T and a hypothesis H, and given a set of weighted rules derived from the distributional semantics (as explained in section 2.6) composing the knowledge base KB, we build a PSL model that supports determining the truth value of H in the most probable interpretation (i.e. MPE) given T and KB.

Consider the pair of sentences is "A man is driving", and "A guy is walking". Parsing into logical form gives:

$T: \exists x, y.\ man(x) \wedge agent(y, x) \wedge drive(y)$

$H: \exists x, y.\ guy(x) \wedge agent(y, x) \wedge walk(y)$

The PSL program is constructed as follows:

T: The text is represented in the evidence set. For the example, after Skolemizing the existential quantifiers, this contains the ground atoms: $\{man(A), agent(B, A), drive(B)\}$

KB: The knowledge base is a set of lexical and phrasal rules generated from distributional semantics, along with a similarity score for each rule (section 2.6). For the example, we generate the rules: $\forall x.\ man(x) \wedge vs\_sim(\text{"}man\text{"}, \text{"}guy\text{"}) \rightarrow guy(x)$, $\forall x. drive(x) \wedge vs\_sim(\text{"}drive\text{"}, \text{"}walk\text{"}) \rightarrow walk(x)$

where vs_sim is a similarity function that calculates the distributional similarity score between the two lexical predicates. All rules are assigned the same weight because all rules are equally important.

H: The hypothesis is represented as $H \rightarrow result()$, and then PSL is queried for the truth value of the atom $result()$. For our example, the rule is: $\forall x, y.\ guy(x) \wedge agent(y, x) \wedge walk(y) \rightarrow result()$.

Priors: A low prior is given to all predicates. This encourages the truth values of ground atoms to be zero, unless there is evidence to the contrary.

For each STS pair of sentences S_1, S_2, we run PSL twice, once where $T = S_1$, $H = S_2$ and another where $T = S_2$, $H = S_1$, and output the two scores. To produce a final similarity score, we train a regressor to learn the mapping between the two PSL scores and the overall similarity score. As in Beltagy et al., (2013) we use Additive Regression (Friedman, 2002).

3.2 Changing Conjunction

As mentioned above, Lukasiewicz's formula for conjunction is very restrictive and does not work well for STS. For example, for T: "A man is driving" and H: "A man is driving a car", if we use the standard PSL formula for conjunction, the output value is zero because there is no evidence for a car and $max(0, X + 0 - 1) = 0$ for any truth value $0 \leq X \leq 1$. However, humans find these sentences to be quite similar.

Therefore, we introduce a new averaging interpretation of conjunction that we use for the hypothesis H. The truth value for a conjunction is defined as $I(p_1 \wedge .... \wedge p_n) = \frac{1}{n} \sum_{i=1}^{n} I(p_i)$. This averaging function is linear, and the result is a valid truth value in the interval [0, 1], therefore this change is easily incorporated into PSL without changing the complexity of inference which remains a linear-programming problem.

It would perhaps be even better to use a weighted average, where weights for different components are learned from a supervised training set. This is an important direction for future work.

3.3 Grounding Process

Grounding is the process of instantiating the variables in the quantified rules with concrete constants in order to construct the nodes and links in the final graphical model. In principle, grounding requires instantiating each rule in all possible ways, substituting every possible constant for each variable in the rule. However, this is a combinatorial process that can easily result in an explosion in the size of the final network. Therefore, PSL employs a "lazy" approach to grounding that avoids the construction of irrelevant groundings. If there is no evidence for one of the antecedents in a particular grounding of a rule, then the normal PSL formula for conjunction guarantees that the rule is

Algorithm 1 Heuristic Grounding

Input: $r_{body} = a_1 \wedge .... \wedge a_n$: antecedent of a rule with average interpretation of conjunction
Input: V: set of variables used in r_{body}
Input: $Ant(v_i)$: subset of antecedents a_j containing variable v_i
Input: $Const(v_i)$: list of possible constants of variable v_i
Input: $Gnd(a_i)$: set of ground atoms of a_i.
Input: $GndConst(a, g, v)$: takes an atom a, grounding g for a, and variable v, and returns the constant that substitutes v in g
Input: gnd_limit: limit on the number of groundings
1: **for all** $v_i \in V$ **do**
2: **for all** $C \in Const(v_i)$ **do**
3: $score(C) = \sum_{a \in Ant(v_i)}(max\ I(g))$ for $g \in Gnd(a) \wedge GndConst(a, g, v_i) = C$
4: **end for**
5: sort $Const(v_i)$ on scores, descending
6: **end for**
7: **return** For all $v_i \in V$, take the Cartesian-product of the sorted $Const(v_i)$ and return the top gnd_limit results

trivially satisfied ($I(r) = 1$) since the truth value of the antecedent is zero. Therefore, its distance to satisfaction is also zero, and it can be omitted from the ground network without impacting the result of MPE inference.

However, this technique does not work once we switch to using averaging to interpret conjunctions. For example, given the rule $\forall x.\ p(x) \wedge q(x) \rightarrow t()$ and only one piece of evidence $p(C)$ there are no relevant groundings because there is no evidence for $q(C)$, and therefore, for normal PSL, $I(p(C) \wedge q(C)) = 0$ which does not affect $I(t())$. However, when using averaging with the same evidence, we need to generate the grounding $p(C) \wedge q(C)$ because $I(p(C) \wedge q(C)) = 0.5$ which *does* affect $I(t())$.

One way to solve this problem is to eliminate lazy grounding and generate all possible groundings. However, this produces an intractably large network. Therefore, we developed a heuristic approximate grounding technique that generates a subset of the most impactful groundings.

Pseudocode for this heuristic approach is shown in algorithm 1. Its goal is to find constants that participate in ground propositions with high truth value and preferentially use them to construct a limited number of groundings of each rule.

The algorithm takes the antecedents of a rule employing averaging conjunction as input. It also takes the *grounding limit* which is a threshold on the number of groundings to be returned. The algorithm uses several subroutines, they are:

- $Ant(v_i)$: given a variable v_i, it returns the set of rule antecedent atoms containing v_i. E.g, for the rule: $a(x) \wedge b(y) \wedge c(x)$, $Ant(x)$ returns the set of atoms $\{a(x), c(x)\}$.
- $Const(v_i)$: given a variable v_i, it returns the list of possible constants that can be used to instantiate the variable v_i.
- $Gnd(a_i)$: given an atom a_i, it returns the set of all possible ground atoms generated for a_i.
- $GndConst(a, g, v)$: given an atom a and grounding g for a, and a variable v, it finds the constant that substitutes for v in g. E.g, assume there is an atom $a = a_i(v_1, v_2)$, and the ground atom $g = a_i(A, B)$ is one of its groundings. $GndConst(a, g, v_2)$ would return the constant B since it is the substitution for the variable v_2 in g.

Lines 1-6 loop over all variables in the rule. For each variable, lines 2-5 construct a list of constants for that variable and sort it based on a heuristic score. In line 3, each constant is assigned a score that indicates the importance of this constant in terms of its impact on the truth value of the overall grounding. A constant's score is the sum, over all antedents that contain the variable in question, of the maximum truth value of any grounding of that antecedent that contains that constant.

Pushing constants with high scores to the top of each variable's list will tend to make the overall truth value of the top groundings high. Line 7 computes a subset of the Cartesian product of the sorted lists of constants, selecting constants in ranked order and limiting the number of results to the grounding limit.

One point that needs to be clarified about this approach is how it relies on the truth values of ground atoms when the goal of inference is to actually find these values. PSL's inference is actually an iterative process where in each iteration a grounding phase is followed by an optimization phase (solving the linear program). This loop repeats until convergence, i.e. until the truth

values stop changing. The truth values used in each grounding phase come from the previous optimization phase. The first grounding phase assumes only the propositions in the evidence provided have non-zero truth values.

4 Evaluation

This section evaluates the performance of PSL on the STS task.

4.1 Datasets

We evaluate our system on three STS datasets.

- **msr-vid**: Microsoft Video Paraphrase Corpus from STS 2012. The dataset consists of 1,500 pairs of short video descriptions collected using crowdsourcing (Chen and Dolan, 2011) and subsequently annotated for the STS task (Agirre et al., 2012). Half of the dataset is for training, and the second half is for testing.

- **msr-par**: Microsoft Paraphrase Corpus from STS 2012 task. The dataset is 5,801 pairs of sentences collected from news sources (Dolan et al., 2004). Then, for STS 2012, 1,500 pairs were selected and annotated with similarity scores. Half of the dataset is for training, and the second half is for testing.

- **SICK**: Sentences Involving Compositional Knowledge is a dataset collected for SemEval 2014. Only the training set is available at this point, which consists of 5,000 pairs of sentences. Pairs are annotated for RTE and STS, but we only use the STS data. Training and testing was done using 10-fold cross validation.

4.2 Systems Compared

We compare our PSL system with several others. In all cases, we use the distributional word vectors employed by Beltagy et al. (2013) based on context windows from Gigaword.

- **vec-add**: Vector Addition (Landauer and Dumais, 1997). We compute a vector representation for each sentence by adding the distributional vectors of all of its words and measure similarity using cosine. This is a simple yet powerful baseline that uses only distributional information.

- **vec-mul**: Component-wise Vector Multiplication (Mitchell and Lapata, 2008). The same as **vec-add** except uses component-wise multiplication to combine word vectors.

- **MLN**: The system of Beltagy et al. (2013), which uses Markov logic instead of PSL for probabilistic inference. MLN inference is very slow in some cases, so we use a 10 minute timeout. When MLN times out, it backs off to a simpler sentence representation as explained in section 2.6.

- **PSL**: Our proposed PSL system for combining logical and distributional information.

- **PSL-no-DIR**: Our PSL system without distributional inference rules(empty knowledge base). This system uses PSL to compute similarity of logical forms but does not use distributional information on lexical or phrasal similarity. It tests the impact of the probabilistic logic only

- **PSL+vec-add**: **PSL** ensembled with **vec-add**. Ensembling the MLN approach with a purely distributional approach was found to improve results (Beltagy et al., 2013), so we also tried this with PSL. The methods are ensembled by using both entailment scores of both systems as input features to the regression step that learns to map entailment scores to STS similarity ratings. This way, the training data is used to learn how to weight the contribution of the different components.

- **PSL+MLN**: **PSL** ensembled with **MLN** in the same manner.

4.3 Experiments

Systems are evaluated on two metrics, Pearson correlation and average CPU time per pair of sentences.

- Pearson correlation: The Pearson correlation between the system's similarity scores and the human gold-standards.

- CPU time: This metric only applies to MLN and PSL. The CPU time taken by the inference step is recorded and averaged over all pairs in each of the test datasets. In many cases, MLN inference is very slow, so we timeout after 10 minutes and report the number of timed-out pairs on each dataset.

	msr-vid	msr-par	SICK
vec-add	0.78	0.24	0.65
vec-mul	0.76	0.12	0.62
MLN	0.63	0.16	0.47
PSL-no-DIR	0.74	0.46	0.68
PSL	0.79	**0.53**	0.70
PSL+vec-add	**0.83**	0.49	**0.71**
PSL+MLN	0.79	0.51	0.70
Best Score (Bär et al., 2012)	0.87	0.68	n/a

Table 1: STS Pearson Correlations

	PSL	MLN	
	time	time	timeouts/total
msr-vid	8s	1m 31s	132/1500
msr-par	30s	11m 49s	1457/1500
SICK	10s	4m 24s	1791/5000

Table 2: Average CPU time per STS pair, and number of timed-out pairs in MLN with a 10 minute time limit. PSL's grounding limit is set to 10,000 groundings.

We also evaluated the effect of changing the grounding limit on both Pearson correlation and CPU time for the **msr-par** dataset. Most of the sentences in **msr-par** are long, which results is large number of groundings, and limiting the number of groundings has a visible effect on the overall performance. In the other two datasets, the sentences are fairly short, and the full number of groundings is not large; therefore, changing the grounding limit does not significantly affect the results.

4.4 Results and Discussion

Table 1 shows the results for Pearson correlation. **PSL** out-performs the purely distributional baselines (**vec-add** and **vec-mul**) because **PSL** is able to combine the information available to **vec-add** and **vec-mul** in a better way that takes sentence structure into account. **PSL** also outperforms the unaided probabilistic-logic baseline that does not use distributional information (**PSL-no-DIR**). **PSL-no-DIR** works fairly well because there is significant overlap in the exact words and structure of the paired sentences in the test data, and PSL combines the evidence from these similarities effectively. In addition, **PSL** always does significantly better than **MLN**, because of the large

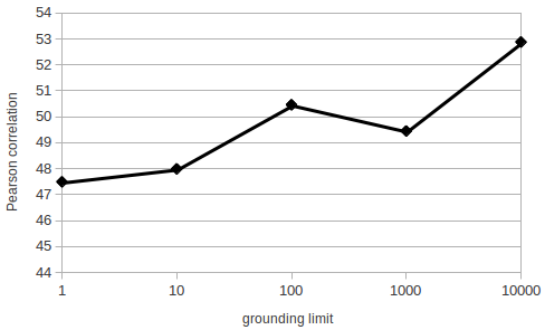

Figure 1: Effect of **PSL**'s grounding limit on the correlation score for the **msr-par** dataset

number of timeouts, and because the conjunction-averaging in PSL is combining evidence better than MLN's average-combiner, whose performance is sensitive to various parameters. These results further support the claim that using probabilistic logic to integrate logical and distributional information is a promising approach to natural-language semantics. More specifically, they strongly indicate that PSL is a more effective probabilistic logic for judging semantic similarity than MLNs.

Like for MLNs (Beltagy et al., 2013), ensembling PSL with vector addition improved the scores a bit, except for **msr-par** where **vec-add**'s performance is particularly low. However, this ensemble still does not beat the state of the art (Bär et al., 2012) which is a large ensemble of many different systems. It would be informative to add our system to their ensemble to see if it could improve it even further.

Table 2 shows the CPU time for **PSL** and **MLN**. The results clearly demonstrate that **PSL** is an order of magnitude faster than **MLN**.

Figures 1 and 2 show the effect of changing the grounding limit on Pearson correlation and CPU time. As expected, as the grounding limit is increased, accuracy improves but CPU time also increases. However, note that the difference in scores between the smallest and largest grounding limit tested is not large, suggesting that the heuristic approach to limiting grounding is quite effective.

5 Future Work

As mentioned in Section 3.2, it would be good to use a *weighted* average to compute the truth

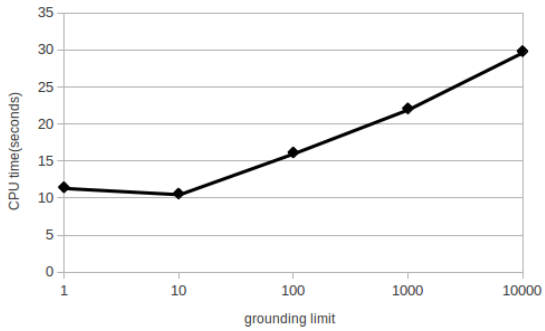

Figure 2: Effect of **PSL**'s grounding limit on CPU time for the **msr-par** dataset

values for conjunctions, weighting some predicates more than others rather than treating them all equally. Appropriate weights for different components could be learned from training data. For example, such an approach could learn that the type of an object determined by a noun should be weighted more than a property specified by an adjective. As a result, "black dog" would be appropriately judged more similar to "white dog" than to "black cat."

One of the advantages of using a probabilistic logic is that additional sources of knowledge can easily be incorporated by adding additional soft inference rules. To complement the soft inference rules capturing distributional lexical and phrasal similarities, PSL rules could be added that encode explicit paraphrase rules, such as those mined from monolingual text (Berant et al., 2011) or multi-lingual parallel text (Ganitkevitch et al., 2013).

This paper has focused on STS; however, as shown by Beltagy et al. (2013), probabilistic logic is also an effective approach to *recognizing textual entailment* (RTE). By using the appropriate functions to combine truth values for various logical connectives, PSL could also be adapted for RTE. Although we have shown that PSL outperforms MLNs on STS, we hypothesize that MLNs may still be a better approach for RTE. However, it would be good to experimentally confirm this intuition. In any case, the high computational complexity of MLN inference could mean that PSL is still a more practical choice for RTE.

6 Conclusion

This paper has presented an approach that uses Probabilistic Soft Logic (PSL) to determine Semantic Textual Similarity (STS). The approach uses PSL to effectively combine logical semantic representations of sentences with soft inference rules for lexical and phrasal similarities computed from distributional information. The approach builds upon a previous method that uses Markov Logic (MLNs) for STS, but replaces the probabilistic logic with PSL in order to improve the efficiency and accuracy of probabilistic inference. The PSL approach was experimentally evaluated on three STS datasets and was shown to outperform purely distributional baselines as well as the MLN approach. The PSL approach was also shown to be much more scalable and efficient than using MLNs

Abstract

We propose a novel abstractive query-based summarization system for conversations, where queries are defined as phrases reflecting a user information needs. We rank and extract the utterances in a conversation based on the overall content and the phrasal query information. We cluster the selected sentences based on their lexical similarity and aggregate the sentences in each cluster by means of a word graph model. We propose a ranking strategy to select the best path in the constructed graph as a query-based abstract sentence for each cluster. A resulting summary consists of abstractive sentences representing the phrasal query information and the overall content of the conversation. Automatic and manual evaluation results over meeting, chat and email conversations show that our approach significantly outperforms baselines and previous extractive models.

1 Introduction

Our lives are increasingly reliant on multimodal conversations with others. We email for business and personal purposes, attend meetings in person, chat online, and participate in blog or forum discussions. While this growing amount of personal and public conversations represent a valuable source of information, going through such overwhelming amount of data, to satisfy a particular information need, often leads to an information overload problem (Jones et al., 2004). Automatic summarization has been proposed in the past as a way to address this problem (e.g., (Sakai and Sparck-Jones, 2001)). However, often a good summary cannot be generic and should be a brief and well-organized paragraph that answer a user's information need.

The Document Understanding Conference (DUC)[1] has launched query-focused multidocument summarization as its main task since 2004, by focusing on complex queries with very specific answers. For example, "*How were the bombings of the US embassies in Kenya and Tanzania conducted? How and where were the attacks planned?*". Such complex queries are appropriate for a user who has specific information needs and can formulate the questions precisely. However, especially when dealing with conversational data that tend to be less structured and less topically focused, a user is often initially only exploring the source documents, with less specific information needs. Moreover, following the common practice in search engines, users are trained to form simpler and shorter queries (Meng and Yu, 2010). For example, when a user is interested in certain characteristics of an entity in online reviews (e.g., "*location*" or "*screen*") or a specific entity in a blog discussion (e.g., "*new model of iphone*"), she would not initially compose a complex query.

To address these issues, in this work, we tackle the task of conversation summarization based on *phrasal* queries. We define a phrasal query as a concatenation of two or more keywords, which is a more realistic representation of a user's information needs. For conversational data, this definition is more similar to the concept of search queries in information retrieval systems as well as to the concept of topic labels in the task of topic modeling. Example 1 shows two queries and their associated human written summaries based on a single chat log. We can observe that the two summaries, although generated from the same chat log, are totally distinct. This further demonstrates the importance of phrasal query-based summarization systems for long conversations.

To date, most systems in the area of summa-

Query-1: Test/Sample database for GNUe
Abstract-1: James Thompson asked Reinhard: I was going to work on the sample tonight. You mentioned wanting a fishhook and all data types. Any other things you want to see in there? Reinhard said that master/detail would be good, as there have been bugs only appearing in 3-level case. James said he already included that and I know I need to add a boolean. Did you want date as well as date-time? Reinhard said yes - we also have time values (time without date). They are especially interesting. James had not ever had use for something like that so I'm not sure where I would graft that in.
Query-2: Passing parameters to Forms
Abstract-2: James Thompson (jamest) asked how did parameter support in forms change recently? He reported the trigger namespace function referencesGFForm.parameters - which no longer exists. Reinhard said every GFForm should have a parameters. James said he was using parameters in on-startup. Reinhard said that's probably the only place where they don't work. James said that I'm thinking about moving that to on-activation instead of on-startup anyway as it should still work for a main form - but i still wonder if the on-startup parameter issue should be considered a bug - as it shouldn't choke. Reinhard was sure it should be considered a bug but I have no idea how to fix it. We haven't found a way to deal with parameters that works for every case. I don't know if there is any chance to pass the parameters to the form before it is activated. James asked how are parameters handled now? Reinhard replied that they are passed to activateForm so they are available from activation for the –main– form, the command line parameters are passed and for dialogs, the parameters are passed that were given in runDialog.

Example 1: Sample queries and associated human-written query-based summaries for a chat log.

rization focus on news or other well-written documents, while research on summarizing multiparty written conversations (e.g., chats, emails) has been limited. This is because traditional NLP approaches developed for formal texts often are not satisfactory when dealing with multiparty written conversations, which are typically in a casual style and do not display a clear syntactic structure with proper grammar and spelling. Even though some works try to address the problem of summarizing multiparty written conversions (e.g., (Mehdad et al., 2013b; Wang and Cardie, 2013; Murray et al., 2010; Zhou and Hovy, 2005; Gillick et al., 2009)), they do so in a generic way (not query-based) and focus on only one conversational domain (e.g., meetings). Moreover, most of the proposed systems for conversation summarization are extractive.

To address such limitations, we propose a fully automatic *unsupervised* abstract generation framework based on phrasal queries for multimodal conversation summarization. Our key contributions in this work are as follows:

1) To the best of our knowledge, our framework is the first abstractive system that generates summaries based on users phrasal queries, instead of well-formed questions. As a by-product of our approach, we also propose an extractive summarization model based on phrasal queries to select the summary-worthy sentences in the conversation based on query terms and signature terms (Lin and Hovy, 2000).

2) We propose a novel ranking strategy to select the best path in the constructed word graph by taking the query content, overall information content and grammaticality (i.e., fluency) of the sentence into consideration.

3) Although most of the current summarization approaches use supervised algorithms as a part of their system (e.g., (Wang et al., 2013)), our method can be totally unsupervised and does not depend on human annotation.

4) Although different conversational modalities (e.g., email vs. chat vs. meeting) underline domain-specific characteristics, in this work, we take advantage of their underlying similarities to generalize away from specific modalities and determine effective method for query-based summarization of multimodal conversations.

We evaluate our system over GNUe Traffic archive[2] Internet Relay Chat (IRC) logs, AMI meetings corpus (Carletta et al., 2005) and BC3 emails dataset (Ulrich et al., 2008). Automatic evaluation on the chat dataset and manual evaluation over the meetings and emails show that our system uniformly and statistically significantly outperforms baseline systems, as well as a state-of-the-art query-based extractive summarization system.

2 Phrasal Query Abstraction Framework

Our phrasal query abstraction framework generates a grammatical abstract from a conversation following three steps, as shown in Figure 1.

2.1 Utterance Extraction

Abstractive summary sentences can be created by aggregating and merging multiple sentences into an abstract sentence. In order to generate such a sentence, we need to identify which sentences from the original document should be extracted and combined to generate abstract sentences. In other words, we want to identify the summary-worthy sentences in the text that can be combined into an abstract sentence. This task can be considered as content selection. Moreover, this step, stand alone, corresponds to an extractive summarization system.

[2] http://kt.earth.li/GNUe/index.html

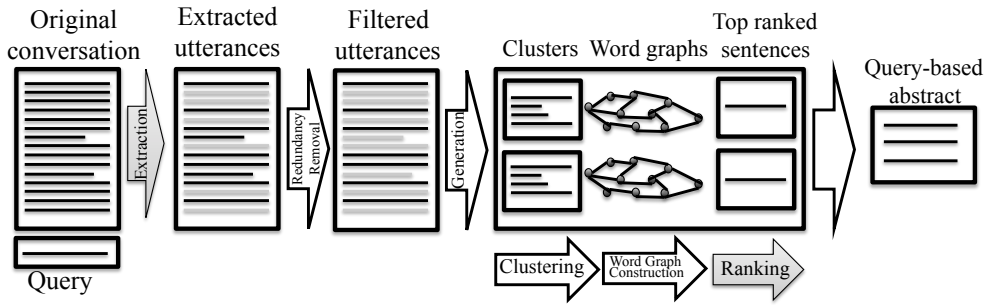

Figure 1: Phrasal query abstraction framework. The steps (arrows) influenced by the query are highlighted.

Signature terms: navigator, functionality, reports, UI, schema, gnu

Chat log:
- but watching them build a UI in the flash demo's is pretty damn impressive... and have started moving my sales app to all UI being built via ...
- i'll be expanding the technotes in navigator for a while ...
- ... in terms of functionality of the underlying databases ...
- you mean if I start GNU again I have to read bug reports too?
- no, just in case you want to enter bug report
- ...I expand the schema before populating with test data ...
- i'm willing to scrap it if there is a better schema hidden in gnue somewhere :)

Example 2: Sample signature terms for a part of a chat log.

In order to select and extract the informative summary-worthy utterances, based on the phrasal query and the original text, we consider two criteria: *i)* utterances should carry the essence of the original text; and *ii)* utterances should be relevant to the query. To fulfill such requirements we define the concepts of signature terms and query terms.

2.1.1 Signature Terms

Signature terms are generally indicative of the content of a document or collection of documents. To identify such terms, we can use frequency, word probability, standard statistic tests, information-theoretic measures or log-likelihood ratio. In this work, we use log-likelihood ratio to extract the signature terms from chat logs, since log-likelihood ratio leads to better results (Gupta et al., 2007). We use a method described in (Lin and Hovy, 2000) in order to identify such terms and their associated weight. Example 2 demonstrates a chat log and associated signature terms.

2.1.2 Query Terms

Query terms are indicative of the content in a phrasal query. In order to identify such terms, we first extract all content terms from the query. Then, following previous studies (e.g., (Gonzalo et al., 1998)), we use the synsets relations in WordNet for query expansion. We extract all concepts that are synonyms to the query terms and add them to the original set of query terms. Note that we limit our synsets to the nouns since verb synonyms do not prove to be effective in query expansion (Hunemark, 2010). While signature terms are weighted, we assume that all query terms are equally important and they all have wight equal to 1.

2.1.3 Utterance Scoring

To estimate the utterance score, we view both the query terms and the signature terms as the terms that should appear in a human query-based summary. To achieve this, the most relevant (summary-worthy) utterances that we select are the ones that maximize the coverage of such terms. Given the query terms and signature terms, we can estimate the utterance score as follows:

$$Score_Q = \frac{1}{n}\sum_{i=1}^{n} t(q)_i \quad (1)$$

$$Score_S = \frac{1}{n}\sum_{i=1}^{n} t(s)_i \times w(s)_i \quad (2)$$

$$Score = \alpha \cdot Score_Q + \beta \cdot Score_S \quad (3)$$

where n is number of content words in the utterance, $t(q)_i = 1$ if the term t_i is a query term and 0 otherwise, and $t(s)_i = 1$ if t_i is a signature term and 0 otherwise, and $w(s)_i$ is the normalized associated weight for signature terms. The parameters α and β are tuned on a development set and sum up to 1.

After all the utterances are scored, the top scored utterances are selected to be sent to the next step. We estimate the percentage of the retrieved utterances based on the development set.

2.2 Redundancy Removal

Utterances selected in previous step often include redundant information, which is semantically equivalent but may vary in lexical choices. By identifying the semantic relations between the sentences, we can discover what information in one sentence is semantically equivalent, novel, or more/less informative with respect to the content of the other sentences. Similar to earlier work (Berant et al., 2011; Adler et al., 2012), we set this problem as a variant of the Textual Entailment (TE) recognition task (Dagan and Glickman, 2004). Using entailment in this phase is motivated by taking advantage of semantic relations instead of pure statistical methods (e.g., Maximal Marginal Relevance) and shown to be more effective (Mehdad et al., 2013a). We follow the same practice as (Mehdad et al., 2013a) to build an entailment graph for all selected sentences to identify relevant sentences and eliminate the redundant (in terms of meaning) and less informative ones.

2.3 Abstract Generation

In this phase, our goal is to generate understandable informative abstract sentences that capture the content of the source sentences and represents the information needs defined by queries. There are several ways of generating abstract sentences (e.g. (Barzilay and McKeown, 2005; Liu and Liu, 2009; Ganesan et al., 2010; Murray et al., 2010)); however, most of them rely heavily on the sentence structure. We believe that such approaches are suboptimal, especially in dealing with conversational data, because multiparty written conversations are often poorly structured. Instead, we apply an approach that does not rely on syntax, nor on a standard NLG architecture. Moreover, since dealing with user queries efficiency is an important aspect, we aim for an approach that is also motivated by the speed with which the abstracts are obtained. We perform the task of abstract generation in three steps, as follows:

2.3.1 Clustering

In order to generate an abstract summary, we need to identify which sentences from the previous step (i.e., redundancy removal) can be clustered and combined in generated abstract sentences. This task can be viewed as sentence clustering, where each sentence cluster can provide the content for an abstract sentence.

We use the K-mean clustering algorithm by cosine similarity as a distance function between sentence vectors composed of *tf.idf* scores. Also notice that the lexical similarity between sentences in one cluster facilitates both the construction of the word graph and finding the best path in the word graph, as described next.

2.3.2 Word Graph

In order to construct a word graph, we adopt the method recently proposed by (Mehdad et al., 2013a; Filippova, 2010) with some optimizations. Below, we show how the word graph is applied to generate the abstract sentences.

Let $G = (W, L)$ be a directed graph with the set of nodes W representing words and a set of directed edges L representing the links between words. Given a cluster of related sentences $S = \{s_1, s_2, ..., s_n\}$, a word graph is constructed by iteratively adding sentences to it. In the first step, the graph represents one sentence plus the start and end symbols. A node is added to the graph for each word in the sentence, and words adjacent are linked with directed edges. When adding a new sentence, a word from the sentence is merged in an existing node in the graph providing that they have the same POS tag and they satisfy one of the following conditions:

i) They have the same word form;

ii) They are connected in WordNet by the synonymy relation. In this case the lexical choice for the node is selected based on the *tf.idf* score of each node;

iii) They are from a hypernym/hyponym pair or share a common direct hypernym. In this case, both words are replaced by the hypernym;

iv) They are in an entailment relation. In this case, the entailing word is replaced by the entailed one.

The motivation behind merging non-identical words is to enrich the common terms between the phrases to increase the chance that they could merge into a single phrase. This also helps to move beyond the limitation of original lexical choices. In case the merging is not possible a new node is created in the graph. When a node can be merged with multiple nodes (i.e., merging is ambiguous), either the preceding and following words in the sentence and the neighboring nodes in the graph or the frequency is used to select the candidate node.

We connect adjacent words with directed edges.

For the new nodes or unconnected nodes, we draw an edge with a weight of 1. In contrast, when two already connected nodes are added (merged), the weight of their connection is increased by 1.

2.3.3 Path Ranking

A word graph, as described above, may contain many sequences connecting start and end. However, it is likely that most of the paths are not readable. We are aiming at generating an informative abstractive sentence for each cluster based on a user query. Moreover, the abstract sentence should be grammatically correct.

In order to satisfy both requirements, we have devised the following ranking strategy. First, we prune the paths in which a verb does not exist, to filter ungrammatical sentences. Then we rank other paths as follows:

Query focus: to identify the summary sentence with the highest coverage of query content, we propose a score that counts the number of query terms that appear in the path. In order to reward the ranking score to cover more salient terms in the query content, we also consider the *tf.idf* score of query terms in the coverage formulation.

$$Q(P) = \frac{\sum_{q_i \in P} tfidf(q_i)}{\sum_{q_i \in G} tfidf(q_i)}$$

where the q_i are the query terms.

Fluency: in order to improve the grammaticality of the generated sentence, we coach our ranking model to select more fluent (i.e., grammatically correct) paths in the graph. We estimate the grammaticality of generated paths ($Pr(P)$) using a language model.

Path weight: The purpose of this function is twofold: i) to generate a grammatical sentence by favoring the links between nodes (words) which appear often; and ii) to generate an informative sentence by increasing the weight of edges connecting salient nodes. For a path P with m nodes, we define the edge weight $w(n_i, n_j)$ and the path weight $W(P)$ as below:

$$w(n_i, n_j) = \frac{freq(n_i) + freq(n_j)}{\sum_{\substack{P' \in G \\ n_i, n_j \in P'}} diff(P', n_i, n_j)^{-1}}$$

$$W(P) = \frac{\sum_{i=1}^{m-1} w(n_i, n_{i+1})}{m-1}$$

where the function *diff*(P', n_i, n_j) refers to the distance between the offset positions $pos(P', n_i)$ of nodes n_i and n_j in path P' (any path in G containing n_i and n_j) and is defined as $|pos(P', n_j) - pos(P', n_i)|$.

Overal ranking score: In order to generate a query-based abstract sentence that combines the scores above, we employ a ranking model. The purpose of such a model is three-fold: i) to cover the content of query information optimally; ii) to generate a more readable and grammatical sentence; and iii) to favor strong connections between the concepts. Therefore, the final ranking score of path P is calculated over the normalized scores as:

$$Score(P) = \alpha \cdot Q(P) + \beta \cdot Pr(P) - \gamma \cdot W(P)$$

Where α, β and γ are the coefficient factors to tune the ranking score and they sum up to 1. In order to rank the graph paths, we select all the paths that contain at least one verb and rerank them using our proposed ranking function to find the best path as the summary of the original sentences in each cluster.

3 Experimental Setup

In this section, we show the evaluation results of our proposed framework and its comparison to the baselines and a state-of-the-art query-focused extractive summarization system.

3.1 Datasets

One of the challenges of this work is to find suitable conversational datasets that can be used for evaluating our query-based summarization system. Most available conversational corpora do not contain any human written summaries, or the gold standard human written summaries are generic (Carletta et al., 2005; Joty et al., 2013). In this work, we use available corpora for emails and chats for written conversations, while for spoken conversation, we employ an available corpus in multiparty meeting conversations.

Chat: to the best of our knowledge, the only publicly available chat logs with human written summaries can be downloaded from the GNUe Traffic archive (Zhou and Hovy, 2005; Uthus and Aha, 2011; Uthus and Aha, 2013). Each chat log has a human created summary in the form of a digest. Each digest summarizes IRC logs for a period and consists of few summaries over each chat log with a unique title for the associated human written summary. In this way, the title of each summary

can be counted as a phrasal query and the corresponding summary is considered as the query-based abstract of the associated chat log including only the information most relevant to the title. Therefore, we can use the human-written query-based abstract as gold standards and evaluate our system automatically. Our chat dataset consists of 66 query-based (title-based) human written summaries with their associated queries (titles) and chat logs, created from 40 original chat logs. The average number of tokens are 1840, 325 and 6 for chat logs, query-based summaries and queries, respectively.

Meeting: we use the AMI meeting corpus (Carletta et al., 2005) that consists of 140 multiparty meetings with a wide range of annotations, including generic abstractive summaries for each meeting. In order to create queries, we extract three key-phrases from generic abstractive summaries using TextRank algorithm (Mihalcea and Tarau, 2004). We use the extracted key-phrases as queries to generate query-based abstracts. Since there is no human-written query-based summary for AMI corpus, we randomly select 10 meetings and evaluate our system manually.

Email: we use BC3 (Ulrich et al., 2008), which contains 40 threads from the W3C corpus. BC3 corpus is annotated with generic human-written abstractive summaries, and it has been used in several previous works (e.g., (Joty et al., 2011)). In order to adapt this corpus to our framework, we followed the same query generation process as for the meeting dataset. Finally, we randomly select 10 emails threads and evaluate the results manually.

3.2 Baselines

We compare our approach with the following baselines:

1) Cosine-1st: we rank the utterances in the chat log based on the cosine similarity between the utterance and query. Then, we select the first uttrance as the summary;

2) Cosine-all: we rank the utterances in the chat log based on the cosine similarity between the utterance and query and then select the utterances with a cosine similarity greater than 0;

3) TextRank: a widely used graph-based ranking model for single-document sentence extraction that works by building a graph of all sentences in a document and use similarity as edges to compute the salience of sentences in the graph (Mihalcea and Tarau, 2004);

4) LexRank: another popular graph-based content selection algorithm for multi-document summarization (Erkan and Radev, 2004);

5) Biased LexRank: is a state-of-the-art query-focused summarization that uses LexRank algorithm in order to recursively retrieve additional passages that are similar to the query, as well as to the other nodes in the graph (Otterbacher et al., 2009).

Moreover, we compare our abstractive system with the first part of our framework (utterance extraction in Figure 1), which can be presented as an extractive query-based summarization system (our extractive system). We also show the results of the version we use in our pipeline (our pipeline extractive system). The only difference between the two versions is the length of the generated summaries. In our pipeline we aim at higher recall, since we later filter sentences and aggregate them to generate new abstract sentences. In contrast, in the stand alone version (extractive system) we limit the number of retrieved sentences to the desired length of the summary. We also compare the results of our full system (i.e., with tuning) with a non-optimized version when the ranking coefficients are distributed equally ($\alpha = \beta = \gamma = 0.33$). For parameters estimation, we tune all parameters (utterance selection and path ranking) exhaustively with 0.1 intervals using our development set.

For manual evaluation of query-based abstracts (meeting and email datasets), we perform a simple user study assessing the following aspects: *i) Overall quality* given a query (5-point scale)?; and *ii) Responsiveness*: how responsive is the generated summary to the query (5-point scale)? Each query-based abstract was rated by two annotators (native English speaker). Evaluators are presented with the original conversation, query and generated summary. For the manual evaluation, we only compare our full system with LexRank (LR) and Biased LexRank (Biased LR). We also ask the evaluators to select the best summary for each query and conversation, given our system generated summary and the two baselines.

To evaluate the grammaticality of our generated summaries, following common practice (Barzilay and McKeown, 2005), we randomly selected 50 sentences from original conversations and system

Systems in italics use the query in generating the summary.

generated abstracts, for each dataset. Then, we asked annotators to give one of three possible ratings for each sentence based on grammaticality: perfect (2 pts), only one mistake (1 pt) and not acceptable (0 pts), ignoring capitalization or punctuation. Each sentence was rated by two annotators. Note that each sentence was evaluated individually, so the human judges were not affected by intra-sentential problems posed by coreference and topic shifts.

3.3 Experimental Settings

For preprocessing our dataset we use OpenNLP[3] for tokenization, stemming and part-of-speech tagging. We use six randomly selected query-logs from our chat dataset (about 10% of the dataset) for tuning the coefficient parameters. We set the k parameter in our clustering phase to 10 based on the average number of sentences in the human written summaries. For our language model, we use a tri-gram smoothed language model trained using the newswire text provided in the English Gigaword corpus (Graff and Cieri, 2003). For the automatic evaluation we use the official ROUGE software with standard options and report ROUGE-1 and ROUGE-2 precision, recall and F-1 scores.

3.4 Results

3.4.1 Automatic Evaluation (Chat dataset)

Abstractive vs. Extractive: our full query-based abstractive summariztion system show statistically significant improvements over baselines and other pure extractive summarization systems for ROUGE-1[4]. This means our systems can effectively aggregate the extracted sentences and generate abstract sentences based on the query content. We can also observe that our full system produces the highest ROUGE-1 precision score among all models, which further confirms the success of this model in meeting the user information needs imposed by queries. The absolute improvement of 10% in precision for ROUGE-1 in our abstractive model over our extractive model (our pipeline) further confirms the effectiveness of our ranking method in generating the abstract sentences considering the query related information.

Our extractive query-based method beats all other extractive systems with a higher ROUGE-1 and ROUGE-2 which shows the effectiveness of our utterance extraction model in comparison with other extractive models. In other words, using our extractive model described in section 2.1, as a stand alone system, is an effective query-based extractive summarization model. We also observe that our extractive model outperforms our abstractive model for ROUGE-2 score. This can be due to word merging and word replacement choices in the word graph construction, which sometimes change or remove a word in a bigram and consequently may decrease the bigram overlap score.

Query Relevance: another interesting observation is that relying only on the cosine similarity (i.e., *cosine-all*) to measure the query relevance presents a quite strong baseline. This proves the importance of query content in our dataset and further supports the main claim of our work that a

Table 3: Average rating and distribution over grammaticality scores for phrasal query abstraction system in comparison with original sentences.

good summary should express a brief and well-organized abstract that answers the user's query. Moreover, a precision of 71% for ROUGE-1 from the simple *cosine-1st* baseline confirms that some utterances contain more query relevant information in conversational discussions.

Query-based vs. Generic: the high recall and low precision in *TextRank* baseline, both for the ROUGE-1 and ROUGE-2 scores, shows the strength of the model in extracting the generic information from chat conversations while missing the query-relevant content. The *LexRank* baseline improves the results of the *TextRank* system by increasing the precision and balancing the precision and recall scores for ROUGE-1 score. We believe that this is due to the robustness of the *LexRank* method in dealing with noisy texts (chat conversations) (Erkan and Radev, 2004). In addition, the *Biased LexRank* model slightly improves the generic *LexRank* system. Considering this marginal improvement and relatively high results of pure extractive systems, we can infer that the *Biased LexRank* extracted summaries do not carry much query relevant content. In contrast, the significant improvement of our model over the extractive methods demonstrates the success of our approach in presenting the query related content in generated abstracts.

An example of a short chat log, its related query and corresponding manual and automatic summaries are shown in Example 3.

3.4.2 Manual Evaluation

Content and User Preference: Table 2 demonstrates overall quality, responsiveness (query relatedness) and user preference scores for the abstracts generated by our system and two baselines. Results indicate that our system significantly outperforms baselines in overall quality and responsiveness, for both meeting and email datasets. This confirms the validity of the results we obtained by conducting automatic evaluation over the chat dataset. We also can observe that the absolute improvements in overall quality and responsiveness for emails (0.9 and 0.7) is greater than for meetings (0.4 and 0.6). This is expected since dealing with spoken conversations is more challenging than written ones. Note that the responsiveness scores are greater than overall scores. This further proves the effectiveness of our approach in dealing with phrasal queries. We also evaluate the users' summary preferences. For both datasets (meeting and email), in majority of cases (70% and 60% respectively), the users prefer the query-based abstractive summary generated by our system.

Grammaticality: Table 3 shows grammaticality scores and distributions over the three possible scores for all datasets. The chat dataset results demonstrate the highest scores: 73% of the sentences generated by our phrasal query abstraction model are grammatically correct and 24% of the generated sentences are almost correct with only one grammatical error, while only 3% of the abstract sentences are grammatically incorrect. However, the results varies moving to other datasets. For meeting dataset, the percentage of completely grammatical sentences drops dramatically. This is due to the nature of spoken conversations which is more error prone and ungrammatical. The grammaticality score of the original sentences also proves that the sentences from meet-

Query: Trigger namespace and the self property
Chat log: A: good morning B: good morning C: good morning everyone D: good morning D: good night all F: New GNUe Traffic online F: loadsa deep metaphyisical stuff this week F: D & E discuss the meaning of 'self' ;-) E: yes, and he took the more metaphysical route, where I took the more scientific route E: I say self's meaning is derived from one's ancestry E: self's meaning is derived from how others use you E: okay, analogy extended too far, I guess :) F: is this a friends vs family debate? E: also noted that the cool part about that is if you have code that needs to happen both on a pre-insert and a pre-update - but only a few lines of the code is different E: you could have one block of trigger code that used self.action to find out why it had been called and branch accordingly. E: there was a big jump from the previous paragraph to that E: that took that out of context E: iirc, I was saying an alternative was that "self" could refer to neither the trigger's owner nor to the trigger's caller E: but to the event itself E: so self.action could be what action is being performed E: self.parent could be the trigger's owner E: and self.context could be the caller E: and self.name could be the name of the trigger F: umm, I'm afraid apparant non-sequiturs are always a hazard of doing summaries ;-) E: iow, I was presenting a 3rd alternative where self referred to something specific to the trigger F: I normally try to write around them, but not 100% successful E: I'm just convulsing my thoughts to the irc log E: for an errata next week :) E: I think convulsing is a good description F: heh
TexRank: There was a big jump from the previous paragraph to that. that took that out of context iirc, I was saying an alternative was that "self" could refer to neither the trigger's owner nor to the trigger's caller. but to the event itself. so self.action could be what action is being performed, self.parent could be the trigger's owner, and self.context could be the caller and self.name could be the name of the trigger. umm, I'm afraid apparant non-sequiturs are always a hazard of doing summaries ;-)
LexRank: good morning everyone. heh. I'm just convulsing my thoughts to the irc log good morning. Jason also noted that the cool part about that is if you have code that needs to happen both on a pre-insert and a pre-update - but only a few lines of the code is different - you could have one block of trigger code that used self.action to find out why it had been called and branch accordingly. for an errata next week :) self's meaning is derived from how others use you. I think convulsing is a good description reinhard & jcater discuss the meaning of 'self' ;-)
Biased-LexRank: good morning everyone. heh. I'm just convulsing my thoughts to the irc log. Jason also noted that the cool part about that is if you have code that needs to happen both on a pre-insert and a pre-update - but only a few lines of the code is different - you could have one block of trigger code that used self.action to find out why it had been called and branch accordingly. yes, and he took the more metaphysical route, where I took the more scientific route there was a big jump from the previous paragraph to that but to the event itself. iow, I was presenting a 3rd alternative where self referred to something specific to the trigger.
Our system: self could refer to neither the triggers owner nor caller. I was saying an alternative where self referred to something specific to the trigger. and self.name could be the name. so self.action could be what action is being performed, self.parent the triggers owner and self.context caller.
Gold: Further to, E clarified that he had suggested that "self" could refer to neither the trigger's owner nor to the trigger's caller - but to the event itself. So self.action could be what action is being performed, self.parent could be the trigger's owner, and self.context could be the caller. In other words, I was presenting a 3rd alternative where self referred to something specific to the trigger.

Example 3. Summaries generated by our system and other baselines in comparison with the human-written summary for a short chat log. Speaker information have been anonymized.

ing transcripts, although generated by humans, are not fully grammatical. In comparison with the original sentences, for all datasets, our model reports slightly lower results for the grammaticality score. Considering the fact that the abstract sentences are automatically generated and the original sentences are human-written, the grammaticality score and the percentage of fully grammatical sentences generated by our system, with higher ROUGE or quality scores in comparison with other methods, demonstrates that our system is an effective phrasal query abstraction framework for both spoken and written conversations.

4 Conclusion

We have presented an unsupervised framework for abstractive summarization of spoken and written conversations based on phrasal queries. For content selection, we propose a sentence extraction model that incorporates query relevance and content importance into the extraction process. For the generation phase, we propose a ranking strategy which selects the best path in the constructed word graph based on fluency, query relevance and content. Both automatic and manual evaluation of our model show substantial improvement over extraction-based methods, including Biased LexRank, which is considered a state-of-the-art system. Moreover, our system also yields good grammaticality score for human evaluation and achieves comparable scores with the original sentences. Our future work is four-fold. First, we are trying to improve our model by incorporating conversational features (e.g., speech acts). Second, we aim at implementing a strategy to order the clusters for generating more coherent abstracts. Third, we try to improve our generated summary by resolving coreferences and incorporating speaker information (e.g., names) in the clustering and sentence generation phases. Finally, we plan to take advantage of topic shifts to better segment the relevant parts of conversations in relation to phrasal queries.

Acknowledgments

We would like to thank the anonymous reviewers for their valuable comments and suggestions to improve the paper, and the NSERC Business Intelligence Network for financial support. We also would like to acknowledge the early discussions on the related topics with Frank Tompa.

Comparing Multi-label Classification with Reinforcement Learning for Summarisation of Time-series Data

Dimitra Gkatzia, Helen Hastie, and Oliver Lemon
School of Mathematical and Computer Sciences, Heriot-Watt University, Edinburgh
{dg106, h.hastie, o.lemon}@hw.ac.uk

Abstract

We present a novel approach for automatic report generation from time-series data, in the context of student feedback generation. Our proposed methodology treats content selection as a multi-label (ML) classification problem, which takes as input time-series data and outputs a set of templates, while capturing the dependencies between selected templates. We show that this method generates output closer to the feedback that lecturers actually generated, achieving 3.5% higher accuracy and 15% higher F-score than multiple simple classifiers that keep a history of selected templates. Furthermore, we compare a ML classifier with a Reinforcement Learning (RL) approach in simulation and using ratings from real student users. We show that the different methods have different benefits, with ML being more accurate for predicting what was seen in the training data, whereas RL is more exploratory and slightly preferred by the students.

1 Introduction

Summarisation of time-series data refers to the task of automatically generating text from variables whose values change over time. We consider the task of automatically generating feedback summaries for students describing their performance during the lab of a Computer Science module over the semester. Students' learning can be influenced by many variables, such as difficulty of the material (Person et al., 1995), other deadlines (Craig et al., 2004), attendance in lectures (Ames, 1992), etc. These variables have two important qualities. Firstly, they change over time, and secondly they can be dependent on or independent of each other. Therefore, when generating feedback, we need to take into account all variables simultaneously in order to capture potential dependencies and provide more effective and useful feedback that is relevant to the students.

In this work, we concentrate on content selection which is the task of choosing what to say, i.e. what information is to be included in a report (Reiter and Dale, 2000). Content selection decisions based on trends in time-series data determine the selection of the useful and important variables, which we refer to here as *factors*, that should be conveyed in a summary. The decisions of factor selection can be influenced by other factors that their values are correlated with; can be based on the appearance or absence of other factors in the summary; and can be based on the factors' behaviour over time. Moreover, some factors may have to be discussed together in order to achieve some communicative goal, for instance, a teacher might want to refer to student's marks as a motivation for increasing the number of hours studied.

We frame content selection as a simple classification task: given a set of time-series data, decide for each template whether it should be included in a summary or not. In this paper, with the term 'template' we refer to a quadruple consisting of an *id*, a *factor* (bottom left of Table 1), a *reference type* (trend, weeks, average, other) and *surface text*. However, simple classification assumes that the templates are independent of each other, thus the decision for each template is taken in isolation from the others, which is not appropriate for our domain. In order to capture the dependencies in the context, multiple simple classifiers can make the decisions for each template iteratively. After each iteration, the feature space grows by 1 feature, in order to include the history of the previous template decisions. Here, we propose an alternative method that tackles the challenge of interdependent data by using multi-label (ML) classification, which is efficient in taking data dependencies

(8) lectures_attended (LA)	trend_other
(9) revision (R)	trend_decreasing

Summary

Your overall performance **was excellent** during the semester. Keep up the good work and maybe try some more challenging exercises. Your attendance was **varying** over the semester. Have a think about how to use time in lectures to improve your understanding of the material. You spent **2 hours studying the lecture material on average**. You should dedicate more time to study. You seem to find the material **easier to understand compared to the beginning of the semester**. Keep up the good work! You revised **part of** the learning material. Have a think whether revising has improved your performance.

Table 1: The table on the top left shows an example of the time-series raw data for feedback generation. The table on the bottom left shows an example of described trends. The box on the right presents a target summary (target summaries have been constructed by teaching staff).

into account and generating a set of labels (in our case templates) simultaneously (Tsoumakas et al., 2010). ML classification requires no history, i.e. does not keep track of previous decisions, and thus has a smaller feature space.

Our contributions to the field are as follows: we present a novel and efficient method for tackling the challenge of content selection using a ML classification approach; we applied this method to the domain of feedback summarisation; we present a comparison with an optimisation technique (Reinforcement Learning), and we discuss the similarities and differences between the two methods.

In the next section, we refer to the related work on Natural Language Generation from time-series data and on Content Selection. In Section 4.2, we describe our approach and we carry out a comparison with simple classification methods. In Section 5, we present the evaluation setup and in Section 6 we discuss the results, obtained in simulation and with real students. Finally, in Section 8, directions for future work are discussed.

2 Related Work

Natural Language Generation from time-series data has been investigated for various tasks such as weather forecast generation (Belz and Kow, 2010; Angeli et al., 2010; Sripada et al., 2004), report generation from clinical data (Hunter et al., 2011; Gatt et al., 2009), narrative to assist children with communication needs (Black et al., 2010) and audiovisual debrief generation from sensor data from Autonomous Underwater Vehicles missions (Johnson and Lane, 2011).

The important tasks of time-series data summarisation systems are *content selection* (what to say), *surface realisation* (how to say it) and *information presentation* (Document Planning, Ordering, etc.). In this work, we concentrate on content selection. Previous methods for content selection include Reinforcement Learning (Rieser et al., 2010); multi-objective optimisation (Gkatzia et al., 2014); Gricean Maxims (Sripada et al., 2003); Integer Linear Programming (Lampouras and Androutsopoulos, 2013); collective content selection (Barzilay and Lapata, 2004); interest scores assigned to content (Androutsopoulos et al., 2013); a combination of statistical and template-based approaches to NLG (Kondadadi et al., 2013); statistical acquisition of rules (Duboue and McKeown, 2003) and the Hidden Markov model approach for Content Selection and ordering (Barzilay and Lee, 2004).

Collective content selection (Barzilay and Lapata, 2004) is similar to our proposed method in that it is a classification task that predicts the templates from the same instance simultaneously. The difference between the two methods lies in that the

collective content selection requires the consideration of an individual preference score (which is defined as the preference of the entity to be selected or omitted, and it is based on the values of entity attributes and is computed using a boosting algorithm) and the identification of links between the entities with similar labels. In contrast, ML classification does not need the computation of links between the data and the templates. ML classification can also apply to other problems whose features are correlated, such as text classification (Madjarov et al., 2012), when an aligned dataset is provided.

ML classification algorithms have been divided into three categories: algorithm adaptation methods, problem transformation and ensemble methods (Tsoumakas and Katakis, 2007; Madjarov et al., 2012). Algorithm adaptation approaches (Tsoumakas et al., 2010) extend simple classification methods to handle ML data. For example, the k-nearest neighbour algorithm is extended to ML-kNN by Zhang and Zhou (2007). ML-kNN identifies for each new instance its k nearest neighbours in the training set and then it predicts the label set by utilising the maximum a posteriori principle according to statistical information derived from the label sets of the k neighbours. Problem transformation approaches (Tsoumakas and Katakis, 2007) transform the ML classification task into one or more simple classification tasks. Ensemble methods (Tsoumakas et al., 2010) are algorithms that use ensembles to perform ML learning and they are based on problem transformation or algorithm adaptation methods. In this paper, we applied RAkEL (Random k-labelsets) (Tsoumakas et al., 2010): an ensemble problem transformation method, which constructs an ensemble of simple-label classifiers, where each one deals with a random subset of the labels.

Finally, our domain for feedback generation is motivated by previous studies (Law et al., 2005; van den Meulen et al., 2010) who show that text summaries are more effective in decision making than graphs therefore it is advantageous to provide a summary over showing users the raw data graphically. In addition, feedback summarisation from time-series data can be applied to the field of Intelligent Tutoring Systems (Gross et al., 2012).

3 Data

The dataset consists of 37 instances referring to the activities of 26 students. For a few students there is more than 1 instance. An example of one such instance is presented in Table 1. Each instance includes time-series information about the student's learning habits and the selected templates that lecturers used to provide feedback to this student. The time-series information includes for each week of the semester: (1) the marks achieved at the lab; (2) the hours that the student spent studying; (3) the understandability of the material; (4) the difficulty of the lab exercises as assessed by the student; (5) the number of other deadlines that the student had that week; (6) health issues; (7) personal issues; (8) the number of lectures attended; and (9) the amount of revision that the student had performed. The templates describe these factors in four different ways:

1. <**trend**>**:** referring to the trend of a factor over the semester (e.g. "Your performance *was increasing*..."),
2. <**weeks**>**:** explicitly describing the factor value at specific weeks (e.g. "In *weeks 2, 3 and 9*..."),
3. <**average**>**:** considering the average of a factor value (e.g. "You dedicated *1.5 hours studying on average*..."), and
4. <**other**>**:** mentioning other relevant information (e.g. "*Revising material will improve your performance*").

For the corpus creation, 11 lecturers selected the content to be conveyed in a summary, given the set of raw data (Gkatzia et al., 2013). As a result, for the same student there are various summaries provided by the different experts. This characteristic of the dataset, that each instance is associated with more than one solution, additionally motivates the use of multi-label classification, which is concerned with learning from examples, where each example is associated with multiple labels.

Our analysis of the dataset showed that there are significant correlations between the factors, for example, the number of lectures attended (LA) correlates with the student's understanding of the material (Und), see Table 2. As we will discuss further in Section 5.1, content decisions are influenced by the previously generated content, for example, if the lecturer has previously mentioned health_issues, mentioning hours_studied has a high probability of also being mentioned.

Table 2: The table presents the Pearson's correlation coefficients of the factors (* means $p<0.05$).

4 Methodology

In this section, the content selection task and the suggested multi-label classification approach are presented. The development and evaluation of the time-series generation system follows the following pipeline (Gkatzia et al., 2013):

1. Time-Series data collection from students
2. Template construction by Learning and Teaching (L&T) expert
3. Feedback summaries constructed by lecturers; random summaries rated by lecturers
4. Development of time-series generation systems (Section 4.2, Section 5.3): ML system, RL system, Rule-based and Random system
5. Evaluation: (Section 5)
   - Offline evaluation (Accuracy and Reward)
   - Online evaluation (Subjective Ratings)

4.1 The Content Selection Task

Our learning task is formed as follows: given a set of 9 time-series factors, select the content that is most appropriate to be included in a summary. Content is regarded as labels (each template represents a label) and thus the task can be thought of as a classification problem. As mentioned, there are 4 ways to refer to a factor: (1) describing the trend, (2) describing what happened in every time stamp, (3) mentioning the average and (4) making another general statement. Overall, for all factors there are 29 different templates[1]. An example of the input data is shown in Table 1. There are two decisions that need to be made: (1) whether to talk about a factor and (2) in which way to refer to it. Instead of dealing with this task in a hierarchical way, where the algorithm will first learn whether to talk about a factor and then to decide how to refer to it, we transformed the task in order to reduce the learning steps. Therefore, classification can reduce the decision workload by deciding either in which way to talk about it, or not to talk about a factor at all.

[1]There are fewer than 36 templates, because for some factors there are less than 4 possible ways of referring to them.

4.2 The Multi-label Classification Approach

Traditional single-label classification is the task of identifying which label one new observation is associated with, by choosing from a set of labels L (Tsoumakas et al., 2010). Multi-label classification is the task of associating an observation with a set of labels $Y \subseteq L$ (Tsoumakas et al., 2010).

One set of factor values can result in various sets of templates as interpreted by the different experts. A ML classifier is able to make decisions for all templates simultaneously and capture these differences. The RAndom k-labELsets (RAkEL) (Tsoumakas et al., 2010) was applied in order to perform ML classification. RAkEL is based on Label Powerset (LP), a problem transformation method (Tsoumakas et al., 2010). LP benefits from taking into consideration label correlations, but does not perform well when trained with few examples as in our case (Tsoumakas et al., 2010). RAkEL overcomes this limitation by constructing a set of LP classifiers, which are trained with different random subsets of the set of labels (Tsoumakas et al., 2010).

The LP method transforms the ML task, into one single-label multi-class classification task, where the possible set of predicted variables for the transformed class is the powerset of labels present in the original dataset. For instance, the set of labels $L = \{temp_0, temp_1, ...temp_{28}\}$ could be transformed to $\{temp_{0,1,2}, temp_{28,3,17,}...\}$. This algorithm does not perform well when considering a large number of labels, due to the fact that the label space grows exponentially (Tsoumakas

Classifier	Accuracy (10-fold)	Precision	Recall	F score
Decision Tree (no history)	*75.95%	67.56	75.96	67.87
Decision Tree (with predicted history)	**73.43%	65.49	72.05	70.95
Decision Tree (with real history)	**78.09%	74.51	78.11	75.54
Majority-class (single label)	**72.02%	61.73	77.37	68.21
RAkEL (multi-label) (no history)	76.95%	**85.08**	**85.94**	**85.50**

Table 3: Average, precision, recall and F-score of the different classification methods (T-test, * denotes significance with $p<0.05$ and ** significance with $p<0.01$, when comparing each result to RAkEL).

et al., 2010). RAkEL tackles this problem by constructing an ensemble of LP classifiers and training each one on a different random subset of the set of labels (Tsoumakas et al., 2010).

4.2.1 The Production Phase of RAkEL

The algorithm was implemented using the MULAN Open Source Java library (Tsoumakas et al., 2011), which is based on WEKA (Witten and Frank, 2005). The algorithm works in two phases:

1. the production of an ensemble of LP algorithms, and
2. the combination of the LP algorithms.

RAkEL takes as input the following parameters: (1) the numbers of iterations m (which is developer specified and denotes the number of models that the algorithm will produce), (2) the size of labelset k (which is also developer specified), (3) the set of labels L, and (4) the training set D. During the initial phase it outputs an ensemble of LP classifiers and the corresponding k-labelsets. A pseudocode for the production phase is shown below:

Algorithm 1 RAkEL production phase

```
1: Input: iterations m, k labelsets,
          labels L, training data D

2: for i=0 to m
3:       Select random k-labelset from L
4:       Train an LP on D
5:       Add LP to ensemble
6: end for

7: Output: the ensemble of LPs
       with corresponding k-labelsets
```

4.2.2 The Combination Phase

During the combination phase, the algorithm takes as input the results of the production phase, i.e. the ensemble of LPs with the corresponding k-labelsets, the set of labels L, and the new instance x and it outputs the result vector of predicted labels for instance x. During run time, RAkEL estimates the average decision for each label in L and if the average is greater than a threshold t (determined by the developer) it includes the label in the predicted labelset. We used the standard parameter values of t, k and m (t = 0.5, k = 3 and m equals to 58 (2*29 templates)). In future, we could perform parameter optimisation by using a technique similar to (Gabsdil and Lemon, 2004).

5 Evaluation

Firstly, we performed a preliminary evaluation on classification methods, comparing our proposed ML classification with multiple iterated classification approaches. The summaries generated by the ML classification system are then compared with the output of a RL system and two baseline systems in simulation and with real students.

5.1 Comparison with Simple Classification

We compared the RAkEL algorithm with single-label (SL) classification. Different SL classifiers were trained using WEKA: JRip, Decision Trees, Naive Bayes, k-nearest neighbour, logistic regression, multi-layer perceptron and support vector machines. It was found out that Decision Trees achieved on average 3% higher accuracy. We, therefore, went on to use Decision Trees that use generation history in three ways.

Firstly, for **Decision Tree (no history)**, 29 decision-tree classifiers were trained, one for each template. The input of these classifiers were the 9 factors and each classifier was trained in order to decide whether to include a specific template or not. This method did not take into account other selected templates – it was only based on the time-series data.

Secondly, for **Decision Tree (with predicted history)**, 29 classifiers were also trained, but this time the input included the previous decisions made by the previous classifiers (i.e. the history)

as well as the set of time-series data in order to emulate the dependencies in the dataset. For instance, classifier n was trained using the data from the 9 factors and the template decisions for templates 0 to $n-1$.

Thirdly, for **Decision Tree (with real history)**, the real, expert values were used rather than the predicted ones in the history. The above-mentioned classifiers are compared with, the **Majority-class (single label)** baseline, which labels each instance with the most frequent template.

The accuracy, the weighted precision, the weighted recall, and the weighted F-score of the classifiers are shown in Table 3. It was found that in 10-fold cross validation RAkEL performs significantly better in all these automatic measures (accuracy = 76.95%, F-score = 85.50%). Remarkably, ML achieves more than 10% higher F-score than the other methods (Table 3). The average accuracy of the single-label classifiers is 75.95% (10-fold validation), compared to 73.43% of classification with history. The reduced accuracy of the classification with predicted history is due to the error in the predicted values. In this method, at every step, the predicted outcome was used including the incorrect decisions that the classifier made. The upper-bound accuracy is 78.09% calculated by using the expert previous decisions and not the potentially erroneous predicted decisions. This result is indicative of the significance of the relations between the factors showing that the predicted decisions are dependent due to existing correlations as discussed in Section 1, therefore the system should not take these decisions independently. ML classification performs better because it does take into account these correlations and dependencies in the data.

5.2 The Reinforcement Learning System

Reinforcement Learning (RL) is a machine learning technique that defines how an agent learns to take optimal actions so as to maximise a cumulative reward (Sutton and Barto, 1998). Content selection is seen as a Markov Decision problem and the goal of the agent is to learn to take the sequence of actions that leads to optimal content selection. The Temporal Difference learning method was used to train an agent for content selection.

Actions and States: The state consists of the time-series data and the selected templates. In order to explore the state space the agent selects a factor (e.g. marks, deadlines etc.) and then decides whether to talk about it or not.

Reward Function: The reward function reflects the lecturers' preferences on summaries and is derived through linear regression analysis of a dataset containing lecturer constructed summaries and ratings of randomly generated summaries. Specifically, it is the following cumulative multivariate function:

$$Reward = a + \sum_{i=1}^{n} b_i * x_i + c * length$$

where $X = \{x_1, x_2, ..., x_n\}$ describes the combinations of the data trends observed in the time-series data and a particular template. a, b and c are the regression coefficients, and their values vary from -99 to 221. The value of x_i is given by the function:

$$x_i = \begin{cases} 1, & \text{the combination of a factor trend} \\ & \text{and a template type is included} \\ & \text{in a summary} \\ 0, & \text{if not.} \end{cases}$$

The RL system differs from the classification system in the way it performs content selection. In the training phase, the agent selects a factor and then decides whether to talk about it or not. If the agent decides to refer to a factor, the template is selected in a deterministic way, i.e. from the available templates it selects the template that results in higher expected cumulative future reward.

5.3 The Baseline Systems

We compared the ML system and the RL system with two baselines described below by measuring the accuracy of their outputs, the reward achieved by the reward function used for the RL system, and finally we also performed evaluation with student users. In order to reduce the confounding variables, we kept the ordering of content in all systems the same, by adopting the ordering of the rule-based system. The baselines are as follows:

1. Rule-based System: generates summaries based on Content Selection rules derived by working with a L&T expert and a student (Gkatzia et al., 2013).

2. Random System: initially, selects a factor randomly and then selects a template randomly, until it makes decisions for all factors.

Time-Series Summarisation Systems	Accuracy	Reward	Rating Mode (mean)	Data Source
Multi-label Classification	**85%**	65.4	7 (6.24)	Lecturers' constructed summaries
Reinforcement Learning	**66%	**243.82**	**8 (6.54)**	Lecturers' ratings & summaries
Rule-based	**65%	107.77	7, 8 (5.86)	L&T expert
Random	**45.2%	43.29	*2 (*4.37)	Random

Table 4: Accuracy, average rewards (based on lecturers' preferences) and averages of the means of the student ratings. Accuracy significance (Z-test) with RAkEL at $p<0.05$ is indicated as * and at $p<0.01$ as **. Student ratings significance (Mann Whitney U test) with RAkEL at $p<0.05$ is indicated as *.

6 Results

Each of the four systems described above generated 26 feedback summaries corresponding to the 26 student profiles. These summaries were evaluated in simulation and with real student users.

6.1 Results in Simulation

Table 4 presents the accuracy, reward, and mode of student rating of each algorithm when used to generate the 26 summaries. Accuracy was estimated as the proportion of the correctly classified templates to the population of templates. In order to have a more objective view on the results, the score achieved by each algorithm using the reward function was also calculated. ML classification achieved significantly higher accuracy, which was expected as it is a supervised learning method. The rule-based system and the RL system have lower accuracy compared to the ML system. There is evidently a mismatch between the rules and the test-set; the content selection rules are based on heuristics provided by a L&T Expert rather than by the same pool of lecturers that created the test-set. On the contrary, the RL is trained to optimise the selected content and not to replicate the existing lecturer summaries, hence there is a difference in accuracy.

Accuracy measures how similar the generated output is to the gold standard, whereas the reward function calculates a score regarding how good the output is, given an objective function. RL is trained to optimise for this function, and therefore it achieves higher reward, whereas ML is trained to learn by examples, therefore it produces output closer to the gold standard (lecturer's produced summaries). RL uses exploration and exploitation to discover combinations of content that result in higher reward. The reward represents predicted ratings that lecturers would give to the summary. The reward for the lecturers' produced summaries is 124.62 and for the ML method is 107.77. The ML classification system performed worse than this gold standard in terms of reward, which is expected given the error in predictions (supervised methods learn to reproduce the gold standard). Moreover, each decision is rewarded with a different value as some combinations of factors and templates have greater or negative regression coefficients. For instance, the combination of the factors "deadlines" and the template that corresponds to <weeks> is rewarded with 57. On the other hand, when mentioning the <average> difficulty the summary is "punished" with -81 (see description of the reward function in Section 5.2). Consequently, a single poor decision in the ML classification can result in much less reward.

6.2 Subjective Results with Students

37 first year computer science students participated in the study. Each participant was shown a graphical representation of the time-series data of one student and four different summaries generated by the four systems (see Figure 1). The order of the presented summaries was randomised. They were asked to rate each feedback summary on a 10-point rating scale in response to the following statement: "Imagine you are the following student. How would you evaluate the following feedback summaries from 1 to 10?", where 10 corresponds to the most preferred summary and 1 to the least preferred.

The difference in ratings between the ML classification system, the RL system and the Rule-based system is not significant (see Mode (mean) in Table 4, $p>0.05$). However, there is a trend towards the RL system. The classification method reduces the generation steps, by making the decision of the factor selection and the template selection jointly. Moreover, the training time for the classification method is faster (a couple of seconds compared to over an hour). Finally, the student

Figure 1: The Figure show the evaluation setup. Students were presenting with the data in a graphical way and then they were asked to evaluate each summary in a 10-point Rating scale. Summaries displayed from left to right: ML system, RL, rule-based and random.

significantly prefer all the systems over the random.

7 Summary

We have shown that ML classification for summarisation of our time-series data has an accuracy of 76.95% and that this approach significantly outperforms other classification methods as it is able to capture dependencies in the data when making content selection decisions. ML classification was also directly compared to a RL method. It was found that although ML classification is almost 20% more accurate than RL, both methods perform comparably when rated by humans. This may be due to the fact that the RL optimisation method is able to provide more varied responses over time rather than just emulating the training data as with standard supervised learning approaches. Foster (2008) found similar results when performing a study on generation of emphatic facial displays. A previous study by Belz and Reiter (2006) has demonstrated that automatic metrics can correlate highly with human ratings if the training dataset is of high quality. In our study, the human ratings correlate well to the average scores achieved by the reward function. However, the human ratings do not correlate well to the accuracy scores. It is interesting that the two methods that score differently on various automatic metrics, such as accuracy, reward, precision, recall and F-score, are evaluated similarly by users.

The comparison shows that each method can serve different goals. Multi-label classification generates output closer to gold standard whereas RL can optimise the output according to a reward function. ML classification could be used when the goal of the generation is to replicate phenomena seen in the dataset, because it achieves high accuracy, precision and recall. However, optimisation methods can be more flexible, provide more varied output and can be trained for different goals, e.g. for capturing preferences of different users.

8 Future Work

For this initial experiment, we evaluated with students and not with lecturers, since the students are the recipients of feedback. In future, we plan to evaluate with students' own data under real circumstances as well as with ratings from lecturers. Moreover, we plan to utilise the results from this student evaluation in order to train an optimisation algorithm to perform summarisation according to students' preferences. In this case, optimisation would be the preferred method as it would not be appropriate to collect gold standard data from students. In fact, it would be of interest to investigate multi-objective optimisation techniques that can balance the needs of the lecturers to convey important content to the satisfaction of students.

Approximation Strategies for Multi-Structure Sentence Compression

Kapil Thadani
Department of Computer Science
Columbia University
New York, NY 10025, USA
kapil@cs.columbia.edu

Abstract

Sentence compression has been shown to benefit from joint inference involving both n-gram and dependency-factored objectives but this typically requires expensive integer programming. We explore instead the use of Lagrangian relaxation to decouple the two subproblems and solve them separately. While dynamic programming is viable for bigram-based sentence compression, finding optimal compressed trees within graphs is NP-hard. We recover approximate solutions to this problem using LP relaxation and maximum spanning tree algorithms, yielding techniques that can be combined with the efficient bigram-based inference approach using Lagrange multipliers. Experiments show that these approximation strategies produce results comparable to a state-of-the-art integer linear programming formulation for the same joint inference task along with a significant improvement in runtime.

1 Introduction

Sentence compression is a text-to-text generation task in which an input sentence must be transformed into a shorter output sentence which accurately reflects the meaning in the input and also remains grammatically well-formed. The compression task has received increasing attention in recent years, in part due to the availability of datasets such as the Ziff-Davis corpus (Knight and Marcu, 2000) and the Edinburgh compression corpora (Clarke and Lapata, 2006), from which the following example is drawn.

Original: In 1967 Chapman, who had cultivated a conventional image with his ubiquitous tweed jacket and pipe, by his own later admission stunned a party attended by his friends and future Python colleagues by coming out as a homosexual.

Compressed: In 1967 Chapman, who had cultivated a conventional image, stunned a party by coming out as a homosexual.

Following an assumption often used in compression systems, the compressed output in this corpus is constructed by dropping tokens from the input sentence without any paraphrasing or reordering.[1]

A number of diverse approaches have been proposed for deletion-based sentence compression, including techniques that assemble the output text under an n-gram factorization over the input text (McDonald, 2006; Clarke and Lapata, 2008) or an arc factorization over input dependency parses (Filippova and Strube, 2008; Galanis and Androutsopoulos, 2010; Filippova and Altun, 2013). Joint methods have also been proposed that invoke integer linear programming (ILP) formulations to simultaneously consider multiple structural inference problems—both over n-grams and input dependencies (Martins and Smith, 2009) or n-grams and all possible dependencies (Thadani and McKeown, 2013). However, it is well-established that the utility of ILP for optimal inference in structured problems is often outweighed by the worst-case performance of ILP solvers on large problems without unique integral solutions. Furthermore, approximate solutions can often be adequate for real-world generation systems, particularly in the presence of linguistically-motivated constraints such as those described by Clarke and Lapata (2008), or domain-specific

[1] This is referred to as *extractive compression* by Cohn and Lapata (2008) & Galanis and Androutsopoulos (2010) following the terminology used in document summarization.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1241–1251,
Baltimore, Maryland, USA, June 23-25 2014.

pruning strategies such as the use of sentence templates to constrain the output.

In this work, we develop approximate inference strategies to the joint approach of Thadani and McKeown (2013) which trade the optimality guarantees of exact ILP for faster inference by separately solving the n-gram and dependency subproblems and using Lagrange multipliers to enforce consistency between their solutions. However, while the former problem can be solved efficiently using the dynamic programming approach of McDonald (2006), there are no efficient algorithms to recover maximum weighted non-projective subtrees in a general directed graph. Maximum spanning tree algorithms, commonly used in non-projective dependency parsing (McDonald et al., 2005), are not easily adaptable to this task since the maximum-weight subtree is not necessarily a part of the maximum spanning tree.

We therefore consider methods to recover approximate solutions for the subproblem of finding the maximum weighted subtree in a graph, common among which is the use of a linear programming relaxation. This linear program (LP) appears empirically tight for compression problems and our experiments indicate that simply using the non-integral solutions of this LP in Lagrangian relaxation can empirically lead to reasonable compressions. In addition, we can recover approximate solutions to this problem by using the Chu-Liu Edmonds algorithm for recovering maximum spanning trees (Chu and Liu, 1965; Edmonds, 1967) over the relatively sparse subgraph defined by a solution to the relaxed LP. Our proposed approximation strategies are evaluated using automated metrics in order to address the question: under what conditions should a real-world sentence compression system implementation consider exact inference with an ILP or approximate inference? The contributions of this work include:

- An empirically-useful technique for approximating the maximum-weight subtree in a weighted graph using LP-relaxed inference.
- Multiple approaches to generate good approximate solutions for joint multi-structure compression, based on Lagrangian relaxation to enforce equality between the sequential and syntactic inference subproblems.
- An analysis of the tradeoffs incurred by joint approaches with regard to runtime as well as performance under automated measures.

2 Multi-Structure Sentence Compression

Even though compression is typically formulated as a token deletion task, it is evident that dropping tokens independently from an input sentence will likely not result in fluent and meaningful compressive text. Tokens in well-formed sentences participate in a number of syntactic and semantic relationships with other tokens, so one might expect that accounting for heterogenous structural relationships between tokens will improve the coherence of the output sentence. Furthermore, much recent work has focused on the challenge of joint sentence extraction and compression, also known as *compressive summarization* (Martins and Smith, 2009; Berg-Kirkpatrick et al., 2011; Almeida and Martins, 2013; Li et al., 2013; Qian and Liu, 2013), in which questions of efficiency are paramount due to the larger problems involved; however, these approaches largely restrict compression to pruning parse trees, thereby imposing a dependency on parser performance. We focus in this work on a sentence-level compression system to approximate the ILP-based inference of Thadani and McKeown (2013) which does not restrict compressions to follow input parses but permits the generation of novel dependency relations in output compressions.

The rest of this section is organized as follows: §2.1 provies an overview of the joint sequential and syntactic objective for compression from Thadani and McKeown (2013) while §2.2 discusses the use of Lagrange multipliers to enforce consistency between the different structures considered. Following this, §2.3 discusses a dynamic program to find maximum weight bigram subsequences from the input sentence, while §2.4 covers LP relaxation-based approaches for approximating solutions to the problem of finding a maximum-weight subtree in a graph of potential output dependencies. Finally, §2.5 discusses the features and model training approach used in our experimental results which are presented in §3.

2.1 Joint objective

We begin with some notation. For an input sentence S comprised of n tokens including duplicates, we denote the set of tokens in S by $T \triangleq \{t_i : 1 \leq i \leq n\}$. Let C represent a compression of S and let $x_i \in \{0, 1\}$ denote an indicator variable whose value corresponds to whether token $t_i \in T$ is present in the compressed sentence

C. In addition, we define bigram indicator variables $y_{ij} \in \{0, 1\}$ to represent whether a particular order-preserving bigram[2] $\langle t_i, t_j \rangle$ from S is present as a contiguous bigram in C as well as dependency indicator variables $z_{ij} \in \{0, 1\}$ corresponding to whether the dependency arc $t_i \rightarrow t_j$ is present in the dependency parse of C. The score for a given compression C can now be defined to factor over its tokens, n-grams and dependencies as follows.

$$\begin{aligned} score(C) \;=\; & \sum_{t_i \in T} x_i \cdot \theta_{\text{tok}}(t_i) \\ & + \sum_{\substack{t_i \in T \cup \{\text{START}\}, \\ t_j \in T \cup \{\text{END}\}}} y_{ij} \cdot \theta_{\text{bgr}}(\langle t_i, t_j \rangle) \\ & + \sum_{\substack{t_i \in T \cup \{\text{ROOT}\}, \\ t_j \in T}} z_{ij} \cdot \theta_{\text{dep}}(t_i \rightarrow t_j) \end{aligned} \quad (1)$$

where θ_{tok}, θ_{bgr} and θ_{dep} are feature-based scoring functions for tokens, bigrams and dependencies respectively. Specifically, each $\theta_v(\cdot) \equiv \mathbf{w}_v^\top \boldsymbol{\phi}_v(\cdot)$ where $\boldsymbol{\phi}_v(\cdot)$ is a feature map for a given variable type $v \in \{\text{tok, bgr, dep}\}$ and $\mathbf{w}_v$ is the corresponding vector of learned parameters.

The inference task involves recovering the highest scoring compression C^* under a particular set of model parameters $\mathbf{w}$.

$$\begin{aligned} C^* &= \arg\max_C \; score(C) \\ &= \arg\max_{\mathbf{x},\mathbf{y},\mathbf{z}} \; \mathbf{x}^\top \boldsymbol{\theta}_{\text{tok}} + \mathbf{y}^\top \boldsymbol{\theta}_{\text{bgr}} + \mathbf{z}^\top \boldsymbol{\theta}_{\text{dep}} \end{aligned} \quad (2)$$

where the incidence vector $\mathbf{x} \triangleq \langle x_i \rangle_{t_i \in T}$ represents an entire token configuration over T, with $\mathbf{y}$ and $\mathbf{z}$ defined analogously to represent configurations of bigrams and dependencies. $\boldsymbol{\theta}_v \triangleq \langle \theta_v(\cdot) \rangle$ denotes a corresponding vector of scores for each variable type v under the current model parameters. In order to recover meaningful compressions by optimizing (2), the inference step must ensure:

1. The configurations $\mathbf{x}$, $\mathbf{y}$ and $\mathbf{z}$ are *consistent* with each other, i.e., all configurations cover the same tokens.
2. The structural configurations $\mathbf{y}$ and $\mathbf{z}$ are *non-degenerate*, i.e, the bigram configuration $\mathbf{y}$ represents an acyclic path while the dependency configuration $\mathbf{z}$ forms a tree.

These requirements naturally rule out simple approximate inference formulations such as search-based approaches for the joint objective.[3] An ILP-based inference solution is demonstrated in Thadani and McKeown (2013) that makes use of linear constraints over the boolean variables x_i, y_{ij} and z_{ij} to guarantee consistency, as well as auxiliary real-valued variables and constraints representing the flow of commodities (Magnanti and Wolsey, 1994) in order to establish structure in $\mathbf{y}$ and $\mathbf{z}$. In the following section, we propose an alternative formulation that exploits the modularity of this joint objective.

2.2 Lagrangian relaxation

Dual decomposition (Komodakis et al., 2007) and Lagrangian relaxation in general are often used for solving joint inference problems which are decomposable into individual subproblems linked by equality constraints (Koo et al., 2010; Rush et al., 2010; Rush and Collins, 2011; DeNero and Macherey, 2011; Martins et al., 2011; Das et al., 2012; Almeida and Martins, 2013). This approach permits sub-problems to be solved separately using problem-specific efficient algorithms, while consistency over the structures produced is enforced through Lagrange multipliers via iterative optimization. Exact solutions are guaranteed when the algorithm converges on a consistent primal solution, although this convergence itself is not guaranteed and depends on the tightness of the underlying LP relaxation. The primary advantage of this technique is the ability to leverage the underlying structure of the problems in inference rather than relying on a generic ILP formulation while still often producing exact solutions.

The multi-structure inference problem described in the previous section seems in many ways to be a natural fit to such an approach since output scores factor over different types of structure that comprise the output compression. Even if ILP-based approaches perform reasonably at the scale of single-sentence compression problems, the exponential worst-case complexity of general-purpose ILPs will inevitably pose challenges when scaling up to (a) handle larger inputs, (b) use higher-order structural fragments, or (c) incorporate additional models.

[2] Although Thadani and McKeown (2013) is not restricted to bigrams or order-preserving n-grams, we limit our discussion to this scenario as it also fits the assumptions of McDonald (2006) and the datasets of Clarke and Lapata (2006).

[3] This work follows Thadani and McKeown (2013) in recovering non-projective trees for inference. However, recovering projective trees is tractable when a total ordering of output tokens is assumed. This will be addressed in future work.

Consider once more the optimization problem characterized by (2) The two structural problems that need to be solved in this formulation are the extraction of a maximum-weight acyclic subsequence of bigrams $\mathbf{y}$ from the lattice of all order-preserving bigrams from S and the recovery of a maximum-weight directed subtree $\mathbf{z}$. Let $\boldsymbol{\alpha}(\mathbf{y}) \in \{0,1\}^n$ denote the incidence vector of tokens contained in the n-gram sequence $\mathbf{y}$ and $\boldsymbol{\beta}(\mathbf{z}) \in \{0,1\}^n$ denote the incidence vector of words contained in the dependency tree $\mathbf{z}$. We can now rewrite the objective in (2) while enforcing the constraint that the words contained in the sequence $\mathbf{y}$ are the same as the words contained in the tree $\mathbf{z}$, i.e., $\boldsymbol{\alpha}(\mathbf{y}) = \boldsymbol{\beta}(\mathbf{z})$, by introducing a vector of Lagrange multipliers $\boldsymbol{\lambda} \in \mathbb{R}^n$. In addition, the token configuration $\mathbf{x}$ can be rewritten in the form of a weighted combination of $\boldsymbol{\alpha}(\mathbf{y})$ and $\boldsymbol{\beta}(\mathbf{z})$ to ensure its consistency with $\mathbf{y}$ and $\mathbf{z}$. This results in the following Lagrangian:

$$\begin{aligned} L(\boldsymbol{\lambda}, \mathbf{y}, \mathbf{z}) = \mathbf{y}^\top \boldsymbol{\theta}_{\text{bgr}} + \mathbf{z}^\top \boldsymbol{\theta}_{\text{dep}} \\ + \boldsymbol{\theta}_{\text{tok}}^\top (\psi \cdot \boldsymbol{\alpha}(\mathbf{y}) + (1-\psi) \cdot \boldsymbol{\beta}(\mathbf{z})) \\ + \boldsymbol{\lambda}^\top (\boldsymbol{\alpha}(\mathbf{y}) - \boldsymbol{\beta}(\mathbf{z})) \end{aligned} \tag{3}$$

Finding the $\mathbf{y}$ and $\mathbf{z}$ that maximize this Lagrangian above yields a dual objective, and the dual problem corresponding to the primal objective specified in (2) is therefore the minimization of this objective over the Lagrange multipliers $\boldsymbol{\lambda}$.

$$\begin{aligned} &\min_{\boldsymbol{\lambda}} \max_{\mathbf{y},\mathbf{z}} L(\boldsymbol{\lambda}, \mathbf{y}, \mathbf{z}) \\ =&\min_{\boldsymbol{\lambda}} \max_{\mathbf{y}} \mathbf{y}^\top \boldsymbol{\theta}_{\text{bgr}} + (\boldsymbol{\lambda} + \psi \cdot \boldsymbol{\theta}_{\text{tok}})^\top \boldsymbol{\alpha}(\mathbf{y}) \\ &+ \max_{\mathbf{z}} \mathbf{z}^\top \boldsymbol{\theta}_{\text{dep}} - (\boldsymbol{\lambda} + (\psi - 1) \cdot \boldsymbol{\theta}_{\text{tok}})^\top \boldsymbol{\beta}(\mathbf{z}) \\ =&\min_{\boldsymbol{\lambda}} \max_{\mathbf{y}} f(\mathbf{y}, \boldsymbol{\lambda}, \psi, \boldsymbol{\theta}) \\ &+ \max_{\mathbf{z}} g(\mathbf{z}, \boldsymbol{\lambda}, \psi, \boldsymbol{\theta}) \end{aligned} \tag{4}$$

This can now be solved with the iterative subgradient algorithm illustrated in Algorithm 1. In each iteration i, the algorithm solves for $\mathbf{y}^{(i)}$ and $\mathbf{z}^{(i)}$ under $\boldsymbol{\lambda}^{(i)}$, then generates $\boldsymbol{\lambda}^{(i+1)}$ to penalize inconsistencies between $\boldsymbol{\alpha}(\mathbf{y}^{(i)})$ and $\boldsymbol{\beta}(\mathbf{z}^{(i)})$. When $\boldsymbol{\alpha}(\mathbf{y}^{(i)}) = \boldsymbol{\beta}(\mathbf{z}^{(i)})$, the resulting primal solution is exact, i.e., $\mathbf{y}^{(i)}$ and $\mathbf{z}^{(i)}$ represent the optimal structures under (2). Otherwise, if the algorithm starts oscillating between a few primal solutions, the underlying LP must have a non-integral solution in which case approximation heuristics can be employed.[4] The application of this Lagrangian relaxation strategy is contingent upon the existence of algorithms to solve the maximization subproblems for $f(\mathbf{y}, \boldsymbol{\lambda}, \psi, \boldsymbol{\theta})$ and $g(\mathbf{z}, \boldsymbol{\lambda}, \psi, \boldsymbol{\theta})$. The following sections discuss our approach to these problems.

Algorithm 1 Subgradient-based joint inference

Input: scores $\boldsymbol{\theta}$, ratio ψ, repetition limit l_{max}, iteration limit i_{max}, learning rate schedule $\boldsymbol{\eta}$
Output: token configuration $\mathbf{x}$

$\boldsymbol{\lambda}^{(0)} \leftarrow \langle 0 \rangle^n$
$M \leftarrow \varnothing, M_{\text{repeats}} \leftarrow \varnothing$
for iteration $i < i_{\text{max}}$ **do**
  $\hat{\mathbf{y}} \leftarrow \arg\max_{\mathbf{y}} f(\mathbf{y}, \boldsymbol{\lambda}, \psi, \boldsymbol{\theta})$
  $\hat{\mathbf{z}} \leftarrow \arg\max_{\mathbf{z}} g(\mathbf{z}, \boldsymbol{\lambda}, \psi, \boldsymbol{\theta})$
  if $\boldsymbol{\alpha}(\hat{\mathbf{y}}) = \boldsymbol{\beta}(\hat{\mathbf{z}})$ **then return** $\boldsymbol{\alpha}(\hat{\mathbf{y}})$
  if $\boldsymbol{\alpha}(\hat{\mathbf{y}}) \in M$ **then**
    $M_{\text{repeats}} \leftarrow M_{\text{repeats}} \cup \{\boldsymbol{\alpha}(\hat{\mathbf{y}})\}$
  if $\boldsymbol{\beta}(\hat{\mathbf{z}}) \in M$ **then**
    $M_{\text{repeats}} \leftarrow M_{\text{repeats}} \cup \{\boldsymbol{\beta}(\hat{\mathbf{z}})\}$
  if $|M_{\text{repeats}}| \geq l_{\text{max}}$ **then break**
  $M \leftarrow M \cup \{\boldsymbol{\alpha}(\hat{\mathbf{y}}), \boldsymbol{\beta}(\hat{\mathbf{z}})\}$
  $\boldsymbol{\lambda}^{(i+1)} \leftarrow \boldsymbol{\lambda}^{(i)} - \eta_i \left(\boldsymbol{\alpha}(\hat{\mathbf{y}}) - \boldsymbol{\beta}(\hat{\mathbf{z}})\right)$
return $\arg\max_{\mathbf{x} \in \mathbf{M}_{\text{repeats}}} score(\mathbf{x})$

2.3 Bigram subsequences

McDonald (2006) provides a Viterbi-like dynamic programming algorithm to recover the highest-scoring sequence of order-preserving bigrams from a lattice, either in unconstrained form or with a specific length constraint. The latter requires a dynamic programming table $Q[i][r]$ which represents the best score for a compression of length r ending at token i. The table can be populated using the following recurrence:

$$\begin{aligned} Q[i][1] &= score(S, \text{START}, i) \\ Q[i][r] &= \max_{j<i} Q[j][r-1] + score(S, i, j) \\ Q[i][R+1] &= Q[i][R] + score(S, i, \text{END}) \end{aligned}$$

where R is the required number of output tokens and the scoring function is defined as

$$score(S, i, j) \triangleq \theta_{\text{bgr}}(\langle t_i, t_j \rangle) + \lambda_j + \psi \cdot \theta_{\text{tok}}(t_j)$$

so as to solve $f(\mathbf{y}, \boldsymbol{\lambda}, \psi, \boldsymbol{\theta})$ from (4). This approach requires $O(n^2 R)$ time in order to identify

[4] Heuristic approaches (Komodakis et al., 2007; Rush et al., 2010), tightening (Rush and Collins, 2011) or branch and bound (Das et al., 2012) can still be used to retrieve optimal solutions, but we did not explore these strategies here.

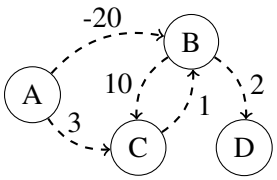

Figure 1: An example of the difficulty of recovering the maximum-weight subtree (B→C, B→D) from the maximum spanning tree (A→C, C→B, B→D).

the highest scoring sequence $\mathbf{y}$ and corresponding token configuration $\boldsymbol{\alpha}(\mathbf{y})$.

2.4 Dependency subtrees

The maximum-weight non-projective subtree problem over general graphs is not as easily solved. Although the maximum *spanning* tree for a given token configuration can be recovered efficiently, Figure 1 illustrates that the maximum-scoring subtree is not necessarily found within it. The problem of recovering a maximum-weight subtree in a graph has been shown to be NP-hard even with uniform edge weights (Lau et al., 2006).

In order to produce a solution to this subproblem, we use an LP relaxation of the relevant portion of the ILP from Thadani and McKeown (2013) by omitting integer constraints over the token and dependency variables in $\mathbf{x}$ and $\mathbf{z}$ respectively. For simplicity, however, we describe the ILP version rather than the relaxed LP in order to motivate the constraints with their intended purpose rather than their effect in the relaxed problem. The objective for this LP is given by

$$\max_{\mathbf{x},\mathbf{z}} \; \mathbf{x}^\top \boldsymbol{\theta'}_{\text{tok}} + \mathbf{z}^\top \boldsymbol{\theta}_{\text{dep}} \tag{5}$$

where the vector of token scores is redefined as

$$\boldsymbol{\theta'}_{\text{tok}} \triangleq (1 - \psi) \cdot \boldsymbol{\theta}_{\text{tok}} - \boldsymbol{\lambda} \tag{6}$$

in order to solve $g(\mathbf{z}, \boldsymbol{\lambda}, \psi, \boldsymbol{\theta})$ from (4).

Linear constraints are introduced to produce dependency structures that are close to the optimal dependency trees. First, tokens in the solution must only be active if they have a single active incoming dependency edge. In addition, to avoid producing multiple disconnected subtrees, only one dependency is permitted to attach to the ROOT pseudo-token.

$$x_j - \sum_i z_{ij} = 0, \quad \forall t_j \in T \tag{7}$$

$$\sum_j z_{ij} = 1, \quad \text{if } t_i = \text{ROOT} \tag{8}$$

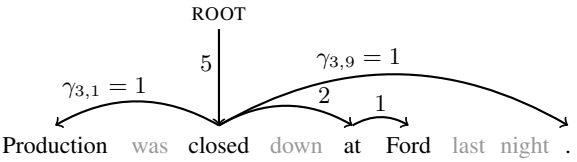

Figure 2: An illustration of commodity values for a valid solution of the non-relaxed ILP.

In order to avoid cycles in the dependency tree, we include additional variables to establish *single-commodity flow* (Magnanti and Wolsey, 1994) between all pairs of tokens. These γ_{ij} variables carry non-negative real values which must be consumed by active tokens that they are incident to.

$$\gamma_{ij} \geq 0, \quad \forall t_i, t_j \in T \tag{9}$$

$$\sum_i \gamma_{ij} - \sum_k \gamma_{jk} = x_j, \quad \forall t_j \in T \tag{10}$$

These constraints ensure that cyclic structures are not possible in the non-relaxed ILP. In addition, they serve to establish connectivity for the dependency structure $\mathbf{z}$ since commodity can only originate in one location—at the pseudo-token ROOT which has no incoming commodity variables. However, in order to enforce these properties on the output dependency structure, this acyclic, connected commodity structure must constrain the activation of the z variables.

$$\gamma_{ij} - C_{\text{max}} z_{ij} \leq 0, \quad \forall t_i, t_j \in T \tag{11}$$

where C_{max} is an arbitrary upper bound on the value of γ_{ij} variables. Figure 2 illustrates how these commodity flow variables constrain the output of the ILP to be a tree. However, the effect of these constraints is diminished when solving an LP relaxation of the above problem.

In the LP relaxation, x_i and z_{ij} are redefined as real-valued variables in $[0, 1]$, potentially resulting in fractional values for dependency and token indicators. As a result, the commodity flow network is able to establish connectivity but cannot enforce a tree structure, for instance, directed acyclic structures are possible and token indicators x_i may be partially be assigned to the solution structure. This poses a challenge in implementing $\boldsymbol{\beta}(\mathbf{z})$ which is needed to recover a token configuration from the solution of this subproblem.

We propose two alternative solutions to address this issue in the context of the joint inference strategy. The first is to simply use the relaxed token configuration identified by the LP in Algorithm 1,

i.e., to set $\boldsymbol{\beta}(\tilde{\mathbf{z}}) = \tilde{x}$ where $\tilde{\mathbf{x}}$ and $\tilde{\mathbf{z}}$ represent the real-valued counterparts of the incidence vectors $\mathbf{x}$ and $\mathbf{z}$. The viability of this approximation strategy is due to the following:

- The relaxed LP is empirically fairly tight, yielding integral solutions 89% of the time on the compression datasets described in §3.
- The bigram subproblem is guaranteed to return a well-formed integral solution which obeys the imposed compression rate, so we are assured of a source of valid—if non-optimal—solutions in line 13 of Algorithm 1.

We also consider another strategy that attempts to approximate a valid integral solution to the dependency subproblem. In order to do this, we first include an additional constraint in the relaxed LP which restrict the number of tokens in the output to a specific number of tokens R that is given by an input compression rate.

$$\sum_i x_i = R \tag{12}$$

The addition of this constraint to the relaxed LP reduces the rate of integral solutions drastically—from 89% to approximately 33%—but it serves to ensure that the resulting token configuration $\tilde{\mathbf{x}}$ has at least as many non-zero elements as R, i.e., there are at least as many tokens activated in the LP solution as are required in a valid solution.

We then construct a subgraph $G(\tilde{\mathbf{z}})$ consisting of all dependency edges that were assigned non-zero values in the solution, assigning to each edge a score equal to the score of that edge in the LP as well as the score of its dependent word, i.e., each z_{ij} in $G(\tilde{\mathbf{z}})$ is assigned a score of $\theta_{\text{dep}}(\langle t_i, t_j \rangle) - \lambda_j + (1 - \psi) \cdot \theta_{\text{tok}}(t_j)$. Since the commodity flow constraints in (9)–(11) ensure a connected $\tilde{\mathbf{z}}$, it is therefore possible to recover a maximum-weight spanning tree from $G(\tilde{\mathbf{z}})$ using the Chu-Liu Edmonds algorithm (Chu and Liu, 1965; Edmonds, 1967).[5] Although the runtime of this algorithm is cubic in the size of the input graph, it is fairly speedy when applied on relatively sparse graphs such as the solutions to the LP described above. The resulting spanning tree is a useful integral approximation of $\tilde{\mathbf{z}}$ but, as mentioned previously, may contain more nodes than R due to fractional values in $\tilde{\mathbf{x}}$; we therefore repeatedly prune leaves with the lowest incoming edge weight in the current tree until exactly R nodes remain. The resulting tree is assumed to be a reasonable approximation of the optimal integral solution to this LP.

The Chu-Liu Edmonds algorithm is also employed for another purpose: when the underlying LP for the joint inference problem is not tight—a frequent occurrence in our compression experiments—Algorithm 1 will not converge on a single primal solution and will instead oscillate between solutions that are close to the dual optimum. We identify this phenomenon by counting repeated solutions and, if they exceed some threshold l_{max} with at least one repeated solution from either subproblem, we terminate the update procedure for Lagrange multipliers and instead attempt to identify a good solution from the repeating ones by scoring them under (2). It is straightforward to recover and score a bigram configuration $\mathbf{y}$ from a token configuration $\boldsymbol{\beta}(\mathbf{z})$. However, scoring solutions produced by the dynamic program from §2.3 also requires the score over a corresponding parse tree; this can be recovered by constructing a dependency subgraph containing across only the tokens that are active in $\boldsymbol{\alpha}(\mathbf{y})$ and retrieving the maximum spanning tree for that subgraph using the Chu-Liu Edmonds algorithm.

2.5 Learning and Features

The features used in this work are largely based on the features from Thadani and McKeown (2013).

- $\boldsymbol{\phi}_{\text{tok}}$ contains features for part-of-speech (POS) tag sequences of length up to 3 around the token, features for the dependency label of the token conjoined with its POS, lexical features for verb stems and non-word symbols and morphological features that identify capitalized sequences, negations and words in parentheses.
- $\boldsymbol{\phi}_{\text{bgr}}$ contains features for POS patterns in a bigram, the labels of dependency edges incident to it, its likelihood under a Gigaword language model (LM) and an indicator for whether it is present in the input sentence.
- $\boldsymbol{\phi}_{\text{dep}}$ contains features for the probability of a dependency edge under a smoothed dependency grammar constructed from the Penn Treebank and various conjunctions of the following features: (a) whether the edge appears as a dependency or ancestral relation in the input parse (b) the directionality of the depen-

[5] A detailed description of the Chu-Liu Edmonds algorithm for MSTs is available in McDonald et al. (2005).

dency (c) the label of the edge (d) the POS tags of the tokens incident to the edge and (e) the labels of their surrounding chunks and whether the edge remains within the chunk.

For the experiments in the following section, we trained models using a variant of the structured perceptron (Collins, 2002) which incorporates minibatches (Zhao and Huang, 2013) for easy parallelization and faster convergence.[6] Overfitting was avoided by averaging parameters and monitoring performance against a held-out development set during training. All models were trained using variants of the ILP-based inference approach of Thadani and McKeown (2013). We followed Martins et al. (2009) in using LP-relaxed inference during learning, assuming algorithmic separability (Kulesza and Pereira, 2007) for these problems.

3 Experiments

We ran compression experiments over the newswire (NW) and broadcast news transcription (BN) corpora compiled by Clarke and Lapata (2008) which contain gold compressions produced by human annotators using only word deletion. The datasets were filtered to eliminate instances with less than 2 and more than 110 tokens for parser compatibility and divided into training/development/test sections following the splits from Clarke and Lapata (2008), yielding 953/63/603 instances for the NW corpus and 880/78/404 for the BN corpus. Gold dependency parses were approximated by running the Stanford dependency parser[7] over reference compressions.

Following evaluations in machine translation as well as previous work in sentence compression (Unno et al., 2006; Clarke and Lapata, 2008; Martins and Smith, 2009; Napoles et al., 2011b; Thadani and McKeown, 2013), we evaluate system performance using F_1 metrics over n-grams and dependency edges produced by parsing system output with RASP (Briscoe et al., 2006) and the Stanford parser. All ILPs and LPs were solved using Gurobi,[8] a high-performance commercial-grade solver. Following a recent analysis of compression evaluations (Napoles et al., 2011b) which revealed a strong correlation between system compression rate and human judgments of compression quality, we constrained all systems to produce compressed output at a specific rate—determined by the the gold compressions available for each instance—to ensure that the reported differences between the systems under study are meaningful.

3.1 Systems

We report results over the following systems grouped into three categories of models: tokens + n-grams, tokens + dependencies, and joint models.

- **3-LM:** A reimplementation of the unsupervised ILP of Clarke and Lapata (2008) which infers order-preserving trigram variables parameterized with log-likelihood under an LM and a significance score for token variables inspired by Hori and Furui (2004), as well as various linguistically-motivated constraints to encourage fluency in output compressions.
- **DP:** The bigram-based dynamic program of McDonald (2006) described in §2.3.[9]
- **LP→MST:** An approximate inference approach based on an LP relaxation of **ILP-Dep**. As discussed in §2.4, a maximum spanning tree is recovered from the output of the LP and greedily pruned in order to generate a valid integral solution while observing the imposed compression rate.
- **ILP-Dep:** A version of the joint ILP of Thadani and McKeown (2013) without n-gram variables and corresponding features.
- **DP+LP→MST:** An approximate joint inference approach based on Lagrangian relaxation that uses **DP** for the maximum weight subsequence problem and **LP→MST** for the maximum weight subtree problem.
- **DP+LP:** Another Lagrangian relaxation approach that pairs **DP** with the non-integral solutions from an LP relaxation of the maximum weight subtree problem (cf. §2.4).
- **ILP-Joint:** The full ILP from Thadani and McKeown (2013), which provides an upper bound on the performance of the proposed approximation strategies.

The learning rate schedule for the Lagrangian relaxation approaches was set as $\eta_i \triangleq \tau/(\tau + i)$,[10] while the hyperparameter ψ was tuned using the

[6] We used a minibatch size of 4 in all experiments.

In both tables, bold entries show significant gains within a column under the paired t-test ($p < 0.05$) and Wilcoxon's signed rank test ($p < 0.01$).

development split of each corpus.[11]

3.2 Results

Tables 1 and 2 summarize the results from our compression experiments on the BN and NW corpora respectively. Starting with the n-gram approaches, the performance of **3-LM** leads us to observe that the gains of supervised learning far outweigh the utility of higher-order n-gram factorization, which is also responsible for a significant increase in wall-clock time. In contrast, **DP** is an order of magnitude faster than all other approaches studied here although it is not competitive under parse-based measures such as RASP $F_1\%$ which is known to correlate with human judgments of grammaticality (Clarke and Lapata, 2006).

We were surprised by the strong performance of the dependency-based inference techniques, which yielded results that approached the joint model in both n-gram and parse-based measures. The exact **ILP-Dep** approach halves the runtime of **ILP-Joint** to produce compressions that have similar (although statistically distinguishable) scores. Approximating dependency-based inference with **LP→MST** yields similar performance for a further halving of runtime; however, the performance of this approach is notably worse.

Turning to the joint approaches, the strong performance of **ILP-Joint** is expected; less so is the relatively high but yet practically reasonable runtime that it requires. We note, however, that these ILPs are solved using a highly-optimized commercial-grade solver that can utilize all CPU cores[12] while our approximation approaches are implemented as single-processed Python code without significant effort toward optimization. Comparing the two approximation strategies shows a clear performance advantage for **DP+LP** over **DP+LP→MST**: the latter approach entails slower inference due to the overhead of running the Chu-Liu Edmonds algorithm at every dual update, and furthermore, the error introduced by approximating an integral solution re-

[11] We were surprised to observe that performance improved significantly when ψ was set closer to 1, thereby emphasizing token features in the dependency subproblem. The final values chosen were $\psi_{\text{BN}} = 0.9$ and $\psi_{\text{NW}} = 0.8$.

[12] 16 cores in our experimental environment.

sults in a significant decrease in dependency recall. In contrast, **DP+LP** directly optimizes the dual problem by using the relaxed dependency solution to update Lagrange multipliers and achieves the best performance on parse-based F_1 outside of the slower ILP approaches. Convergence rates also vary for these two techniques: **DP+LP** has a lower rate of empirical convergence (15% on BN and 4% on NW) when compared to **DP+LP→MST** (19% on BN and 6% on NW).

Figure 3 shows the effect of input sentence length on inference time and performance for **ILP-Joint** and **DP+LP** over the NW test corpus.[13] The timing results reveal that the approximation strategy is consistently faster than the ILP solver. The variation in RASP F_1% with input size indicates the viability of a hybrid approach which could balance accuracy and speed by using **ILP-Joint** for smaller problems and **DP+LP** for larger ones.

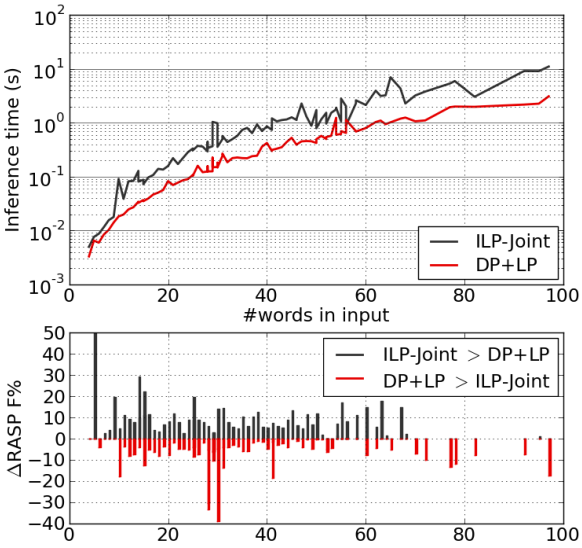

Figure 3: Effect of input size on (a) inference time, and (b) the corresponding difference in RASP F_1% (**ILP-Joint** – **DP+LP**) on the NW corpus.

4 Related Work

Sentence compression is one of the better-studied text-to-text generation problems and has been observed to play a significant role in human summarization (Jing, 2000; Jing and McKeown, 2000). Most approaches to sentence compression are supervised (Knight and Marcu, 2002; Riezler et al., 2003; Turner and Charniak, 2005; McDonald, 2006; Unno et al., 2006; Galley and McKeown, 2007; Nomoto, 2007; Cohn and Lapata, 2009; Galanis and Androutsopoulos, 2010; Ganitkevitch et al., 2011; Napoles et al., 2011a; Filippova and Altun, 2013) following the release of datasets such as the Ziff-Davis corpus (Knight and Marcu, 2000) and the Edinburgh compression corpora (Clarke and Lapata, 2006; Clarke and Lapata, 2008), although unsupervised approaches—largely based on ILPs—have also received consideration (Clarke and Lapata, 2007; Clarke and Lapata, 2008; Filippova and Strube, 2008). Compression has also been used as a tool for document summarization (Daumé and Marcu, 2002; Zajic et al., 2007; Clarke and Lapata, 2007; Martins and Smith, 2009; Berg-Kirkpatrick et al., 2011; Woodsend and Lapata, 2012; Almeida and Martins, 2013; Molina et al., 2013; Li et al., 2013; Qian and Liu, 2013), with recent work formulating the summarization task as joint sentence extraction and compression and often employing ILP or Lagrangian relaxation. Monolingual compression also faces many obstacles common to decoding in machine translation, and a number of approaches which have been proposed to combine phrasal and syntactic models (Huang and Chiang, 2007; Rush and Collins, 2011) *inter alia* offer directions for future research into compression problems.

5 Conclusion

We have presented approximate inference strategies to jointly compress sentences under bigram and dependency-factored objectives by exploiting the modularity of the task and considering the two subproblems in isolation. Experiments show that one of these approximation strategies produces results comparable to a state-of-the-art integer linear program for the same joint inference task with a 60% reduction in average inference time.

Abstract

This paper defines a systematic approach to Opinion Mining (OM) on YouTube comments by (i) modeling classifiers for predicting the opinion polarity and the type of comment and (ii) proposing robust shallow syntactic structures for improving model adaptability. We rely on the tree kernel technology to automatically extract and learn features with better generalization power than bag-of-words. An extensive empirical evaluation on our manually annotated YouTube comments corpus shows a high classification accuracy and highlights the benefits of structural models in a cross-domain setting.

1 Introduction

Social media such as Twitter, Facebook or YouTube contain rapidly changing information generated by millions of users that can dramatically affect the reputation of a person or an organization. This raises the importance of automatic extraction of sentiments and opinions expressed in social media.

YouTube is a unique environment, just like Twitter, but probably even richer: multi-modal, with a social graph, and discussions between people sharing an interest. Hence, doing sentiment research in such an environment is highly relevant for the community. While the linguistic conventions used on Twitter and YouTube indeed show similarities (Baldwin et al., 2013), focusing on YouTube allows to exploit context information, possibly also multi-modal information, not available in isolated tweets, thus rendering it a valuable resource for the future research.

Nevertheless, there is almost no work showing effective OM on YouTube comments. To the best of our knowledge, the only exception is given by the classification system of YouTube comments proposed by Siersdorfer et al. (2010).

While previous state-of-the-art models for opinion classification have been successfully applied to traditional corpora (Pang and Lee, 2008), YouTube comments pose additional challenges: (i) polarity words can refer to either video or product while expressing contrasting sentiments; (ii) many comments are unrelated or contain spam; and (iii) learning supervised models requires training data for each different YouTube domain, e.g., *tablets*, *automobiles*, etc. For example, consider a typical comment on a YouTube review video about a *Motorola Xoom* tablet:

> *this guy really puts a negative spin on this , and I 'm not sure why , this seems crazy fast , and I 'm not entirely sure why his pinch to zoom his laggy all the other* ***xoom*** *reviews*

The comment contains a product name *xoom* and some negative expressions, thus, a bag-of-words model would derive a negative polarity for this product. In contrast, the opinion towards the product is neutral as the negative sentiment is expressed towards the video. Similarly, the following comment:

> *iPad 2 is better. the superior apps just destroy the* ***xoom***.

contains two positive and one negative word, yet the sentiment towards the product is negative (the negative word *destroy* refers to *Xoom*). Clearly, the bag-of-words lacks the structural information linking the sentiment with the target product.

In this paper, we carry out a systematic study on OM targeting YouTube comments; its contribution is three-fold: firstly, to solve the problems outlined above, we define a classification schema, which separates spam and not related comments from the informative ones, which are, in turn, further categorized into video- or product-related comments

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1252–1261,
Baltimore, Maryland, USA, June 23-25 2014.

(type classification). At the final stage, different classifiers assign polarity (positive, negative or neutral) to each type of a meaningful comment. This allows us to filter out irrelevant comments, providing accurate OM distinguishing comments about the video and the target product.

The second contribution of the paper is the creation and annotation (by an expert coder) of a comment corpus containing 35k manually labeled comments for two product YouTube domains: *tablets* and *automobiles*.[1] It is the first manually annotated corpus that enables researchers to use supervised methods on YouTube for comment classification and opinion analysis. The comments from different product domains exhibit different properties (cf. Sec. 5.2), which give the possibility to study the domain adaptability of the supervised models by training on one category and testing on the other (and vice versa).

The third contribution of the paper is a novel structural representation, based on shallow syntactic trees enriched with conceptual information, i.e., tags generalizing the specific topic of the video, e.g., *iPad*, *Kindle*, *Toyota Camry*. Given the complexity and the novelty of the task, we exploit structural kernels to automatically engineer novel features. In particular, we define an efficient tree kernel derived from the Partial Tree Kernel, (Moschitti, 2006a), suitable for encoding structural representation of comments into Support Vector Machines (SVMs). Finally, our results show that our models are adaptable, especially when the structural information is used. Structural models generally improve on both tasks – polarity and type classification – yielding up to 30% of relative improvement, when little data is available. Hence, the impractical task of annotating data for each YouTube category can be mitigated by the use of models that adapt better across domains.

2 Related work

Most prior work on more general OM has been carried out on more standardized forms of text, such as consumer reviews or newswire. The most commonly used datasets include: the MPQA corpus of news documents (Wilson et al., 2005), web customer review data (Hu and Liu, 2004), Amazon review data (Blitzer et al., 2007), the JDPA corpus of blogs (Kessler et al., 2010), etc. The aforementioned corpora are, however, only partially suitable for developing models on social media, since the informal text poses additional challenges for Information Extraction and Natural Language Processing. Similar to Twitter, most YouTube comments are very short, the language is informal with numerous accidental and deliberate errors and grammatical inconsistencies, which makes previous corpora less suitable to train models for OM on YouTube. A recent study focuses on sentiment analysis for Twitter (Pak and Paroubek, 2010), however, their corpus was compiled automatically by searching for emoticons expressing positive and negative sentiment only.

Siersdorfer et al. (2010) focus on exploiting user ratings (counts of 'thumbs up/down' as flagged by other users) of YouTube video comments to train classifiers to predict the community acceptance of new comments. Hence, their goal is different: predicting comment ratings, rather than predicting the sentiment expressed in a YouTube comment or its information content. Exploiting the information from user ratings is a feature that we have not exploited thus far, but we believe that it is a valuable feature to use in future work.

Most of the previous work on supervised sentiment analysis use feature vectors to encode documents. While a few successful attempts have been made to use more involved linguistic analysis for opinion mining, such as dependency trees with latent nodes (Täckström and McDonald, 2011) and syntactic parse trees with vectorized nodes (Socher et al., 2011), recently, a comprehensive study by Wang and Manning (2012) showed that a simple model using bigrams and SVMs performs on par with more complex models.

In contrast, we show that adding structural features from syntactic trees is particularly useful for the cross-domain setting. They help to build a system that is more robust across domains. Therefore, rather than trying to build a specialized system for every new target domain, as it has been done in most prior work on domain adaptation (Blitzer et al., 2007; Daumé, 2007), the domain adaptation problem boils down to finding a more robust system (Søgaard and Johannsen, 2012; Plank and Moschitti, 2013). This is in line with recent advances in parsing the web (Petrov and McDonald, 2012), where participants where asked to build a single system able to cope with different yet re-

[1] The corpus and the annotation guidelines are publicly available at: `http://projects.disi.unitn.it/iKernels/projects/sentube/`

lated domains.

Our approach relies on robust syntactic structures to automatically generate patterns that adapt better. These representations have been inspired by the semantic models developed for Question Answering (Moschitti, 2008; Severyn and Moschitti, 2012; Severyn and Moschitti, 2013) and Semantic Textual Similarity (Severyn et al., 2013). Moreover, we introduce additional tags, e.g., video concepts, polarity and negation words, to achieve better generalization across different domains where the word distribution and vocabulary changes.

3 Representations and models

Our approach to OM on YouTube relies on the design of classifiers to predict comment type and opinion polarity. Such classifiers are traditionally based on bag-of-words and more advanced features. In the next sections, we define a baseline feature vector model and a novel structural model based on kernel methods.

3.1 Feature Set

We enrich the traditional bag-of-word representation with features from a sentiment lexicon and features quantifying the negation present in the comment. Our model (`FVEC`) encodes each document using the following feature groups:

- **word n-grams**: we compute unigrams and bigrams over lower-cased word lemmas where binary values are used to indicate the presence/absence of a given item.
- **lexicon**: a sentiment lexicon is a collection of words associated with a positive or negative sentiment. We use two manually constructed sentiment lexicons that are freely available: the MPQA Lexicon (Wilson et al., 2005) and the lexicon of Hu and Liu (2004). For each of the lexicons, we use the number of words found in the comment that have *positive* and *negative* sentiment as a feature.
- **negation**: the count of negation words, e.g., {*don't, never, not, etc.*}, found in a comment.[2] Our structural representation (defined next) enables a more involved treatment of negation.
- **video concept**: cosine similarity between a comment and the title/description of the video. Most of the videos come with a title and a short description, which can be used to encode the topicality of each comment by looking at their overlap.

3.2 Structural model

We go beyond traditional feature vectors by employing structural models (`STRUCT`), which encode each comment into a shallow syntactic tree. These trees are input to tree kernel functions for generating structural features. Our structures are specifically adapted to the noisy user-generated texts and encode important aspects of the comments, e.g., words from the sentiment lexicons, product concepts and negation words, which specifically targets the sentiment and comment type classification tasks.

In particular, our shallow tree structure is a two-level syntactic hierarchy built from word lemmas (leaves) and part-of-speech tags that are further grouped into chunks (Fig. 1). As full syntactic parsers such as constituency or dependency tree parsers would significantly degrade in performance on noisy texts, e.g., Twitter or YouTube comments, we opted for shallow structures, which rely on simpler and more robust components: a part-of-speech tagger and a chunker. Moreover, such taggers have been recently updated with models (Ritter et al., 2011; Gimpel et al., 2011) trained specifically to process noisy texts showing significant reductions in the error rate on user-generated texts, e.g., Twitter. Hence, we use the CMU Twitter pos-tagger (Gimpel et al., 2011; Owoputi et al., 2013) to obtain the part-of-speech tags. Our second component – chunker – is taken from (Ritter et al., 2011), which also comes with a model trained on Twitter data[3] and shown to perform better on noisy data such as user comments.

To address the specifics of OM tasks on YouTube comments, we enrich syntactic trees with semantic tags to encode: (i) central concepts of the video, (ii) sentiment-bearing words expressing *positive* or *negative* sentiment and (iii) negation words. To automatically identify concept words of the video we use context words (tokens detected as nouns by the part-of-speech tagger) from the video title and video description and match them in the tree. For the matched words, we enrich labels of their parent nodes (part-of-speech and chunk) with the `PRODUCT` tag. Similarly, the nodes associated with words found in

[2] The list of negation words is adopted from http://sentiment.christopherpotts.net/lingstruc.html

[3] The chunker from (Ritter et al., 2011) relies on its own POS tagger, however, in our structural representations we favor the POS tags from the CMU Twitter tagger and take only the chunk tags from the chunker.

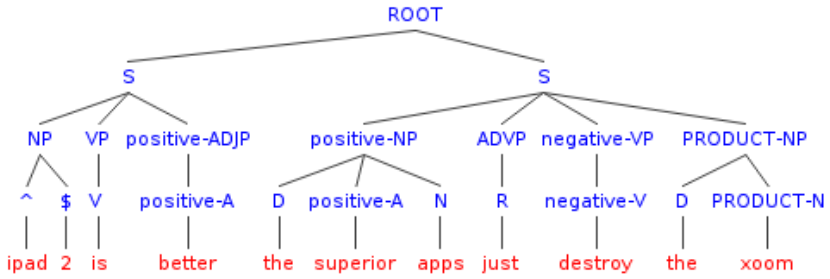

Figure 1: Shallow tree representation of the example comment (labeled with `product` type and `negative` sentiment): *"iPad 2 is better. the superior apps just destroy the xoom."* (lemmas are replaced with words for readability) taken from the video "Motorola Xoom Review". We introduce additional tags in the tree nodes to encode the central concept of the video (motorola *xoom*) and sentiment-bearing words *(better, superior, destroy)* directly in the tree nodes. For the former we add a `PRODUCT` tag on the chunk and part-of-speech nodes of the word *xoom*) and polarity tags (*positive* and *negative*) for the latter. Two sentences are split into separate root nodes `S`.

the sentiment lexicon are enriched with a polarity tag (either *positive* or *negative*), while negation words are labeled with the `NEG` tag. It should be noted that vector-based (`FVEC`) model relies only on feature counts whereas the proposed tree encodes powerful contextual syntactic features in terms of tree fragments. The latter are automatically generated and learned by SVMs with expressive tree kernels.

For example, the comment in Figure 1 shows two *positive* and one *negative* word from the sentiment lexicon. This would strongly bias the `FVEC` sentiment classifier to assign a `positive` label to the comment. In contrast, the `STRUCT` model relies on the fact that the negative word, *destroy*, refers to the PRODUCT (*xoom*) since they form a verbal phase (VP). In other words, the tree fragment: `[S [negative-VP [negative-V [destroy]] [PRODUCT-NP [PRODUCT-N [xoom]]]]` is a strong feature (induced by tree kernels) to help the classifier to discriminate such hard cases. Moreover, tree kernels generate all possible subtrees, thus producing generalized (back-off) features, e.g., `[S [negative-VP [negative-V [destroy]] [PRODUCT-NP]]]]` or `[S [negative-VP [PRODUCT-NP]]]]`.

3.3 Learning

We perform OM on YouTube using supervised methods, e.g., SVM. Our goal is to learn a model to automatically detect the sentiment and type of each comment. For this purpose, we build a multi-class classifier using the one-vs-all scheme. A binary classifier is trained for each of the classes and the predicted class is obtained by taking a class from the classifier with a maximum prediction score. Our back-end binary classifier is SVM-light-TK[4], which encodes structural kernels in the SVM-light (Joachims, 2002) solver. We define a novel and efficient tree kernel function, namely, **Sh**allow syntactic **T**ree **K**ernel (SHTK), which is as expressive as the Partial Tree Kernel (PTK) (Moschitti, 2006a) to handle feature engineering over the structural representations of the `STRUCT` model. A polynomial kernel of degree 3 is applied to feature vectors (`FVEC`).

Combining structural and vector models. A typical kernel machine, e.g., SVM, classifies a test input $\boldsymbol{x}$ using the following prediction function: $h(\boldsymbol{x}) = \sum_i \alpha_i y_i K(\boldsymbol{x}, \boldsymbol{x}_i)$, where α_i are the model parameters estimated from the training data, y_i are target variables, $\boldsymbol{x}_i$ are support vectors, and $K(\cdot,\cdot)$ is a kernel function. The latter computes the *similarity* between two comments. The `STRUCT` model treats each comment as a tuple $\boldsymbol{x} = \langle \boldsymbol{T}, \boldsymbol{v} \rangle$ composed of a shallow syntactic tree $\boldsymbol{T}$ and a feature vector $\boldsymbol{v}$. Hence, for each pair of comments $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$, we define the following comment similarity kernel:

$$K(\boldsymbol{x}_1, \boldsymbol{x}_2) = K_{\text{TK}}(\boldsymbol{T}_1, \boldsymbol{T}_2) + K_{\text{v}}(\boldsymbol{v}_1, \boldsymbol{v}_2), \quad (1)$$

where K_{TK} computes SHTK (defined next), and K_{v} is a kernel over feature vectors, e.g., linear, polynomial, Gaussian, etc.

Shallow syntactic tree kernel. Following the convolution kernel framework, we define the new

[4] http://disi.unitn.it/moschitti/Tree-Kernel.htm

SHTK function from Eq. 1 to compute the similarity between tree structures. It counts the number of common substructures between two trees T_1 and T_2 without explicitly considering the whole fragment space. The general equations for Convolution Tree Kernels is:

$$TK(T_1, T_2) = \sum_{n_1 \in N_{T_1}} \sum_{n_2 \in N_{T_2}} \Delta(n_1, n_2), \quad (2)$$

where N_{T_1} and N_{T_2} are the sets of the T_1's and T_2's nodes, respectively and $\Delta(n_1, n_2)$ is equal to the number of common fragments rooted in the n_1 and n_2 nodes, according to several possible definition of the atomic fragments.

To improve the speed computation of TK, we consider pairs of nodes (n_1, n_2) belonging to the same tree level. Thus, given H, the height of the `STRUCT` trees, where each level h contains nodes of the same type, i.e., chunk, POS, and lexical nodes, we define SHTK as the following[5]:

$$SHTK(T_1, T_2) = \sum_{h=1}^{H} \sum_{n_1 \in N_{T_1}^h} \sum_{n_2 \in N_{T_2}^h} \Delta(n_1, n_2), \quad (3)$$

where $N_{T_1}^h$ and $N_{T_2}^h$ are sets of nodes at height h.

The above equation can be applied with any Δ function. To have a more general and expressive kernel, we use Δ previously defined for PTK. More formally: if n_1 and n_2 are leaves then $\Delta(n_1, n_2) = \mu\lambda(n_1, n_2)$; else $\Delta(n_1, n_2) =$

$$\mu\Big(\lambda^2 + \sum_{\vec{I}_1, \vec{I}_2, |\vec{I}_1| = |\vec{I}_2|} \lambda^{d(\vec{I}_1) + d(\vec{I}_2)} \prod_{j=1}^{|\vec{I}_1|} \Delta(c_{n_1}(\vec{I}_{1j}), c_{n_2}(\vec{I}_{2j}))\Big),$$

where $\lambda, \mu \in [0, 1]$ are decay factors; the large sum is adopted from a definition of the subsequence kernel (Shawe-Taylor and Cristianini, 2004) to generate children subsets with gaps, which are then used in a recursive call to Δ. Here, $c_{n_1}(i)$ is the i^{th} child of the node n_1; $\vec{I}_1$ and $\vec{I}_2$ are two sequences of indexes that enumerate subsets of children with gaps, i.e., $\vec{I} = (i_1, i_2, .., |I|)$, with $1 \leq i_1 < i_2 < .. < i_{|I|}$; and $d(\vec{I}_1) = \vec{I}_{1l(\vec{I}_1)} - \vec{I}_{11} + 1$ and $d(\vec{I}_2) = \vec{I}_{2l(\vec{I}_2)} - \vec{I}_{21} + 1$, which penalizes subsequences with larger gaps.

It should be noted that: firstly, the use of a subsequence kernel makes it possible to generate child subsets of the two nodes, i.e., it allows for gaps, which makes matching of syntactic patterns less rigid. Secondly, the resulting SHTK is essentially a special case of PTK (Moschitti, 2006a), adapted to the shallow structural representation `STRUCT` (see Sec. 3.2). When applied to `STRUCT` trees, SHTK exactly computes the same feature space as PTK, but in faster time (on average). Indeed, SHTK required to be only applied to node pairs from the same level (see Eq. 3), where the node labels can match – chunk, POS or lexicals. This reduces the time for selecting the matching-node pairs carried out in PTK (Moschitti, 2006a; Moschitti, 2006b). The fragment space is obviously the same, as the node labels of different levels in `STRUCT` are different and will not be matched by PTK either.

Finally, given its recursive definition in Eq. 3 and the use of subsequence (with gaps), SHTK can derive useful dependencies between its elements. For example, it will generate the following subtree fragments: `[positive-NP [positive-AN]]`, `[S [negative-VP [negative-V [destroy]] [PRODUCT-NP]]]` and so on.

4 YouTube comments corpus

To build a corpus of YouTube comments, we focus on a particular set of videos (technical reviews and advertisings) featuring commercial products. In particular, we chose two product categories: automobiles (`AUTO`) and tablets (`TABLETS`). To collect the videos, we compiled a list of products and queried the YouTube gData API[6] to retrieve the videos. We then manually excluded irrelevant videos. For each video, we extracted all available comments (limited to maximum 1k comments per video) and manually annotated each comment with its type and polarity. We distinguish between the following types:

product: discuss the topic product in general or some features of the product;

video: discuss the video or some of its details;

spam: provide advertising and malicious links; and

off-topic: comments that have almost no content ("lmao") or content that is not related to the video ("Thank you!").

Regarding the polarity, we distinguish between {*positive, negative, neutral*} sentiments with respect to the product and the video. If the comment contains several statements of different polarities, it is annotated as both *positive* and *negative*: "Love the video but waiting for iPad 4". In total we have

[5] To have a similarity score between 0 and 1, a normalization in the kernel space, i.e. $\frac{SHTK(T_1,T_2)}{\sqrt{SHTK(T_1,T_1) \times SHTK(T_2,T_2)}}$ is applied.

[6] https://developers.google.com/youtube/v3/

annotated 208 videos with around 35k comments (128 videos TABLETS and 80 for AUTO).

To evaluate the quality of the produced labels, we asked 5 annotators to label a sample set of one hundred comments and measured the agreement. The resulting annotator agreement α value (Krippendorf, 2004; Artstein and Poesio, 2008) scores are 60.6 (AUTO), 72.1 (TABLETS) for the sentiment task and 64.1 (AUTO), 79.3 (TABLETS) for the **type** classification task. For the rest of the comments, we assigned the entire annotation task to a single coder. Further details on the corpus can be found in Uryupina et al. (2014).

5 Experiments

This section reports: (i) experiments on individual subtasks of opinion and type classification; (ii) the full task of predicting type and sentiment; (iii) study on the adaptability of our system by learning on one domain and testing on the other; (iv) learning curves that provide an indication on the required amount and type of data and the scalability to other domains.

5.1 Task description

Sentiment classification. We treat each comment as expressing positive, negative or neutral sentiment. Hence, the task is a three-way classification.

Type classification. One of the challenging aspects of sentiment analysis of YouTube data is that the comments may express the sentiment not only towards the product shown in the video, but also the video itself, i.e., users may post positive comments to the video while being generally negative about the product and vice versa. Hence, it is of crucial importance to distinguish between these two types of comments. Additionally, many comments are irrelevant for both the product and the video (off-topic) or may even contain spam. Given that the main goal of sentiment analysis is to select sentiment-bearing comments and identify their polarity, distinguishing between off-topic and spam categories is not critical. Thus, we merge the spam and off-topic into a single uninformative category. Similar to the opinion classification task, comment type classification is a multi-class classification with three classes: video, product and uninform.

Full task. While the previously discussed sentiment and type identification tasks are useful to model and study in their own right, our end goal is: given a stream of comments, to jointly predict both the type and the sentiment of each comment. We cast this problem as a single multi-class classification task with seven classes: the Cartesian product between {product, video} type labels and {positive, neutral, negative} sentiment labels plus the uninformative category (*spam* and *off-topic*). Considering a real-life application, it is important not only to detect the polarity of the comment, but to also identify if it is expressed towards the product or the video.[7]

Task	class	AUTO		TABLETS	
		TRAIN	TEST	TRAIN	TEST
Sentiment	positive	2005 (36%)	807 (27%)	2393 (27%)	1872 (27%)

	total	8196	5041	11766	8927

Table 1: Summary of YouTube comments data used in the sentiment, type and full classification tasks. The comments come from two product categories: AUTO and TABLETS. Numbers in parenthesis show proportion w.r.t. to the total number of comments used in a task.

5.2 Data

We split all the videos 50% between training set (TRAIN) and test set (TEST), where each video contains all its comments. This ensures that all comments from the same video appear either in TRAIN or in TEST. Since the number of comments per video varies, the resulting sizes of each set are different (we use the larger split for TRAIN). Table 1 shows the data distribution across the task-specific classes – **sentiment** and **type** classification. For the **sentiment** task we exclude off-topic and spam comments as well as comments with ambiguous sentiment, i.e., an-

[7] We exclude comments annotated as both video and product. This enables the use of a simple flat multi-classifiers with seven categories for the full task, instead of a hierarchical multi-label classifiers (i.e., type classification first and then opinion polarity). The number of comments assigned to both product and video is relatively small (8% for TABLETS and 4% for AUTO).

notated as both positive and negative.

For the **sentiment** task about 50% of the comments have neutral polarity, while the negative class is much less frequent. Interestingly, the ratios between polarities expressed in comments from AUTO and TABLETS are very similar across both TRAIN and TEST. Conversely, for the **type** task, we observe that comments from AUTO are uniformly distributed among the three classes, while for the TABLETS the majority of comments are product related. It is likely due to the nature of the TABLETS videos, that are more geek-oriented, where users are more prone to share their opinions and enter involved discussions about a product. Additionally, videos from the AUTO category (both commercials and user reviews) are more visually captivating and, being generally oriented towards a larger audience, generate more video-related comments. Regarding the **full** setting, where the goal is to have a joint prediction of the comment sentiment and type, we observe that video-negative and video-positive are the most scarce classes, which makes them the most difficult to predict.

5.3 Results

We start off by presenting the results for the traditional in-domain setting, where both TRAIN and TEST come from the same domain, e.g., AUTO or TABLETS. Next, we show the learning curves to analyze the behavior of FVEC and STRUCT models according to the training size. Finally, we perform a set of cross-domain experiments that describe the enhanced adaptability of the patterns generated by the STRUCT model.

5.3.1 In-domain experiments

We compare FVEC and STRUCT models on three tasks described in Sec. 5.1: sentiment, type and full. Table 2 reports the per-class performance and the overall accuracy of the multi-class classifier. Firstly, we note that the performance on TABLETS is much higher than on AUTO across all tasks. This can be explained by the following: (i) TABLETS contains more training data and (ii) videos from AUTO and TABLETS categories draw different types of audiences – well-informed users and geeks expressing better-motivated opinions about a product for the former vs. more general audience for the latter. This results in the different quality of comments with the AUTO being more challenging to analyze. Secondly, we observe that the STRUCT model provides 1-3% of absolute improvement in accuracy over FVEC for every task. For individual categories the F1 scores are also improved by the STRUCT model (except for the *negative* classes for AUTO, where we see a small drop). We conjecture that sentiment prediction for AUTO category is largely driven by one-shot phrases and statements where it is hard to improve upon the bag-of-words and sentiment lexicon features. In contrast, comments from TABLETS category tend to be more elaborated and well-argumented, thus, benefiting from the expressiveness of the structural representations.

Considering per-class performance, correctly predicting negative sentiment is most difficult for both AUTO and TABLETS, which is probably caused by the smaller proportion of the negative comments in the training set. For the **type** task, video-related class is substantially more difficult than product-related for both categories. For the **full** task, the class video-negative accounts for the largest error. This is confirmed by the results from the previous sentiment and type tasks, where we saw that handling negative sentiment and detecting video-related comments are most difficult.

5.3.2 Learning curves

The learning curves depict the behavior of FVEC and STRUCT models as we increase the size of the training set. Intuitively, the STRUCT model relies on more general syntactic patterns and may overcome the sparseness problems incurred by the FVEC model when little training data is available.

Nevertheless, as we see in Figure 2, the learning curves for sentiment and type classification tasks across both product categories do not confirm this intuition. The STRUCT model consistently outperforms the FVEC across all training sizes, but the gap in the performance does not increase when we move to smaller training sets. As we will see next, this picture changes when we perform the cross-domain study.

5.3.3 Cross-domain experiments

To understand the performance of our classifiers on other YouTube domains, we perform a set of cross-domain experiments by training on the data from one product category and testing on the other.

Table 3 reports the accuracy for three tasks when we use all comments (TRAIN + TEST) from AUTO to predict on the TEST from TABLETS

Task	class	AUTO						TABLETS

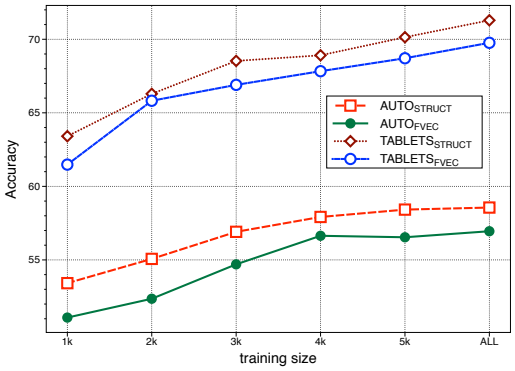
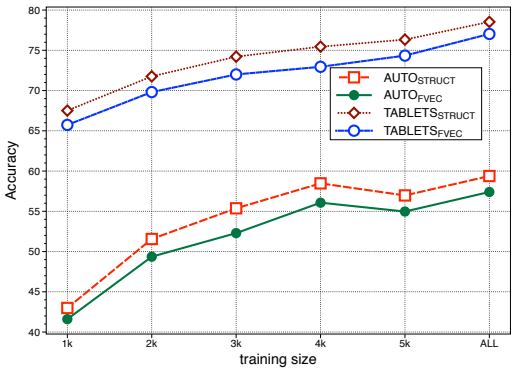
Table 2: In-domain experiments on AUTO and TABLETS using two models: FVEC and STRUCT. The results are reported for sentiment, type and full classification tasks. The metrics used are precision (P), recall (R) and F1 for each individual class and the general accuracy of the multi-class classifier (Acc).



(a) Sentiment classification



(b) Type classification

Figure 2: In-domain learning curves. ALL refers to the entire TRAIN set for a given product category, i.e., AUTO and TABLETS (see Table 1)

and in the opposite direction (TABLETS→AUTO). When using AUTO as a source domain, STRUCT model provides additional 1-3% of absolute improvement, except for the sentiment task.

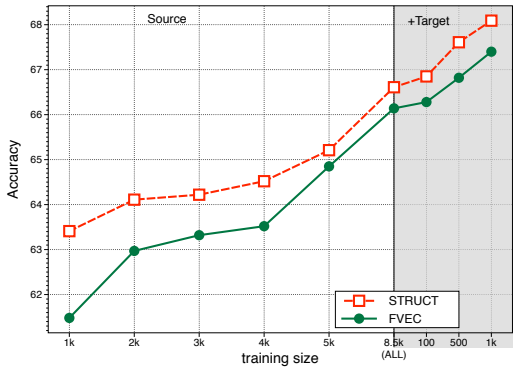
Source	Target	Task	FVEC	STRUCT
AUTO	TABLETS	Sent	66.1	66.6
		Type	59.9	64.1†
		Full	35.6	38.3†
TABLETS	AUTO	Sent	60.4	61.9†
		Type	54.2	55.6†
		Full	43.4	44.7†

Table 3: Cross-domain experiment. Accuracy using FVEC and STRUCT models when trained/tested in both directions, i.e. AUTO→TABLETS and TABLETS→AUTO. † denotes results statistically significant at 95% level (via pairwise t-test).

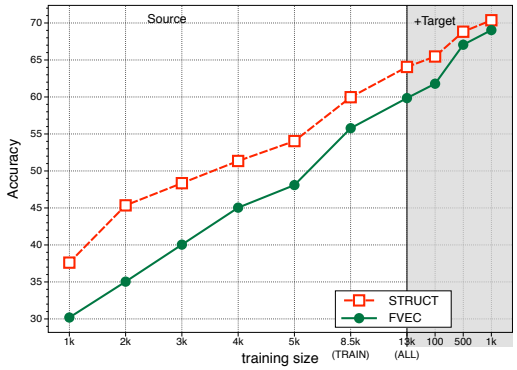
Similar to the in-domain experiments, we studied the effect of the source domain size on the target test performance. This is useful to assess the adaptability of features exploited by the FVEC and STRUCT models with the change in the number of labeled examples available for training. Additionally, we considered a setting including a small amount of training data from the target data (i.e., supervised domain adaptation).

For this purpose, we drew the learning curves of the FVEC and STRUCT models applied to the **sentiment** and **type** tasks (Figure 3): AUTO is used as the source domain to train models, which are tested on TABLETS.[8] The plot shows that when

[8]The results for the other direction (TABLETS→AUTO) show similar behavior.



(a) Sentiment classification



(b) Type classification

Figure 3: Learning curves for the cross-domain setting (AUTO→TABLETS). Shaded area refers to adding a small portion of comments from the same domain as the target test data to the training.

little training data is available, the features generated by the STRUCT model exhibit better adaptability (up to 10% of improvement over FVEC). The bag-of-words model seems to be affected by the data sparsity problem which becomes a crucial issue when only a small training set is available. This difference becomes smaller as we add data from the same domain. This is an important advantage of our structural approach, since we cannot realistically expect to obtain manual annotations for 10k+ comments for each (of many thousands) product domains present on YouTube.

5.4 Discussion

Our STRUCT model is more accurate since it is able to induce structural patterns of sentiment. Consider the following comment: *optimus pad is better. this xoom is just to bulky but optimus pad offers better functionality*. The FVEC bag-of-words model misclassifies it to be positive, since it contains two positive expressions (*better*, *better functionality*) that outweigh a single negative expression (*bulky*). The structural model, in contrast, is able to identify the product of interest (*xoom*) and associate it with the negative expression through a structural feature and thus correctly classify the comment as negative.

Some issues remain problematic even for the structural model. The largest group of errors are implicit sentiments. Thus, some comments do not contain any explicit positive or negative opinions, but provide detailed and well-argumented criticism, for example, *this phone is heavy*. Such comments might also include irony. To account for these cases, a deep understanding of the product domain is necessary.

6 Conclusions and Future Work

We carried out a systematic study on OM from YouTube comments by training a set of supervised multi-class classifiers distinguishing between video and product related opinions. We use standard feature vectors augmented by shallow syntactic trees enriched with additional conceptual information.

This paper makes several contributions: (i) it shows that effective OM can be carried out with supervised models trained on high quality annotations; (ii) it introduces a novel annotated corpus of YouTube comments, which we make available for the research community; (iii) it defines novel structural models and kernels, which can improve on feature vectors, e.g., up to 30% of relative improvement in type classification, when little data is available, and demonstrates that the structural model scales well to other domains.

In the future, we plan to work on a joint model to classify all the comments of a given video, s.t. it is possible to exploit latent dependencies between entities and the sentiments of the comment thread. Additionally, we plan to experiment with hierarchical multi-label classifiers for the full task (in place of a flat multi-class learner).

Automatic Keyphrase Extraction: A Survey of the State of the Art

Kazi Saidul Hasan and **Vincent Ng**

Richardson, TX 75083-0688
{saidul,vince}@hlt.utdallas.edu

Abstract

While automatic keyphrase extraction has been examined extensively, state-of-the-art performance on this task is still much lower than that on many core natural language processing tasks. We present a survey of the state of the art in automatic keyphrase extraction, examining the major sources of errors made by existing systems and discussing the challenges ahead.

1 Introduction

Automatic keyphrase extraction concerns "the automatic selection of important and topical phrases from the body of a document" (Turney, 2000). In other words, its goal is to extract a set of phrases that are related to the main topics discussed in a given document (Tomokiyo and Hurst, 2003; Liu et al., 2009b; Ding et al., 2011; Zhao et al., 2011).

Document keyphrases have enabled fast and accurate searching for a given document from a large text collection, and have exhibited their potential in improving many natural language processing (NLP) and information retrieval (IR) tasks, such as text summarization (Zhang et al., 2004), text categorization (Hulth and Megyesi, 2006), opinion mining (Berend, 2011), and document indexing (Gutwin et al., 1999).

Owing to its importance, automatic keyphrase extraction has received a lot of attention. However, the task is far from being solved: state-of-the-art performance on keyphrase extraction is still much lower than that on many core NLP tasks (Liu et al., 2010). Our goal in this paper is to survey the state of the art in keyphrase extraction, examining the major sources of errors made by existing systems and discussing the challenges ahead.

2 Corpora

Automatic keyphrase extraction systems have been evaluated on corpora from a variety of sources ranging from long scientific publications to short paper abstracts and email messages. Table 1 presents a listing of the corpora grouped by their sources as well as their statistics.[1] There are at least four corpus-related factors that affect the difficulty of keyphrase extraction.

Length The difficulty of the task increases with the length of the input document as longer documents yield more candidate keyphrases (i.e., phrases that are eligible to be keyphrases (see Section 3.1)). For instance, each *Inspec* abstract has on average 10 annotator-assigned keyphrases and 34 candidate keyphrases. In contrast, a scientific paper typically has at least 10 keyphrases and hundreds of candidate keyphrases, yielding a much bigger search space (Hasan and Ng, 2010). Consequently, it is harder to extract keyphrases from scientific papers, technical reports, and meeting transcripts than abstracts, emails, and news articles.

Structural consistency In a structured document, there are certain locations where a keyphrase is most likely to appear. For instance, most of a scientific paper's keyphrases should appear in the abstract and the introduction. While structural information has been exploited to extract keyphrases from scientific papers (e.g., title, section information) (Kim et al., 2013), web pages (e.g., metadata) (Yih et al., 2006), and chats (e.g., dialogue acts) (Kim and Baldwin, 2012), it is most useful when the documents from a source exhibit structural similarity. For this reason, structural information is likely to facilitate keyphrase extraction from scientific papers and technical reports because of their standard format (i.e., standard sections such as abstract, introduction, conclusion, etc.). In contrast, the lack of structural consistency in other types of structured documents (e.g., web pages, which can be blogs, forums, or reviews)

[1] Many of the publicly available corpora can be found in http://github.com/snkim/AutomaticKeyphraseExtraction/ and http://code.google.com/p/maui-indexer/downloads/list.

may render structural information less useful.

Topic change An observation commonly exploited in keyphrase extraction from scientific articles and news articles is that keyphrases typically appear not only at the beginning (Witten et al., 1999) but also at the end (Medelyan et al., 2009) of a document. This observation does not necessarily hold for conversational text (e.g., meetings, chats), however. The reason is simple: in a conversation, the topics (i.e., its talking points) change as the interaction moves forward in time, and so do the keyphrases associated with a topic. One way to address this complication is to detect a topic change in conversational text (Kim and Baldwin, 2012). However, topic change detection is not always easy: while the topics listed in the form of an agenda at the beginning of formal meeting transcripts can be exploited, such clues are absent in casual conversations (e.g., chats).

Topic correlation Another observation commonly exploited in keyphrase extraction from scientific articles and news articles is that the keyphrases in a document are typically *related* to each other (Turney, 2003; Mihalcea and Tarau, 2004). However, this observation does not necessarily hold for informal text (e.g., emails, chats, informal meetings, personal blogs), where people can talk about any number of potentially uncorrelated topics. The presence of uncorrelated topics implies that it may no longer be possible to exploit relatedness and therefore increases the difficulty of keyphrase extraction.

3 Keyphrase Extraction Approaches

A keyphrase extraction system typically operates in two steps: (1) extracting a list of words/phrases that serve as *candidate keyphrases* using some heuristics (Section 3.1); and (2) determining which of these candidate keyphrases are correct keyphrases using supervised (Section 3.2) or unsupervised (Section 3.3) approaches.

3.1 Selecting Candidate Words and Phrases

As noted before, a set of phrases and words is typically extracted as candidate keyphrases using heuristic rules. These rules are designed to avoid spurious instances and keep the number of candidates to a minimum. Typical heuristics include (1) using a stop word list to remove stop words (Liu et al., 2009b), (2) allowing words with certain part-of-speech tags (e.g., nouns, adjectives, verbs) to be candidate keywords (Mihalcea and Tarau, 2004; Wan and Xiao, 2008b; Liu et al., 2009a), (3) allowing n-grams that appear in Wikipedia article titles to be candidates (Grineva et al., 2009), and (4) extracting n-grams (Witten et al., 1999; Hulth, 2003; Medelyan et al., 2009) or noun phrases (Barker and Cornacchia, 2000; Wu et al., 2005) that satisfy pre-defined lexico-syntactic pattern(s) (Nguyen and Phan, 2009).

Many of these heuristics have proven effective with their high recall in extracting gold keyphrases from various sources. However, for a long document, the resulting list of candidates can be long. Consequently, different *pruning* heuristics have been designed to prune candidates that are unlikely to be keyphrases (Huang et al., 2006; Kumar and Srinathan, 2008; El-Beltagy and Rafea, 2009; You et al., 2009; Newman et al., 2012).

3.2 Supervised Approaches

Research on supervised approaches to keyphrase extraction has focused on two issues: *task reformulation* and *feature design*.

3.2.1 Task Reformulation

Early supervised approaches to keyphrase extraction recast this task as a binary *classification* problem (Frank et al., 1999; Turney, 1999; Witten et al., 1999; Turney, 2000). The goal is to train a classifier on documents annotated with keyphrases to determine whether a candidate phrase is a keyphrase. Keyphrases and non-keyphrases are used to generate positive and negative examples, respectively. Different learning algorithms have been used to train this classifier, including naïve Bayes (Frank et al., 1999; Witten et al., 1999), decision trees (Turney, 1999; Turney, 2000), bagging (Hulth, 2003), boosting (Hulth et al., 2001), maximum entropy (Yih et al., 2006; Kim and Kan, 2009), multi-layer perceptron (Lopez and Romary, 2010), and support vector machines (Jiang et al., 2009; Lopez and Romary, 2010).

Recasting keyphrase extraction as a classification problem has its weaknesses, however. Recall that the goal of keyphrase extraction is to identify the most representative phrases for a document. In other words, if a candidate phrase c_1 is more representative than another candidate phrase c_2, c_1 should be preferred to c_2. Note that a binary classifier classifies each candidate keyphrase independently of the others, and consequently it does not allow us to determine which candidates are better than the others (Hulth, 2004; Wang and Li, 2011).

Motivated by this observation, Jiang et al. (2009) propose a *ranking* approach to keyphrase extraction, where the goal is to learn a ranker to rank two candidate keyphrases. This pairwise ranking approach therefore introduces competition between candidate keyphrases, and has been shown to significantly outperform KEA (Witten et al., 1999; Frank et al., 1999), a popular supervised baseline that adopts the traditional supervised classification approach (Song et al., 2003; Kelleher and Luz, 2005).

3.2.2 Features

The features commonly used to represent an instance for supervised keyphrase extraction can be broadly divided into two categories.

3.2.2.1 Within-Collection Features

Within-collection features are computed based solely on the training documents. These features can be further divided into three types.

Statistical features are computed based on statistical information gathered from the training documents. Three such features have been extensively used in supervised approaches. The first one, *tf*idf* (Salton and Buckley, 1988), is computed based on candidate frequency in the given text and inverse document frequency (i.e., number of other documents where the candidate appears).[2] The second one, the *distance* of a phrase, is defined as the number of words preceding its first occurrence normalized by the number of words in the document. Its usefulness stems from the fact that keyphrases tend to appear early in a document. The third one, *supervised keyphraseness*, encodes the number of times a phrase appears as a keyphrase in the training set. This feature is designed based on the assumption that a phrase frequently tagged as a keyphrase is more likely to be a keyphrase in an unseen document. These three features form the feature set of KEA (Witten et al., 1999; Frank et al., 1999), and have been shown to perform consistently well on documents from various sources (Yih et al., 2006; Kim et al., 2013). Other statistical features include *phrase length* and *spread* (i.e., the number of words between the first and last occurrences of a phrase in the document).

Structural features encode how different instances of a candidate keyphrase are located in different parts of a document. A phrase is more likely to be a keyphrase if it appears in the abstract or introduction of a paper or in the metadata section of a web page. In fact, features that encode how frequently a candidate keyphrase occurs in various sections of a scientific paper (e.g., introduction, conclusion) (Nguyen and Kan, 2007) and those that encode the location of a candidate keyphrase in a web page (e.g., whether it appears in the title) (Chen et al., 2005; Yih et al., 2006) have been shown to be useful for the task.

Syntactic features encode the syntactic patterns of a candidate keyphrase. For example, a candidate keyphrase has been encoded as (1) a *PoS tag sequence*, which denotes the sequence of part-of-speech tag(s) assigned to its word(s); and (2) a *suffix sequence*, which is the sequence of morphological suffixes of its words (Yih et al., 2006; Nguyen and Kan, 2007; Kim and Kan, 2009). However, ablation studies conducted on web pages (Yih et al., 2006) and scientific articles

[2] A tf*idf-based baseline, where candidate keyphrases are ranked and selected according to tf*idf, has been widely used by both supervised and unsupervised approaches (Zhang et al., 2005; Dredze et al., 2008; Paukkeri et al., 2008; Grineva et al., 2009).

(Kim and Kan, 2009) reveal that syntactic features are not useful for keyphrase extraction in the presence of other feature types.

3.2.2.2 External Resource-Based Features

External resource-based features are computed based on information gathered from resources other than the training documents, such as lexical knowledge bases (e.g., Wikipedia) or the Web, with the goal of improving keyphrase extraction performance by exploiting external knowledge. Below we give an overview of the external resource-based features that have proven useful for keyphrase extraction.

Wikipedia-based keyphraseness is computed as a candidate's document frequency multiplied by the ratio of the number of Wikipedia articles where the candidate appears as a link to the number of articles where it appears (Medelyan et al., 2009). This feature is motivated by the observation that a candidate is likely to be a keyphrase if it occurs frequently as a link in Wikipedia. Unlike supervised keyphraseness, Wikipedia-based keyphraseness can be computed without using documents annotated with keyphrases and can work even if there is a mismatch between the training domain and the test domain.

Yih et al. (2006) employ a feature that encodes whether a candidate keyphrase appears in the *query log* of a search engine, exploiting the observation that a candidate is potentially important if it was used as a search query. Terminological databases have been similarly exploited to encode the salience of candidate keyphrases in scientific papers (Lopez and Romary, 2010).

While the aforementioned external resource-based features attempt to encode how salient a candidate keyphrase is, Turney (2003) proposes features that encode the semantic relatedness between two candidate keyphrases. Noting that candidate keyphrases that are not semantically related to the predicted keyphrases are unlikely to be keyphrases in technical reports, Turney employs *coherence features* to identify such candidate keyphrases. Semantic relatedness is encoded in the coherence features as two candidate keyphrases' pointwise mutual information, which Turney computes by using the Web as a corpus.

3.3 Unsupervised Approaches

Existing unsupervised approaches to keyphrase extraction can be categorized into four groups.

3.3.1 Graph-Based Ranking

Intuitively, keyphrase extraction is about finding the important words and phrases from a document. Traditionally, the *importance* of a candidate has often been defined in terms of how related it is to other candidates in the document. Informally, a candidate is important if it is related to (1) a large number of candidates and (2) candidates that are important. Researchers have computed *relatedness* between candidates using co-occurrence counts (Mihalcea and Tarau, 2004; Matsuo and Ishizuka, 2004) and semantic relatedness (Grineva et al., 2009), and represented the relatedness information collected from a document as a graph (Mihalcea and Tarau, 2004; Wan and Xiao, 2008a; Wan and Xiao, 2008b; Bougouin et al., 2013).

The basic idea behind a graph-based approach is to build a graph from the input document and rank its nodes according to their importance using a graph-based ranking method (e.g., Brin and Page (1998)). Each node of the graph corresponds to a candidate keyphrase from the document and an edge connects two *related* candidates. The edge weight is proportional to the syntactic and/or semantic relevance between the connected candidates. For each node, each of its edges is treated as a "vote" from the other node connected by the edge. A node's score in the graph is defined recursively in terms of the edges it has and the scores of the neighboring nodes. The top-ranked candidates from the graph are then selected as keyphrases for the input document. TextRank (Mihalcea and Tarau, 2004) is one of the most well-known graph-based approaches to keyphrase extraction.

This instantiation of a graph-based approach overlooks an important aspect of keyphrase extraction, however. A set of keyphrases for a document should ideally cover the main topics discussed in it, but this instantiation does not guarantee that all the main topics will be represented by the extracted keyphrases. Despite this weakness, a graph-based representation of text was adopted by many approaches that propose different ways of computing the similarity between two candidates.

3.3.2 Topic-Based Clustering

Another unsupervised approach to keyphrase extraction involves grouping the candidate keyphrases in a document into *topics*, such that each topic is composed of all and only those candidate keyphrases that are related to that topic (Grineva et al., 2009; Liu et al., 2009b; Liu et

al., 2010). There are several motivations behind this topic-based clustering approach. First, a keyphrase should ideally be relevant to one or more main topic(s) discussed in a document (Liu et al., 2010; Liu et al., 2012). Second, the extracted keyphrases should be comprehensive in the sense that they should cover all the main topics in a document (Liu et al., 2009b; Liu et al., 2010; Liu et al., 2012). Below we examine three representative systems that adopt this approach.

KeyCluster Liu et al. (2009b) adopt a clustering-based approach (henceforth KeyCluster) that clusters semantically similar candidates using Wikipedia and co-occurrence-based statistics. The underlying hypothesis is that each of these clusters corresponds to a topic covered in the document, and selecting the candidates close to the centroid of each cluster as keyphrases ensures that the resulting set of keyphrases covers all the topics of the document.

While empirical results show that KeyCluster performs better than both TextRank and Hulth's (2003) supervised system, KeyCluster has a potential drawback: by extracting keyphrases from each topic cluster, it essentially gives each topic equal importance. In practice, however, there could be topics that are not important and these topics should not have keyphrase(s) representing them.

Topical PageRank (TPR) Liu et al. (2010) propose TPR, an approach that overcomes the aforementioned weakness of KeyCluster. It runs TextRank multiple times for a document, once for each of its topics induced by a Latent Dirichlet Allocation (Blei et al., 2003). By running TextRank once for each topic, TPR ensures that the extracted keyphrases cover the main topics of the document. The final score of a candidate is computed as the sum of its scores for each of the topics, weighted by the probability of that topic in that document. Hence, unlike KeyCluster, candidates belonging to a less probable topic are given less importance.

TPR performs significantly better than both tf*idf and TextRank on the DUC-2001 and *Inspec* datasets. TPR's superior performance strengthens the hypothesis of using topic clustering for keyphrase extraction. However, though TPR is conceptually better than KeyCluster, Liu et al. did not compare TPR against KeyCluster.

CommunityCluster Grineva et al. (2009) propose CommunityCluster, a variant of the topic clustering approach to keyphrase extraction. Like TPR, CommunityCluster gives more weight to more important topics, but unlike TPR, it extracts *all* candidate keyphrases from an important topic, assuming that a candidate that receives little focus in the text should still be extracted as a keyphrase as long as it is related to an important topic. CommunityCluster yields much better recall (without losing precision) than extractors such as tf*idf, TextRank, and the Yahoo! term extractor.

3.3.3 Simultaneous Learning

Since keyphrases represent a dense summary of a document, researchers hypothesized that text summarization and keyphrase extraction can potentially benefit from each other if these tasks are performed simultaneously. Zha (2002) proposes the first graph-based approach for simultaneous summarization and keyphrase extraction, motivated by a key observation: a sentence is important if it contains important words, and important words appear in important sentences. Wan et al. (2007) extend Zha's work by adding two assumptions: (1) an important sentence is connected to other important sentences, and (2) an important word is linked to other important words, a TextRank-like assumption. Based on these assumptions, Wan et al. (2007) build three graphs to capture the association between the sentences (S) and the words (W) in an input document, namely, a S–S graph, a bipartite S–W graph, and a W–W graph. The weight of an edge connecting two sentence nodes in a S–S graph corresponds to their content similarity. An edge weight in a S–W graph denotes the word's importance in the sentence it appears. Finally, an edge weight in a W–W graph denotes the co-occurrence or knowledge-based similarity between the two connected words. Once the graphs are constructed for an input document, an iterative reinforcement algorithm is applied to assign scores to each sentence and word. The top-scored words are used to form keyphrases.

The main advantage of this approach is that it combines the strengths of both Zha's approach (i.e., bipartite S–W graphs) and TextRank (i.e., W–W graphs) and performs better than both of them. However, it has a weakness: like TextRank, it does not ensure that the extracted keyphrases will cover all the main topics. To address this problem, one can employ a topic clustering algorithm on the W–W graph to produce the topic clusters, and then ensure that keyphrases are chosen from every main topic cluster.

3.3.4 Language Modeling

Many existing approaches have a separate, heuristic module for extracting candidate keyphrases prior to keyphrase ranking/extraction. In contrast, Tomokiyo and Hurst (2003) propose an approach (henceforth LMA) that combines these two steps.

LMA scores a candidate keyphrase based on two features, namely, *phraseness* (i.e., the extent to which a word sequence can be treated as a phrase) and *informativeness* (i.e., the extent to which a word sequence captures the central idea of the document it appears in). Intuitively, a phrase that has high scores for phraseness and informativeness is likely to be a keyphrase. These feature values are estimated using language models (LMs) trained on a *foreground* corpus and a *background* corpus. The foreground corpus is composed of the set of documents from which keyphrases are to be extracted. The background corpus is a large corpus that encodes general knowledge about the world (e.g., the Web). A unigram LM and an n-gram LM are constructed for each of these two corpora. Phraseness, defined using the foreground LM, is calculated as the loss of information incurred as a result of assuming a unigram LM (i.e., conditional independence among the words of the phrase) instead of an n-gram LM (i.e., the phrase is drawn from an n-gram LM). Informativeness is computed as the loss that results because of the assumption that the candidate is sampled from the background LM rather than the foreground LM. The loss values are computed using Kullback-Leibler divergence. Candidates are ranked according to the sum of these two feature values.

In sum, LMA uses a language model rather than heuristics to identify phrases, and relies on the language model trained on the background corpus to determine how "unique" a candidate keyphrase is to the domain represented by the foreground corpus. The more unique it is to the foreground's domain, the more likely it is a keyphrase for that domain. While the use of language models to identify phrases cannot be considered a major strength of this approach (because heuristics can identify phrases fairly reliably), the use of a background corpus to identify candidates that are unique to the foreground's domain is a unique aspect of this approach. We believe that this idea deserves further investigation, as it would allow us to discover a keyphrase that is unique to the foreground's domain but may have a low tf*idf value.

4 Evaluation

In this section, we describe metrics for evaluating keyphrase extraction systems as well as state-of-the-art results on commonly-used datasets.

4.1 Evaluation Metrics

Designing evaluation metrics for keyphrase extraction is by no means an easy task. To score the output of a keyphrase extraction system, the typical approach, which is also adopted by the SemEval-2010 shared task on keyphrase extraction, is (1) to create a mapping between the keyphrases in the gold standard and those in the system output using *exact match*, and then (2) score the output using evaluation metrics such as precision (P), recall (R), and F-score (F).

Conceivably, exact match is an overly strict condition, considering a predicted keyphrase incorrect even if it is a variant of a gold keyphrase. For instance, given the gold keyphrase "neural network", exact match will consider a predicted phrase incorrect even if it is an expanded version of the gold keyphrase ("artificial neural network") or one of its morphological ("neural networks") or lexical ("neural net") variants. While morphological variations can be handled using a stemmer (El-Beltagy and Rafea, 2009), other variations may not be handled easily and reliably.

Human evaluation has been suggested as a possibility (Matsuo and Ishizuka, 2004), but it is time-consuming and expensive. For this reason, researchers have experimented with two types of automatic evaluation metrics. The first type of metrics addresses the problem with exact match. These metrics reward a partial match between a predicted keyphrase and a gold keyphrase (i.e., overlapping n-grams) and are commonly used in machine translation (MT) and summarization evaluations. They include BLEU, METEOR, NIST, and ROUGE. Nevertheless, experiments show that these MT metrics only offer a partial solution to problem with exact match: they can only detect a subset of the near-misses (Kim et al., 2010a).

The second type of metrics focuses on how a system ranks its predictions. Given that two systems A and B have the same number of correct predictions, binary preference measure (Bpref) and mean reciprocal rank (MRR) (Liu et al., 2010) will award more credit to A than to B if the ranks of the correct predictions in A's output are higher than those in B's output. R-precision (R_p) is an

IR metric that focuses on ranking: given a document with n gold keyphrases, it computes the precision of a system over its n highest-ranked candidates (Zesch and Gurevych, 2009). The motivation behind the design of R_p is simple: a system will achieve a perfect R_p value if it ranks all the keyphrases above the non-keyphrases.

4.2 The State of the Art

Table 2 lists the best scores on some popular evaluation datasets and the corresponding systems. For example, the best F-scores on the *Inspec* test set, the DUC-2001 dataset, and the SemEval-2010 test set are 45.7, 31.7, and 27.5, respectively.[3]

Two points deserve mention. First, F-scores decrease as document length increases. These results are consistent with the observation we made in Section 2 that it is more difficult to extract keyphrases correctly from longer documents. Second, recent unsupervised approaches have rivaled their supervised counterparts in performance (Mihalcea and Tarau, 2004; El-Beltagy and Rafea, 2009; Liu et al., 2009b). For example, KP-Miner (El-Beltagy and Rafea, 2010), an unsupervised system, ranked third in the SemEval-2010 shared task with an F-score of 25.2, which is comparable to the best supervised system scoring 27.5.

5 Analysis

With the goal of providing directions for future work, we identify the errors commonly made by state-of-the-art keyphrase extractors below.

5.1 Error Analysis

Although a few researchers have presented a sample of their systems' output and the corresponding gold keyphrases to show the differences between them (Witten et al., 1999; Nguyen and Kan, 2007; Medelyan et al., 2009), a systematic analysis of the major types of errors made by state-of-the-art keyphrase extraction systems is missing.

To fill this gap, we ran four keyphrase extraction systems on four commonly-used datasets of varying sources, including *Inspec* abstracts (Hulth, 2003), DUC-2001 news articles (Over, 2001), scientific papers (Kim et al., 2010b), and meeting transcripts (Liu et al., 2009a). Specifically, we randomly selected 25 documents from each of these four datasets and manually analyzed the output of the four systems, including tf*idf, the most frequently used baseline, as well as three state-of-the-art keyphrase extractors, of which two are unsupervised (Wan and Xiao, 2008b; Liu et al., 2009b) and one is supervised (Medelyan et al., 2009).

Dataset	Approach and System [Supervised?]	Score		
		P	R	F
Abstracts (*Inspec*)	Topic clustering (Liu et al., 2009b) [×]	35.0	66.0	45.7
Blogs	Topic community detection (Grineva et al., 2009) [×]	35.1	61.5	44.7
News (DUC -2001)	Graph-based ranking for extended neighborhood (Wan and Xiao, 2008b) [×]	28.8	35.4	31.7
Papers (SemEval -2010)	Statistical, semantic, and distributional features (Lopez and Romary, 2010) [✓]	27.2	27.8	27.5

Table 2: Best scores achieved on various datasets.

Our analysis reveals that the errors fall into four major types, each of which contributes significantly to the overall errors made by the four systems, despite the fact that the contribution of each of these error types varies from system to system. Moreover, we do not observe any significant difference between the types of errors made by the four systems other than the fact that the supervised system has the expected tendency to predict keyphrases seen in the training data. Below we describe these four major types of errors.

Overgeneration errors are a major type of precision error, contributing to 28–37% of the overall error. Overgeneration errors occur when a system correctly predicts a candidate as a keyphrase because it contains a word that appears frequently in the associated document, but at the same time erroneously outputs other candidates as keyphrases because they contain the same word. Recall that for many systems, it is not easy to reject a non-keyphrase containing a word with a high term frequency: many unsupervised systems score a candidate by summing the score of each of its component words, and many supervised systems use unigrams as features to represent a candidate. To be more concrete, consider the news article on athlete *Ben Johnson* in Figure 1, where the keyphrases are boldfaced. As we can see, the word *Olympic(s)* has a significant presence in the document. Consequently, many systems not only correctly predict *Olympics* as a keyphrase, but also erroneously predict *Olympic movement* as a keyphrase, yielding overgeneration errors.

Infrequency errors are a major type of re-

[3] A more detailed analysis of the results of the SemEval-2010 shared task and the approaches adopted by the participating systems can be found in Kim et al. (2013).

Canadian **Ben Johnson** left the **Olympics** today "in a complete state of shock," accused of cheating with drugs in the world's fastest **100-meter dash** and stripped of his **gold medal**. The prize went to American **Carl Lewis**. Many athletes accepted the accusation that Johnson used a muscle-building but dangerous and illegal anabolic steroid called **stanozolol** as confirmation of what they said they know has been going on in track and field. Two tests of Johnson's urine sample proved positive and his denials of **drug use** were rejected today. "This is a blow for the Olympic Games and the Olympic movement," said International Olympic Committee President Juan Antonio Samaranch.

Figure 1: A news article on *Ben Johnson* from the DUC-2001 dataset. The keyphrases are boldfaced.

call error contributing to 24–27% of the overall error. Infrequency errors occur when a system fails to identify a keyphrase owing to its infrequent presence in the associated document (Liu et al., 2011). Handling infrequency errors is a challenge because state-of-the-art keyphrase extractors rarely predict candidates that appear only once or twice in a document. In the *Ben Johnson* example, many keyphrase extractors fail to identify *100-meter dash* and *gold medal* as keyphrases, resulting in infrequency errors.

Redundancy errors are a type of precision error contributing to 8–12% of the overall error. Redundancy errors occur when a system correctly identifies a candidate as a keyphrase, but at the same time outputs a semantically equivalent candidate (e.g., its alias) as a keyphrase. This type of error can be attributed to a system's failure to determine that two candidates are semantically equivalent. Nevertheless, some researchers may argue that a system should not be penalized for redundancy errors because the extracted candidates are in fact keyphrases. In our example, *Olympics* and *Olympic games* refer to the same concept, so a system that predicts both of them as keyphrases commits a redundancy error.

Evaluation errors are a type of recall error contributing to 7–10% of the overall error. An evaluation error occurs when a system outputs a candidate that is semantically equivalent to a gold keyphrase, but is considered erroneous by a scoring program because of its failure to recognize that the predicted phrase and the corresponding gold keyphrase are semantically equivalent. In other words, an evaluation error is not an error made by a keyphrase extractor, but an error due to the naivety of a scoring program. In our example, while *Olympics* and *Olympic games* refer to the same concept, only the former is annotated as keyphrase. Hence, an evaluation error occurs if a system predicts *Olympic games* but not *Olympics* as a keyphrase and the scoring program fails to identify them as semantically equivalent.

5.2 Recommendations

We recommend that *background knowledge* be extracted from external lexical databases (e.g., YAGO2 (Suchanek et al., 2007), Freebase (Bollacker et al., 2008), BabelNet (Navigli and Ponzetto, 2012)) to address the four types of errors discussed above.

First, we discuss how **redundancy errors** could be addressed by using the background knowledge extracted from external databases. Note that if we can identify semantically equivalent candidates, then we can reduce redundancy errors. The question, then, is: can background knowledge be used to help us identify semantically equivalent candidates? To answer this question, note that Freebase, for instance, has over 40 million *topics* (i.e., real-world entities such as people, places, and things) from over 70 domains (e.g., music, business, education). Hence, before a system outputs a set of candidates as keyphrases, it can use Freebase to determine whether any of them is mapped to the same Freebase topic. Referring back to our running example, both *Olympics* and *Olympic games* are mapped to a Freebase topic called *Olympic games*. Based on this information, a keyphrase extractor can determine that the two candidates are aliases and should output only one of them, thus preventing a redundancy error.

Next, we discuss how **infrequency errors** could be addressed using background knowledge. A natural way to handle this problem would be to make an infrequent keyphrase frequent. To accomplish this, we suggest exploiting an influential idea in the keyphrase extraction literature: the importance of a candidate is defined in terms of how related it is to other candidates in the text (see Section 3.3.1). In other words, if we could relate an infrequent keyphrase to other candidates in the text, we could boost its importance.

We believe that this could be accomplished using background knowledge. The idea is to boost the importance of infrequent keyphrases using their frequent counterparts. Consider again our running example. All four systems have managed to identify *Ben Johnson* as a keyphrase due to its

significant presence. Hence, we can boost the importance of *100-meter dash* and *gold medal* if we can relate them to *Ben Johnson*.

To do so, note that Freebase maps a candidate to one or more pre-defined topics, each of which is associated with one or more types. Types are similar to entity classes. For instance, the candidate *Ben Johnson* is mapped to a Freebase topic with the same name, which is associated with Freebase types such as *Person*, *Athlete*, and *Olympic athlete*. Types are defined for a specific domain in Freebase. For instance, *Person*, *Athlete*, and *Olympic athlete* are defined in the *People*, *Sports*, and *Olympics* domains, respectively. Next, consider the two infrequent candidates, *100-meter dash* and *gold medal*. *100-meter dash* is mapped to the topic *Sprint* of type *Sports* in the *Sports* domain, whereas *gold medal* is mapped to a topic with the same name of type *Olympic medal* in the *Olympics* domain. Consequently, we can relate *100-meter dash* to *Ben Johnson* via the *Sports* domain (i.e., they belong to different types under the same domain). Additionally, *gold medal* can be related to *Ben Johnson* via the *Olympics* domain.

As discussed before, the relationship between two candidates is traditionally established using co-occurrence information. However, using co-occurrence windows has its shortcomings. First, an *ad-hoc* window size cannot capture related candidates that are not inside the window. So it is difficult to predict *100-meter dash* and *gold medal* as keyphrases: they are more than 10 tokens away from frequent words such as *Johnson* and *Olympics*. Second, the candidates inside a window are all assumed to be related to each other, but it is apparently an overly simplistic assumption. There have been a few attempts to design Wikipedia-based relatedness measures, with promising initial results (Grineva et al., 2009; Liu et al., 2009b; Medelyan et al., 2009).[4]

Overgeneration errors could similarly be addressed using background knowledge. Recall that *Olympic movement* is not a keyphrase in our example although it includes an important word (i.e., *Olympic*). Freebase maps *Olympic movement* to a topic with the same name, which is associated with a type called *Musical Recording* in the *Music* domain. However, it does not map *Olympic movement* to any topic in the *Olympics* domain. The absence of such a mapping in the *Olympics* domain could be used by a keyphrase extractor as a supporting evidence against predicting *Olympic movement* as a keyphrase.

Finally, as mentioned before, **evaluation errors** should not be considered errors made by a system. Nevertheless, they reveal a problem with the way keyphrase extractors are currently evaluated. To address this problem, one possibility is to conduct human evaluations. Cheaper alternatives include having human annotators identify semantically equivalent keyphrases during manual labeling, and designing scoring programs that can automatically identify such semantic equivalences.

6 Conclusion and Future Directions

We have presented a survey of the state of the art in automatic keyphrase extraction. While unsupervised approaches have started to rival their supervised counterparts in performance, the task is far from being solved, as reflected by the fairly poor state-of-the-art results on various commonly-used evaluation datasets. Our analysis revealed that there are at least three major challenges ahead.

1. Incorporating background knowledge. While much recent work has focused on algorithmic development, keyphrase extractors need to have a deeper "understanding" of a document in order to reach the next level of performance. Such an understanding can be facilitated by the incorporation of background knowledge.

2. Handling long documents. While it may be possible to design better algorithms to handle the large number of candidates in long documents, we believe that employing sophisticated features, especially those that encode background knowledge, will enable keyphrases and non-keyphrases to be distinguished more easily even in the presence of a large number of candidates.

3. Improving evaluation schemes. To more accurately measure the performance of keyphrase extractors, they should not be penalized for evaluation errors. We have suggested several possibilities as to how this problem can be addressed.

Acknowledgments

We thank the anonymous reviewers for their detailed and insightful comments on earlier drafts of this paper. This work was supported in part by NSF Grants IIS-1147644 and IIS-1219142.

[4]Note that it may be difficult to employ our recommendations to address infrequency errors in informal text with uncorrelated topics because the keyphrases it contains may not be related to each other (see Section 2).

Pattern Dictionary of English Prepositions

Ken Litkowski
CL Research

ken@clres.com

Abstract

We present a new lexical resource for the study of preposition behavior, the Pattern Dictionary of English Prepositions (PDEP). This dictionary, which follows principles laid out in Hanks' theory of norms and exploitations, is linked to 81,509 sentences for 304 prepositions, which have been made available under The Preposition Project (TPP). Notably, 47,285 sentences, initially untagged, provide a representative sample of preposition use, unlike the tagged sentences used in previous studies. Each sentence has been parsed with a dependency parser and our system has near-instantaneous access to features developed with this parser to explore and annotate properties of individual senses. The features make extensive use of WordNet. We have extended feature exploration to include lookup of FrameNet lexical units and VerbNet classes for use in characterizing preposition behavior. We have designed our system to allow public access to any of the data available in the system.

1 Introduction

Recent studies (Zapirain et al. (2013); Srikumar and Roth (2011)) have shown the value of prepositional phrases in joint modeling with verbs for semantic role labeling. Although recent studies have shown improved preposition disambiguation, they have received little systematic treatment from a lexicographic perspective. Recently, a new corpus has been made available that promises to be much more representative of preposition behavior. Our initial examination of this corpus has suggested clear indications of senses previously overlooked and reduced prominence for senses thought to constitute a large role in preposition use.

In section 2, we describe the interface to the Pattern Dictionary of English Prepositions (PDEP), identifying how we are building upon data developed in The Preposition Project (TPP) and investigating its sense inventory with corpora also made available under TPP. Section 3 describes the procedures for tagging a representative corpus drawn from the British National Corpus, including some findings that have emerged in assessing previous studies of preposition disambiguation. Section 4 describes how we are able to investigate the relationship of WordNet, FrameNet, and VerbNet to this effort and how this examination of preposition behavior can be used in working with these resources. Section 5 describes how we can use PDEP for the analysis of semantic role and semantic relation inventories. Section 6 describes how we envision further developments of PDEP and how the data are available for further analysis. In section 7, we present our conclusions for PDEP.

2 The Pattern Dictionary of English Prepositions

Litkowski and Hargraves (2005) and Litkowski and Hargraves (2006) describe The Preposition Project (TPP) as an attempt to describe preposition behavior using a sense inventory made available for public use from the *Oxford Dictionary of English* (Stevenson and Soanes, 2003) by tagging sentences drawn from FrameNet. In TPP, each sense was characterized with its complement and attachment (or governor) properties, its class and semantic relation, substitutable prepositions, its syntactic positions, and any FrameNet frame and frame element usages (where available). The FrameNet sentences were sense-tagged using the sense inventory and were

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1274–1283,
Baltimore, Maryland, USA, June 23-25 2014.

later used as the basis for a preposition disambiguation task in SemEval 2007 (Litkowski and Hargraves, 2007).

Initial results in SemEval achieved a best accuracy of 69.3 percent (Ye and Baldwin, 2007). The data from SemEval has subsequently been used in several further investigations of preposition disambiguation. Most notably, Tratz (2011) achieved a result of 88.4 percent accuracy and Srikumar and Roth (2013) achieved a similar result. However, Litkowski (2013b) showed that these results did not extend to other corpora, concluding that the FrameNet-based corpus may not have been representative, with a reduction of accuracy to 39.4 percent using a corpus developed by Oxford.

Litkowski (2013a) announced the creation of the TPP corpora in order to develop a more representative account of preposition behavior. The TPP corpora includes three subcorpora: (1) the full SemEval 2007 corpus (drawn from FrameNet data, henceforth FN), (2) sentences taken from the Oxford English Corpus to exemplify preposition senses in the *Oxford Dictionary of English* (henceforth, OEC), and (3) a sample of sentences drawn from the written portion of the British National Corpus (BNC), using the Word Sketch Engine as implemented in the system for the Corpus Pattern Analysis of verbs (henceforth, CPA or TPP).

We have used the TPP data and the TPP corpora to implement an editorial interface, the Pattern Dictionary of English Prepositions (PDEP).[1] This dictionary is intended to identify the prototypical syntagmatic patterns with which prepositions in use are associated, identifying linguistic units used sequentially to make well-formed structures and characterizing the relationship between these units. In the case of prepositions, the units are the complement (object) of the preposition and the governor (point of attachment) of the prepositional phrase. The editorial interface is used to make changes in the underlying databases, as described in the following subsections. Editorial access to make changes is limited, but the system can be explored publicly and the underlying data can be accessed publicly, either in its entirety or through publicly available scripts used in accessing the data during editorial operations.

Standard dictionaries include definitions of prepositions, but only loosely characterize the syntagmatic patterns associated with each sense. PDEP takes this a step further, looking for prototypical sentence contexts to characterize the patterns. PDEP is modeled on the principles of Corpus Pattern Analysis (CPA), developed to characterize syntagmatic patterns for verbs.[2] These principles are described more fully in Hanks (2013). Currently, CPA is being used in the project Disambiguation of Verbs by Collocation to develop a Pattern Dictionary of English Verbs (PDEV).[3] PDEP is closely related to PDEV, since most syntagmatic patterns for prepositions are related to the main verb in a clause. PDEP is viewed as subordinate to PDEV, sufficiently so that PDEP employs significant portions of code being used in PDEV, with appropriate modifications as necessary to capture the syntagmatic patterns for prepositions.[4]

2.1 The Preposition Inventory

After a start page for entry into PDEP, a table of all prepositions in the sense inventory is displayed. Figure 1 contains a truncated snapshot of this table. The table has a row for each of 304 prepositions as identified in TPP. The second column indicates the number of patterns (senses) for each preposition. The next two columns show the number of TPP (CPA) instances that have been tagged and the total number of TPP instances that have been obtained as the sample from the total number of instances in the BNC.

Preposition ↑	Patterns	TPP Tagged	TPP Insts	BNC Freq
because of	1	250	250	9346
before	4	125	250	20821
behind	9	0	250	6207
below	4	16	250	2646
beneath	6	0	250	1277
beside	3	0	250	932
besides	1	0	250	468
between	9	8	250	58865

Figure 1. Preposition Inventory

Additional columns not shown in Figure 1 show (1) the status of the analysis for the preposition, (2) the number of instances from FrameNet (i.e., FN Insts, as developed for SemEval 2007), and (3) the number of instances from the Oxford English Corpus (i.e., OEC Insts). The number of prepositions with

[1] http://www.clres.com/db/TPPEditor.html

[2] See http://nlp.fi.muni.cz/projects/cpa/.

[3] See http://clg.wlv.ac.uk/projects/DVC

[4] PDEP is implemented as a combination of HTML and Javascript. Within the Javascript code, calls are made to PHP scripts to retrieve data from MySQL database tables and from additional files (described below).

FrameNet instances is 57 (larger than the 34 prepositions used in SemEval). There are no OEC instances for 57 prepositions. There are no TPP instances for 41 prepositions. Notwithstanding the lack of instances, there are TPP characterizations for all 304 prepositions.

The BNC frequency shown in Figure 1 provides a basis for extrapolating results from PDEP to the totality of prepositions. In total, the number of instances in the BNC is 5,391,042, which can be used as the denominator when examining the relative frequency of any preposition (e.g., *between* has a frequency of 0.0109, 58,865/5,391,042).[5]

In general, the target sample size was 250 CPA instances. If the number available was less than 250, all instances were used. The TPP CPA corpus contains 250 instances for 170 prepositions. Where the number of senses for a preposition was large (about 15 or more), larger samples of 750 (*of*, *to*, *on*, and *with*) or 500 (*in*, *for*, *by*, *from*, *at*, *into*, *over*, *like*, and *through*) were drawn.

2.2 Preposition Patterns

When a row in Figure 1 is clicked, the preposition is selected and a new page is opened to show the patterns for that preposition. Figure 2 shows the four patterns for *below*. Each pattern is presented as an instance of the template **[[Governor]] prep [[Complement]]**, followed by its primary implicature, where the current definition is substituted for the preposition.

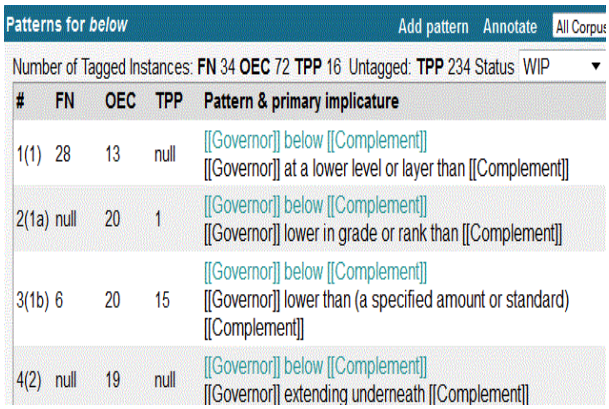

Figure 2. Preposition Pattern List

The display in Figure 2 provides an overview for each preposition, with the top line showing the number of tagged instances available from each corpus. For the TPP instances, this identifies the number of instances that have been tagged and the number that remain to be tagged. In the body of the table, the first column shows the TPP sense number. The next three columns show the number of instances that have been tagged with this sense. Note that the top line of the pattern list includes a menu option for adding a pattern, for the case when we find that a new sense is required by the corpus evidence.

Clicking on any row in the pattern list opens the details for that pattern, with a pattern box entitled with the preposition and the pattern number, as shown in Figure 3. The pattern box contains data developed in TPP and several new fields intended to capture our enhancements.

TPP data include the fields for the **Complement**, the **Governor**, the **TPP Class**, the **TPP Relation**, the **Substitutable Prepositions**, the **Syntactic Position**, the **Quirk Reference**, the **Sense Relation**, and the **Comment**. We have added the checkboxes for complement type (common nouns, proper nouns, WH-phrases, and -ing phrases), as well as a field to identify a particular lexical item (lexset) if the sense is an idiomatic usage. We have added the **Selector** fields for the complement and the governor. For the complement, we have a field **Category** to hold its ontological category (using the shallow ontology being developed for verbs in the DVC project mentioned above).[6] We also provided a field for the **Semantic Class** of the governor; this field has not yet been implemented.

We have added two **Cluster/Relation** fields. The **Cluster** field is based on data available from Tratz (2011), where senses in the SemEval 2007 data have been put into 34 clusters. The **Relation** field is based on data available from Srikumar and Roth (2013), where senses in the SemEval 2007 data have been put into 32 classes. A key element of Srikumar and Roth was the use of these classes to model semantic relations across prepositions (e.g., grouping all the Temporal senses of the SemEval prepositions). In the pattern box, each of these two fields has a drop-down list of the clusters and relations, enabling us to categorize the senses of other prepositions with these classes. Below, we describe how we are able to use the TPP classes and relations along with the Tratz clusters and Srikumar relations in an analysis of these classes across the

[5] The total number of instances for *of* and *in* in this estimate is 1,000,000. As a result, the relative frequency calculation should not be construed as completely accurate.

[6] This ontology is an evolution of the Brandeis Semantic Ontology (Pustejovsky et al., 2006).

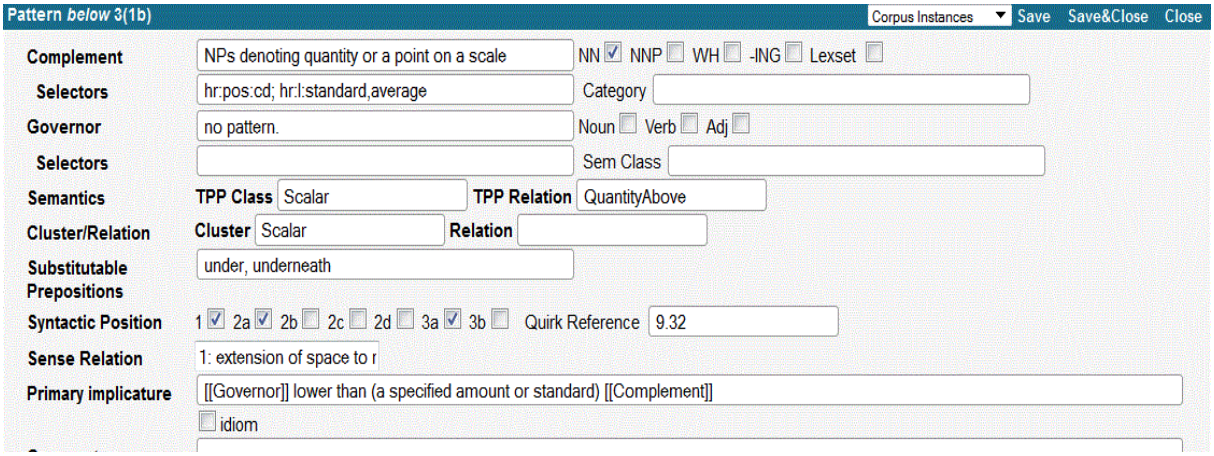

Figure 3. Preposition Pattern Details

full set of prepositions, instead of just those used in SemEval.

Any number of pattern boxes may be opened at one time. The data in any of the fields may be altered (with the menu bar changing color to red) and then saved to the underlying databases. An individual pattern box may then be closed.

The drop-down box labeled **Corpus Instances** in the menu bar is used to open the set of corpus instances for the given sense. As shown in Figure 2, this sense has 6 FN instances, 20 OEC instances, and 15 TPP instances. The drop-down box has an option for each of these sets, along with an option for all TPP instances that have not yet been tagged. When one of these options is selected, the corresponding set of instances is opened in a new tab, discussed in the next section.

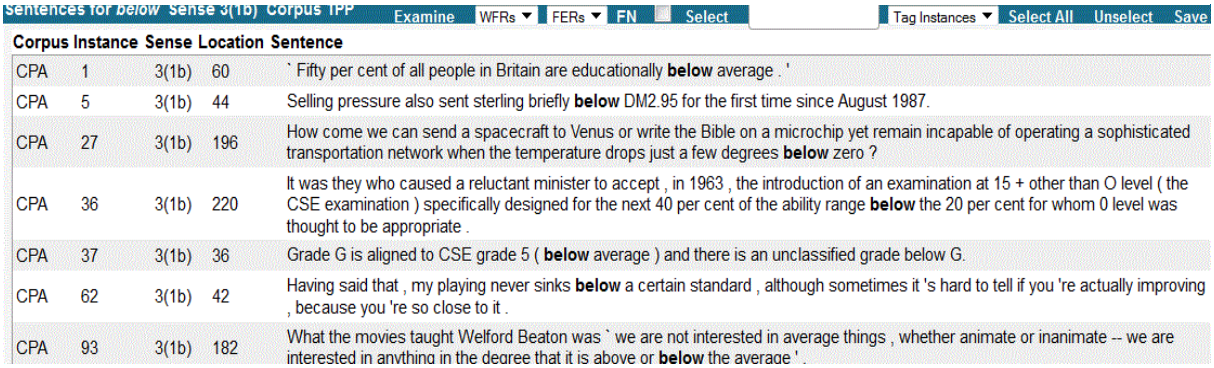
2.3 Preposition Corpus Instances

As indicated, selecting an instance set from the pattern box opens this set in a separate tab, as shown in Figure 4. This tab, labeled **Annotation: below (3(1b))**, identifies the preposition and the sense, if any, associated with the instance set (the sense will be identified as **unk** if the set has not yet been tagged. The instance set is displayed, identifying the corpus, the instance identifier, the TPP sense (if identified, or "unk" if not), the location in the sentence of the target preposition, and the sentence, with the preposition in bold.

This tab is where the annotation takes place. Any set of sentences may be selected; each selected sentence is highlighted in yellow (as shown in Figure 6). The sense value may be changed using the drop-down box labeled **Tag Instances** in the menu bar. This drop-down box contains all the current senses for the preposition, along with possible tags **x** (to indicate that the instance is invalid for the preposition) and **unk** (to indicate that a tagging decision has not yet been made). The sense tags in Figure 4 were originally untagged in the CPA (TPP) corpus and were tagged in this manner.

In general, sense-tagging follows standard lexicographic principles, where an attempt is made to group instances that appear to represent distinct senses. PDEP provides an enhanced environment for this process. Firstly, we can make use of the current TPP sense inventory to tag sentences. Since the pattern sets (definitions) are based on the *Oxford Dictionary of English*, the likelihood that the coverage and accuracy of the sense distinctions is quite high. However, since prepositions have not generally received the close attention of words in other parts of speech,

Figure 4. Preposition Corpus Instance Annotation



Corpus	Instance	Sense	Location	Sentence
CPA	1	3(1b)	60	` Fifty per cent of all people in Britain are educationally **below** average . '
CPA	5	3(1b)	44	Selling pressure also sent sterling briefly **below** DM2.95 for the first time since August 1987.
CPA	27	3(1b)	196	How come we can send a spacecraft to Venus or write the Bible on a microchip yet remain incapable of operating a sophisticated transportation network when the temperature drops just a few degrees **below** zero ?
CPA	36	3(1b)	220	It was they who caused a reluctant minister to accept , in 1963 , the introduction of an examination at 15 + other than O level (the CSE examination) specifically designed for the next 40 per cent of the ability range **below** the 20 per cent for whom 0 level was thought to be appropriate .
CPA	37	3(1b)	36	Grade G is aligned to CSE grade 5 (**below** average) and there is an unclassified grade below G.
CPA	62	3(1b)	42	Having said that , my playing never sinks **below** a certain standard , although sometimes it 's hard to tell if you 're actually improving , because you 're so close to it .
CPA	93	3(1b)	182	What the movies taught Welford Beaton was ` we are not interested in average things , whether animate or inanimate -- we are interested in anything in the degree that it is above or **below** the average ' .

PDEP is intended to ensure the coverage and accuracy. During the tagging of the SemEval instances, the lexicographer found it necessary to increase the number of senses by about 10 percent. Since the lack of coverage of FrameNet is well-recognized, the representative sample developed for the TPP corpus should provide the basis for ensuring the coverage and accuracy.

In addition to adhering to standard lexicographic principles, the availability of the tagged FN and OEC instances can be used as the basis for tagging decisions. Where available, these tagged instances can be opened in separate tabs and used as examples for tagging the unknown TPP instances.

3 Tagging the TPP Corpus

3.1 Examining Corpus Instances

The main contribution of the present work is the ability to interactively examine characteristics of the context surrounding the target preposition in the corpus instances. In the menu bar shown in Figure 4, there is an **Examine** item. Next to it are two drop-down boxes, one labeled **WFRs** (word-finding rules) and one labeled **FERs** (feature extraction rules). These rules are taken from the system described in Tratz and Hovy (2011) and Tratz (2011).[7] The TPP corpora described in Litkowski (2013a) includes full dependency parses and feature files for all sentences. Each sentence may have as many as 1500 features describing the context of the target preposition. We have made the feature files for these sentences (1309 MB) available for exploration in PDEP.

In our system, we make available seven word-finding rules and nine feature extraction rules. The word-finding rules fall into two groups: words pertaining to the governor and words pertaining to the complement. The five governor word-finding rules are (1) verb or head to the left (**l**), (2) head to the left (**hl**), (3) verb to the left (**vl**), (4) word to the left (**wl**), and (5) governor (**h**). The two complement word-finding rules are (1) syntactic preposition complement (**c**) and (2) heuristic preposition complement (**hr**). The feature extraction rules are (1) word class (**wc**), (2) part of speech (**pos**), (3) lemma (**l**), (4) word (**w**), (5) WordNet lexical name (**ln**), (6) WordNet synonyms (**s**), (7) WordNet hypernyms (**h**), (8) whether the word is capitalized (**c**), and (9) affixes (**af**). Thus, we are able to examine any of 63 WFR FER combinations for whatever corpus set happens to be open.

In addition to these features, we are able to determine the extent to which prepositions associated with FrameNet lexical units and VerbNet classes occur in a given corpus set. In Figure 4, there is a checkbox labeled FN next to the FERs drop-down list to examine FrameNet lexical units. There is a similar checkbox labeled VN to examine members of VerbNet classes. These boxes appear only when either of these resources has identified the given preposition as part of its frame (75 for FrameNet and 31 for VerbNet).

When a particular WFR-FER combination is selected and the **Examine** menu item is clicked, a new tab is opened showing the values for those features for the given corpus set, as shown in Figure 5. The tab shows the WFR and FER that were used, the number of features for which the value was found in the feature data, the values, and the count for each feature. The description column is used when displaying results for the part of speech, the affix type, FrameNet frame elements, and VerbNet classes, since the value column for these hits are not self-explanatory. The example in Figure 5 is showing the lemma, which requires no further explanation.

Feature Examination Results for *below*

Word-Finding Rule: *Preposition Complement (Heuristic)*

Feature Extraction Rule: *Lemma*

Number of hits: *13* out of 15 instances

Value	Count	Description
5	1	
20	1	
average	9	
standard	1	
zero	1	

Figure 5. Feature Examination Results

For most features (e.g., lemma or part of speech), the number of possible values is relatively small, limited by the number of instances in the corpus set. For features such as the WordNet lexical name, synonyms and hypernyms, the number of values may be much larger. For FrameNet and VerbNet, the feature examination is limited to the combination of the WFR for the governor (**h**) and the FER lemma (**l**), both of which will generally identify verbs in the value column.

The general objective of examining features is to identify those that are diagnostic of specific senses. When applied to the full untagged TPP corpus set, this process is akin to developing

[7] An updated version of this system is available at http://sourceforge.net/projects/miacp/.

Figure 6. Selected Corpus Instances

word sketches for prepositions (Kilgarriff et al., 2004). However, since we have tagged corpus sets for most preposition senses, we can begin our efforts looking at these sets. The hypothesis is that the tagged corpora will show patterns which can then be used for tagging instances in the TPP corpus.[8]

The first step in examining features generally is to look at the word classes and parts of speech for the complement and the governor.[9] These are useful for filling in their checkboxes in Figure 3. Another useful feature is word to the left (**wl**), which can be used to verify the syntactic position checkboxes, particularly the adverbial positions (adjunct, subjunct, disjunct, and conjunct). These first steps provide a general overview of a sense's behavior.

The next step of feature examination delves more into the semantic characteristics of the complement and the governor. Tratz (2011) reported that the use of heuristics provided a more accurate identification of the preposition complement; this is the WFR **hr** in our system. After getting some idea of the word class and the part of speech, we next examine the WordNet lexical name of the complement to determine its broad semantic grouping. As mentioned, this feature may return a number of values larger than the size of the corpus set, since WordNet senses for a given lexeme may be polysemous. Notwithstanding, this feature examination generally shows the dominant categories and can be used to characterize and act as a selector for the complement in the pattern details. Similar procedures are used for characterizing the governor selection criteria.

In the example in Figure 3, for *below*, sense *3(1b)*, our preliminary analysis shows **hr:pos:cd** (i.e., a cardinal number) and **hr:l:average, standard** (i.e., the lemmas *average* and *standard*) are particularly useful for identifying this sense.

3.2 Selecting Corpus Instances

In addition to enabling feature examination, PDEP also facilitates selection of corpus instances. We can use the specifications for any WFR - FER combination, along with one of the values (as shown in Figure 5), to select the corpus instances having that feature. Figure 6 shows, in part, the result of the WFR **hr** and FER **l** with the value *average*, against the instances in the open corpus set.

As shown in the menu bar in Figure 6, we can select all instances and unselect all selections. Based on any selections, we can then tag such instances with one of the options that appear in the **Tag Instances** drop-down box. In the specific example, we could change all the selected instances to some other sense, if we have decided that the current assignment is not the best.

The selection mechanism is not used absolutely. For example, in examining the untagged instances for *over*, we used the specification **hr:ln:noun.time** (looking for instances with the heuristic complement having the WordNet lexical name **noun.time**). Out of 500 instances, we found 122 with this property. We then scrolled through the selected items, deselecting instances that did not provide a time period, and then tagged 99 instances with the sense *14(5)*, with the meaning *expressing duration*. Once we have made such a tagging, we can look at just those instances the next time we examine this sense. In this case, we might decide, pace the TPP lexicographer's comment, that the instances should be

[8] Currently, 21.5 percent of the TPP instances (10347 of 47,285) have been tagged.

[9] Accurate identification of the complement and governor is likely improved with the reliance on the Tratz dependency parser. Moreover, this is likely to improve the word sketches in PDEP. Ambati et al. (2012) report that dependency parses provide improved word sketches over purpose-built finite-state grammars. Their findings provide additional support for the methods presented here.

broken down into those which express a time period and those which describe "accompanying circumstances" (e.g., *over coffee*).

3.3 Accuracy of Features

PDEP uses the output from Tratz' system (2011), which is of high quality, but which is not always correct. In addition, the TPP corpus also has some shortcomings, which are revealed in examining the instances. The TPP corpus has not been cleaned in the same manner as the FN and the OEC corpora. As a result, we see many cases which are more difficult to parse and hence, from which to generate feature sets. We believe this provides a truer real-world picture of the complexities of preposition behavior. As a result, in the **Tag Instances** drop-down box, we have included an option to tag a sentence as **x**, to indicate that it is not a valid instance.

A small percentage of the TPP instances are ill-formed, i.e., incomplete sentences; these are marked as **x**. For some prepositions, e.g., *down*, a substantial number of instances are not prepositions, but rather adverbs or particles. For some phrasal prepositions, such as *on the strength of*, the phrase is literal, rather than the preposition idiom; in this case, 20 of 124 instances were marked as **x**. The occurrence of these invalid instances provides an opportunity for improving taggers, parsers, and semantic role labelers.

4 Assessment of Lexical Resources

Since the PDEP system enables exploration of features from WordNet, FrameNet, and VerbNet, we are able to make some assessment of these resources.

WordNet played a statistically significant role in the systems developed by Tratz (2011) and Srikumar and Roth (2013). This includes the WordNet lexicographer's file name (e.g., **noun.time**), synsets, and hypernyms. We make extensive use of the file name, but less so from the synsets and hypernyms. However, in general, we find that the file names are too coarse-grained and the synsets and hypernyms too fine-grained for generalizations on the selectors for the complements and the governors. The issue of granularity also affects the use of the DVC ontology. We discuss this issue further in section 6, on investigations of suitable categorization schemes for PDEP.

In using FrameNet, our results illustrate the unbalanced corpus used in SemEval 2007 (as suggested in Litkowski (2013b)). For the sense of *of*, "used to indicate the contents of a container", we first examined the FrameNet corpus set for that sense, which contains 278 instances (out of 4482, or 6.2 percent). Using PDEP, we found that FrameNet feature values for the governor accounted for 264 of these instances (95 percent), all of which were related to the frame elements *Contents* or *Stuff*. However, in the TPP corpus, only 3 out of 750 instances were identified for this sense (0.4 percent). Thus, while FrameNet culled a large number of instances which had these frame element realizations, these instances do not appear to be representative of their occurrence in a random sample of *of* uses. We have seen similar patterns for the other SemEval prepositions.

A similar situation exists for *Cause* senses of major prepositions: *for* (385 in FrameNet, 5/500 in TPP), *from* (71 in FrameNet, 16/500 in TPP), *of* (68 in FrameNet, 0/750 in TPP), and *with* (127 in FrameNet, 8/750 in TPP). Each of these cases further emphasizes how the SemEval 2007 instances are not representative and thus degrade the ability *to* apply existing preposition disambiguation results beyond these instances.)We discuss *Cause* senses further in the wider context of all PDEP prepositions in the next section on class analyses.)

As indicated earlier, VerbNet identifies fewer prepositions in its frames than FrameNet. We believe this is the case since VerbNet prepositions are generally arguments, rather than adjuncts. Many of the FrameNet prepositions are evoking peripheral and extra-thematic frame elements, so the number of prepositions is correspondingly higher. Also, VerbNet contains fewer members in its verb classes. As a result, the number of hits when using VerbNet is somewhat smaller, although some use of VerbNet classes is possible with the governor selectors.

PDEP provides a vehicle for expanding the items in all these resources. While prepositions are not central to these resources, their supporting role provides additional information that might be useful in developing and using these other resources.

5 Class Analyses

In SemEval 2007, Yuret (2007) investigated the possibility of using the substitutable prepositions as the basis for disambiguation (as part of more general lexical sample substitution). Although his methodology yielded significant gains over the baseline, his best results were only 54.7 per-

cent accuracy, concluding that preposition use is highly idiosyncratic. Srikumar and Roth (2013) broadened this perspective by considering a class-based approach by collapsing semantically-related senses across prepositions, thereby deriving a semantic relation inventory. While their emphasis was on modeling semantic relations, they achieved an accuracy of 83.53 percent for preposition disambiguation.

As mentioned above, PDEP has a field for the Srikumar semantic relation, initially populated for the SemEval prepositions, and being extended to cover all other prepositions. For example, Srikumar and Roth identified 21 temporal senses across 14 SemEval prepositions, while we have thus far identified 62 senses across 50 prepositions. Similar increases in the sizes of other classes occur as well. For causal senses, Srikumar and Roth identified 11 senses over 7 prepositions, while PDEP has 27 senses under 25 prepositions.

PDEP enables an in-depth analysis of TPP classes, Tratz clusters, and Srikumar semantic realations. First, we query the database underlying Figure 3 to identify all senses with a particular class. We then examine each sense on each list in detail.

We follow the procedures laid out above for examining the features to add information about selectors, complement types, and categories. We use this information to tag the TPP instances, conservatively assuring the tagging, e.g., leaving untagged questionable instances. Finally, we carefully place each sense into a preposition class or subclass, grouping senses together and making annotations that attempt to capture any nuance of meaning that distinguishes the sense from other members of the class.

To build a description of the class and its subclasses, we make use of the Quirk reference in Figure 3 (i.e., the relevant discussions in Quirk et al. (1985)). We build the description of a class as a separate web page and make this available as a menu item in Figure 3 (not shown for the Scalar class when that screenshot was made). The description provides an overview of the class, making use of the TPP data and the Quirk discussion, and indicating the number of senses and the number of prepositions. Next, the description provides a list of the categories within the class, characterizing the complements of the category and then listing each sense in the category, with any nuance of meaning as necessary. Finally, we attempt to summarize the selection criteria that have been used across all the senses in the class.

The process of building a class description reveals inconsistencies in each of the class fields. When we place a preposition sense into the class, we may find it necessary to make changes in the underlying data.

At the top level, these class analyses in effect constitute a coarse-grained sense inventory. As the subclasses are developed, a finer-grained analysis of a particular area is available. We believe these analyses may provide a comprehensive characterization of particular semantic roles that can be used for various NLP applications.

6 Availability of PDEP Data and Potential for Further Enhancements

As indicated above, each of the tables shown in the figures is generated in Javascript through a system call to a PHP script. Each of these scripts is described in detail at the PDEP web site. Each script returns data in Javascript Object Notation (JSON), enabling users to obtain whatever data is of interest to them and perhaps using this data dynamically.

While PDEP provides access to a large amount of data, the architecture is very flexible and easy to extend. For this, we are grateful for the Tratz parser and the DVC code.

In building PDEP, we found it necessary to reprocess the SemEval 2007 data of the full 28,052 sentences that were available through TPP, rather than just those that were used in the SemEval task itself. Tagging, parsing, and creating feature files for these sentences took less than 10 minutes, with an equal time to upload the feature files. We would be able to add or substitute new corpora to the PDEP databases with relatively little effort.

Similarly, we can add new elements or modify existing elements that describe preposition patterns. This would require easily-made modifications to the underlying MySQL database tables. The PHP scripts that access these tables are also easily developed or modified. Most of these scripts use less than 100 lines of code.

In developing PDEP, we have added various resources incrementally. This applies to such resources as the DVC ontology, FrameNet, and VerbNet. Each of these resources required relatively little effort to integrate into PDEP. We will continue to investigate the utility of other resources that will assist in characterizing preposition behavior. We have begun to look at the noun clusters used in Srikumar and Roth (2013) for better characterizing complements. We are also

examining an Oxford noun hierarchy as another alternative for complement analysis. We are examining the WordNet detour to FrameNet, as described in Burchardt et al. (2005), particularly for use in further characterizing the governors.

We recognize that an important element of PDEP will be in its utility for preposition disambiguation. While we have not yet begun the necessary experimentation and evaluation, we believe the representativeness and sample sizes of the TPP corpus (mostly with 250 or more sentences per preposition) should provide a basis for constructing the needed studies. We expect that this will follow techniques used by Cinkova et al. (2012), in examining the Pattern Dictionary of English Verbs developed as the precursor to DVC.

We expect that interaction with the NLP community will help PDEP evolve into a useful resource, not only for characterizing preposition behavior, but also for assisting in the development of other lexical resources.

7 Conclusion and Future Plans

We have described the Pattern Dictionary of English Prepositions (PDEP) as a new lexical resource for examining and recording preposition behavior. PDEP does not introduce any ideas that have not already been explored in the investigation of other parts of speech. However, by bringing together work from these disparate sources, we have shown that it is possible to analyze preposition behavior in a manner equivalent to the major parts of speech. Since dictionary publishers have not previously devoted much effort in analyzing preposition behavior, we believe PDEP may serve an important role, particularly for various NLP applications in which semantic role labeling is important.

On the other hand, PDEP as described in this paper is only in its initial stages. In following the principles laid out for verbs in PDEV, a main goal is to provide a sufficient characterization of how frequently different preposition patterns (senses) occur, with some idea of a statistical characterization of the probability of the conjunction of a preposition, its complement, and its governor. Better development of a desired syntagmatic characterization of preposition behavior, consistent with the principles of TNE, is still needed. Since preposition behavior is strongly linked to verb behavior, further effort is needed to link PDEP to PDEV.

The resource will benefit from futher experimentation and evaluation stages. We expect that desired improvements will come from usage in various NLP tasks, particularly word-sense disambiguation and semantic role labeling. In particular, we anticipate that interaction with the NLP community will identify further enhancements, developments, and hints from usage.

Acknowledgments

Stephen Tratz (and Dirk Hovy) provided considerable assistance in using the Tratz parser. Vivek Srikumar graciously provided his data on preposition classes. Vitek Baisa similarly helped with the adaptation of the PDEV Javascript modules. Orin Hargraves, Patrick Hanks, and Eduard Hovy continued to provide valuable insights. Reviewer comments helped sharpen the draft version of the paper.

Looking at Unbalanced Specialized Comparable Corpora for Bilingual Lexicon Extraction

Emmanuel Morin and **Amir Hazem**
Université de Nantes, LINA UMR CNRS 6241
2 rue de la houssinière, BP 92208, 44322 Nantes Cedex 03, France
{emmanuel.morin,amir.hazem}@univ-nantes.fr

Abstract

The main work in bilingual lexicon extraction from comparable corpora is based on the implicit hypothesis that corpora are balanced. However, the historical context-based projection method dedicated to this task is relatively insensitive to the sizes of each part of the comparable corpus. Within this context, we have carried out a study on the influence of unbalanced specialized comparable corpora on the quality of bilingual terminology extraction through different experiments. Moreover, we have introduced a regression model that boosts the observations of word co-occurrences used in the context-based projection method. Our results show that the use of unbalanced specialized comparable corpora induces a significant gain in the quality of extracted lexicons.

1 Introduction

The bilingual lexicon extraction task from bilingual corpora was initially addressed by using parallel corpora (i.e. a corpus that contains source texts and their translation). However, despite good results in the compilation of bilingual lexicons, parallel corpora are scarce resources, especially for technical domains and for language pairs not involving English. For these reasons, research in bilingual lexicon extraction has focused on another kind of bilingual corpora comprised of texts sharing common features such as domain, genre, sampling period, etc. without having a source text/target text relationship (McEnery and Xiao, 2007). These corpora, well known now as *comparable corpora*, have also initially been introduced as *non-parallel corpora* (Fung, 1995; Rapp, 1995), and *non-aligned corpora* (Tanaka and Iwasaki, 1996). According to Fung and Cheung (2004), who range bilingual corpora from parallel corpora to quasi-comparable corpora going through comparable corpora, there is a continuum from parallel to comparable corpora (i.e. a kind of filiation).

The bilingual lexicon extraction task from comparable corpora inherits this filiation. For instance, the historical context-based projection method (Fung, 1995; Rapp, 1995), known as the *standard approach*, dedicated to this task seems implicitly to lead to work with balanced comparable corpora in the same way as for parallel corpora (i.e. each part of the corpus is composed of the same amount of data).

In this paper we want to show that the assumption that comparable corpora should be balanced for bilingual lexicon extraction task is unfounded. Moreover, this assumption is prejudicial for specialized comparable corpora, especially when involving the English language for which many documents are available due the prevailing position of this language as a standard for international scientific publications. Within this context, our main contribution consists in a re-reading of the standard approach putting emphasis on the unfounded assumption of the balance of the specialized comparable corpora. In specialized domains, the comparable corpora are traditionally of small size (around 1 million words) in comparison with comparable corpus-based general language (up to 100 million words). Consequently, the observations of word co-occurrences which is the basis of the standard approach are unreliable. To make them more reliable, our second contribution is to contrast different regression models in order to boost the observations of word co-occurrences. This strategy allows to improve the quality of extracted bilingual lexicons from comparable corpora.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1284–1293,
Baltimore, Maryland, USA, June 23-25 2014.

2 Bilingual Lexicon Extraction

In this section, we first describe the standard approach that deals with the task of bilingual lexicon extraction from comparable corpora. We then present an extension of this approach based on regression models. Finally, we discuss works related to this study.

2.1 Standard Approach

The main work in bilingual lexicon extraction from comparable corpora is based on lexical context analysis and relies on the simple observation that a word and its translation tend to appear in the same lexical contexts. The basis of this observation consists in the identification of "first-order affinities" for each source and target language: "*First-order affinities describe what other words are likely to be found in the immediate vicinity of a given word*" (Grefenstette, 1994, p. 279). These affinities can be represented by context vectors, and each vector element represents a word which occurs within the window of the word to be translated (e.g. a seven-word window approximates syntactic dependencies). In order to emphasize significant words in the context vector and to reduce word-frequency effects, the context vectors are normalized according to an association measure. Then, the translation is obtained by comparing the source context vector to each translation candidate vector after having translated each element of the source vector with a general dictionary.

The implementation of the standard approach can be carried out by applying the following three steps (Rapp, 1999; Chiao and Zweigenbaum, 2002; Déjean et al., 2002; Morin et al., 2007; Laroche and Langlais, 2010, among others):

Computing context vectors We collect all the words in the context of each word i and count their occurrence frequency in a window of n words around i. For each word i of the source and the target languages, we obtain a context vector v_i which gathers the set of co-occurrence words j associated with the number of times that j and i occur together $cooc(i, j)$. In order to identify specific words in the lexical context and to reduce word-frequency effects, we normalize context vectors using an association score such as Mutual Information, Log-likelihood, or the discounted log-odds (LO) (Evert, 2005) (see equation 1 and Table 1 where $N = a + b + c + d$).

Transferring context vectors Using a bilingual dictionary, we translate the elements of the source context vector. If the bilingual dictionary provides several translations for an element, we consider all of them but weight the different translations according to their frequency in the target language.

Finding candidate translations For a word to be translated, we compute the similarity between the translated context vector and all target vectors through vector distance measures such as Jaccard or Cosine (see equation 2 where $assoc^i_j$ stands for "association score", v_k is the transferred context vector of the word k to translate, and v_l is the context vector of the word l in the target language). Finally, the candidate translations of a word are the target words ranked following the similarity score.

	j	$\neg j$
i	$a = cooc(i, j)$	$b = cooc(i, \neg j)$
$\neg i$	$c = cooc(\neg i, j)$	$d = cooc(\neg i, \neg j)$

Table 1: Contingency table

$$LO(i, j) = \log \frac{(a + \frac{1}{2}) \times (d + \frac{1}{2})}{(b + \frac{1}{2}) \times (c + \frac{1}{2})} \quad (1)$$

$$Cosine^{v_k}_{v_l} = \frac{\sum_t assoc^l_t \, assoc^k_t}{\sqrt{\sum_t {assoc^l_t}^2} \sqrt{\sum_t {assoc^k_t}^2}} \quad (2)$$

This approach is sensitive to the choice of parameters such as the size of the context, the choice of the association and similarity measures. The most complete study about the influence of these parameters on the quality of word alignment has been carried out by Laroche and Langlais (2010).

The standard approach is used by most researchers so far (Rapp, 1995; Fung, 1998; Peters and Picchi, 1998; Rapp, 1999; Chiao and Zweigenbaum, 2002; Déjean et al., 2002; Gaussier et al., 2004; Morin et al., 2007; Laroche and Langlais, 2010; Prochasson and Fung, 2011;

Table 2: Characteristics of the comparable corpora used for bilingual lexicon extraction

Bouamor et al., 2013, among others) with the implicit hypothesis that comparable corpora are balanced. As McEnery and Xiao (2007, p. 21) observe, a specialized comparable corpus is built as balanced by analogy with a parallel corpus: "*Therefore, in relation to parallel corpora, it is more likely for comparable corpora to be designed as general balanced corpora.*". For instance, Table 2 describes the comparable corpora used in the main work dedicated to bilingual lexicon extraction for which the ratio between the size of the source and the target texts is comprised between 1 and 1.8.

In fact, the assumption that words which have the same meaning in different languages should have the same lexical context distributions does not involve working with balanced comparable corpora. To our knowledge, no attention[1] has been paid to the problem of using unbalanced comparable corpora for bilingual lexicon extraction. Since the context vectors are computed from each part of the comparable corpus rather than through the parts of the comparable corpora, the standard approach is relatively insensitive to differences in corpus sizes. The only precaution for using the standard approach with unbalanced corpora is to normalize the association measure (for instance, this can be done by dividing each entry of a given context vector by the sum of its association scores).

2.2 Prediction Model

Since comparable corpora are usually small in specialized domains (see Table 2), the discriminative power of context vectors (i.e. the observations of word co-occurrences) is reduced. One way to deal with this problem is to re-estimate co-occurrence counts by a prediction function (Hazem and Morin, 2013). This consists in assigning to each observed co-occurrence count of a small comparable corpora, a new value learned beforehand from a large training corpus.

In order to make co-occurrence counts more discriminant and in the same way as Hazem and Morin (2013), one strategy consists in addressing this problem through regression: given training corpora of small and large size (abundant in the general domain), we predict word co-occurrence counts in order to make them more reliable. We then apply the resulting regression function to each word co-occurrence count as a pre-processing step of the standard approach. Our work differs from Hazem and Morin (2013) in two ways. First, while they experienced the linear regression model, we propose to contrast different regression models. Second, we apply regression to unbalanced comparable corpora and study the impact of prediction when applied to the source texts, the target texts and both source and target texts of the used comparable corpora.

We use regression analysis to describe the relationship between word co-occurrence counts in a large corpus (the response variable) and word co-occurrence counts in a small corpus (the predictor variable). As most regression models have already been described in great detail (Christensen, 1997; Agresti, 2007), the derivation of most models is only briefly introduced in this work.

As we can not claim that the prediction of word co-occurrence counts is a linear problem, we consider in addition to the simple linear regression

[1]We only found mention of this aspect in Diab and Finch (2000, p. 1501) "*In principle, we do not have to have the same size corpora in order for the approach to work*".

model (Lin), a generalized linear model which is the logistic regression model ($Logit$) and non linear regression models such as polynomial regression model ($Poly^n$) of order n. Given an input vector $x \in \mathbb{R}^m$, where x_1,...,x_m represent features, we find a prediction $\hat{y} \in \mathbb{R}^m$ for the co-occurrence count of a couple of words $y \in \mathbb{R}$ using one of the regression models presented below:

$$\hat{y}_{Lin} = \beta_0 + \beta_1 x \quad (3)$$

$$\hat{y}_{Logit} = \frac{1}{1 + \exp(-(\beta_0 + \beta_1 x))} \quad (4)$$

$$\hat{y}_{Poly^n} = \beta_0 + \beta_1 x + \beta_2 x^2 + ... + \beta_n x^n \quad (5)$$

where β_i are the parameters to estimate.

Let us denote by f the regression function and by $cooc(w_i, w_j)$ the co-occurrence count of the words w_i and w_j. The resulting predicted value of $cooc(w_i, w_j)$, noted $\hat{cooc}(w_i, w_j)$ is given by the following equation:

$$\hat{cooc}(w_i, w_j) = f(cooc(w_i, w_j)) \quad (6)$$

2.3 Related Work

In the past few years, several contributions have been proposed to improve each step of the standard approach.

Prochasson et al. (2009) enhance the representativeness of the context vector by strengthening the context words that happen to be transliterated words and scientific compound words in the target language. Ismail and Manandhar (2010) also suggest that context vectors should be based on the most important contextually relevant words (in-domain terms), and thus propose a method for filtering the noise of the context vectors. In another way, Rubino and Linarès (2011) improve the context words based on the hypothesis that a word and its candidate translations share thematic similarities. Yu and Tsujii (2009) and Otero (2007) propose, for their part, to replace the window-based method by a syntax-based method in order to improve the representation of the lexical context.

To improve the transfer context vectors step, and increase the number of elements of translated context vectors, Chiao and Zweigenbaum (2003) and Morin and Prochasson (2011) combine a standard general language dictionary with a specialized dictionary, whereas Déjean et al. (2002) use the hierarchical properties of a specialized thesaurus. Koehn and Knight (2002) automatically induce the initial seed bilingual dictionary by using identical spelling features such as cognates and similar contexts. As regards the problem of words ambiguities, Bouamor et al. (2013) carried out word sense disambiguation process only in the target language whereas Gaussier et al. (2004) solve the problem through the source and target languages by using approaches based on CCA (Canonical Correlation Analysis) and multilingual PLSA (Probabilistic Latent Semantic Analysis).

The rank of candidate translations can be improved by integrating different heuristics. For instance, Chiao and Zweigenbaum (2002) introduce a heuristic based on word distribution symmetry. From the ranked list of candidate translations, the standard approach is applied in the reverse direction to find the source counterparts of the first target candidate translations. And then only the target candidate translations that had the initial source word among the first reverse candidate translations are kept. Laroche and Langlais (2010) suggest a heuristic based on the graphic similarity between source and target terms. Here, candidate translations which are cognates of the word to be translated are ranked first among the list of translation candidates.

3 Linguistic Resources

In this section, we outline the different textual resources used for our experiments: the comparable corpora, the bilingual dictionary and the terminology reference lists.

3.1 Specialized Comparable Corpora

For our experiments, we used two specialized French/English comparable corpora:

Breast cancer corpus This comparable corpus is composed of documents collected from the Elsevier website[2]. The documents were taken from the medical domain within the subdomain of "breast cancer". We have automatically selected the documents published between 2001 and 2008 where the title or the keywords contain the term *cancer du sein* in French and *breast cancer* in English. We collected 130 French documents (about 530,000 words) and 1,640 English documents (about

[2] http://www.elsevier.com

7.4 million words). We split the English documents into 14 parts each containing about 530,000 words.

Diabetes corpus The documents making up the French part of the comparable corpus have been craweled from the web using three keywords: *diabète* (diabetes), *alimentation* (food), and *obésité* (obesity). After a manual selection, we only kept the documents which were relative to the medical domain. As a result, 65 French documents were extracted (about 257,000 words). The English part has been extracted from the medical website PubMed[3] using the keywords: *diabetes*, *nutrition* and *feeding*. We only kept the free fulltext available documents. As a result, 2,339 English documents were extracted (about 3,5 million words). We also split the English documents into 14 parts each containing about 250,000 words.

The French and English documents were then normalised through the following linguistic preprocessing steps: tokenisation, part-of-speech tagging, and lemmatisation. These steps were carried out using the TTC TermSuite[4] that applies the same method to several languages including French and English. Finally, the function words were removed and the words occurring less than twice in the French part and in each English part were discarded. Table 3 shows the number of distinct words (# words) after these steps. It also indicates the comparability degree in percentage (comp.) between the French part and each English part of each comparable corpus. The comparability measure (Li and Gaussier, 2010) is based on the expectation of finding the translation for each word in the corpus and gives a good idea about how two corpora are comparable. We can notice that all the comparable corpora have a high degree of comparability with a better comparability of the breast cancer corpora as opposed to the diabetes corpora. In the remainder of this article, [breast cancer corpus i] for instance stands for the breast cancer comparable corpus composed of the unique French part and the English part i ($i \in [1, 14]$).

3.2 Bilingual Dictionary

The bilingual dictionary used in our experiments is the French/English dictionary ELRA-M0033 available from the ELRA catalogue[5]. This resource is a general language dictionary which contains only a few terms related to the medical domain.

	Breast cancer # words (comp.)	Diabetes # words (comp.)
French		
Part 1	7,376	4,982
English		
Part 1	8,214 (79.2)	5,181 (75.2)
Part 2	7,788 (78.8)	5,446 (75.9)
Part 3	8,370 (78.8)	5,610 (76.6)
Part 4	7,992 (79.3)	5,426 (74.8)
Part 5	7,958 (78.7)	5,610 (75.0)
Part 6	8,230 (79.1)	5,719 (73.6)
Part 7	8,035 (78.3)	5,362 (75.6)
Part 8	8,008 (78.8)	5,432 (74.6)
Part 9	8,334 (79.6)	5,398 (74.2)
Part 10	7,978 (79.1)	5,059 (75.6)
Part 11	8,373 (79.4)	5,264 (74.9)
Part 12	8,065 (78.9)	4,644 (73.4)
Part 13	7,847 (80.0)	5,369 (74.8)
Part 14	8,457 (78.9)	5,669 (74.8)

Table 3: Number of distinct words (# words) and degree of comparability (comp.) for each comparable corpora

3.3 Terminology Reference Lists

To evaluate the quality of terminology extraction, we built a bilingual terminology reference list for each comparable corpus. We selected all French/English single words from the UMLS[6] meta-thesaurus. We kept only i) the French single words which occur more than four times in the French part and ii) the English single words which occur more than four times in each English part i[7]. As a result of filtering, 169 French/English single words were extracted for the breast cancer corpus and 244 French/English single words were extracted for the diabetes corpus. It should be noted that the evaluation of terminology extraction using specialized comparable corpora of-

[3] http://www.ncbi.nlm.nih.gov/pubmed/

[4] http://code.google.com/p/ttc-project

[5] http://www.elra.info/

[6] http://www.nlm.nih.gov/research/umls

[7] The threshold sets to four is required to build a bilingual terminology reference list composed of about a hundred words. This value is very low to obtain representative context vectors. For instance, Prochasson and Fung (2011) showed that the standard approach is not relevant for infrequent words (since the context vectors are very unrepresentative i.e. poor in information).

	Breast cancer corpus													
	1	2	3	4	5	6	7	8	9	10	11	12	13	14
Balanced	26.1	26.2	21.0	27.0	22.8	27.1	26.3	25.8	29.2	23.3	21.7	**29.6**	29.1	26.1

ten relies on lists of a small size: 95 single words in Chiao and Zweigenbaum (2002), 100 in Morin et al. (2007), 125 and 79 in Bouamor et al. (2013).

4 Experiments and Results

In this section, we present experiments to evaluate the influence of comparable corpus size and prediction models on the quality of bilingual terminology extraction.

We present the results obtained for the terms belonging to the reference list for English to French direction measured in terms of the Mean Average Precision (MAP) (Manning et al., 2008) as follows:

$$MAP(Ref) = \frac{1}{|Ref|} \sum_{i=1}^{|Ref|} \frac{1}{r_i} \quad (7)$$

where $|Ref|$ is the number of terms of the reference list and r_i the rank of the correct candidate translation i.

4.1 Standard Approach Evaluation

In order to evaluate the influence of corpus size on the bilingual terminology extraction task, two experiments have been carried out using the standard approach. We first performed an experiment using each comparable corpus independently of the others (we refer to these corpora as balanced corpora). We then conducted a second experiment where we varied the size of the English part of the comparable corpus, from 530,000 to 7.4 million words for the breast cancer corpus in 530,000 words steps, and from 250,000 to 3.5 million words for the diabetes corpus in 250,000 words steps (we refer to these corpora as unbalanced corpora). In the experiments reported here, the size of the context window w was set to 3 (i.e. a seven-word window that approximates syntactic dependencies), the retained association and similarity measures were the discounted log-odds and the Cosine (see Section 2.1). The results shown were those that give the best performance for the comparable corpora used individually.

Table 4 shows the results of the standard approach on the balanced and the unbalanced breast cancer and diabetes comparable corpora. Each column corresponds to the English part i ($i \in [1, 14]$) of a given comparable corpus. The first line presents the results for each individual comparable corpus and the second line presents the results for the cumulative comparable corpus. For instance, the column 3 indicates the MAP obtained by using a comparable corpus that is composed i) only of [breast cancer corpus 3] (MAP of 21.0%), and ii) of [breast cancer corpus 1, 2 and 3] (MAP of 34.7%).

As a preliminary remark, we can notice that the results differ noticeably according to the comparable corpus used individually (MAP variation between 21.0% and 29.6% for the breast cancer corpora and between 10.5% and 16.5% for the diabetes corpora). We can also note that the MAP of all the unbalanced comparable corpora is always higher than any individual comparable corpus. Overall, starting with a MAP of 26.1% as provided by the balanced [breast cancer corpus 1], we are able to increase it to 42.3% with the unbalanced [breast cancer corpus 12] (the variation observed for some unbalanced corpora such as [diabetes corpus 12, 13 and 14] can be explained by the fact that adding more data in the source language increases the error rate of the translation phase of the standard approach, which leads to the introduction of additional noise in the translated context vectors).

	Balanced breast cancer corpus													
	1	2	3	4	5	6	7	8	9	10	11	12	13	14
$No\ prediction$	26.1	26.2	21.0	27.0	22.8	27.1	26.3	25.8	29.2	23.3	21.7	**29.6**	29.1	26.1
$Source_{pred}$	26.5	26.0	23.0	30.0	25.4	30.1	28.3	29.4	**32.1**	24.9	24.4	30.5	30.1	29.0

Table 5: Results (MAP %) of the standard approach using the Lin regression model on the balanced breast cancer and diabetes corpora (comparison of predicting the source side, the target side and both sides of the comparable corpora)

4.2 Prediction Evaluation

The aim of this experiment is two-fold: first, we want to evaluate the usefulness of predicting word co-occurrence counts and second, we want to find out whether it is more appropriate to apply prediction to the source side, the target side or both sides of the bilingual comparable corpora.

	Breast cancer	Diabetes
$No\ prediction$	29.6	16.5
Lin	30.5	**17.6**
$Poly^2$	**30.6**	17.5
$Poly^3$	30.4	**17.6**
$Logit$	22.3	13.6

Table 6: Results (MAP %) of the standard approach using different regression models on the balanced breast cancer and diabetes corpora

4.2.1 Regression Models Comparison

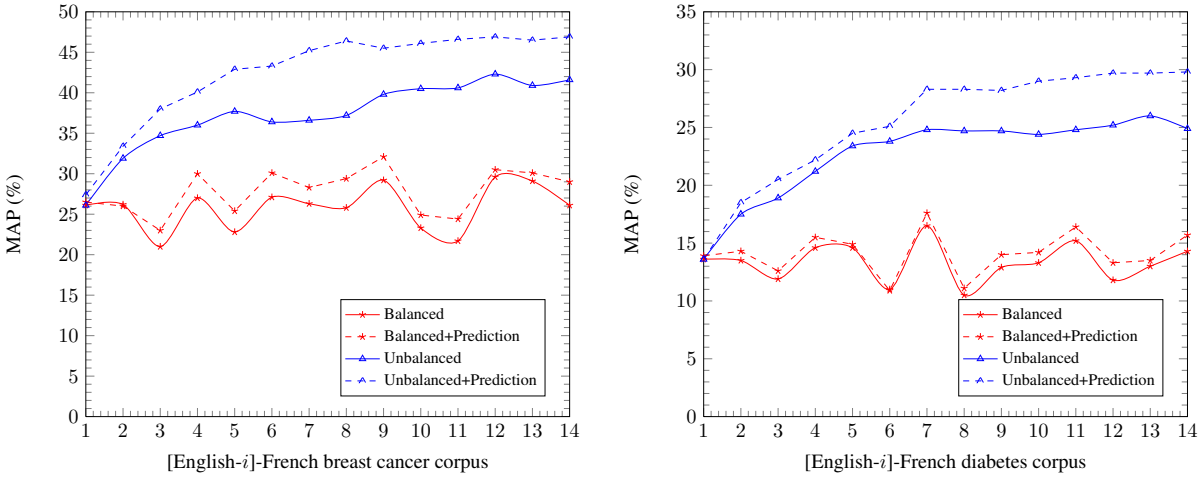
We contrast the prediction models presented in Section 2.2 to findout which is the most appropriate model to use as a pre-processing step of the standard approach. We chose the balanced corpora where the standard approach has shown the best results in the previous experiment, namely [breast cancer corpus 12] and [diabetes corpus 7].

Table 6 shows a comparison between the standard approach without prediction noted $No\ prediction$ and the standard approach with prediction models. We contrast the simple linear regression model (Lin) with the second and the third order polynomial regressions ($Poly^2$ and $Poly^3$) and the logistic regression model ($Logit$). We can notice that except for the $Logit$ model, all the regression models outperform the baseline ($No\ prediction$). Also, as we can see, the results obtained with the linear and polynomial regressions are very close. This suggests that both linear and polynomial regressions are suitable as a pre-processing step of the standard approach, while the logistic regression seems to be inappropriate according to the results shown in Table 6.

That said, the gain of regression models is not significant. This may be due to the regression parameters that have been learned from a training corpus of the general domain. Another reason that could explain these results is the prediction process. We applied the same regression function to all co-occurrence counts while learning models for low and high frequencies should have been more appropriate. In the light of the above results, we believe that prediction can be beneficial to our task.

4.2.2 Source versus Target Prediction

Table 5 shows a comparison between the standard approach without prediction noted $No\ prediction$ and the standard approach based on the prediction of the source side noted $Source_{pred}$, the target side noted $Target_{pred}$ and both sides noted $Source_{pred}$+$Target_{pred}$. If prediction can not replace a large amount of data, it aims at increasing co-occurrence counts as if large amounts of data were at our disposal. In this case, applying prediction to the source side may simulate a configuration of using unbalanced comparable corpora where the source side is n times bigger than the target side. Predicting the target side only, may



(a) (b)

Figure 1: Results (MAP %) of the standard approach using the best configurations of the prediction models (Lin for $Balanced + Prediction$ and $Poly^2$ for $Unbalanced + Prediction$) on the breast cancer and the diabetes corpora

leads us to the opposite configuration where the target side is n times bigger than the source side. Finally, predicting both sides may simulate a large comparable corpora on both sides. In this experiment, we chose to use the linear regression model (Lin) for the prediction part. That said, the other regression models have shown the same behavior as Lin.

We can see that the best results are obtained by the $Source_{pred}$ approach for both comparable corpora. We can also notice that predicting the target side and both sides of the comparable corpora degrades the results. It is not surprising that predicting the target side only leads to lower results, since it is well known that a better characterization of a word to translate (given from the source side) leads to better results. We can deduce from Table 5 that source prediction is the most appropriate configuration to improve the quality of extracted lexicons. This configuration which simulates the use of unbalanced corpora leads us to think that using prediction with unbalanced comparable corpora should also increase the performance of the standard approach. This assumption is evaluated in the next Subsection.

4.3 Predicting Unbalanced Corpora

In this last experiment we contrast the standard approach applied to the balanced and unbalanced corpora noted $Balanced$ and $Unbalanced$ with the standard approach combined with the prediction model noted $Balanced + Prediction$ and $Unbalanced + Prediction$.

Figure 1(a) illustrates the results of the experiments conducted on the breast cancer corpus. We can see that the $Unbalanced$ approach significantly outperforms the baseline ($Balanced$). The big difference between the $Balanced$ and the $Unbalanced$ approaches would indicate that the latter is optimal. We can also notice that the prediction model applied to the balanced corpus ($Balanced + Prediction$) slightly outperforms the baseline while the $Unbalanced + Prediction$ approach significantly outperforms the three other approaches (moreover the variation observed with the $Unbalanced$ approach are lower than the $Unbalanced + Prediction$ approach). Overall, the prediction increases the performance of the standard approach especially for unbalanced corpora.

The results of the experiments conducted on the diabetes corpus are shown in Figure 1(b). As for the previous experiment, we can see that the $Unbalanced$ approach significantly outperforms the $Balanced$ approach. This confirms the unbalanced hypothesis and would motivate the use of unbalanced corpora when they are available. We can also notice that the $Balanced + Prediction$ approach slightly outperforms the baseline while the $Unbalanced + Prediction$ approach gives the best results. Here also, the prediction increases the performance of the standard approach especially for unbalanced corpora. It is clear that in addition to the benefit of using unbalanced comparable

corpora, prediction shows a positive impact on the performance of the standard approach.

5 Conclusion

In this paper, we have studied how an unbalanced specialized comparable corpus could influence the quality of the bilingual lexicon extraction. This aspect represents a significant interest when working with specialized comparable corpora for which the quantity of the data collected may differ depending on the languages involved, especially when involving the English language as many scientific documents are available. More precisely, our different experiments show that using an unbalanced specialized comparable corpus always improves the quality of word translations. Thus, the MAP goes up from 29.6% (best result on the balanced corpora) to 42.3% (best result on the unbalanced corpora) in the breast cancer domain, and from 16.5% to 26.0% in the diabetes domain. Additionally, these results can be improved by using a prediction model of the word co-occurrence counts. Here, the MAP goes up from 42.3% (best result on the unbalanced corpora) to 46.9% (best result on the unbalanced corpora with prediction) in the breast cancer domain, and from 26.0% to 29.8% in the diabetes domain. We hope that this study will pave the way for using specialized unbalanced comparable corpora for bilingual lexicon extraction.

Validating and Extending Semantic Knowledge Bases using Video Games with a Purpose

Abstract

Large-scale knowledge bases are important assets in NLP. Frequently, such resources are constructed through automatic mergers of complementary resources, such as WordNet and Wikipedia. However, manually validating these resources is prohibitively expensive, even when using methods such as crowdsourcing. We propose a cost-effective method of validating and extending knowledge bases using *video games* with a purpose. Two video games were created to validate concept-concept and concept-image relations. In experiments comparing with crowdsourcing, we show that video game-based validation consistently leads to higher-quality annotations, even when players are not compensated.

1 Introduction

Large-scale knowledge bases are an essential component of many approaches in Natural Language Processing (NLP). Semantic knowledge bases such as WordNet (Fellbaum, 1998), YAGO (Suchanek et al., 2007), and BabelNet (Navigli and Ponzetto, 2010) provide ontological structure that enables a wide range of tasks, such as measuring semantic relatedness (Budanitsky and Hirst, 2006) and similarity (Pilehvar et al., 2013), paraphrasing (Kauchak and Barzilay, 2006), and word sense disambiguation (Navigli and Ponzetto, 2012; Moro et al., 2014). Furthermore, such knowledge bases are essential for building unsupervised algorithms when training data is sparse or unavailable. However, constructing and updating semantic knowledge bases is often limited by the significant time and human resources required.

Recent approaches have attempted to build or extend these knowledge bases automatically. For example, Snow et al. (2006) and Navigli (2005) extend WordNet using distributional or structural features to identify novel semantic connections between concepts. The recent advent of large semi-structured resources has enabled the creation of new semantic knowledge bases (Medelyan et al., 2009; Hovy et al., 2013) through automatically merging WordNet and Wikipedia (Suchanek et al., 2007; Navigli and Ponzetto, 2010; Niemann and Gurevych, 2011). While these automatic approaches offer the scale needed for open-domain applications, the automatic processes often introduce errors, which can prove detrimental to downstream applications. To overcome issues from fully-automatic construction methods, several works have proposed validating or extending knowledge bases using crowdsourcing (Biemann and Nygaard, 2010; Eom et al., 2012; Sarasua et al., 2012). However, these methods, too, are limited by the resources required for acquiring large numbers of responses.

In this paper, we propose validating and extending semantic knowledge bases using **video games with a purpose**. Here, the annotation tasks are transformed into elements of a video game where players accomplish their jobs by virtue of playing the game, rather than by performing a more traditional annotation task. While prior efforts in NLP have incorporated games for performing annotation and validation (Siorpaes and Hepp, 2008b; Herdağdelen and Baroni, 2012; Poesio et al., 2013), these games have largely been text-based, adding game-like features such as high-scores on top of an existing annotation task. In contrast, we introduce two video games with graphical 2D gameplay that is similar to what game players are familiar with. The fun nature of the games provides an intrinsic motivation for players to keep playing, which can increase the quality of their work and lower the cost per annotation.

Our work provides the following three contributions. First, we demonstrate effective video game-based methods for both validating and extending

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1294–1304,
Baltimore, Maryland, USA, June 23-25 2014.

semantic networks, using two games that operate on complementary sources of information: semantic relations and sense-image mappings. In contrast to previous work, the annotation quality is determined in a fully automatic way. Second, we demonstrate that converting games with a purpose into more traditional video games creates an increased player incentive such that players annotate for free, thereby significantly lowering annotation costs below that of crowdsourcing. Third, for both games, we show that games produce better quality annotations than crowdsourcing.

2 Related Work

Multiple works have proposed linguistic annotation-based games with a purpose for tasks such as anaphora resolution (Hladká et al., 2009; Poesio et al., 2013), paraphrasing (Chklovski and Gil, 2005), term associations (Artignan et al., 2009; Lafourcade and Joubert, 2010), query expansion (Simko et al., 2011), and word sense disambiguation (Chklovski and Mihalcea, 2002; Seemakurty et al., 2010; Venhuizen et al., 2013). Notably, all of these linguistic games focus on users interacting with text, in contrast to other highly successful games with a purpose in other domains, such as Foldit (Cooper et al., 2010), in which players fold protein sequences, and the ESP game (von Ahn and Dabbish, 2004), where players label images with words.

Most similar to our work are games that create or validate common sense knowledge. Two games with a purpose have incorporated video game-like mechanics for annotation. First, Herdağdelen and Baroni (2012) validate automatically acquired common sense relations using a slot machine game where players must identify valid relations and arguments from randomly aligned data within a time limit. Although the validation is embedded in a game-like setting, players are limited to one action (pulling the lever) unlike our games, which feature a variety of actions and rich gameplay experience to keep players interested longer. Second, Kuo et al. (2009) describe a pet-raising game where players must answer common sense questions in order to obtain pet food. While their game is among the most video game-like, the annotation task is a chore the player must perform in order to return to the game, rather than an integrated, fun part of the game's objectives, which potentially decreases motivation for answering correctly.

Several works have proposed adapting existing word-based board game designs to create or validate common sense knowledge. von Ahn et al. (2006) generate common sense facts by using a game similar to Taboo™, where one player must list facts about a computer-selected lemma and a second player must guess the original lemma having seen only the facts. Similarly, Vickrey et al. (2008) gather free associations to a target word with the constraint, similar to Taboo™, where players cannot enter a small set of banned words. Vickrey et al. (2008) also present two games similar to the Scattergories™, where players are given a category and then must list things in that category. The two variants differ in the constraints imposed on the players, such as beginning all items with a specific letter. For all three games, two players play the same game under time limits and then are rewarded if their answers match.

Last, three two-player games have focused on validating and extending knowledge bases. Rzeniewicz and Szymański (2013) extend WordNet with common-sense knowledge using a 20 Questions-like game. In a rapid-play style game, OntoPronto attempts to classify Wikipedia pages as either categories or individuals (Siorpaes and Hepp, 2008a). SpotTheLink uses a similar rapid question format to have players align the DBpedia and PROTON ontologies by agreeing on the distinctions between classes (Thaler et al., 2011).

Unlike dynamic gaming elements common in our video games, the above games are all focused on interacting with textual items. Another major limitation is their need for always having two players, which requires them to sustain enough interest to always maintain an active pool of players. While the computer can potentially act as a second player, such a simulated player is often limited to using preexisting knowledge or responses, which makes it difficult to validate new types of entities or create novel answers. In contrast, we drop this requirement thanks to a new strategy for assigning confidence scores to the annotations based on negative associations.

3 Video Game with a Purpose Design

To create video games, our development process focused on a common design philosophy and a common data set.

3.1 Design Objectives

Three design objectives were used to develop the video games. First, the annotation task should be a central and natural action with familiar video game mechanics. That is, the annotation should

be supplied by common actions such as collecting items, puzzles, or destroying objects, rather than through extrinsic tasks that players must complete in order to return to the game. This design has the benefits of (1) growing the annotator pool with video games players, and (2) potentially increasing annotator enjoyment.

Second, the game should be playable by a single player, with reinforcement for correct game play coming from gold standard examples.[1] We note that gold standard examples may come from both true positive and true negative items.

Third, the game design should be sufficiently general to annotate a variety of linguistic phenomena, such that only the game data need be changed to accomplish a different annotation task. While some complex linguistic annotation tasks such as preposition attachment may be difficult to integrate directly into gameplay, many simpler but still necessary annotation tasks such as word and image associations can be easily modeled with traditional video game mechanics.

3.2 Annotation Setup

Tasks We focused on two annotation tasks: (1) validating associations between two concepts, and (2) validating associations between a concept and an image. For each task we developed a video game with a purpose that integrates the task within the game, as illustrated in Sections 4 and 5.

Knowledge base As the reference knowledge base, we chose BabelNet[2] (Navigli and Ponzetto, 2010), a large-scale multilingual semantic ontology created by automatically merging WordNet with other collaboratively-constructed resources such as Wikipedia and OmegaWiki. BabelNet data offers two necessary features for generating the games' datasets. First, by connecting WordNet synsets to Wikipedia pages, most synsets are associated with a set of pictures; while often noisy, these pictures sometimes illustrate the target concept and are an ideal case for validation. Second, BabelNet contains the semantic relations from both WordNet and hyperlinks in Wikipedia; these relations are again an ideal case of validation, as not all hyperlinks connect semantically-related pages in Wikipedia. Last, we stress that while our games use BabelNet data, they could easily validate or extend other knowledge bases such as YAGO (Suchanek et al., 2007) as well.

[1] This design is in contrast to two-player games where mutual agreement reinforces correct behavior.

[2] http://babelnet.org

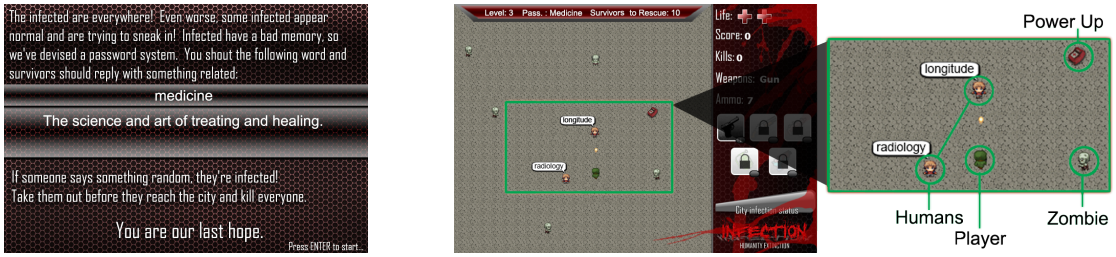
Data We created a common set of concepts, C, used in both games, containing sixty synsets selected from all BabelNet synsets with at least fifty associated images. Using the same set of synsets, separate datasets were created for the two validation tasks. In each dataset, a concept $c \in C$ is associated with two sets: a set V_c containing items to validate, and a set N_c with examples of true negative items (i.e., items where the relation to c does not hold). We use the notation V and N when referring to the to-validate and true negative sets for all concepts in a dataset, respectively.

For the concept-concept dataset, V_c is the union of V_c^B, which contains the lemmas of all synsets incident to c in BabelNet, and V_c^n, which contains novel lemmas derived from statistical associations. Specifically, novel lemmas were selected by computing the χ^2 statistic for co-occurrences between the lemmas of c and all other part of speech-tagged lemmas in Wikipedia. The 30 lemmas with the highest χ^2 are included in V_c. To enable concept-to-concept annotations, we disambiguate novel lemmas using a simple heuristic based on link co-occurrence count (Navigli and Ponzetto, 2012). Each set V_c contains 77.6 lemmas on average.

For the concept-image data, V_c is the union of V_c^B, which contains all images associated with c in BabelNet, and V_c^n, which contains web-gathered images using a lemma of c as the query. Web-gathered images were retrieved using Yahoo! Boss image search and the first result set (35 images) was added to V_c. Each set V_c contains 77.0 images on average.

For both datasets, each negative set N_c is constructed as $\cup_{c' \in C \setminus \{c\}} V_{c'}^B$, i.e., from the items related in BabelNet to all other concepts in C. By constructing N_c directly from the knowledge base, play actions may be validated based on recognition of true negatives, removing the heavy burden for ever manually creating a gold standard test set.

Annotation Aggregation In each game, an item is annotated when players make a binary choice as to whether the item's relation is true (e.g., whether an image is related to a concept). To produce a final annotation, a rating of $p - n$ is computed, where p and n denote the number of times players have marked the item's relation as true or false, respectively. Items with a positive rating after aggregating are marked as true examples of the relation and false otherwise.



(a) The passphrase shown at the start (b) Main gameplay screen with a close-up of a player's interaction with two humans

Figure 1: Screenshots of the key elements of Infection

4 Game 1: Infection

The first game, *Infection*, validates the concept-concept relation dataset.

Design Infection is designed as a top-down shooter game in the style of Commando. Infection features the classic game premise that a virus has partially infected humanity, turning people into zombies. The player's responsibility is to stop zombies from reaching the city and rescue humans that are fleeing to the city. Both zombies and humans appear at the top of the screen, advance to the bottom and, upon reaching it, enter the city.

In the game, some humans are infected, but have not yet become zombies; these infected humans must be stopped before reaching the city. Because infected and uninfected humans look identical, the player uses a passphrase call-and-response mechanism to distinguish between the two. Each level features a randomly-chosen passphrase that the player's character shouts. Uninfected humans are expected to respond with a word or phrase related to the passphrase; in contrast, infected humans have become confused due to the infection and will say something completely unrelated in an attempt to sneak past. When an infected human reaches the city, the city's total infection level increases; should the infection level increase beyond a certain threshold, the player fails the stage and must replay it to advance the game. Furthermore, if any time after ten humans have been seen, the player has killed more than 80% of the uninfected humans, the player's gun is taken by the survivors and she loses the stage.

Figure 1a shows instructions for the passphrase "medicine." In the corresponding gameplay, shown in the close up of Figure 1b, a human shouts a valid response, "radiology" for the level's passphrase, while the nearby infected human shouts an incorrect response "longitude."

Gameplay is divided into eight stages, each with increasing difficulty. Each stage has a goal of saving a specific number of uninfected humans. Infection incorporates common game mechanics, such as unlockable weapons, power-ups that restore health, and achievements. Scoring is based on both the number of zombies killed and the percentage of uninfected humans saved, motivating players to kill infected humans in order to increase their score. Importantly, Infection also includes a leaderboard where players compete for top positions based on their total scores.

Annotation Each human is assigned a response selected uniformly from V or N. Humans with responses from N are treated as infected. Players annotate by selecting which humans are infected: Allowing a human with a response from V to enter the city is treated as a positive annotation; killing that human is treated as a negative annotation.

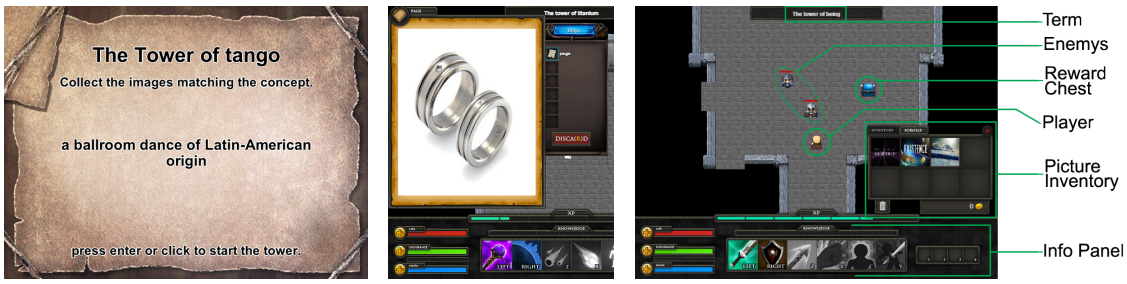
The design of Infection enables annotating multiple types of conceptual relations such as synonymy or antonymy by changing only the description of the passphrase and how uninfected humans are expected to respond.

Quality Enforcement Mechanisms Infection includes two game mechanics to limit adversarial players from creating many low quality annotations. Specifically, the game prevents players from both (1) allowing all humans to live, via the city infection level and (2) killing all humans, via survivors taking the player's gun; these actions would both generate many false positives and false negatives, respectively. These mechanics ensure the game naturally produces better quality annotations; in contrast, common crowdsourcing platforms do not support analogous mechanics for enforcing this type of correctness at annotation time.

5 Game 2: The Knowledge Towers

The second game, *The Knowledge Towers* (TKT), validates the concept-image dataset.

Design TKT is designed as a single-player role playing game (RPG) where the player explores a



(a) An example tower's concept (b) Image selection screen (c) Gameplay

Figure 2: Screenshots of the key elements of The Knowledge Towers.

series of towers to unlock long-forgotten knowledge. At the start of each tower, a target concept is shown, e.g., the tower of "tango," along with a description of the concept (Figure 2a). The player must then recover the knowledge of the target concept by acquiring pictures of it. Pictures are obtained through defeating monsters and opening treasure chests, such as those shown in Figure 2c. However, players must distinguish pictures of the tower's concept from unrelated pictures. When an image is picked up, the player may keep or discard it, as shown in Figure 2b. A player's inventory is limited to eight pictures to encourage them to select the most relevant pictures only.

Once the player has collected enough pictures, the door to the boss room is unlocked and the player may enter to defeat the boss and complete the tower. Pictures may also be deposited in special reward chests that grant experience bonuses if the deposited pictures are from V. Gathering unrelated pictures has adverse effects on the player. If the player finishes the level with a majority of unrelated pictures, the player's journey is unsuccessful and she must replay the tower.

TKT includes RPG game elements commonly found in game series such as Diablo and the Legend of Zelda: players begin with a specific character class that has class-specific skills, such as Warrior or Thief, but will unlock the ability to play as other classes by successfully completing the towers. Last, TKT includes a leaderboard where players can compete for positions; a player's score is based on increasing her character's abilities and her accuracy at discarding images from N.

Annotation Players annotate by deciding which images to keep in their inventory. Images receive positive rating annotations from: (1) depositing the image in a reward chest, and (2) ending the level with the image still in the inventory. Conversely, images receive a negative rating when a player (1) views the image but intentionally avoids picking it up or (2) drops the image from her inventory.

TKT is designed to assist in the validation and extension of automatically-created image libraries that link to semantic concepts, such as ImageNet (Deng et al., 2009) and that of Torralba et al. (2008). However, its general design allows for other types of annotations, such as image labeling, by changing the tower's instructions and pictures.

Quality Enforcement Mechanisms Similar to Infection, TKT includes analogous mechanisms for limiting adversarial player annotations. Players who collect no images are prevented from entering the boss room, limiting their ability to generate false negative annotations. Similarly, players who collect all images are likely to have half of their images from N and therefore fail the tower's quality-check after defeating the boss.

6 Experiments

Two experiments were performed with Infection and TKT: (1) an evaluation of players' ability to play accurately and to validate semantic relations and image associations and (2) a comprehensive cost comparison. Each experiment compared (a) free and financially-incentivized versions of each game, (b) crowdsourcing, and (c) a non-video game with a purpose.

6.1 Experimental Setup

Gold Standard Data To compare the quality of annotation from games and crowdsourcing, a gold standard annotation was produced for a 10% sample of each dataset (cf. Section 3.2). Two annotators independently rated the items and, in cases of disagreement, a third expert annotator adjudicated. Unlike in the game setting, annotators were free to consult additional resources such as Wikipedia.

To measure inter-annotator agreement (IAA) on the gold standard annotations, we calculated Krip-

pendorff's α (Krippendorff, 2004; Artstein and Poesio, 2008); α ranges between [-1,1] where 1 indicates complete agreement, -1 indicates systematic disagreement, and values near 0 indicate agreement at chance levels. Gold standard annotators had high agreement, 0.774, for concept-concept relations. However, image-concept agreement was only moderate, 0.549. A further analysis revealed differences in the annotators' thresholds for determining association, with one annotator permitting more abstract relations. However, the adjudication process resolved these disputes, resulting in substantial agreement by all annotators on the final gold annotations.

Incentives At the start of each game, players were shown brief descriptions of the game and a description of a contest where the top-ranked players would win either (1) monetary prizes in the form of gift cards, or (2) a mention and thanks in this paper. We refer to these as the paid and free versions of the game, respectively. In the paid setting, the five top-ranking players were offered gift cards valued at 25, 15, 15, 10, and 10 USD, starting from first place (a total of 75 USD per game). To increase competition among players and to perform a fairer time comparison with crowdsourcing, the contest period was limited to two weeks.

6.2 Comparison Methods

To compare with the video games, items were annotated using two additional methods: crowdsourcing and a non-video game with a purpose.

Crowdsourcing Setup Crowdsourcing was performed using the CrowdFlower platform. Annotation tasks were designed to closely match each game's annotation process. A task begins with a description of a target synset and its textual definition; following, ten annotation questions are shown. Separate tasks were used for validating concept-concept and concept-image relations. Each tasks' questions were shown as a binary choice of whether the item is related to the task's concept. Workers were paid 0.05 USD per task. Each question was answered by three workers.

Following common practices for guarding against adversarial workers (Mason and Suri, 2012), the tasks for concept c include quality check questions using items from N_c. Workers who rate too many relations from N_c as valid are removed by CrowdFlower and prevented from participating further. One of the ten questions in a task used an item from N_c, resulting in a task mixture of 90% annotation questions and 10% quality-check questions. However, we note that both of our video games use data that is 50% annotation, 50% quality-check. While the crowdsourcing task could be adjusted to use an increased number of quality-check options, such a design is uncommon and artificially inflates the cost of the crowdsourcing comparison beyond what would be expected. Therefore, although the crowdsourcing and game-based annotation tasks differ slightly, we chose to use the common setup in order to create a fair cost-comparison between the two.

Non-video Game with a Purpose To measure the impact of the video game itself on the annotation process, we developed a non-video game with a purpose, referred to as *SuchGame*. Players perform a single action in SuchGame: after being shown a concept c and its textual definition, a player answers whether an item is related to the concept. Items are drawn equally from V_c and N_c, with players scoring a point each time they select that an item from N is not related. A round of gameplay contains ten questions. After the round ends, players see their score for that round and the current leaderboard. Two versions of SuchGame were released, one for each dataset. SuchGame was promoted with same free recognition incentive as Infection and TKT.

6.3 Game Release

Both video games were released to multiple online forums, social media sites, and Facebook groups. SuchGame was released to separate Facebook groups promoting free webgames and groups for indie games. For each release, we estimated an upper-bound of the audience sizes using available statistics such as Facebook group sites, website analytics, and view counts. The free and paid versions had sizes of 21,546 and 14,842 people, respectively; SuchGame had an upper bound of 569,131 people. Notices promoting the game were separated so that audiences saw promotions for one of either the paid or free incentive version. Games were also released in such a way as to preserve the anonymity of the study, which limited our ability to advertise to public venues where the anonymity might be compromised.

7 Results and Discussion

7.1 Gameplay Analysis

In this section we analyze the games in terms of participation and player's ability to correctly play. Players completed over 1388 games during the

Infection paid	163	3355	65.9	0.330	69.1	54.8	61.1	$0.022
Crowdflower	1097	13764	-	0.167	16.9	96.4	59.6	$0.008

Table 1: Annotation statistics from all sources. N-Accuracy denotes accuracy at rejecting items from N; G.S. Agreement denotes percentage agreement of the aggregated annotations with the gold standard.

study period. The paid and free versions of TKT had similar numbers of players, while the paid version of Infection attracted nearly twice the players compared to the free version, shown in Table 1, Column 1. However, both versions created approximately the same number of annotations, shown in Column 2. Surprisingly, SuchGame received little attention, with only a few players completing a full round of game play. We believe this emphasizes the strength of video game-based annotation; adding incentives and game-like features to an annotation task will not necessarily increase its appeal. Given SuchGame's minimal interest, we omit it from further analysis.

Second, the type of incentive did not change the percentage of items from N that players correctly reject, shown for all players as N-accuracy in Table 1 Column 3 and per-player in Figure 3. However, players were much more accurate at rejecting items from N in TKT than in Infection. We attribute this difference to the nature of the items and the format of the games. The images used by TKT provide concrete examples of a concept, which can be easily compared with the game's current concept; in addition, TKT allows players to inspect items as long as a player prefers. In contrast, concept-concept associations require more background knowledge to determine if a relation exists; furthermore, Infection gives players limited time to decide (due to board length) and also contains cognitive distractors (zombies). Nevertheless, player accuracy remains high for both games (Table 1, Col. 3) indicating the games represent a viable medium for making annotation decisions.

Last, the distribution of player annotation frequencies (Figure 3) suggests that the leaderboard and incentives motivated players. Especially in the paid condition, a clear group appears in the top five positions, which were advertised as receiving prizes. The close proximity of players in the paid positions is a result of continued competition as players jostled for higher-paying prizes.

7.2 Annotation Quality

This section assesses the annotation quality of both games and of CrowdFlower in terms of (1) the IAA of the participants, measured using Krippendorff's α, and (2) the percentage agreement of the resulting annotations with the gold standard. Players in both free and paid games had similar IAA, though the free version is consistently higher (Table 1, Col. 4).[3] For images, crowdsourcing workers have a higher IAA than game players; however, this increased agreement is due to adversarial workers consistently selecting the same, incorrect answer. In contrast, both video games contain mechanisms for limiting such behavior.

The strength of both crowdsourcing and games with a purpose comes from aggregating multiple annotations of a single item; i.e., while IAA may

[3]In conversations with players after the contest ended, several mentioned that being aware their play was contributing to research motivated them to play more accurately.

Lemma	Abbreviated Definition	Most-selected Items
atom	The smallest possible particle of a chemical element	spectrum, nonparticulate radiation, **molecule**, **hydrogen**, **electron** chord	A combination of three or more notes	**voicing**, **triad**, **tonality**,‡ **strum**, **note**, **harmony** 
color	An attribute from reflected or emitted light	**orange**, brown,‡ video, sadness, **RGB**, **pigment** fire	The state of combustion in which inflammable material burns	**sprinkler**, machine gun, chemical reduction, volcano, organic chemistry religion	The expression of man's belief in and reverence for a superhuman power	**polytheistic**,‡ **monotheistic**, **Jainism**, **Christianity**,‡ Freedom of religion 

Table 2: Examples of the most-selected words and images from the free version of both games. Bolded words and images with a dashed border denote items not in BabelNet. Only the items marked with a ‡ were rated as valid in the aggregated CrowdFlower annotations.

be low, the majority annotation of an item may be correct. Therefore, in Table 1, we calculate the percentage agreement of the aggregated annotations with the gold standard annotations for approving valid relations (true positives; Col. 5), rejecting invalid relations (true negatives; Col. 6), and for both combined (Col. 7). On average, both video games in all settings produce more accurate annotations than crowdsourcing. Indeed, despite having lower IAA for images, the free version of TKT provides an absolute 16.3% improvement in gold standard agreement over crowdsourcing.

Examining the difference in annotation quality for true positives and negatives, we see a strong bias with crowdsourcing towards rejecting all items. This bias leads to annotations with few false positives, but as Column 5 shows, crowdflower workers consistently performed much worse than game players at identifying valid relations, producing many false negative annotations. Indeed, for concept-concept relations, workers identified only 16.9% of the valid relations.

In contrast to crowdsourcing, both games were effective at identifying valid relations. Table 2 shows examples of the most frequently chosen items from V for the free versions of both games. For both games, players were equally likely to select novel items, suggesting the games can serve a useful purpose of adding these missing relations in automatically constructed knowledge bases. Highlighting one example, the five most selected concept-concept relations for *chord* were all novel; BabelNet included many relations to highly-specific concepts (e.g., "Circle of fifths") but did not include relations to more commonly-associated concepts, like *note* and *harmony*.

7.3 Cost Analysis

This section provides a cost-comparison between the video games and crowdsourcing. The free versions of both games proved highly successful, yielding high-quality annotations at no direct cost. Both free and paid conditions produced similar volumes of annotations, suggesting that players do not need financial incentives provided that the games are fun to play. It could be argued that the recognition incentive was motivating players in the free condition and thus some incentive was required. However, player behavior indicates otherwise: After the contest period ended, *no* players in the free setting registered for being acknowledged by name, which strongly suggests the incentive was not contributing to their motivation for playing. Furthermore, a minority of players continued to play even after the contest period ended, suggesting that enjoyment was a driving factor.

Last, while crowdsourcing has seen different quality and volume from workers in paid and unpaid settings (Rogstadius et al., 2011), in contrast, our games produced approximately-equivalent results from players in both settings.

Crowdsourcing was slightly more cost-effective than both games in the paid condition, as shown in Table 1, Column 8. However, three additional factors need to be considered. First, both games intentionally uniformly sample between V and N to increase player engagement,[4] which generates a larger number of annotations for items in N than are produced by crowdsourcing. When annotations on items in N are included for both games and crowdsourcing, the costs per annotation drop to comparable levels: \$0.007 for CrowdFlower tasks, \$0.008 for TKT, and \$0.011 for Infection.

Second, for both annotation tasks, crowdsourcing produced lower quality annotations, especially for valid relations. Based on agreement with the gold standard (Table 1, Col. 5), the estimated cost for crowdsourcing a *correct* true positive annotation increases to \$0.014 for a concept-image and a \$0.048 for concepts-concept annotation. In contrast, the cost when using video games increases only to \$0.033 for concept-image and \$0.031 for concept-concept. These cost increases suggest that crowdsourcing is not always cheaper with respect to quality.

Third, we note that both video games in the paid setting incur a fixed cost (for the prizes) and therefore additional games played can only further decrease the cost per annotation. Indeed, the present study divided the audience pool into two separate groups which effectively halved the potential number of annotations per game. Assuming combining the audiences would produce the same number of annotations, both our games' costs per annotation drop to \$0.012.

Last, video games can potentially come with indirect costs due to software development and maintenance. Indeed, Poesio et al. (2013) report spending 60,000£ in developing their Phrase Detectives game with a purpose over a two-year period. In contrast, both games here were developed as a part of student projects using open source software and assets and thus incurred no cost; furthermore, games were created in a few months, rather than years. Given that few online games attain significant sustained interest, we argue that our lightweight model is preferable for producing video games with a purpose. While using students is not always possible, the development process is fast enough to sufficiently reduce costs below those reported for Phrase Detectives.

[4]Earlier versions that used mostly items from V proved less engaging due to players frequently performing the same action, e.g., saving most humans or collecting most pictures.

8 Conclusion

Two video games have been presented for validating and extending knowledge bases. The first game, Infection, validates concept-concept relations, and the second, The Knowledge Towers, validates image-concept relations. In experiments involving online players, we demonstrate three contributions. First, games were released in two conditions whereby players either saw financial incentives for playing or a personal satisfaction incentive where they were thanked by us. We demonstrated that both conditions produced nearly identical numbers of annotations and, moreover, that players were disinterested in the satisfaction incentive, suggesting they played out of interest in the game itself. Furthermore, we demonstrated the effectiveness of a novel design for games with a purpose which does not require two players for validation and instead reinforces behavior only using true negative items that required no manual annotation. Second, in a comparison with crowdsourcing, we demonstrate that video game-based annotations consistently generated higher-quality annotations. Last, we demonstrate that video game-based annotation can be more cost-effective than crowdsourcing or annotation tasks with game-like features: The significant number of annotations generated by the satisfaction incentive condition shows that a fun game can generate high-quality annotations at virtually no cost. All annotated resources, demos of the games, and a live version of the top-ranking items for each concept are currently available online.[5]

In the future we will apply our video games to the validation of more data, such as the new Wikipedia bitaxonomy (Flati et al., 2014).

Abstract

Designing measures that capture various aspects of language ability is a central task in the design of systems for automatic scoring of spontaneous speech. In this study, we address a key aspect of language proficiency assessment – syntactic complexity. We propose a novel measure of syntactic complexity for spontaneous speech that shows optimum empirical performance on real world data in multiple ways. First, it is both *robust* and *reliable*, producing automatic scores that agree well with human rating compared to the state-of-the-art. Second, the measure makes sense theoretically, both from algorithmic and native language acquisition points of view.

1 Introduction

Assessment of a speaker's proficiency in a second language is the main task in the domain of automatic evaluation of spontaneous speech (Zechner et al., 2009). Prior studies in language acquisition and second language research have conclusively shown that proficiency in a second language is characterized by several factors, some of which are, fluency in language production, pronunciation accuracy, choice of vocabulary, grammatical sophistication and accuracy. The design of automated scoring systems for non-native speaker speaking proficiency is guided by these studies in the choice of pertinent objective measures of these key aspects of language proficiency.

The focus of this study is the design and performance analysis of a measure of the syntactic complexity of non-native English responses for use in automatic scoring systems. The state-of-the art automated scoring system for spontaneous speech (Zechner et al., 2009; Higgins et al., 2011) currently uses measures of fluency and pronunciation (acoustic aspects) to produce scores that are in reasonable agreement with human-rated scores of proficiency. Despite its good performance, there is a need to extend its coverage to higher order aspects of language ability. Fluency and pronunciation may, by themselves, already be good indicators of proficiency in non-native speakers, but from a construct validity perspective[1], it is necessary that an automatic assessment model measure higher-order aspects of language proficiency. Syntactic complexity is one such aspect of proficiency. By "syntactic complexity", we mean a learner's ability to use a wide range of sophisticated grammatical structures.

This study is different from studies that focus on capturing grammatical errors in non-native speakers (Foster and Skehan, 1996; Iwashita et al., 2008). Instead of focusing on grammatical errors that are found to be highly representative of language proficiency, our interest is in capturing the *range* of forms that surface in language production and the degree of *sophistication* of such forms, collectively referred to as *syntactic complexity* in (Ortega, 2003).

The choice and design of objective measures of language proficiency is governed by two crucial constraints:

1. Validity: a measure should show high discriminative ability between various levels of language proficiency, and the scores produced by the use of this measure should show high agreement with human-assigned scores.
2. Robustness: a measures should be derived automatically and should be robust to errors in the measure generation process.

A critical impediment to the robustness constraint in the state-of-the-art is the multi-stage au-

[1]Construct validity is the degree to which a test measures what it claims, or purports, to be measuring and an important criterion in the development and use of assessments or tests.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1305–1315,
Baltimore, Maryland, USA, June 23-25 2014.

tomated process, where errors in the speech recognition stage (the very first stage) affect subsequent stages. Guided by studies in second language development, we design a measure of syntactic complexity that captures patterns indicative of proficient and non-proficient grammatical structures by a shallow-analysis of spoken language, as opposed to a deep syntactic analysis, and analyze the performance of the automatic scoring model with its inclusion. We compare and contrast the proposed measure with that found to be optimum in Yoon and Bhat (2012).

Our primary contributions in this study are:

- We show that the measure of syntactic complexity derived from a shallow-analysis of spoken utterances satisfies the design constraint of high discriminative ability between proficiency levels. In addition, including our proposed measure of syntactic complexity in an automatic scoring model results in a statistically significant performance gain over the state-of-the-art.
- The proposed measure, derived through a completely automated process, satisfies the robustness criterion reasonably well.
- In the domain of native language acquisition, the presence or absence of a grammatical structure indicates grammatical development. We observe that the proposed approach elegantly and effectively captures this presence-based criterion of grammatical development, since the feature indicative of presence or absence of a grammatical structure is optimal from an algorithmic point of view.

2 Related Work

Speaking in a non-native language requires diverse abilities, including fluency, pronunciation, intonation, grammar, vocabulary, and discourse. Informed by studies in second language acquisition and language testing that regard these factors as key determiners of spoken language proficiency, some researchers have focused on the objective measurement of these aspects of spoken language in the context of automatic assessment of language ability. Notable are studies that have focused on assessment of fluency (Cucchiarini et al., 2000; Cucchiarini et al., 2002), pronunciation (Witt and Young, 1997; Witt, 1999; Franco et al., 1997; Neumeyer et al., 2000), and intonation (Zechner et al., 2009). The relative success of these studies has yielded objective measures of acoustic aspects of speaking ability, resulting in a shift in focus to more complex aspects of assessment of grammar (Bernstein et al., 2010; Chen and Yoon, 2011; Chen and Zechner, 2011), topic development (Xie et al., 2012), and coherence (Wang et al., 2013).

In an effort to assess grammar and usage in a second language learning environment, numerous studies have focused on identifying relevant quantitative measures. These measures have been used to estimate proficiency levels in English as a second language (ESL) writing with reasonable success. Wolf-Quintero et al. (1998), Ortega (2003), and Lu (2010) found that measures such as mean length of T-unit[2] and dependent clauses per clause (henceforth termed as length-based measures) are well correlated with holistic proficiency scores suggesting that these quantitative measures can be used as objective indices of grammatical development.

In the context of spoken ESL, these measures have been studied as well but the results have been inconclusive. The measures could only broadly discriminate between students' proficiency levels, rated on a scale with moderate to weak correlations, and strong data dependencies on the participant groups were observed (Halleck, 1995; Iwashita et al., 2008; Iwashita, 2010).

With the recent interest in the area of automatic assessment of speech, there is a concurrent need to assess the grammatical development of ESL students automatically. Studies that explored the applicability of length-based measures in an automated scoring system (Chen and Zechner, 2011; Chen and Yoon, 2011) observed another important drawback of these measures in that setting. Length-based measures do not meet the constraints of the design, that, in order for measures to be effectively incorporated in the automated speech scoring system, they must be generated in a fully automated manner, via a multi-stage automated process that includes speech recognition, part of speech (POS) tagging, and parsing.

A major bottleneck in the multi-stage process of an automated speech scoring system for second language is the stage of automated speech recognition (ASR). Automatic recognition of non-native speakers' spontaneous speech is a challenging task as evidenced by the error rate of the state-of-the-

[2]T-units are defined as "the shortest grammatically allowable sentences into which writing can be split." (Hunt, 1965)

art speech recognizer. For instance, Chen and Zechner (2011) reported a 50.5% word error rate (WER) and Yoon and Bhat (2012) reported a 30% WER in the recognition of ESL students' spoken responses. These high error rates at the recognition stage negatively affect the subsequent stages of the speech scoring system in general, and in particular, during a deep syntactic analysis, which operates on a long sequence of words as its context. As a result, measures of grammatical complexity that are closely tied to a correct syntactic analysis are rendered unreliable. Not surprisingly, Chen and Zechner (2011) studied measures of grammatical complexity via syntactic parsing and found that a Pearson's correlation coefficient of 0.49 between syntactic complexity measures (derived from manual transcriptions) and proficiency scores, was drastically reduced to near non-existence when the measures were applied to ASR word hypotheses. This suggests that measures that rely on deep syntactic analysis are unreliable in current ASR-based scoring systems for spontaneous speech.

In order to avoid the problems encountered with deep analysis-based measures, Yoon and Bhat (2012) explored a shallow analysis-based approach, based on the assumption that the level of grammar sophistication at each proficiency level is reflected in the distribution of part-of-speech (POS) tag bigrams. The idea of capturing differences in POS tag distributions for classification has been explored in several previous studies. In the area of text-genre classification, POS tag distributions have been found to capture genre differences in text (Feldman et al., 2009; Marin et al., 2009); in a language testing context, it has been used in grammatical error detection and essay scoring (Chodorow and Leacock, 2000; Tetreault and Chodorow, 2008). We will see next what aspects of syntactic complexity are captured by such a shallow-analysis.

3 Shallow-analysis approach to measuring syntactic complexity

The measures of syntactic complexity in this approach are POS bigrams and are not obtained by a deep analysis (syntactic parsing) of the structure of the sentence. Hence we will refer to this approach as 'shallow analysis'. In a shallow-analysis approach to measuring syntactic complexity, we rely on the distribution of POS bigrams at every proficiency level to be representative of the range and sophistication of grammatical constructions at that level. At the outset, POS-bigrams may seem too simplistic to represent any aspect of true syntactic complexity. We illustrate to the contrary, that they are indeed able to capture certain grammatical errors and sophisticated constructions by means of the following instances. Consider the two sentence fragments below taken from actual responses (the bigrams of interest and their associated POS tags are bold-faced).

1. They ***can/MD to/TO*** survive ...
2. They created ***the culture/NN that/WDT now/RB*** is common in the US.

We notice that Example 1 is not only less grammatically sophisticated than Example 2 but also has a grammatical error. The error stems from the fact that it has a modal verb followed by the word "to". On the other hand, Example 2 contains a relative clause composed of a noun introduced by "that". Notice how these grammatical expressions (one erroneous and the other sophisticated) can be detected by the POS bigrams "MD-TO" and "NN-WDT", respectively.

The idea that the level of syntactic complexity (in terms of its range and sophistication) can be assessed based on the distribution of POS-tags is informed by prior studies in second language acquisition. It has been shown that the usage of certain grammatical constructions (such as that of the embedded relative clause in the second sentence above) are indicators of specific milestones in grammar development (Covington et al., 2006). In addition, studies such as Foster and Skehan (1996) have successfully explored the utility of frequency of grammatical errors as objective measures of grammatical development.

Based on this idea, Yoon and Bhat (2012) developed a set of features of syntactic complexity based on POS sequences extracted from a large corpus of ESL learners' spoken responses, grouped by human-assigned scores of proficiency level. Unlike previous studies, it did not rely on the occurrence of *normative* grammatical constructions. The main assumption was that each score level is characterized by different types of prominent grammatical structures. These representative constructions are gathered from a collection of ESL learners' spoken responses rated for overall proficiency. The syntactic complexity of a test spoken response was estimated based on its

similarity to the proficiency groups in the reference corpus with respect to the score-specific constructions. A score was assigned to the response based on how similar it was to the high score group. In Section 4.1, we go over the approach in further detail.

Our current work is inspired by the shallow analysis-based approach of Yoon and Bhat (2012) and operates under the same assumptions of capturing the range and sophistication of grammatical constructions at each score level. However, the approaches differ in the way in which a spoken response is assigned to a score group. We first analyze the limitations of the model studied in (Yoon and Bhat, 2012) and then describe how our model can address those limitations. The result is a new measure based on POS bigrams to assess ESL learners' mastery of syntactic complexity.

4 Models for Measuring Grammatical Competence

We mentioned that the measure proposed in this study is derived from assumptions similar to those studied in (Yoon and Bhat, 2012). Accordingly, we will summarize the previously studied model, outline its limitations, show how our proposed measure addresses those limitations and compare the two measures for the task of automatic scoring of speech.

4.1 Vector-Space Model based approach

Yoon and Bhat (2012) explored an approach inspired by information retrieval. They treat the concatenated collection of responses from a particular score-class as a 'super' document. Then, regarding POS bigrams as terms, they construct POS-based vector space models for each score-class (there are four score classes denoting levels of proficiency as will be explained in Section 5.2), thus yielding four score-specific vector-space models (VSMs). The terms of the VSM are weighted by the term frequency-inverse document frequency (tf-idf) weighting scheme (Salton et al., 1975). The intuition behind the approach is that responses in the same proficiency level often share similar grammar and usage patterns. The similarity between a test response and a score-specific vector is then calculated by a cosine similarity metric. Although a total of 4 cosine similarity scores (one per score group) were generated, only $cos_4$from among the four similarity scores, and $cosmax$, were selected as features.

- cos_4: the cosine similarity score between the test response and the vector of POS bigrams for the highest score class (level 4); and,
- $cosmax$: the score level of the VSM with which the given response shows maximum similarity.

Of these, $cos_4$was selected based on its empirical performance (it showed the strongest correlation with human-assigned scores of proficiency among the distance-based measures). In addition, an intuitive justification for the choice is that the score-4 vector is a grammatical "norm" representing the *average* grammar usage distribution of the most proficient ESL students. The measure of syntactic complexity of a response, cos_4, is its similarity to the highest score class.

The study found that the measures showed reasonable discriminative ability across proficiency levels. Despite its encouraging empirical performance, the VSM method of capturing grammatical sophistication has the following limitations.

First, the VSM-based method is likely to overestimate the contribution of the POS bigrams when highly correlated bigrams occur as terms in the VSM. Consider the presence of a grammar pattern represented by more than one POS bigram. For example, both "NN-WDT" and "WDT-RB" in Sentence 2 reflect the learner's usage of a relative clause. However, we note that the two bigrams are correlated and including them both results in an over-estimation of their contribution. The VSM set-up has no mechanism to handle correlated features.

Second, the tf-idf weighting scheme for relatively rare POS bigrams does not adequately capture their underlying distribution with respect to score groups. Grammatical expressions that occur frequently in one score level but rarely in other levels can be assumed to be characteristic of a specific score level. Therefore, the more uneven the distribution of a grammatical expression across score classes, the more important that grammatical expression should be as an indicator of a particular score class. However, the simple idf scheme cannot capture this uneven distribution. A pattern that occurs rarely but uniformly across different score groups can get the same weight as a pattern which is unevenly distributed to one score group. Martineau and Finin (2009) observed this weakness of the tf-idf weighting in the domain of sentiment

analysis. When using tf-idf weighting to extract words that were strongly associated with positive sentiment in a movie review corpus (they considered each review as a document and a word as a term), it was found that a substantial proportion of words with the highest tf-idf were rare words (e.g., proper nouns) which were not directly associated with the sentiment.

We propose to address these important limitations of the VSM approach by the use of a method that accounts for each of the deficiencies. This is done by resorting to a maximum entropy model based approach, to which we turn next.

4.2 Maximum Entropy-Based model

In order to address the limitations discussed in 4.1, we propose a classification-based approach. Taking an approach different from previous studies, we formulate the task of assigning a score of syntactic complexity to a spoken response as a classification problem: given a spoken response, assign the response to a proficiency class. A classifier is trained in an inductive fashion, using a large corpus of learner responses that is divided into proficiency scores as the training data and then used to test data that is similar to the training data. A distinguishing feature of the current study is that the measure is based on a comparison of characteristics of the test response to models trained on large amounts of data from each score point, as opposed to measures that are simply characteristics of the responses themselves (which is how measures have been considered in prior studies).

The inductive classifier we use here is the maximum-entropy model (MaxEnt) which has been used to solve several statistical natural language processing problems with much success (Berger et al., 1996; Borthwick et al., 1998; Borthwick, 1999; Pang et al., 2002; Klein et al., 2003; Rosenfeld, 2005). The productive feature engineering aspects of incorporating features into the discriminative MaxEnt classifier motivate the model choice for the problem at hand. In particular, the ability of the MaxEnt model's estimation routine to handle overlapping (correlated) features makes it directly applicable to address the first limitation of the VSM model. The second limitation, related to the ineffective weighting of terms via the the tf-idf scheme, seems to be addressed by the fact that the MaxEnt model assigns a weight to each feature (in our case, POS bigrams) on a per-class basis (in our case, score group), by taking every instance into consideration. Therefore, a MaxEnt model has an advantage over the model described in 4.1 in that it uses four different weight schemes (one per score level) and each scheme is optimized for each score level. This is beneficial in situations where the features are not evenly important across all score levels.

5 Experimental Setup

Our experiments seek answers to the following questions.

1. To what extent does a MaxEnt-score of syntactic complexity discriminate between levels of proficiency?
2. What is the effect of including the proposed measure of syntactic complexity in the state-of-the-art automatic scoring model?
3. How robust is the measure to errors in the various stages of automatic generation?

5.1 Tasks

In order to answer the motivating questions of the study, we set-up two tasks. In the first task, we compare the extent to which the VSM-based measure and the MaxEnt-based measure (outlined in 4.1 and 4.2 above) discriminate between levels of syntactic complexity. Additionally, we compare the performance of an automatic scoring model of overall proficiency that includes the measures of syntactic complexity from each of the two models being compared and analyze the gains with respect to the state-of-the-art. In the second task, we study the measures' robustness to errors incurred by ASR.

5.2 Data

In this study, we used a collection of responses from an international English language assessment. The assessment consisted of questions to which speakers were prompted to provide spontaneous spoken responses lasting approximately 45-60 seconds per question. Test takers read and/or listened to stimulus materials and then responded to questions based on the stimuli. All questions solicited spontaneous, unconstrained natural speech.

A small portion of the available data with inadequate audio quality and lack of student response was excluded from the study. The remaining responses were partitioned into two datasets: the ASR set and the scoring model training/test (SM)

set. The ASR set, with 47,227 responses, was used for ASR training and POS similarity model training. The SM set, with 2,950 responses, was used for feature evaluation and automated scoring model evaluation. There was no overlap in speakers between the ASR set and the SM set.

Each response was rated for overall proficiency by trained human scorers using a 4-point scoring scale, where 1 indicates low speaking proficiency and 4 indicated high speaking proficiency. The distribution of proficiency scores, along with other details of the data sets, are presented in Table 1.

As seen in Table 1, there is a strong bias towards the middle scores (score 2 and 3) with approximately 84-85% of the responses belonging to these two score levels. Although the skewed distribution limits the number of score-specific instances for the highest and lowest scores available for model training, we used the data without modifying the distribution since it is representative of responses in a large-scale language assessment scenario.

Human raters' extent of agreement in the subjective task of rating responses for language proficiency constrains the extent to which we can expect a machine's score to agree with that of humans. An estimate of the extent to which human raters agree on the subjective task of proficiency assessment, is obtained by two raters scoring approximately 5% of data (2,388 responses from ASR set and 140 responses from SM set). Pearson correlation r between the scores assigned by the two raters was 0.62 in ASR set and 0.58 in SM set. This level of agreement will guide the evaluation of the human-machine agreement on scores.

5.3 Stages of Automatic Grammatical Competence Assessment

Here we outline the multiple stages involved in the automatic syntactic complexity assessment. The first stage, ASR, yields an automatic transcription, which is followed by the POS tagging stage. Subsequently, the feature extraction stage (a VSM or a MaxEnt model as the case may be) generates the syntactic complexity feature which is then incorporated in a multiple linear regression model to generate a score.

The steps for automatic assessment of overall proficiency follow an analogous process (either including the POS tagger or not), depending on the objective measure being evaluated. The various objective measures are then combined in the multiple regression scoring model to generate an overall score of proficiency.

5.3.1 Automatic Speech Recognizer

An HMM recognizer was trained using ASR set (approximately 733 hours of non-native speech collected from 7,872 speakers). A gender independent triphone acoustic model and combination of bigram, trigram, and four-gram language models were used. A word error rate (WER) of 31% on the SM dataset was observed.

5.3.2 POS tagger

POS tags were generated using the POS tagger implemented in the Open-NLP toolkit[3]. It was trained on the Switchboard (SWBD) corpus. This POS tagger was trained on about 528K word/tag pairs. A combination of 36 tags from the Penn Treebank tag set and 6 tags generated for spoken languages were used in the tagger.

The tagger achieved a tagging accuracy of 96.3% on a Switchboard evaluation set composed of 379K words, suggesting high accuracy of the tagger. However, due to substantial amount of speech recognition errors in our data, the POS error rate (resulting from the combined errors of ASR and automated POS tagger) is expected to be higher.

5.3.3 VSM-based Model

We used the ASR data set to train a POS-bigram VSM for the highest score class and generated cos_4 and $cosmax$ reported in Yoon and Bhat (2012), for the SM data set as outlined in Section 4.1.

5.3.4 Maximum Entropy Model Classifier

The input to the classifier is a set of POS bigrams (1366 bigrams in all) obtained from the POS-tagged output of the data. We considered binary-valued features (whether a POS bigram occurred or not), occurrence frequency, and relative frequency as input for the purpose of experimentation. We used the maximum entropy classifier implementation in the MaxEnt toolkit[4]. The classifier was trained using the LBFGS algorithm for parameter estimation and used equal-scale gaussian priors for smoothing. The results that follow are based on MaxEnt classifier's parameter settings initialized to zero. Since a preliminary

Data set	No. of responses	No. of speakers	Score		Score distribution			
			Mean	SD	1	2	3	4
ASR	47,227	7,872	2.67	0.73	1,953 4%	16,834 36%	23,106 49%	5,334 11%
SM	2,950	500	2.61	0.74	166 6%	1,103 37%	1,385 47%	296 10%

Table 1: Data size and score distribution

analysis of the effect of varying the feature (binary or frequency) revealed that the binary-valued feature was optimal (in terms of yielding the best agreement between human and machine scores), we only report our results for this case. The ASR data set was used to train the MaxEnt classifier and the features generated from the SM data set were used for evaluation.

One straightforward way of using the maximum entropy classifier's prediction for our case is to directly use its predicted score-level – 1, 2, 3 or 4. However, this forces the classifier to make a coarse-grained choice and may over-penalize the classifier's scoring errors. To illustrate this, consider a scenario where the classifier assigns two responses A and B to score level 2 (based on the maximum *a posteriori* condition). Suppose that, for response A, the score class with the second highest probability corresponds to score level 1 and that, for response B, it corresponds to score level 3. It is apparent that the classifier has an overall tendency to assign a higher score to B, but looking at its top preference alone (2 for both responses), masks this tendency.

We thus capture the classifier's finer-grained scoring tendency by calculating the *expected value* of the classifier output. For a given response, the MaxEnt classifier calculates the conditional probability of a score-class given the response, in turn yielding conditional probabilities of each score group given the observation – p_i for score group $i \in \{1, 2, 3, 4\}$. In our case, we consider the predicted score of syntactic complexity to be the expected value of the class label given the observation as, $mescore = 1 \times p_1 + 2 \times p_2 + 3 \times p_3 + 4 \times p_4$. This permits us to better represent the score assigned by the MaxEnt classifier as a relative preference over score assignments.

5.3.5 Automatic Scoring System

We consider a multiple regression automatic scoring model as studied in Zechner et al. (2009; Chen and Zechner (2011; Higgins et al. (2011). In its state-of-the-art set-up, the following model uses the features – HMM acoustic model score (global normalized), speaking rate, word types per second, average chunk length in words and language model score (global normalized). We use these features by themselves (**Base**), and also in conjunction with the VSM-based feature (**cva4**) and the MaxEnt-based feature (**mescore**).

5.4 Evaluation Metric

We evaluate the measures using the metrics chosen in previous studies (Zechner et al., 2009; Chen and Zechner, 2011; Yoon and Bhat, 2012). A measure's utility has been evaluated according to its ability to discriminate between levels of proficiency assigned by human raters. This is done by considering the Pearson correlation coefficient between the feature and the human scores. In an ideal situation, we would have compared machine score with scores of grammatical skill assigned by human raters. In our case, however, with only access to the overall proficiency scores, we use scores of language proficiency as those of grammatical skill.

A criterion for evaluating the performance of the scoring model is the extent to which the automatic scores of overall proficiency agree with the human scores. As in prior studies, here too the level of agreement is evaluated by means of the weighted kappa measure as well as unrounded and rounded Pearson's correlations between machine and human scores (since the output of the regression model can either be rounded or regarded as is). The feature that maximizes this degree of agreement will be preferred.

6 Experimental Results

First, we compare the discriminative ability of measures of syntactic complexity (VSM-model based measure with that of the MaxEnt-based measure) across proficiency levels. Table 2 summarizes our experimental results for this task. We

Features	Manual Transcriptions	ASR
$mescore$	0.57	0.52
cos_4	0.48	0.43
$cosmax$	-	0.31

Table 2: Pearson correlation coefficients between measures and holistic proficiency scores. All values are significant at level 0.01. Only the measures cos_4 and $mescore$ were compared for robustness using manual and ASR transcriptions.

notice that of the measures compared, $mescore$ shows the highest correlation with scores of syntactic complexity. The correlation was approximately 0.1 higher in absolute value than that of cos_4, which was the best performing feature in the VSM-based model and the difference is statistically significant.

Seeking to study the robustness of the measures derived using a shallow analysis, we next compare the two measures studied here, with respect to the impact of speech recognition errors on their correlation with scores of syntactic complexity. Towards this end, we compare $mescore$ and $cos_4$when POS bigrams are extracted from manual transcriptions (ideal ASR) and ASR transcriptions.

In Table 2, noticing that the correlations decrease going along a row, we can say that the errors in the ASR system caused both $mescore$ and $cos_4$to under-perform. However, the performance drop (around 0.05) resulting from a shallow analysis is relatively small compared to the drop observed while employing a deep syntactic analysis. Chen and Zechner (2011) found that while using measures of syntactic complexity obtained from transcriptions, errors in ASR transcripts caused over 0.40 drop in correlation from that found with manual transcriptions[5]. This comparison suggests that the current POS-based shallow analysis approach is more robust to ASR errors compared to a syntactic analysis-based approach.

The effect of the measure of syntactic complexity is best studied by including it in an automatic scoring model of overall proficiency. We compare the performance gains over the state-of-the-art with the inclusion of additional features (VSM-based and MaxEnt-based, in turn). Table 3 shows the system performance with different grammar sophistication measures. The results reported are averaged over a 5-fold cross validation of the multiple regression model, where 80% of the SM data set is used to train the model and the evaluation is done using 20% of the data in every fold.

As seen in Table 3, using the proposed measure, $mescore$, leads to an improved agreement between human and machine scores of proficiency. Comparing the unrounded correlation results in Table 3 we notice that the model **Base+mescore** shows the highest correlation of predicted scores with human scores. In addition, we test the significance of the difference between two dependent correlations using Steiger's Z-test (via the `paired.r` function in the R statistical package (Revelle, 2012)). We note that the performance gain of **Base+mescore** over **Base** as well as over **Base + cos4** is statistically significant at level = 0.01. The performance gain of **Base+cos4** over **Base**, however, is not statistically significant at level = 0.01. Thus, the inclusion of the MaxEnt-based measure of syntactic complexity results in improved agreement between machine and human scores compared to the state-of-the-art model (here, **Base**).

7 Discussions

We now discuss some of the observations and results of our study with respect to the following items.

Improved performance: We sought to verify empirically that the MaxEnt model really outperforms the VSM in the case of correlated POS bigrams. To see this, we separate the test set into three subsets A, B, C. Set A contains responses where MaxEnt outperforms VSM; set B contains responses where VSM outperforms MaxEnt; set C contains responses where their predictions are comparable. For each group of responses $s \in \{A, B, C\}$, we calculate the percentage of responses P_s where two highly correlated POS bigrams occur[6]. We found that the percentages follow the order: $P_A = 12.93\% > P_C = 7.29\% >$

[5]Due to differences in the dataset and ASR system, a direct comparison between the current study and the cited prior study was not possible.

[6]We consider two POS bigrams to be highly correlated, when the their pointwise-mutual information is higher than 4.

Evaluation method	Base	Base+cos4	Base+mescore
Weighted $kappa$	0.503	0.524	**0.546**
Correlation (unrounded)	0.548	0.562	**0.592**
Correlation (rounded)	0.482	0.492	**0.519**

Table 3: Comparison of scoring model performances using features of syntactic complexity studied in this paper along with those available in the state-of-the-art. Here, **Base** is the scoring model without the measures of syntactic complexity. All correlations are significant at level 0.01.

$P_B = 4.41\%$. This suggests that when correlated POS bigrams occur, MaxEnt is more likely to provide better score predictions than VSM does.

Feature design: In the case of MaxEnt, the observation that binary-valued features (presence/absence of POS bigrams) yield better performance than features indicative of the occurrence frequency of the bigram has interesting implications. This was also observed in Pang et al. (2002) where it was interpreted to mean that overall sentiment is indicated by the presence/absence of keywords, as opposed to topic of a text, which is indicated by the repeated use of the same or similar terms. An analogous explanation is applicable here.

At first glance, the use of the presence/absence of grammatical structures may raise concerns about a potential loss of information (e.g. the distinction between an expression that is used once and another that is used multiple times is lost). However, when considered in the context of language acquisition studies, this approach seems to be justified. Studies in native language acquisition, have considered multiple grammatical developmental indices that represent the grammatical levels reached at various stages of language acquisition. For instance, Covington et al. (2006) proposed the revised D-level scale which was originally studied by Rosenberg and Abbeduto (1987). The D-Level Scale categorizes grammatical development into 8 levels according to the presence of a set of diverse grammatical expressions varying in difficulty (for example, level 0 consists of simple sentences, while level 5 consists of sentences joined by a subordinating conjunction). Similarly, Scarborough (1990) proposed the Index of Productive Syntax (IPSyn), according to which, the presence of particular grammatical structures, from a list of 60 structures (ranging from simple ones such as including only subjects and verbs, to more complex constructions such as conjoined sentences) is evidence of language acquisition milestones.

Despite the functional differences between the indices, there is a fundamental operational similarity - that they both use the presence or absence of grammatical structures, rather than their occurrence count, as evidence of acquisition of certain grammatical levels. The assumption that a presence-based view of grammatical level acquisition is also applicable to second language assessment helps validate our observation that binary-valued features yield a better performance when compared with frequency-valued features.

Generalizability: The training and test sets used in this study had similar underlying distributions – they both sought unconstrained responses to a set of items with some minor differences in item type. Looking ahead, an important question is the extent to which our measure is sensitive to a mismatch between training and test data.

8 Conclusions

Seeking alternatives to measuring syntactic complexity of spoken responses via syntactic parsers, we study a shallow-analysis based approach for use in automatic scoring.

Empirically, we show that the proposed measure, based on a maximum entropy classification, satisfied the constraints of the design of an objective measure to a high degree. In addition, the proposed measure was found to be relatively robust to ASR errors. The measure *outperformed* a related measure of syntactic complexity (also based on shallow-analysis of spoken response) previously found to be well-suited for automatic scoring. Including the measure of syntactic complexity in an automatic scoring model resulted in statistically significant performance gains over the state-of-the-art. We also make an interesting observation that the impressionistic evaluation of syntactic complexity is better approximated by the presence or absence of grammar and usage patterns (and not by their frequency of occurrence), an idea supported by studies in native language acquisition.

Can You Repeat That?
Using Word Repetition to Improve Spoken Term Detection

Jonathan Wintrode and **Sanjeev Khudanpur**
Center for Language and Speech Processing
Johns Hopkins University
jcwintr@cs.jhu.edu , khudanpur@jhu.edu

Abstract

We aim to improve *spoken term detection* performance by incorporating contextual information beyond traditional N-gram language models. Instead of taking a broad view of topic context in spoken documents, variability of word co-occurrence statistics across corpora leads us to focus instead the on phenomenon of word repetition within single documents. We show that given the detection of one instance of a term we are more likely to find additional instances of that term in the same document. We leverage this *burstiness* of keywords by taking the most confident keyword hypothesis in each document and interpolating with lower scoring hits. We then develop a principled approach to select interpolation weights using only the ASR training data. Using this re-weighting approach we demonstrate consistent improvement in the term detection performance across all five languages in the BABEL program.

1 Introduction

The *spoken term detection* task arises as a key subtask in applying NLP applications to spoken content. Tasks like topic identification and named-entity detection require transforming a continuous acoustic signal into a stream of discrete tokens which can then be handled by NLP and other statistical machine learning techniques. Given a small vocabulary of interest (1000-2000 words or multi-word terms) the aim of the term detection task is to enumerate occurrences of the keywords within a target corpus. Spoken term detection converts the raw acoustics into time-marked keyword occurrences, which may subsequently be fed (e.g. as a bag-of-terms) to standard NLP algorithms.

Although spoken term detection does not require the use of word-based automatic speech recognition (ASR), it is closely related. If we had perfectly accurate ASR in the language of the corpus, term detection is reduced to an exact string matching task. The word error rate (WER) and term detection performance are clearly correlated. Given resource constraints, domain, channel, and vocabulary limitations, particularly for languages other than English, the errorful token stream makes term detection a non-trivial task.

In order to improve detection performance, and restricting ourselves to an existing ASR system or systems at our disposal, we focus on leveraging *broad document context* around detection hypotheses. ASR systems traditionally use N-gram language models to incorporate prior knowledge of word occurrence patterns into prediction of the next word in the token stream. N-gram models cannot, however, capture complex linguistic or topical phenomena that occur outside the typical 3-5 word scope of the model. Yet, though many language models more sophisticated than N-grams have been proposed, N-grams are empirically hard to beat in terms of WER.

We consider term detection rather than the transcription task in considering how to exploit topic context, because in evaluating the retrieval of certain key terms we need not focus on improving the entire word sequence. Confidence scores from an ASR system (which incorporate N-gram probabilities) are optimized in order to produce the most likely sequence of words rather than the accuracy of individual word detections. Looking at broader document context within a more limited task might allow us to escape the limits of N-gram performance. We will show that by focusing on contextual information in the form of word repetition within documents, we obtain consistent improvement *across five languages* in the so called Base Phase of the IARPA BABEL program.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1316–1325,
Baltimore, Maryland, USA, June 23-25 2014.

1.1 Task Overview

We evaluate term detection and word repetition-based re-scoring on the IARPA BABEL training and development corpora[1] for five languages Cantonese, Pashto, Turkish, Tagalog and Vietnamese (Harper, 2011). The BABEL task is modeled on the 2006 NIST Spoken Term Detection evaluation (NIST, 2006) but focuses on limited resource conditions. We focus specifically on the so called *no target audio reuse* (NTAR) condition to make our method broadly applicable.

In order to arrive at our eventual solution, we take the BABEL Tagalog corpus and analyze word co-occurrence and repetition statistics in detail. Our observation of the variability in co-occurrence statistics between Tagalog training and development partitions leads us to narrow the scope of document context to same word co-occurrences, i.e. *word repetitions*.

We then analyze the tendency towards within-document repetition. The strength of this phenomenon suggests it may be more viable for improving term-detection than, say, topic-sensitive language models. We validate this by developing an interpolation formula to boost putative word repetitions in the search results, and then investigate a method for setting interpolation weights without manually tuning on a development set.

We then demonstrate that the method generalizes well, by applying it to the 2006 English data and the remaining four 2013 BABEL languages. We demonstrate consistent improvements in all languages in both the Full LP (80 hours of ASR training data) and Limited LP (10 hours) settings.

2 Motivation

We seek a workable definition of ***broad document context*** beyond N-gram models that will improve term detection performance on an arbitrary set of queries. Given the rise of unsupervised latent topic modeling with Latent Dirchlet Allocation (Blei et al., 2003) and similar latent variable approaches for discovering meaningful word co-occurrence patterns in large text corpora, we ought to be able to leverage these topic contexts instead of merely N-grams. Indeed there is work in the literature that shows that various topic models, latent or otherwise, can be useful for improving language model perplexity and word error rate (Khudanpur and Wu, 1999; Chen, 2009; Naptali et al., 2012). However, given the preponderance of highly frequent non-content words in the computation of a corpus' WER, it's not clear that a 1-2% improvement in WER would translate into an improvement in term detection.

Still, intuition suggests that knowing the topic context of a detected word ought to be useful in predicting whether or not a term does belong in that context. For example, if we determine the context of the detection hypothesis is about computers, containing words like 'monitor,' 'internet' and 'mouse,' then we would be more confident of a term such as 'keyboard' and less confident of a term such as 'cheese board'. The difficulty in this approach arises from the variability in word co-occurrence statistics. Using topic information will be helpful if 'monitor,' 'keyboard' and 'mouse' consistently predict that 'keyboard' is present. Unfortunately, estimates of co-occurrence from small corpora are not very consistent, and often over- or underestimate concurrence probabilities needed for term detection.

We illustrate this variability by looking at how consistent word co-occurrences are between two separate corpora in the same language: i.e., if we observe words that frequently co-occur with a keyword in the training corpus, do they also co-occur with the keywords in a second held-out corpus? Figure 1, based on the BABEL Tagalog corpus, suggests this is true only for high frequency keywords.

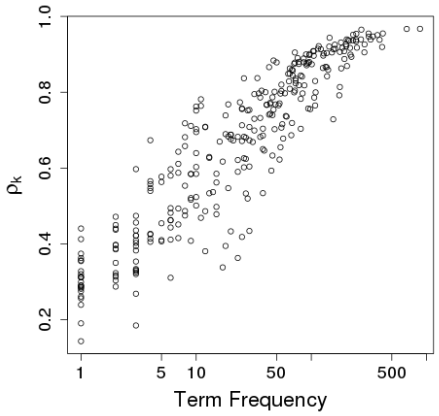

Figure 1: Correlation between the co-occurrence counts in the training and held-out sets for a fixed keyword (term) and all its "context" words.

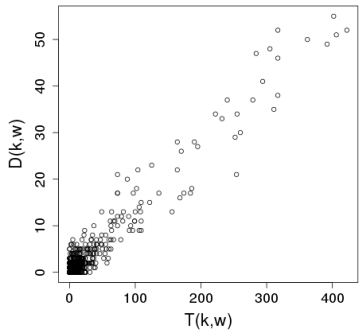
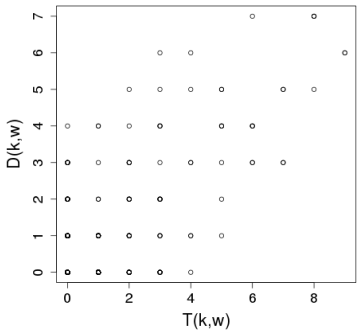
Each point in Figure 1 represents one of 355

[1]Language collection releases IARPA-babel101-v0.4c, IARPA-babel104b-v0.4bY, IARPA-babel105b-v0.4, IARPA-babel106-v0.2g and IARPA-babel107b-v0.7 respectively.



(a) High frequency keyword 'bukas'



(b) Low frequency keyword 'Davao'

Figure 2: The number of times a fixed keyword k co-occurs with a vocabulary word w in the training speech collection — $T(k, w)$ — versus the search collection — $D(k, w)$.

Tagalog keywords used for system development by all BABEL participants. For each keyword k, we count how often it co-occurs in the same conversation as a vocabulary word w in the ASR training data and the development data, and designate the counts $T(k, w)$ and $D(k, w)$ respectively. The x-coordinate of each point in Figure 1 is the frequency of k in the training data, and the y-coordinate is the correlation coefficient ρ_k between $T(k, w)$ and $D(k, w)$. A high ρ_k implies that words w that co-occur frequently with k in the training data also do so in the search collection.

To further illustrate how Figure 1 was obtained, consider the high-frequency keyword *bukas* (count $= \mathbf{879}$) and the low-frequency keyword *Davao* (count $= \mathbf{11}$), and plot $T(k, \cdot)$ versus $D(k, \cdot)$, as done in Figure 2. The correlation coefficients ρ_{bukas} and ρ_{Davao} from the two plots end up as two points in Figure 1.

Figure 1 suggests that (k, w) co-occurrences are consistent between the two corpora ($\rho_k > 0.8$) for keywords occurring 100 or more times. However, if the goal is to help a speech retrieval system detect content-rich (and presumably infrequent) keywords, then using word co-occurrence information (i.e. topic context) does not appear to be too promising, even though intuition suggests that such information ought to be helpful.

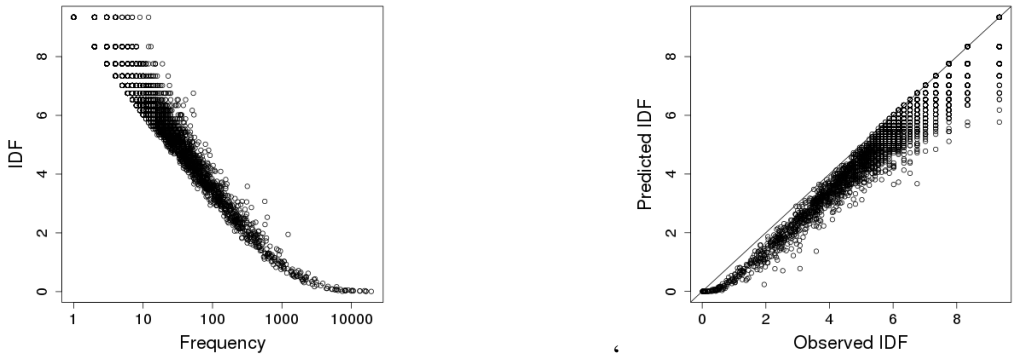
In light of this finding, we will restrict the type of ***context*** we use for term detection to the co-occurrence of the term itself elsewhere within the document. As it turns out this 'burstiness' of words within documents, as the term is defined by Church and Gale in their work on Poisson mixtures (1995), provides a more reliable framework for successfully exploiting document context.

2.1 Related Work

A number of efforts have been made to augment traditional N-gram models with latent topic information (Khudanpur and Wu, 1999; Florian and Yarowsky, 1999; Liu and Liu, 2008; Hsu and Glass, 2006; Naptali et al., 2012) including some of the early work on Probabilistic Latent Semantic Analysis by Hofmann (2001). In all of these cases WER gains in the 1-2% range were observed by interpolating latent topic information with N-gram models.

The re-scoring approach we present is closely related to adaptive or cache language models (Jelinek, 1997; Kuhn and De Mori, 1990; Kneser and Steinbiss, 1993). The primary difference between this and previous work on similar language models is the narrower focus here on the term detection task, in which we consider each search term in isolation, rather than all words in the vocabulary. Most recently, Chiu and Rudnicky (2013) looked at word bursts in the IARPA BABEL conversational corpora, and were also able to successfully improve performance by leveraging the burstiness of language. One advantage of the approach proposed here, relative to their approach, is its simplicity and its not requiring an additional tuning set to estimate parameters.

In the information retrieval community, clustering and latent topic models have yielded improvements over traditional vector space models. We will discuss in detail in the following section related works by Church and Gale (1995, 1999, and 2000). Work by Wei and Croft (2006) and Chen (2009) take a language model-based approach to



(a) f_w versus IDF_w

(b) Obsered versus predicted IDF_w

Figure 3: Tagalog corpus frequency statistics, unigrams

information retrieval, and again, interpolate latent topic models with N-grams to improve retrieval performance. However, in many text retrieval tasks, queries are often tens or hundreds of words in length rather than short spoken phrases. In these efforts, the topic model information was helpful in boosting retrieval performance above the baseline vector space or N-gram models.

Clearly topic or context information is relevant to a retrieval type task, but we need a stable, consistent framework in which to apply it.

3 Term and Document Frequency Statistics

To this point we have assumed an implicit property of low-frequency words which Church and Gale state concisely in their 1999 study of *inverse document frequency*:

> Low frequency words tend to be rich in content, and vice versa. But not all equally frequent words are equally meaningful. Church and Gale (1999).

The typical use of Document Frequency (DF) in information retrieval or text categorization is to emphasize words that occur in only a few documents and are thus more "rich in content". Close examination of DF statistics by Church and Gale in their work on Poisson Mixtures (1995) resulted in an analysis of the *burstiness* of content words.

In this section we look at DF and *burstiness* statistics applying some of the analyses of Church and Gale (1999) to the BABEL Tagalog corpus. We observe, in 648 Tagalog conversations, similar phenomena as observed by Church and Gale on 89,000 AP English newswire articles. We proceed in this fashion to make a case for why burstiness ought to help in the term detection task.

For the Tagalog conversations, as with English newswire, we observe that the document frequency, DF_w, of a word w is not a linear function of word frequency f_w in the log domain, as would be expected under a naive Poisson generative assumption. The implication of deviations from a Poisson model is that *words tend to be concentrated in a small number of documents* rather than occurring uniformly across the corpus. This is the *burstiness* we leverage to improve term detection.

The first illustration of word burstiness can be seen by plotting observed inverse document frequency, IDF_w, versus f_w in the log domain (Figure 3a). We use the same definition of IDF_w as Church and Gale (1999):

$$\mathrm{IDF}_w = -\log_2 \frac{\mathrm{DF}_w}{N}, \tag{1}$$

where N is the number of documents (i.e. conversations) in the corpus.

There is good linear correlation ($\rho = 0.73$) between $\log f_w$ and IDF_w. Yet, visually, the relationship in Figure 3a is clearly not linear. In contrast, the AP English data exhibits a correlation of $\rho = 0.93$ (Church and Gale, 1999). Thus the deviation in the Tagalog corpus is more pronounced, i.e. words are less uniformly distributed across documents.

A second perspective on word burstiness that follows from Church and Gale (1999) is that a Poisson assumption should lead us to predict:

$$\widehat{\mathrm{IDF}}_w = -\log_2 \left(1 - e^{-\frac{f_w}{N}}\right). \tag{2}$$

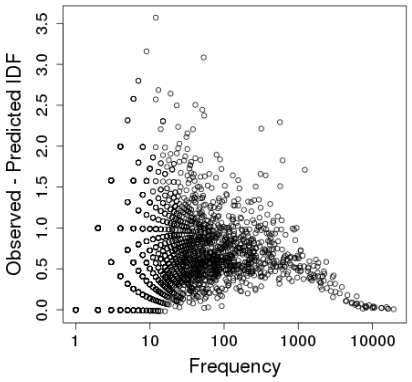


Figure 4: Difference between observed and predicted IDF_w for Tagalog unigrams.

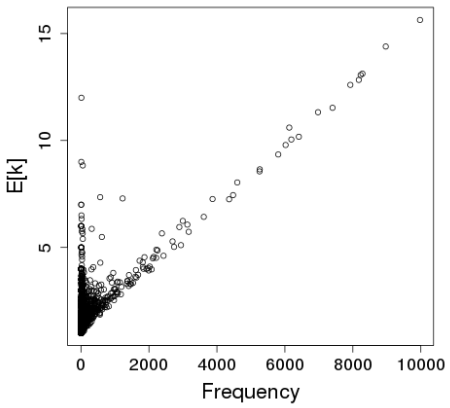

Figure 5: Tagalog *burstiness*.

For the AP newswire, Church and Gale found the largest deviation between the predicted $\widehat{\mathrm{IDF}}_w$ and observed IDF_w to occur in the middle of the frequency range. We see a somewhat different picture for Tagalog speech in Figure 3b. Observed IDF_w values again deviate significantly from their predictions (2), but all along the frequency range.

There is a noticeable quantization effect occurring in the high IDF range, given that our N is at least a factor of 100 smaller than the number of AP articles they studied: 648 vs. 89,000. Figure 4 also shows the difference between and observed IDF_w and Poisson estimate $\widehat{\mathrm{IDF}}_w$ and further illustrates the high variance in IDF_w for low frequency words.

Two questions arise: what is happening with infrequent words, and why does this matter for term detection? To look at the data from a different perspective, we consider the random variable k, which is the number of times a word occurs in a particular document. In Figure 5 we plot the following ratio, which Church and Gale (1995) define as *burstiness* :

$$E_w[k|k > 0] = \frac{f_w}{\mathrm{DF}_w} \tag{3}$$

as a function of f_w. We denote this as $E[k]$ and can interpret burstiness as the expected word count given we see w at least once.

In Figure 5 we see two classes of words emerge. A similar phenomenon is observed concerning adaptive language models (Church, 2000). In general, we can think of using word repetitions to re-score term detection as applying a limited form of adaptive or cache language model (Jelinek, 1997). Likewise, Katz attempts to capture these two classes in his G model of word frequencies (1996).

For the first class, burstiness increases slowly but steadily as w occurs more frequently. Let us label these Class A words. Since our corpus size is fixed, we might expect this to occur, as more word occurrences must be pigeon-holed into the same number of documents

Looking close to the y-axis in Figure 5, we observe a second class of exclusively low frequency words whose burstiness ranges from highly concentrated to singletons. We will refer to these as Class B words. If we take the Class A concentration trend as typical, we can argue that most Class B words exhibit a larger than average concentration. In either case we see evidence that *both high and low frequency words tend towards repeating within a document*.

3.1 Unigram Probabilities

In applying the *burstiness* quantity to term detection, we recall that the task requires us to locate a particular instance of a term, not estimate a count, hence the utility of N-gram language models predicting words in sequence.

We encounter the burstiness property of words again by looking at unigram occurrence probabilities. We compare the unconditional unigram probability (the probability that a given word token is w) with the conditional unigram probability, *given the term has occurred once in the document*. We compute the conditional probability for w using frequency information.

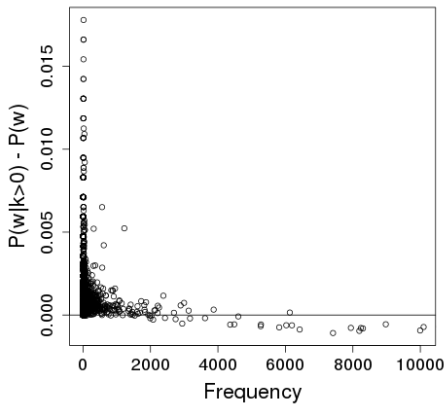

Figure 6: Difference between conditional and unconditional unigram probabilities for Tagalog

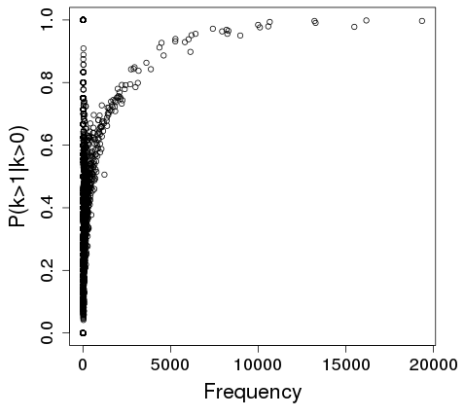

Figure 7: Tagalog word adaptation probability

$$P(w|k>0) = \frac{f_w - \mathrm{DF}_w}{\sum_{D:w\in D}|D|} \quad (4)$$

Figure 6 shows the difference between conditional and unconditional unigram probabilities. Without any other information, Zipf's law suggests that most word types do not occur in a particular document. However, conditioning on one occurrence, most word types are more likely to occur again, due to their burstiness.

Finally we measure the *adaptation* of a word, which is defined by Church and Gale (1995) as:

$$P_{adapt}(w) = P_w(k>1|k>0) \quad (5)$$

When we plot adaptation versus f_w (Figure 7) we see that all high-frequency and a significant number of low-frequency terms have adaptation greater that 50%. To be precise, 26% of all tokens and 25% of low-frequency ($f_w < 100$) have at least 50% adaptation. Given that adaptation values are roughly an order of magnitude higher than the conditional unigram probabilities, in the next two sections we describe how we use adaptation to boost term detection scores.

4 Term Detection Re-scoring

We summarize our re-scoring of repeated words with the observation: *given a correct detection, the likelihood of additional terms in the same documents should increase*. When we observe a term detection score with high confidence, we boost the other lower-scoring terms in the same document to reflect this increased likelihood of repeated terms.

For each term t and document d we propose interpolating the ASR confidence score for a particular detection t_d with the top scoring hit in d which we'll call $\widehat{t}_d$.

$$S(t_d) = (1-\alpha)P_{\mathrm{asr}}(t_d|O) + \alpha P_{\mathrm{asr}}(\widehat{t}_d|O) \quad (6)$$

We will we develop a principled approach to selecting α using the adaptation property of the corpus. However to verify that this approach is worth pursuing, we sweep a range of small α values, on the assumption that we still do want to mostly rely on the ASR confidence score for term detection. For the Tagalog data, we let α range from 0 (the baseline) to 0.4 and re-score each term detection score according to (6). Table 1 shows the results of this parameter sweep and yields us 1 to 2% absolute performance gains in a number of term detection metrics.

α	**ATWV**	$P(\mathrm{Miss})$
0.00	0.470	0.430
0.05	0.481	0.422
0.10	0.483	0.420
0.15	0.484	0.418
0.20	0.483	0.416
0.25	0.480	0.417
0.30	0.477	0.417
0.35	0.475	0.415
0.40	0.471	0.413
0.45	0.465	0.413
0.50	0.462	0.410

Table 1: Term detection scores for swept α values on Tagalog development data

The primary metric for the BABEL program, Actual Term Weighted Value (ATWV) is defined by NIST using a cost function of the false alarm probability $P(\text{FA})$ and $P(\text{Miss})$, averaged over a set of queries (NIST, 2006). The manner in which the components of ATWV are defined:

$$P(\text{Miss}) = 1 - N_{\text{true}}(\text{term})/f_{\text{term}} \quad (7)$$

$$P(\text{FA}) = N_{\text{false}}/Duration_{\text{corpus}} \quad (8)$$

implies that cost of a miss is inversely proportional to the frequency of the term in the corpus, but the cost of a false alarm is fixed. For this reason, we report both ATWV and the $P(\text{Miss})$ component. A decrease in $P(\text{Miss})$ reflects the fact that we are able to boost correct detections of the repeated terms.

4.1 Interpolation Weights

We would prefer to use prior knowledge rather than naive tuning to select an interpolation weight α. Our analysis of word burstiness suggests that *adaptation*, is a reasonable candidate. Adaptation also has the desirable property that we can estimate it for each word in the training vocabulary directly from training data and not post-hoc on a per-query basis. We consider several different estimates and we can show that the favorable result extends across languages.

Intuition suggests that we prefer per-term interpolation weights related to the term's *adaptation*. But despite the strong evidence of the adaptation phenomenon in both high and low-frequency words (Figure 7), we have less confidence in the adaptation strength of any particular word.

As with word co-occurrence, we consider if estimates of $P_{adapt}(w)$ from training data are consistent when estimated on development data. Figure 8 shows the difference between $P_{adapt}(w)$ measured on the two corpora (for words occurring in both).

We see that the adaptation estimates are only consistent between corpora for high-frequency words. Using this $P_{adapt}(w)$ estimate directly actually hurts ATWV performance by 4.7% absolute on the 355 term development query set (Table 2).

Given the variability in estimating $P_{adapt}(w)$, an alternative approach would be take $\widehat{P_w}$ as an upper bound on α, reached as the DF_w increases (cf. Equation 9). We would discount the adaptation factor when DF_w is low and we are unsure of the effect.

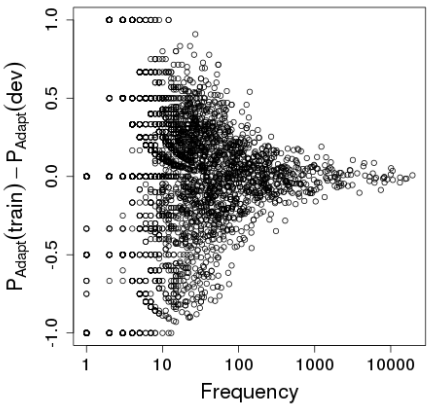

Figure 8: Difference in adaptation estimates between Tagalog training and development corpora

Interpolation Weight	**ATWV**	$P(\text{Miss})$
None	0.470	0.430
$P_{adapt}(w)$	0.423	0.474
$(1 - e^{-\text{DF}_w})P_{adapt}(w)$	0.477	0.415
$\widehat{\alpha}$ = 0.20	**0.483**	**0.416**

Table 2: Term detection performance using various interpolation weight strategies on Tagalog dev data

$$\alpha_w = (1 - e^{-\text{DF}_w}) \cdot \widehat{P}_{adapt}(w) \quad (9)$$

This approach shows a significant improvement (0.7% absolute) over the baseline. However, considering this estimate in light of the two classes of words in Figure 5, there are clearly words in Class B with high burstiness that will be ignored by trying to compensate for the high adaptation variability in the low-frequency range.

Alternatively, we take a weighted average of α_w's estimated on training transcripts to obtain a single $\widehat{\alpha}$ per language (cf. Equation 10).

$$\widehat{\alpha} = \underset{w}{\text{Avg}} \left[\left(1 - e^{-\text{DF}_w}\right) \cdot \widehat{P}_{adapt}(w) \right] \quad (10)$$

Using this average as a single interpolation weight for all terms gives near the best performance as we observed in our parameter sweep. Table 2 contrasts the results for using the three different interpolation heuristics on the Tagalog development queries. Using the mean $\widehat{\alpha}$ instead of individual α_w's provides an additional 0.5% absolute

Language	$\widehat{\alpha}$	**ATWV (%±)**	$P(\text{Miss})$ **(%±)**
Full LP setting			
Tagalog	0.20	**0.523** (+1.1)	0.396 (-1.9)
Cantonese	0.23	**0.418** (+1.3)	0.458 (-1.9)
Pashto	0.19	**0.419** (+1.1)	0.453 (-1.6)
Turkish	0.14	**0.466** (+0.8)	0.430 (-1.3)
Vietnamese	0.30	**0.420** (+0.7)	0.445 (-1.0)
English (Dev06)	0.20	**0.670 (+0.3)**	0.240 (-0.4)
Limited LP setting			
Tagalog	0.22	**0.228** (+0.9)	0.692 (-1.7)
Cantonese	0.26	**0.205** (+1.0)	0.684 (-1.3)
Pashto	0.21	**0.206** (+0.9)	0.682 (-0.9)
Turkish	0.16	**0.202** (+1.1)	0.700 (-0.8)
Vietnamese	0.34	**0.227** (+1.0)	0.646 (+0.4)

Table 3: Word-repetition re-scored results for available CTS term detection corpora

improvement, suggesting that we find additional gains boosting low-frequency words.

5 Results

Now that we have tested word repetition-based re-scoring on a small Tagalog development set we want to know if our approach, and particularly our $\widehat{\alpha}$ estimate is sufficiently robust to apply broadly. At our disposal, we have the five BABEL languages — Tagalog, Cantonese, Pashto, Turkish and Vietnamese — as well as the development data from the NIST 2006 English evaluation. The BABEL evaluation query sets contain roughly 2000 terms each and the 2006 English query set contains roughly 1000 terms.

The procedure we follow for each language condition is as follows. We first estimate adaptation probabilities from the ASR training transcripts. From these we take the weighted average as described previously to obtain a single interpolation weight $\widehat{\alpha}$ for each training condition. We train ASR acoustic and language models from the training corpus using the Kaldi speech recognition toolkit (Povey et al., 2011) following the default BABEL training and search recipe which is described in detail by Chen et al. (2013). Lastly, we re-score the search output by interpolating the top term detection score for a document with subsequent hits according to Equation 6 using the $\widehat{\alpha}$ estimated for this training condition.

For each of the BABEL languages we consider both the FullLP (80 hours) and LimitedLP (10 hours) training conditions. For the English system, we also train a Kaldi system on the 240 hours of the Switchboard conversational English corpus. Although Kaldi can produce multiple types of acoustic models, for simplicity we report results using discriminatively trained Subspace Gaussian Mixture Model (SGMM) acoustic output densities, but we do find that similar results can be obtained with other acoustic model configurations.

Using our final algorithm, we are able to boost repeated term detections and improve results in **all languages and training conditions**. Table 3 lists complete results and the associated estimates for $\widehat{\alpha}$. For the BABEL languages, we observe improvements in ATWV from 0.7% to 1.3% absolute and reductions in the miss rate of 0.8% to 1.9%. The only test for which $P(\text{Miss})$ did not improve was the Vietnamese Limited LP setting, although overall ATWV did improve, reflecting a lower $P(\text{FA})$.

In all conditions we also obtain α estimates which correspond to our expectations for particular languages. For example, adaptation is lowest for the agglutinative Turkish language where longer word tokens should be less likely to repeat. For Vietnamese, with shorter, syllable length word tokens, we observe the lowest adaptation estimates.

Lastly, the reductions in $P(\text{Miss})$ suggests that we are improving the term detection metric, which is sensitive to threshold changes, by doing what we set out to do, which is to boost lower confidence repeated words and correctly asserting them

as true hits. Moreover, we are able to accomplish this in a wide variety of languages.

6 Conclusions

Leveraging the **burstiness** of content words, we have developed a simple technique to consistently boost term detection performance across languages. Using word repetitions, we effectively use a broad document context outside of the typical 2-5 N-gram window. Furthermore, we see improvements across a broad spectrum of languages: languages with syllable-based word tokens (Vietnamese, Cantonese), complex morphology (Turkish), and dialect variability (Pashto).

Secondly, our results are not only effective but also intuitive, given that the interpolation weight parameter matches our expectations for the burstiness of the word tokens in the language on which it is estimated.

We have focused primarily on re-scoring results for the term detection task. Given the effectiveness of the technique across multiple languages, we hope to extend our effort to exploit our human tendency towards redundancy to decoding or other aspects of the spoken document processing pipeline.

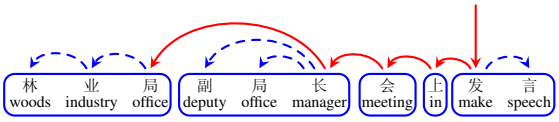
Abstract

Recent work on Chinese analysis has led to large-scale annotations of the internal structures of words, enabling character-level analysis of Chinese syntactic structures. In this paper, we investigate the problem of character-level Chinese dependency parsing, building dependency trees over characters. Character-level information can benefit downstream applications by offering flexible granularities for word segmentation while improving word-level dependency parsing accuracies. We present novel adaptations of two major shift-reduce dependency parsing algorithms to character-level parsing. Experimental results on the Chinese Treebank demonstrate improved performances over word-based parsing methods.

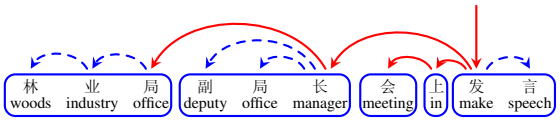
1 Introduction

As a light-weight formalism offering syntactic information to downstream applications such as SMT, the dependency grammar has received increasing interest in the syntax parsing community (McDonald et al., 2005; Nivre and Nilsson, 2005; Carreras et al., 2006; Duan et al., 2007; Koo and Collins, 2010; Zhang and Clark, 2008; Nivre, 2008; Bohnet, 2010; Zhang and Nivre, 2011; Choi and McCallum, 2013). Chinese dependency trees were conventionally defined over *words* (Chang et al., 2009; Li et al., 2012), requiring word segmentation and POS-tagging as pre-processing steps. Recent work on Chinese analysis has embarked on investigating the syntactic roles of characters, leading to large-scale annotations of word internal structures (Li, 2011; Zhang et al., 2013). Such annotations enable dependency parsing on the character level, building dependency trees over Chinese *characters*. Figure 1(c) shows an example of a character-level dependency tree, where the leaf nodes are Chinese characters.

(a) a word-based dependency tree



(b) a character-level dependency tree by Zhao (2009) with real intra-word and pseudo inter-word dependencies



(c) a character-level dependency tree investigated in this paper with both real intra- and inter-word dependencies

Figure 1: An example character-level dependency tree. "林业局副局长在大会上发言 (The deputy director of forestry administration make a speech in the meeting)".

Character-level dependency parsing is interesting in at least two aspects. First, character-level trees circumvent the issue that no universal standard exists for Chinese word segmentation. In the well-known Chinese word segmentation bakeoff tasks, for example, different segmentation standards have been used by different data sets (Emerson, 2005). On the other hand, most disagreement on segmentation standards boils down to disagreement on segmentation granularity. As demonstrated by Zhao (2009), one can extract both fine-grained and coarse-grained words from character-level dependency trees, and hence can adapt to flexible segmentation standards using this formalism. In Figure 1(c), for example, "副局长 (deputy

*Corresponding author.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1326–1336,
Baltimore, Maryland, USA, June 23-25 2014.

director)" can be segmented as both "副 (deputy) | 局长 (director)" and "副局长 (deputy director)", but not "副 (deputy) 局 (office) | 长 (manager)", by dependency coherence. Chinese language processing tasks, such as machine translation, can benefit from flexible segmentation standards (Zhang et al., 2008; Chang et al., 2008).

Second, word internal structures can also be useful for syntactic parsing. Zhang et al. (2013) have shown the usefulness of word structures in Chinese constituent parsing. Their results on the Chinese Treebank (CTB) showed that character-level constituent parsing can bring increased performances even with the pseudo word structures. They further showed that better performances can be achieved when manually annotated word structures are used instead of pseudo structures.

In this paper, we make an investigation of character-level Chinese dependency parsing using Zhang et al. (2013)'s annotations and based on a transition-based parsing framework (Zhang and Clark, 2011). There are two dominant transition-based dependency parsing systems, namely the arc-standard and the arc-eager parsers (Nivre, 2008). We study both algorithms for character-level dependency parsing in order to make a comprehensive investigation. For direct comparison with word-based parsers, we incorporate the traditional word segmentation, POS-tagging and dependency parsing stages in our joint parsing models. We make changes to the original transition systems, and arrive at two novel transition-based character-level parsers.

We conduct experiments on three data sets, including CTB 5.0, CTB 6.0 and CTB 7.0. Experimental results show that the character-level dependency parsing models outperform the word-based methods on all the data sets. Moreover, manually annotated intra-word dependencies can give improved word-level dependency accuracies than pseudo intra-word dependencies. These results confirm the usefulness of character-level syntax for Chinese analysis. The source codes are freely available at `http://sourceforge.net/projects/zpar/, version 0.7`.

2 Character-Level Dependency Tree

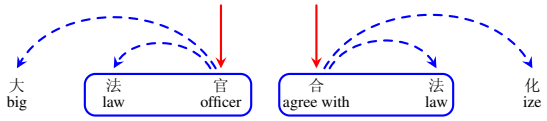
Character-level dependencies were first proposed by Zhao (2009). They show that by annotating character dependencies within words, one can adapt to different segmentation standards. The dependencies they study are restricted to intra-word characters, as illustrated in Figure 1(b). For inter-word dependencies, they use a pseudo right-headed representation.

In this study, we integrate inter-word syntactic dependencies and intra-word dependencies using large-scale annotations of word internal structures by Zhang et al. (2013), and study their interactions. We extract unlabeled dependencies from bracketed word structures according to Zhang et al.'s head annotations. In Figure 1(c), the dependencies shown by dashed arcs are *intra-word* dependencies, which reflect the internal word structures, while the dependencies with solid arcs are *inter-word* dependencies, which reflect the syntactic structures between words.

In this formulation, a character-level dependency tree satisfies the same constraints as the traditional word-based dependency tree for Chinese, including projectivity. We differentiate intra-word dependencies and inter-word dependencies by the arc type, so that our work can be compared with conventional word segmentation, POS-tagging and dependency parsing pipelines under a canonical segmentation standard.

The character-level dependency trees hold to a specific word segmentation standard, but are not limited to it. We can extract finer-grained words of different granulities from a coarse-grained word by taking projective subtrees of different sizes. For example, taking all the intra-word modifier nodes of "长 (manager)" in Figure 1(c) results in the word "副局长 (deputy director)", while taking the first modifier node of "长 (manager)" results in the word "局长 (director)". Note that "副局 (deputy office)" cannot be a word because it does not form a projective span without "长 (manager)".

Inner-word dependencies can also bring benefits to parsing word-level dependencies. The head character can be a less sparse feature compared to a word. As intra-word dependencies lead to fine-grained subwords, we can also use these subwords for better parsing. In this work, we use the innermost left/right subwords as atomic features. To extract the subwords, we find the innermost left/right modifiers of the head character, respectively, and then conjoin them with all their descendant characters to form the smallest left/right subwords. Figure 2 shows an example, where the smallest left subword of "大法官 (chief lawyer)" is "法官 (lawyer)", and the smallest right subword



(a) smallest left subword (b) smallest right subword

Figure 2: An example to illustrate the innermost left/right subwords.

of "合法化 (legalize)" is "合法 (legal)".

3 Character-Level Dependency Parsing

A transition-based framework with global learning and beam search decoding (Zhang and Clark, 2011) has been applied to a number of natural language processing tasks, including word segmentation, POS-tagging and syntactic parsing (Zhang and Clark, 2010; Huang and Sagae, 2010; Bohnet and Nivre, 2012; Zhang et al., 2013). It models a task incrementally from a start state to an end state, where each intermediate state during decoding can be regarded as a partial output. A number of actions are defined so that the state advances step by step. To learn the model parameters, it usually uses the online perceptron algorithm with early-update under the inexact decoding condition (Collins, 2002; Collins and Roark, 2004). Transition-based dependency parsing can be modeled under this framework, where the state consists of a stack and a queue, and the set of actions can be either the arc-eager (Zhang and Clark, 2008) or the arc-standard (Huang et al., 2009) transition systems.

When the internal structures of words are annotated, character-level dependency parsing can be treated as a special case of word-level dependency parsing, with "words" being "characters". A big weakness of this approach is that full words and POS-tags cannot be used for feature engineering. Both are crucial to well-established features for word segmentation, POS-tagging and syntactic parsing. In this section, we introduce novel extensions to the arc-standard and the arc-eager transition systems, so that word-based and character-based features can be used simultaneously for character-level dependency parsing.

3.1 The Arc-Standard Model

The arc-standard model has been applied to joint segmentation, POS-tagging and dependency parsing (Hatori et al., 2012), but with pseudo word structures. For unified processing of annotated word structures and fair comparison between character-level arc-eager and arc-standard systems, we define a different arc-standard transition system, consistent with our character-level arc-eager system.

In the word-based arc-standard model, the transition state includes a stack and a queue, where the stack contains a sequence of partially-parsed dependency trees, and the queue consists of unprocessed input words. Four actions are defined for state transition, including *arc-left* (AL, which creates a left arc between the top element s_0 and the second top element s_1 on the stack), *arc-right* (AR, which creates a right arc between s_0 and s_1), *pop-root* (PR, which defines the root node of a dependency tree when there is only one element on the stack and no element in the queue), and the last *shift* (SH, which shifts the first element q_0 of the queue onto the stack).

For character-level dependency parsing, there are two types of dependencies: inter-word dependencies and intra-word dependencies. To parse them with both character and word features, we extend the original transition actions into two categories, for inter-word dependencies and intra-word dependencies, respectively. The actions for inter-word dependencies include *inter-word arc-left* (AL_w), *inter-word arc-right* (AR_w), *pop-root* (PR) and *inter-word shift* (SH_w). Their definitions are the same as the word-based model, with one exception that the *inter-word shift* operation has a parameter denoting the POS-tag of the incoming word, so that POS disambiguation is performed by the SH_w action.

The actions for intra-word dependencies include *intra-word arc-left* (AL_c), *intra-word arc-right* (AR_c), *pop-word* (PW) and *inter-word shift* (SH_c). The definitions of AL_c, AR_c and SH_c are the same as the word-based arc-standard model, while PW changes the top element on the stack into a full-word node, which can only take inter-word dependencies. One thing to note is that, due to variable word sizes in character-level parsing, the number of actions can vary between different sequences of actions corresponding to different analyses. We use the padding method (Zhu et al., 2013), adding an *IDLE* action to finished transition action sequences, for better alignments between states in the beam.

Figure 3: Character-level dependency parsing of the sentence in Figure 1(c).

system, each word is initialized by the action SH_w with a POS tag, before being incrementally modified by a sequence of intra-word actions, and finally being completed by the action PW. The inter-word actions can be applied when all the elements on the stack are full-word nodes, while the intra-word actions can be applied when at least the top element on the stack is a partial-word node. For the actions AL_c and AR_c to be valid, the top two elements on the stack are both partial-word nodes. For the action PW to be valid, only the top element on the stack is a partial-word node. Figure 3(a) gives an example action sequence.

There are three types of features. The first two types are traditionally established features for the dependency parsing and joint word segmentation and POS-tagging tasks. We use the features proposed by Hatori et al. (2012). The word-level dependency parsing features are added when the inter-word actions are applied, and the features for joint word segmentation and POS-tagging are added when the actions PW, SH_w and SH_c are applied. Following the work of Hatori et al. (2012), we have a parameter α to adjust the weights for joint word segmentation and POS-tagging features. We apply word-based dependency parsing features to intra-word dependency parsing as well, by using subwords (the conjunction of characters spanning the head node) to replace words in word features. The third type of features is word-structure features. We extract the head character and the smallest subwords containing the head character from the intra-word dependencies (Section 2). Table 1 summarizes the features.

3.2 The Arc-Eager Model

Similar to the arc-standard case, the state of a word-based arc-eager model consists of a stack and a queue, where the stack contains a sequence of partial dependency trees, and the queue consists of unprocessed input words. Unlike the arc-standard model, which builds dependencies on the top two elements on the stack, the arc-eager model builds dependencies between the top element of the stack and the first element of the queue. Five actions are defined for state transformation: *arc-left* (AL, which creates a left arc between the top element of the stack s_0 and the first element in the queue q_0, while popping s_0 off the stack), *arc-right* (AR, which creates a right arc between

$Lr\underline{sw} \cdot R\underline{w}$, $L\underline{w} \cdot Rl\underline{sw}$, $L\underline{w} \cdot Rr\underline{sw}$

Table 1: Feature templates encoding intra-word dependencies. L and R denote the two elements over which the dependencies are built; the subscripts $lc1$ and $rc1$ denote the left-most and right-most children, respectively; the subscripts $lc2$ and $rc2$ denote the second left-most and second right-most children, respectively; $\underline{w}$ denotes the word; $\underline{t}$ denotes the POS tag; $\underline{c}$ denotes the head character; $\underline{lsw}$ and $\underline{rsw}$ denote the smallest left and right subwords respectively, as shown in Figure 2.

s_0 and q_0, while shifting q_0 from the queue onto the stack), *pop-root* (PR, which defines the ROOT node of the dependency tree when there is only one element on the stack and no element in the queue), *reduce* (RD, which pops s_0 off the stack), and *shift* (SH, which shifts q_0 onto the stack).

There is no previous work that exploits the arc-eager algorithm for jointly performing POS-tagging and dependency parsing. Since the first element of the queue can be shifted onto the stack by either SH or AR, it is more difficult to assign a POS tag to each word by using a single action. In this work, we make a change to the configuration state, adding a deque between the stack and the queue to save partial words with intra-word dependencies. We divide the transition actions into two categories, one for inter-word dependencies (AR_w, AL_w, SH_w, RD_w and PR) and the other for intra-word dependencies (AR_c, AL_c, SH_c, RD_c and PW), requiring that the intra-word actions be operated between the deque and the queue, while the inter-word actions be operated between the stack and the deque.

For character-level arc-eager dependency parsing, the inter-word actions are the same as the word-based methods. The actions AL_c and AR_c are the same as AL_w and AR_w, except that they operate on characters, but the SH_c operation has a parameter to denote the POS tag of a word. The PW action recognizes a full-word. We also have an *IDLE* action, for the same reason as the arc-standard model.

In the character-level arc-eager transition system, a word is formed in a similar way with that of character-level arc-standard algorithm. Each word is initialized by the action SH_c with a POS tag, and then incrementally changed a sequence of intra-word actions, before being finalized by the action PW. All these actions operate between the queue and deque. For the action PW, only the first element in the deque (close to the queue) is a partial-word node. For the actions AR_c and AL_c to be valid, the first element in the deque must be a partial-word node. The action SH_c have a POS tag when shifting the first character of a word,but does not have such a parameter when shifting the next characters of a word. For the action SH_c with a POS tag to be valid, the first element in the deque must be a full-word node. Different from the arc-standard model, at any stage we can choose either the action SH_c with a POS tag to initialize a new word on the deque, or the inter-word actions on the stack. In order to eliminate the ambiguity, we define a new parameter t to limit the max size of the deque. If the deque is full with t words, inter-word actions are performed; otherwise intra-word actions are performed. All the inter-word actions must be applied on full-word nodes between the stack an the deque. Figure 3(b) gives an example action sequence.

Similar to the arc-standard case, there are three types of features, with the first two types being traditionally established features for dependency parsing and joint word segmentation and POS-tagging. The dependency parsing features are taken from the work of Zhang and Nivre (2011), and the features for joint word segmentation and POS-tagging are taken from Zhang and Clark (2010)[1]. The word-level dependency parsing features are triggered when the inter-word actions are applied, while the features of joint word segmentation and POS-tagging are added when the actions SH_c, AR_c and PW are applied. Again we use a parameter α to adjust the weights for joint word segmentation and POS-tagging features. The word-level features for dependency parsing are applied to intra-word dependency parsing as well, by using subwords to replace words. The third type of features is word-structure features, which are the

[1]Since Hatori et al. (2012) also use Zhang and Clark (2010)'s features, the arc-standard and arc-eager character-level dependency parsing models have the same features for joint word segmentation and POS-tagging.

same as those of the character-level arc-standard model, shown in Table 1.

4 Experiments

4.1 Experimental Settings

We use the Chinese Penn Treebank 5.0, 6.0 and 7.0 to conduct the experiments, splitting the corpora into training, development and test sets according to previous work. Three different splitting methods are used, namely CTB50 by Zhang and Clark (2010), CTB60 by the official documentation of CTB 6.0, and CTB70 by Wang et al. (2011). The dataset statistics are shown in Table 2. We use the head rules of Zhang and Clark (2008) to convert phrase structures into dependency structures. The intra-word dependencies are extracted from the annotations of Zhang et al. (2013)[2].

The standard measures of word-level precision, recall and F1 score are used to evaluate word segmentation, POS-tagging and dependency parsing, following Hatori et al. (2012). In addition, we use the same measures to evaluate intra-word dependencies, which indicate the performance of predicting word structures. A word's structure is correct only if all the intra-word dependencies are all correctly recognized.

4.2 Baseline and Proposed Models

For the baseline, we have two different pipeline models. The first consists of a joint segmentation and POS-tagging model (Zhang and Clark, 2010) and a word-based dependency parsing model using the arc-standard algorithm (Huang et al., 2009). We name this model STD (pipe). The second consists of the same joint segmentation and POS-tagging model and a word-based dependency parsing model using the arc-eager algorithm (Zhang and Nivre, 2011). We name this model EAG (pipe). For the pipeline models, we use a beam of size 16 for joint segmentation and POS-tagging, and a beam of size 64 for dependency parsing, according to previous work.

We study the following character-level dependency parsing models:

- STD (real, pseudo): the arc-standard model with annotated intra-word dependencies and pseudo inter-word dependencies;
- STD (pseudo, real): the arc-standard model with pseudo intra-word dependencies and real inter-word dependencies;
- STD (real, real): the arc-standard model with annotated intra-word dependencies and real inter-word dependencies;
- EAG (real, pseudo): the arc-eager model with annotated intra-word dependencies and pseudo inter-word dependencies;
- EAG (pseudo, real): the arc-eager model with pseudo intra-word dependencies and real inter-word dependencies;
- EAG (real, real): the arc-eager model with annotated intra-word dependencies and real inter-word dependencies.

The annotated intra-word dependencies refer to the dependencies extracted from annotated word structures, while the pseudo intra-word dependencies used in the above models are similar to those of Hatori et al. (2012). For a given word $w = c_1 c_2 \cdots c_m$, the intra-word dependency structure is $c_1 \curvearrowleft c_2 \curvearrowleft \cdots \curvearrowleft c_m$[3]. The real inter-word dependencies refer to the syntactic word-level dependencies by head-finding rules from CTB, while the pseudo inter-word dependencies refer to the word-level dependencies used by Zhao (2009) ($w_1 \curvearrowleft w_2 \curvearrowleft \cdots \curvearrowleft w_n$). The character-level models with annotated intra-word dependencies and pseudo inter-word dependencies are compared with the pipelines on word segmentation and POS-tagging accuracies, and are compared with the character-level models with annotated intra-word dependencies and real inter-word dependencies on word segmentation, POS-tagging and word-structure predicating accuracies. All the proposed

[2] https://github.com/zhangmeishan/wordstructures; their annotation was conducted on CTB 5.0, while we made annotations of the remainder of the CTB 7.0 words. We also make the annotations publicly available at the same site.

[3] We also tried similar structures with right arcs, which gave lower accuracies.

models use a beam of size 64 after considering both speeds and accuracies.

4.3 Development Results

Our development tests are designed for two purposes: adjusting the parameters for the two proposed character-level models and testing the effectiveness of the novel word-structure features. Tuning is conducted by maximizing word-level dependency accuracies. All the tests are conducted on the CTB60 data set.

4.3.1 Parameter Tuning

For the arc-standard model, there is only one parameter α that needs tuning. It adjusts the weights of segmentation and POS-tagging features, because the number of feature templates is much less for the two tasks than for parsing. We set the value of α to $1 \cdots 5$, respectively. Table 3 shows the accuracies on the CTB60 development set. According to the results, we use $\alpha = 4$ for our final character-level arc-standard model.

For the arc-eager model, there are two parameters t and α. t denotes the deque size of the arc-eager model, while α shares the same meaning as the arc-standard model. We take two steps for parameter tuning, first adjusting the more crucial parameter t and then adjusting α on the best t. Both parameters are assigned the values of 1 to 5. Table 4 shows the results. According to results, we set $t = 3$ and $\alpha = 3$ for the final character-level arc-eager model, respectively.

4.3.2 Effectiveness of Word-Structure Features

To test the effectiveness of our novel word-structure features, we conduct feature ablation experiments on the CTB60 development data set for the proposed arc-standard and arc-eager models, respectively. Table 5 shows the results. We can see that both the two models achieve better accuracies on word-level dependencies with the novel word-structure features, while the features do not affect word-structure predication significantly.

4.4 Final Results

Table 6 shows the final results on the CTB50, CTB60 and CTB70 data sets, respectively. The results demonstrate that the character-level dependency parsing models are significantly better than the corresponding word-based pipeline models, for both the arc-standard and arc-eager systems. Similar to the findings of Zhang et al. (2013), we find that the annotated word structures can give better accuracies than pseudo word structures. Another interesting finding is that, although the arc-eager algorithm achieves lower accuracies in the word-based pipeline models, it obtains comparative accuracies in the character-level models.

We also compare our results to those of Hatori et al. (2012), which is comparable to STD (pseudo, real) since similar arc-standard algorithms and features are used. The major difference is the set of transition actions. We rerun their system on the three datasets[4]. As shown in Table 6, our arc-standard system with pseudo word structures

[4] `http://triplet.cc/`. We use a different constituent-to-dependency conversion scheme in comparison with Hatori et al. (2012)'s work.

brings consistent better accuracies than their work on all the three data sets.

Both the pipelines and character-level models with pseudo inter-word dependencies perform word segmentation and POS-tagging jointly, without using real word-level syntactic information. A comparison between them (STD/EAG (pipe) vs. STD/EAG (real, pseudo)) reflects the effectiveness of annotated intra-word dependencies on segmentation and POS-tagging. We can see that both the arc-standard and arc-eager models with annotated intra-word dependencies can improve the segmentation accuracies by 0.3% and the POS-tagging accuracies by 0.5% on average on the three datasets. Similarly, a comparison between the character-level models with pseudo inter-word dependencies and the character-level models with real inter-word dependencies (STD/EAG (real, pseudo) vs. STD/EAG (real, real)) can reflect the effectiveness of annotated inter-word structures on morphology analysis. We can see that improved POS-tagging accuracies are achieved using the real inter-word dependencies when jointly performing inner- and inter-word dependencies. However, we find that the inter-word dependencies do not help the word-structure accuracies.

4.5 Analysis

To better understand the character-level parsing models, we conduct error analysis in this section. All the experiments are conducted on the CTB60 test data sets. The new advantage of the character-level models is that one can parse the internal word structures of intra-word dependencies. Thus we are interested in their capabilities of predicting word structures. We study the word-structure accuracies in two aspects, including OOV, word length, POS tags and the parsing model.

4.5.1 OOV

The word-structure accuracy of OOV words reflects a model's ability of handling unknown words. The overall recalls of OOV word structures are 67.98% by STD (real, real) and 69.01% by EAG (real, real), respectively. We find that most errors are caused by failures of word segmentation. We further investigate the accuracies when words are correctly segmented, where the accuracies of OOV word structures are 87.64% by STD (real, real) and 89.07% by EAG (real, real). The results demonstrate that the structures of Chinese words are not difficult to predict, and confirm the fact that Chinese word structures have some common syntactic patterns.

4.5.2 Parsing Model

From the above analysis in terms of OOV, word lengths and POS tags, we can see that the EAG (real, real) model and the STD (real, real) models behave similarly on word-structure accuracies. Here we study the two models more carefully, comparing their word accuracies sentence by sentence. Figure 4 shows the results, where each point denotes a sentential comparison between STD (real, real) and EAG (real, real), the x-axis denotes the sentential word-structure accuracy of STD (real, real), and the y-axis denotes that of EAG (real, real). The points at the diagonal show the same accuracies by the two models, while others show that the two models perform differently on the corresponding sentences. We can see that most points are beyond the diagonal line, indicat-

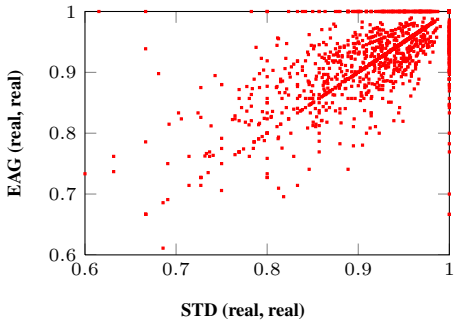

Figure 4: Sentential word-structure accuracies of STD (real, real) and EAG (real, real).

ing that the two parsing models can be complementary in parsing intra-word dependencies.

5 Related Work

Zhao (2009) was the first to study character-level dependencies; they argue that since no consistent word boundaries exist over Chinese word segmentation, dependency-based representations of word structures serve as a good alternative for Chinese word segmentation. Thus their main concern is to parse intra-word dependencies. In this work, we extend their formulation, making use of large-scale annotations of Zhang et al. (2013), so that the syntactic word-level dependencies can be parsed together with intra-word dependencies.

Hatori et al. (2012) proposed a joint model for Chinese word segmentation, POS-tagging and dependency parsing, studying the influence of joint model and character features for parsing, Their model is extended from the arc-standard transition-based model, and can be regarded as an alternative to the arc-standard model of our work when pseudo intra-word dependencies are used. Similar work is done by Li and Zhou (2012). Our proposed arc-standard model is more concise while obtaining better performance than Hatori et al. (2012)'s work. With respect to word structures, real intra-word dependencies are often more complicated, while pseudo word structures cannot be used to correctly guide segmentation.

Zhao (2009), Hatori et al. (2012) and our work all study character-level dependency parsing. While Zhao (2009) focus on word internal structures using pseudo inter-word dependencies, Hatori et al. (2012) investigate a joint model using pseudo intra-word dependencies. We use manual dependencies for both inner- and inter-word structures, studying their influences on each other.

Zhang et al. (2013) was the first to perform Chinese syntactic parsing over characters. They extended word-level constituent trees by annotated word structures, and proposed a transition-based approach to parse intra-word structures and word-level constituent structures jointly. For Hebrew, Tsarfaty and Goldberg (2008) investigated joint segmentation and parsing over characters using a graph-based method. Our work is similar in exploiting character-level syntax. We study the dependency grammar, another popular syntactic representation, and propose two novel transition systems for character-level dependency parsing.

Nivre (2008) gave a systematic description of the arc-standard and arc-eager algorithms, currently two popular transition-based parsing methods for word-level dependency parsing. We extend both algorithms to character-level joint word segmentation, POS-tagging and dependency parsing. To our knowledge, we are the first to apply the arc-eager system to joint models and achieve comparative performances to the arc-standard model.

6 Conclusions

We studied the character-level Chinese dependency parsing, by making novel extensions to two commonly-used transition-based dependency parsing algorithms for word-based dependency parsing. With both pseudo and annotated word structures, our character-level models obtained better accuracies than previous work on segmentation, POS-tagging and word-level dependency parsing. We further analyzed some important factors for intra-word dependencies, and found that two proposed character-level parsing models are complementary in parsing intra-word dependencies. We make the source code publicly available at `http://sourceforge.net/projects/zpar/, version 0.7`.

Abstract

We present a novel approach for inducing unsupervised dependency parsers for languages that have no labeled training data, but have translated text in a resource-rich language. We train probabilistic parsing models for resource-poor languages by transferring cross-lingual knowledge from resource-rich language with entropy regularization. Our method can be used as a purely monolingual dependency parser, requiring no human translations for the test data, thus making it applicable to a wide range of resource-poor languages. We perform experiments on three Data sets — Version 1.0 and version 2.0 of Google Universal Dependency Treebanks and Treebanks from CoNLL shared-tasks, across ten languages. We obtain state-of-the art performance of all the three data sets when compared with previously studied unsupervised and projected parsing systems.

1 Introduction

In recent years, dependency parsing has gained universal interest due to its usefulness in a wide range of applications such as synonym generation (Shinyama et al., 2002), relation extraction (Nguyen et al., 2009) and machine translation (Katz-Brown et al., 2011; Xie et al., 2011). Several supervised dependency parsing algorithms (Nivre and Scholz, 2004; McDonald et al., 2005a; McDonald et al., 2005b; McDonald and Pereira, 2006; Carreras, 2007; Koo and Collins, 2010; Ma and Zhao, 2012; Zhang et al., 2013) have been proposed and achieved high parsing accuracies on several treebanks, due in large part to the availability of dependency treebanks in a number of languages (McDonald et al., 2013). However, the manually annotated treebanks that these parsers rely on are highly expensive to create, in particular when we want to build treebanks for resource-poor languages. This led to a vast amount of research on unsupervised grammar induction (Carroll and Charniak, 1992; Klein and Manning, 2004; Smith and Eisner, 2005; Cohen and Smith, 2009; Spitkovsky et al., 2010; Blunsom and Cohn, 2010; Mareček and Straka, 2013; Spitkovsky et al., 2013), which appears to be a natural solution to this problem, as unsupervised methods require only unannotated text for training parsers. Unfortunately, the unsupervised grammar induction systems' parsing accuracies often significantly fall behind those of supervised systems (McDonald et al., 2011). Furthermore, from a practical standpoint, it is rarely the case that we are completely devoid of resources for most languages.

In this paper, we consider a practically motivated scenario, in which we want to build statistical parsers for resource-poor target languages, using existing resources from a resource-rich source language (like English).[1] We assume that there are absolutely no labeled training data for the target language, but we have access to parallel data with a resource-rich language and a sufficient amount of labeled training data to build an accurate parser for the resource-rich language. This scenario appears similar to the setting in bilingual text parsing. However, most bilingual text parsing approaches require bilingual treebanks — treebanks that have manually annotated tree structures on both sides of source and target languages (Smith and Smith, 2004; Burkett and Klein, 2008), or have tree structures on the source side and translated sentences in the target languages (Huang et

[1] For the sake of simplicity, we refer to the resource-poor language as the "target language", and resource-rich language as the "source language". In addition, in this study we use English as the source resource-rich language, but our methodology can be applied to any resource-rich languages.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1337–1348,
Baltimore, Maryland, USA, June 23-25 2014.

al., 2009; Chen et al., 2010). Obviously, bilingual treebanks are much more difficult to acquire than the resources required in our scenario, since the labeled training data and the parallel text in our case are completely separated. What is more important is that most studies on bilingual text parsing assumed that the parser is applied only on bilingual text. But our goal is to develop a parser that can be used in completely monolingual setting for each target language of interest.

This scenario is applicable to a large set of languages and many research studies (Hwa et al., 2005) have been made on it. Ganchev et al. (2009) presented a parser projection approach via parallel text using the posterior regularization framework (Graca et al., 2007). McDonald et al. (2011) proposed two parser transfer approaches between two different languages — one is directly transferred parser from delexicalized parsers, and the other parser is transferred using constraint driven learning algorithm where constraints are drawn from parallel corpora. In that work, they demonstrate that even the directly transferred delexicalized parser produces significantly higher accuracies than unsupervised parsers. Cohen et al. (2011) proposed an approach for unsupervised dependency parsing with non-parallel multilingual guidance from one or more helper languages, in which parallel data is not used.

In this work, we propose a learning framework for transferring dependency grammars from a resource-rich language to resource-poor languages via parallel text. We train probabilistic parsing models for resource-poor languages by maximizing a combination of likelihood on parallel data and confidence on unlabeled data. Our work is based on the learning framework used in Smith and Eisner (2007), which is originally designed for parser bootstrapping. We extend this learning framework so that it can be used to transfer cross-lingual knowledge between different languages.

Throughout this paper, English is used as the source language and we evaluate our approach on ten target languages — Danish (da), Dutch (nl), French (fr), German (de), Greek (el), Italian (it), Korean (ko), Portuguese (pt), Spanish (es) and Swedish (sv). Our approach achieves significant improvement over previous state-of-the-art unsupervised and projected parsing systems across all the ten languages, and considerably bridges the gap to fully supervised dependency parsing performance.

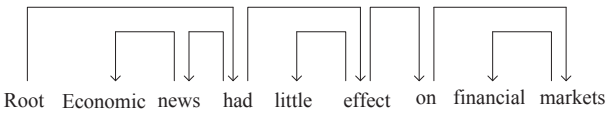

Figure 1: An example dependency tree.

2 Our Approach

Dependency trees represent syntactic relationships through labeled directed edges between heads and their dependents. For example, Figure 1 shows a dependency tree for the sentence, *Economic news had little effect on financial markets*, with the sentence's root-symbol as its root. The focus of this work is on building dependency parsers for target languages, assuming that an accurate English dependency parser and some parallel text between the two languages are available. Central to our approach is a maximizing likelihood learning framework, in which we use an English parser and parallel text to estimate the "transferring distribution" of the target language parsing model (See Section 2.2 for more details). Another advantage of the learning framework is that it combines both the likelihood on parallel data and confidence on unlabeled data, so that both parallel text and unlabeled data can be utilized in our approach.

2.1 Edge-Factored Parsing Model

In this paper, we will use the following notation: $\boldsymbol{x}$ represents a generic input sentence, and $\boldsymbol{y}$ represents a generic dependency tree. $\mathrm{T}(\boldsymbol{x})$ is used to denote the set of possible dependency trees for sentence $\boldsymbol{x}$. The probabilistic model for dependency parsing defines a family of conditional probability $p_\lambda(\boldsymbol{y}|\boldsymbol{x})$ over all $\boldsymbol{y}$ given sentence $\boldsymbol{x}$, with a log-linear form:

$$p_\lambda(\boldsymbol{y}|\boldsymbol{x}) = \frac{1}{Z(\boldsymbol{x})} \exp\left\{\sum_j \lambda_j F_j(\boldsymbol{y}, \boldsymbol{x})\right\} \quad (1)$$

where F_j are feature functions, $\lambda = (\lambda_1, \lambda_2, \ldots)$ are parameters of the model, and $Z(\boldsymbol{x})$ is a normalization factor, which is commonly referred to as the *partition function*:

$$Z(\boldsymbol{x}) = \sum_{\boldsymbol{y} \in \mathrm{T}(\boldsymbol{x})} \exp\left\{\sum_j \lambda_j F_j(\boldsymbol{y}, \boldsymbol{x})\right\} \quad (2)$$

A common strategy to make this parsing model efficiently computable is to *factor* dependency trees into sets of edges:

$$F_j(\boldsymbol{y}, \boldsymbol{x}) = \sum_{e \in y} f_j(e, \boldsymbol{x}). \quad (3)$$

That is, dependency tree y is treated as a set of edges e and each feature function $F_j(\boldsymbol{y}, \boldsymbol{x})$ is equal to the sum of all the features $f_j(e, \boldsymbol{x})$.

We denote the *weight function* of each edge e as follows:

$$w(e, \boldsymbol{x}) = \exp\left\{ \sum_j \lambda_j f_j(e, \boldsymbol{x}) \right\} \quad (4)$$

and the conditional probability $p_\lambda(\boldsymbol{y}|\boldsymbol{x})$ has the following form:

$$p_\lambda(\boldsymbol{y}|\boldsymbol{x}) = \frac{1}{Z(\boldsymbol{x})} \prod_{e \in y} w(e, \boldsymbol{x}) \quad (5)$$

2.2 Model Training

One of the most common model training methods for supervised dependency parser is Maximum conditional likelihood estimation. For a supervised dependency parser with a set of training data $\{(\boldsymbol{x}_i, \boldsymbol{y}_i)\}$, the logarithm of the likelihood (a.k.a. the log-likelihood) is given by:

$$L(\lambda) = \sum_i \log p_\lambda(\boldsymbol{y}_i|\boldsymbol{x}_i) \quad (6)$$

Maximum likelihood training chooses parameters such that the log-likelihood $L(\lambda)$ is maximized.

However, in our scenario we have no labeled training data for target languages but we have some parallel and unlabeled data plus an English dependency parser. For the purpose of transferring cross-lingual information from the English parser via parallel text, we explore the model training method proposed by Smith and Eisner (2007), which presented a generalization of K function (Abney, 2004), and related it to another semi-supervised learning technique, entropy regularization (Jiao et al., 2006; Mann and McCallum, 2007). The objective K function to be minimized is actually the *expected* negative log-likelihood:

$$\begin{aligned} K &= -\sum_i \sum_{\boldsymbol{y}_i} \tilde{p}(\boldsymbol{y}_i|\boldsymbol{x}_i) \log p_\lambda(\boldsymbol{y}_i|\boldsymbol{x}_i) \\ &= \sum_i D(\tilde{p}_i || p_{\lambda,i}) + H(\tilde{p}_i) \end{aligned} \quad (7)$$

where $\tilde{p}_i(\cdot) \stackrel{def}{=} \tilde{p}(\cdot|\boldsymbol{x}_i)$ and $p_{\lambda,i}(\cdot) \stackrel{def}{=} p_\lambda(\cdot|\boldsymbol{x}_i)$. $\tilde{p}(\boldsymbol{y}|\boldsymbol{x})$ is the "transferring distribution" that reflects our uncertainty about the true labels, and we are trying to learn a parametric model $p_\lambda(\boldsymbol{y}|\boldsymbol{x})$ by minimizing the K function.

In our scenario, we have a set of aligned parallel data $P = \{\boldsymbol{x}_i^s, \boldsymbol{x}_i^t, a_i\}$ where a_i is the word alignment for the pair of source-target sentences $(\boldsymbol{x}_i^s, \boldsymbol{x}_i^t)$, and a set of unlabeled sentences of the target language $U = \{\boldsymbol{x}_i^t\}$. We also have a trained English parsing model $p_{\lambda_E}(\boldsymbol{y}|\boldsymbol{x})$. Then the K in equation (7) can be divided into two cases, according to whether $\boldsymbol{x}_i$ belongs to parallel data set P or unlabeled data set U. For the unlabeled examples $\{\boldsymbol{x}_i \in U\}$, some previous studies (e.g., (Abney, 2004)) simply use a uniform distribution over labels (e.g., parses), to reflect that the label is unknown. We follow the method in Smith and Eisner (2007) and take the transferring distribution $\tilde{p}_i$ to be the *actual* current belief $p_{\lambda,i}$. The total contribution of the *unsupervised* examples to K then simplifies to $K_U = \sum_{\boldsymbol{x}_i \in U} H(p_{\lambda,i})$, which may be regarded as the entropy item used to constrain the model's uncertainty H to be low, as presented in the work on entropy regularization (Jiao et al., 2006; Mann and McCallum, 2007).

But how can we define the transferring distribution for the parallel examples $\{\boldsymbol{x}_i^t \in P\}$? We define the transferring distribution by defining the *transferring weight* utilizing the English parsing model $p_{\lambda_E}(\boldsymbol{y}|\boldsymbol{x})$ via parallel data with word alignments:

$$\tilde{w}(e^t, \boldsymbol{x}_i^t) = \begin{cases} w_E(e^s, \boldsymbol{x}_i^s), & \text{if } e^t \stackrel{align}{\longrightarrow} e^s \\ w_E(e_{delex}^t, \boldsymbol{x}_i^s), & \text{otherwise} \end{cases} \quad (8)$$

where $w_E(\cdot,\cdot)$ is the weight function of the English parsing model $p_{\lambda_E}(\boldsymbol{y}|\boldsymbol{x})$, and e_{delex}^t is the delexicalized form[2] of the edge e^t. From the definition of the transferring weight, we can see that, if an edge e^t of the target language sentence $\boldsymbol{x}_i^t$ is aligned to an edge e^s of the English sentence $\boldsymbol{x}_i^s$, we transfer the weight of edge e^t to the corresponding weight of edge e^s in the English parsing model $p_{\lambda_E}(\boldsymbol{y}|\boldsymbol{x})$. If the edge e^t is not aligned to any edges of the English sentence $\boldsymbol{x}_i^s$, we reduce the edge e^t to the delexicalized form and calculate the transferring weight in the English parsing model. There are two advan-

[2]The delexicalized form of an edge is an edge for which only delexicalized features are considered.

tages for this definition of the transferring weight. First, by transferring the weight function to the corresponding weight in the well-developed English parsing model, we can project syntactic information across language boundaries. Second, McDonald et al. (2011) demonstrates that parsers with only delexicalized features produce considerably high parsing performance. By reducing unaligned edges to their delexicalized forms, we can still use those delexicalized features, such as part-of-speech tags, for those unaligned edges, and can address problem that automatically generated word alignments include errors.

From the definition of transferring weight in equation (8), the transferring distribution can be defined in the following way:

$$\tilde{p}(\boldsymbol{y}|\boldsymbol{x}) = \frac{1}{\tilde{Z}(\boldsymbol{x})} \prod_{e \in y} \tilde{w}(e, \boldsymbol{x}) \tag{9}$$

where

$$\tilde{Z}(\boldsymbol{x}) = \sum_{y} \prod_{e \in y} \tilde{w}(e, \boldsymbol{x}) \tag{10}$$

Due to the normalizing factor $\tilde{Z}(\boldsymbol{x})$, the transferring distribution is a valid one.

We introduce a multiplier γ as a trade-off between the two contributions (parallel and unsupervised) of the objective function K, and the final objective function $K^{'}$ has the following form:

$$\begin{aligned} K^{'} &= -\sum_{x_i \in P} \sum_{y_i} \tilde{p}(\boldsymbol{y}_i|\boldsymbol{x}_i) \log p_\lambda(\boldsymbol{y}_i|\boldsymbol{x}_i) \\ &\quad + \gamma \sum_{x_i \in U} H(p_{\lambda,i}) \\ &= K_P + \gamma K_U \end{aligned} \tag{11}$$

K_P and K_U are the contributions of the parallel and unsupervised data, respectively. One may regard γ as a Lagrange multiplier that is used to constrain the parser's uncertainty H to be low, as presented in several studies on entropy regularization (Brand, 1998; Grandvalet and Bengio, 2004; Jiao et al., 2006).

2.3 Algorithms and Complexity for Model Training

To train our parsing model, we need to find out the parameters λ that minimize the objective function $K^{'}$ in equation (11). This optimization problem is typically solved using quasi-Newton numerical methods such as L-BFGS (Nash and Nocedal, 1991), which requires efficient calculation of the objective function and the gradient of the objective function.

The first item (K_P) of the $K^{'}$ function in equation (11) can be rewritten in the following form:

$$\begin{aligned} K_P &= -\sum_{\boldsymbol{x}_i \in P} \Big[\sum_{y_i} \tilde{p}(\boldsymbol{y}_i|\boldsymbol{x}_i) \sum_{e \in \boldsymbol{y}_i} \log w(e, \boldsymbol{x}_i) \\ &\quad - \log Z(\boldsymbol{x}_i) \Big] \end{aligned} \tag{12}$$

and according to equation (1) and (3) the gradient of K_P can be written as:

$$\begin{aligned} \frac{\partial K_P}{\partial \lambda_j} &= \sum_{x_i \in P} \frac{\partial \tilde{p}(\boldsymbol{y}_i|\boldsymbol{x}_i) \log p_\lambda(\boldsymbol{y}_i|\boldsymbol{x}_i)}{\partial \lambda_j} \\ &= \sum_{x_i \in P} \Bigg[\sum_{y_i} \tilde{p}(\boldsymbol{y}_i|\boldsymbol{x}_i) \sum_{e \in y_i} f_j(e, \boldsymbol{x}_i) \\ &\quad - \sum_{y_i} p_\lambda(\boldsymbol{y}_i|\boldsymbol{x}_i) \sum_{e \in y_i} f_j(e, \boldsymbol{x}_i) \Bigg] \end{aligned} \tag{13}$$

According to equation (9), $\tilde{p}(\boldsymbol{y}|\boldsymbol{x})$ can also be factored into the multiplication of the weight of each edge, so both K_P and its gradient can be calculated by running the $O(n^3)$ inside-outside algorithm (Baker, 1979; Paskin, 2001) for projective parsing. For non-projective parsing, the analogy to the inside algorithm is the $O(n^3)$ matrix-tree algorithm based on Kirchhoff's Matrix-Tree Theorem, which is dominated asymptotically by a matrix determinant (Koo et al., 2007; Smith and Smith, 2007). The gradient of a determinant may be computed by matrix inversion, so evaluating the gradient again has the same $O(n^3)$ complexity as evaluating the function.

The second item (K_U) of the $K^{'}$ function in equation (11) is the Shannon entropy of the posterior distribution over parsing trees, and can be written into the following form:

$$\begin{aligned} K_U &= -\sum_{\boldsymbol{x}_i \in U} \Big[\sum_{y_i} p_\lambda(\boldsymbol{y}_i|\boldsymbol{x}_i) \sum_{e \in \boldsymbol{y}_i} \log w(e, \boldsymbol{x}_i) \\ &\quad - \log Z(\boldsymbol{x}_i) \Big] \end{aligned} \tag{14}$$

and the gradient of K_U is in the following:

$$\begin{aligned} \frac{\partial K_U}{\partial \lambda_j} &= \sum_{x_i \in U} \frac{\partial p_\lambda(\boldsymbol{y}_i|\boldsymbol{x}_i) \log p_\lambda(\boldsymbol{y}_i|\boldsymbol{x}_i)}{\partial \lambda_j} \\ &= -\sum_{y_i} p_\lambda(\boldsymbol{y}_i|\boldsymbol{x}_i) \log p_\lambda(\boldsymbol{y}_i|\boldsymbol{x}_i) F_j(\boldsymbol{y}_i, \boldsymbol{x}_i) \\ &\quad + \Big(\sum_{y_i} p_\lambda(\boldsymbol{y}_i|\boldsymbol{x}_i) \log p_\lambda(\boldsymbol{y}_i|\boldsymbol{x}_i) \Big) \\ &\quad \cdot \Big(\sum_{y_i} p_\lambda(\boldsymbol{y}_i|\boldsymbol{x}_i) F_j(\boldsymbol{y}_i, \boldsymbol{x}_i) \Big) \end{aligned} \tag{15}$$

Table 1: Data statistics of two versions of Google Universal Treebanks for the target languages.

Similar with the calculation of K_P, K_U can also be computed by running the inside-outside algorithm (Baker, 1979; Paskin, 2001) for projective parsing. For the gradient of K_U, both the two multipliers of the second item in equation (15) can be computed using the same inside-outside algorithm. For the first item in equation (15), an $O(n^3)$ dynamic programming algorithm that is closely related to the forward-backward algorithm (Mann and McCallum, 2007) for the entropy regularized CRF (Jiao et al., 2006) can be used for projective parsing. For non-projective parsing, however, the runtime rises to $O(n^4)$. In this paper, we focus on projective parsing.

2.4 Summary of Our Approach

To summarize the description in the previous sections, our approach is performed in the following steps:

1. Train an English parsing model $p_{\lambda_E}(\boldsymbol{y}|\boldsymbol{x})$, which is used to estimate the transferring distribution $\tilde{p}(\boldsymbol{y}|\boldsymbol{x})$.

2. Prepare parallel text by running word alignment method to obtain word alignments,[3] and prepare the unlabeled data.

3. Train a parsing model for the target language by minimizing the objective K' function which is the combination of expected negative log-likelihood on parallel and unlabeled data.

[3]The word alignment methods do not require additional resources besides parallel text.

3 Data and Tools

In this section, we illustrate the data sets used in our experiments and the tools for data preparation.

3.1 Choosing Target Languages

Our experiments rely on two kinds of data sets: (i) Monolingual Treebanks with consistent annotation schema — English treebank is used to train the English parsing model, and the Treebanks for target languages are used to evaluate the parsing performance of our approach. (ii) Large amounts of parallel text with English on one side. We select target languages based on the availability of these resources. The monolingual treebanks in our experiments are from the Google Universal Dependency Treebanks (McDonald et al., 2013), for the reason that the treebanks of different languages in Google Universal Dependency Treebanks have consistent syntactic representations.

The parallel data come from the Europarl corpus version 7 (Koehn, 2005) and Kaist Corpus[4]. Taking the intersection of languages in the two kinds of resources yields the following seven languages: French, German, Italian, Korean, Portuguese, Spanish and Swedish.

The treebanks from CoNLL shared-tasks on dependency parsing (Buchholz and Marsi, 2006; Nivre et al., 2007) appear to be another reasonable choice. However, previous studies (McDonald et al., 2011; McDonald et al., 2013) have demonstrated that a homogeneous representation is critical for multilingual language technologies that require consistent cross-lingual analysis for downstream components, and the heterogenous representations used in CoNLL shared-tasks treebanks weaken any conclusion that can be drawn.

Table 3: UAS for two versions of our approach, together with baseline and oracle systems on Google Universal Treebanks version 1.0. "Ave" is the macro-average across the five languages.

For comparison with previous studies, nevertheless, we also run experiments on CoNLL treebanks (see Section 4.4 for more details). We evaluate our approach on three target languages from CoNLL shared task treebanks, which do not appear in Google Universal Treebanks. The three languages are Danish, Dutch and Greek. So totally we have ten target languages. The parallel data for these three languages are also from the Europarl corpus version 7.

3.2 Word Alignments

In our approach, word alignments for the parallel text are required. We perform word alignments with the open source GIZA++ toolkit[5]. The parallel corpus was preprocessed in standard ways, selecting sentences with the length in the range from 3 to 100. Then we run GIZA++ with the default setting to generate word alignments in both directions. We then make the intersection of the word alignments of two directions to generate one-to-one alignments.

3.3 Part-of-Speech Tagging

Several features in our parsing model involve part-of-speech (POS) tags of the input sentences. The set of POS tags needs to be consistent across languages and treebanks. For this reason we use the universal POS tag set of Petrov et al. (2011). This set consists of the following 12 coarse-grained tags: NOUN (nouns), VERB (verbs), ADJ (adjectives), ADV (adverbs), PRON (pronouns), DET (determiners), ADP (prepositions or postpositions), NUM (numerals), CONJ (conjunctions), PRT (particles), PUNC (punctuation marks) and X (a catch-all for other categories such as abbreviations or foreign words).

POS tags are not available for parallel data in the Europarl and Kaist corpus, so we need to provide the POS tags for these data. In our experiments, we train a Stanford POS Tagger (Toutanova et al., 2003) for each language. The labeled training data for each POS tagger are extracted from the training portion of each Treebanks. The average tagging accuracy is around 95%.

Undoubtedly, we are primarily interested in applying our approach to build statistical parsers for resource-poor target languages without any knowledge. For the purpose of evaluation of our approach and comparison with previous work, we need to exploit the gold POS tags to train the POS taggers. As part-of-speech tags are also a form of syntactic analysis, this assumption weakens the applicability of our approach. Fortunately, some recently proposed POS taggers, such as the POS tagger of Das and Petrov (2011), rely only on labeled training data for English and the same kind of parallel text in our approach. In practice we can use this kind of POS taggers to predict POS tags, whose tagging accuracy is around 85%.

4 Experiments

In this section, we will describe the details of our experiments and compare our results with previous methods.

4.1 Data Sets

As presented in Section 3.1, we evaluate our parsing approach on both version 1.0 and version 2.0 of Google Univereal Treebanks for seven languages[6]. We use the standard splits of the treebank for each language as specified in the release of the data[7]. Table 1 presents the statistics of the two versions of Google Universal Treebanks. We strip all

[6] Japanese and Indonesia are excluded as no practicable parallel data are available.

Table 5: Parsing results of our approach with different amount of parallel data on Google Universal Treebanks version 1.0 and 2.0. We omit the results of Swedish for treebanks version 2.0 since the data for Swedish from version 2.0 are exactly the same with those from version 1.0.

the dependency annotations off the training portion of each treebank, and use that as the unlabeled data for that target language. We train our parsing model with different numbers of parallel sentences to analyze the influence of the amount of parallel data on the parsing performance of our approach. The parallel data sets contain 500, 1000, 2000, 5000, 10000 and 20000 parallel sentences, respectively. We randomly extract parallel sentences from each corpora, and smaller data sets are subsets of larger ones. Table 2 shows the number of tokens in the parallel data used in the experiments.

4.2 System performance and comparison on Google Universal Treebanks

For the comparison of parsing performance, we run experiments on the following systems:

DTP: The direct transfer parser (DTP) proposed by McDonald et al. (2011), who train a delexicalized parser on English labeled training data with no lexical features, then apply this parser to parse target languages directly. It is based on the transition-based dependency parsing paradigm (Nivre, 2008). We directly cite the results reported in McDonald et al. (2013). In addition to their original results, we also report results by reimplementing the direct transfer parser based on the first-order projective dependency parsing model (McDonald et al., 2005a) (DTP†).

PTP The projected transfer parser (PTP) described in McDonald et al. (2011). The results of the projected transfer parser reimplemented by us is marked as "PTP†".

-U: Our approach training on only parallel data without unlabeled data for the target language. The parallel data set for each language contains 20,000 sentences.

+U: Our approach training on both parallel and unlabeled data. The parallel data sets are the ones contains 20,000 sentences.

OR: the supervised first-order projective dependency parsing model (McDonald et al., 2005a), trained on the original treebanks with maximum likelihood estimation (equation 6). One may regard this system as an oracle of transfer parsing.

Parsing accuracy is measured with unlabeled attachment score (UAS): the percentage of words with the correct head.

Table 3 and Table 4 shows the parsing results of our approach, together with the results of the baseline systems and the oracle, on version 1.0 and version 2.0 of Google Universal Treebanks, respectively. Our approaches significantly outperform all the baseline systems across all the seven target languages. For the results on Google Universal Treebanks version 1.0, the improvement on average over the projected transfer paper (PTP†) is 3.96%

and up to 6.22% for Korean and 4.80% for German. For the other three languages, the improvements are remarkable, too — 2.33% for French, 3.03% for Spanish and 3.40% for Swedish. By adding entropy regularization from unlabeled data, our full model achieves average improvement of 0.29% over the "-U" setting. Moreover, our approach considerably bridges the gap to fully supervised dependency parsers, whose average UAS is 84.67%. For the results on treebanks version 2.0, we can get similar observation and draw the same conclusion.

4.3 Effect of the Amount of Parallel Text

Table 5 illustrates the UAS of our approach trained on different amounts of parallel data, together with the results of the projected transfer parser re-implemented by us (PTP†). We run two versions of our approach for each of the parallel data sets, one with unlabeled data (+U) and the other without them (-U). From table 5 we can get three observations. First, even the parsers trained with only 500 parallel sentences achieve considerably high parsing accuracies (average 70.10% for version 1.0 and 71.59% for version 2.0). This demonstrates that our approach does not rely on a large amount of parallel data. Second, when gradually increasing the amount of parallel data, the parsing performance continues improving. Third, entropy regularization with unlabeled data makes modest improvement on parsing performance over the parsers without unlabeled data. This proves the effectiveness of the entropy regularization from unlabeled data.

4.4 Experiments on CoNLL Treebanks

To make a thorough empirical comparison with previous studies, we also evaluate our system without unlabeled data (-U) on treebanks from CoNLL shared task on dependency parsing (Buchholz and Marsi, 2006; Nivre et al., 2007). To facilitate comparison, we use the same eight Indo-European languages as target languages: Danish, Dutch, German, Greek, Italian, Portuguese, Spanish and Swedish, and same experimental setup as McDonald et al. (2011). We report both the results of the direct transfer and projected transfer parsers directly cited from McDonald et al. (2011) (DTP and PTP) and re-implemented by us (DTP†and PTP†).

Table 6 gives the results comparing the model without unlabeled data (-U) presented in this work to those five baseline systems and the oracle (OR). The results of unsupervised DMV model (Klein and Manning, 2004) are from Table 1 of McDonald et al. (2011). Our approach outperforms all these baseline systems and achieves state-of-the-art performance on all the eight languages.

Table 6: Parsing results on treebanks from CoNLL shared tasks for eight target languages. The results of unsupervised DMV model are from Table 1 of McDonald et al. (2011).

In order to compare with more previous methods, we also report parsing performance on sentences of length 10 or less after punctuation has been removed. Table 7 shows the results of our system and the results of baseline systems. "USR†" is the weakly supervised system of Naseem et al. (2010). "PGI" is the phylogenetic grammar induction model of Berg-Kirkpatrick and Klein (2010). Both the results of the two systems are cited from Table 4 of McDonald et al. (2011). We also include the results of the unsupervised dependency parsing model with non-parallel multilingual guidance (NMG) proposed by Cohen et al. (2011)[8], and "PR" which is the posterior regularization approach presented in Gillenwater et al. (2010). All the results are shown in Table 7.

From Table 7, we can see that among the eight target languages, our approach achieves best parsing performance on six languages — Danish, German, Greek, Italian, Portuguese and Swedish. It should be noted that the "NMG" system utilizes more than one helper languages. So it is not directly comparable to our work.

4.5 Extensions

In this section, we briefly outline a few extensions to our approach that we want to explore in future work.

[8]For each language, we use the best result of the four systems in Table 3 of Cohen et al. (2011)

	DTP	DTP†	PTP	PTP†	USR†	PGI	PR	NMG	-U

Table 7: UAS on sentences of length 10 or less without punctuation from CoNLL shared task treebanks. "USR†" is the weakly supervised system of Naseem et al. (2010). "PGI" is the phylogenetic grammar induction model of Berg-Kirkpatrick and Klein (2010). Both the "USR†" and "PGI" systems are implemented and reported by McDonald et al. (2011). "NMG" is the unsupervised dependency parsing model with non-parallel multilingual guidance (Cohen et al., 2011). "PR" is the posterior regularization approach presented in Gillenwater et al. (2010). Some systems' results for certain target languages are not available as marked by —.

4.5.1 Non-Projective Parsing

As mentioned in section 2.3, the runtime to compute K_U and its gradient is $O(n^4)$. One reasonable speedup, as presented in Smith and Eisner (2007), is to replace Shannon entropy with Rényi entropy. The **Rényi entropy** is parameterized by α:

$$R_\alpha(p) = \frac{1}{1-\alpha} \log \Big(\sum_y p(y)^\alpha \Big) \qquad (16)$$

With Rényi entropy, the computation of K_U and its gradient is $O(n^3)$, even for non-projective case.

4.5.2 Higher-Order Models for Projective Parsing

Our learning framework can be extended to higher-order dependency parsing models. For example, if we want to make our model capable of utilizing more contextual information, we can extend our transferring weight to higher-order parts:

$$\tilde{w}(p^t, \boldsymbol{x}_i^t) = \begin{cases} w_E(p^s, \boldsymbol{x}_i^s), & \text{if } p^t \overset{align}{\longrightarrow} p^s \\ w_E(p^t_{delex}, \boldsymbol{x}_i^s), & \text{otherwise} \end{cases} \qquad (17)$$

where p is a small *part* of tree $\boldsymbol{y}$ that has limited interactions. For projective parsing, several algorithms (McDonald and Pereira, 2006; Carreras, 2007; Koo and Collins, 2010; Ma and Zhao, 2012) have been proposed to solve the model training problems (calculation of objective function and gradient) for different factorizations.

4.5.3 IGT Data

One possible direction to improve our approach is to replace parallel text with Interlinear Glossed Text (IGT) (Lewis and Xia, 2010), which is a semi-structured data type encoding more syntactic information than parallel data. By using IGT Data, not only can we obtain more accurate word alignments, but also extract useful cross-lingual information for the resource-poor language.

5 Conclusion

In this paper, we propose an unsupervised projective dependency parsing approach for resource-poor languages, using existing resources from a resource-rich source language. By presenting a model training framework, our approach can utilize parallel text to estimate transferring distribution with the help of a well-developed resource-rich language dependency parser, and use unlabeled data as entropy regularization. The experimental results on three data sets across ten target languages show that our approach achieves significant improvement over previous studies.

Unsupervised Morphology-Based Vocabulary Expansion

Mohammad Sadegh Rasooli, Thomas Lippincott, Nizar Habash and **Owen Rambow**
Center for Computational Learning Systems
Columbia University, New York, NY, USA
{rasooli,tom,habash,rambow}@ccls.columbia.edu

Abstract

We present a novel way of generating unseen words, which is useful for certain applications such as automatic speech recognition or optical character recognition in low-resource languages. We test our vocabulary generator on seven low-resource languages by measuring the decrease in out-of-vocabulary word rate on a held-out test set. The languages we study have very different morphological properties; we show how our results differ depending on the morphological complexity of the language. In our best result (on Assamese), our approach can predict 29% of the token-based out-of-vocabulary with a small amount of unlabeled training data.

1 Introduction

In many applications in human language technologies (HLT), the goal is to generate text in a target language, using its standard orthography. Typical examples include automatic speech recognition (ASR, also known as STT or speech-to-text), optical character recognition (OCR), or machine translation (MT) into a target language. We will call such HLT applications "target-language generation technologies" (TLGT). The best-performing systems for these applications today rely on training on large amounts of data: in the case of ASR, the data is aligned audio and transcription, plus large unannotated data for the language modeling; in the case of OCR, it is transcribed optical data; in the case of MT, it is aligned bitexts. More data provides for better results. For languages with rich resources, such as English, more data is often the best solution, since the required data is readily available (including bitexts), and the cost of annotating (e.g., transcribing) data is outweighed by the potential significance of the systems that the data will enable. Thus, in HLT, improvements in quality are often brought about by using larger data sets (Banko and Brill, 2001).

When we move to low-resource languages, the solution of simply using more data becomes less appealing. Unannotated data is less readily available: for example, at the time of publishing this paper, 55% of all websites are in English, the top 10 languages collectively account for 90% of web presence, and the top 36 languages have a web presence that covers at least 0.1% of web sites.[1] All other languages (and all languages considered in this paper except Persian) have a web presence of less than 0.1%. Considering Wikipedia, another resource often used in HLT, English has 4.4 million articles, while only 48 other languages have more than 100,000.[2] As attention turns to developing HLT for more languages, including low-resource languages, alternatives to "more-data" approaches become important.

At the same time, it is often not possible to use knowledge-rich approaches. For low-resource languages, resources such as morphological analyzers are not usually available, and even good scholarly descriptions of the morphology (from which a tool could be built) are often not available. The challenge is therefore to use data, but to make do with a small amount of data, and thus to use data better. This paper is a contribution to this goal. Specifically, we address TLGTs, i.e., the types of HLT mentioned above that generate target language text. We propose a new approach to generating unseen words of the target language which have not been seen in the training data. Our approach is entirely unsupervised. It assumes that word-units are specified, typically by whitespace and punctuation.

[1] http://en.wikipedia.org/wiki/Languages_used_on_the_Internet

[2] http://meta.wikimedia.org/wiki/List_of_Wikipedias

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1349–1359,
Baltimore, Maryland, USA, June 23-25 2014.

Expanding the vocabulary of the target language can be useful for TLGTs in different ways. For ASR and OCR, which can compose words from smaller units (phones or graphically recognized letters), an expanded target language vocabulary can be directly exploited without the need for changing the technology at all: the new words need to be inserted into the relevant resources (lexicon, language model) etc, with appropriately estimated probabilities. In the case of MT into morphologically rich low-resource languages, morphological segmentation is typically used in developing the translation models to reduce sparsity, but this does not guarantee against generating wrong word combinations. The expanded word combinations can be used to extend the language models used for MT to bias against incoherent hypothesized new sequences of segmented words.

Our approach relies on unsupervised morphological segmentation. We do not in this paper contribute to research in unsupervised morphological segmentation; we only use it. The contribution of this paper lies in proposing how to use the results of unsupervised morphological segmentation in order to generate unseen words of the language. We investigate several ways of doing so, and we test them on seven low-resource languages. These languages have very different morphological properties, and we show how our results differ depending on the morphological complexity of the language. In our best result (on Assamese), we show that our approach can predict 29% of the token-based out-of-vocabulary with a small amount of unlabeled training data.

The paper is structured as follows. We first discuss related work in Section 2. We then present our method in Section 3, and present experimental results in Section 4. We conclude with a discussion of future work in Section 5.

2 Related Work

Approaches to Morphological Modeling Computational morphology is a very active area of research with a multitude of approaches that vary in the degree of manual annotation needed, and the amount of machine learning used. At one extreme, we find systems that are painstakingly and carefully designed by hand (Koskenniemi, 1983; Buckwalter, 2004; Habash and Rambow, 2006; Détrez and Ranta, 2012). Next on the continuum, we find work that focuses on defining morphological models with limited lexica that are then extended using raw text (Clément et al., 2004; Forsberg et al., 2006). In the middle of this continuum, we find efforts to learn complete paradigms using fully supervised methods relying on completely annotated data points with rich morphological information (Durrett and DeNero, 2013; Eskander et al., 2013). Next, there is work on minimally supervised methods that use available resources such as dictionaries, bitexts, and other additional morphological annotations (Yarowsky and Wicentowski, 2000; Cucerzan and Yarowsky, 2002; Neuvel and Fulop, 2002; Snyder and Barzilay, 2008). At the other extreme, we find unsupervised methods that learn morphology models from unannotated data (Creutz and Lagus, 2007; Monson et al., 2008; Dreyer and Eisner, 2011; Sirts and Goldwater, 2013).

The work we present in this paper makes no use of any morphological annotations whatsoever, yet we are quite distinct from the approaches cited above. We compare our work to two efforts specifically. First, consider work in automatic morphological segmentation learning from unannotated data (Creutz and Lagus, 2007; Monson et al., 2008). Unlike these approaches which provide segmentations for training data and produce models that can be used to segment unseen words, our approach can generate words that have not been seen in the training data. The focus of efforts is rather complementary: we actually use an off-the-shelf unsupervised segmentation system (Creutz and Lagus, 2007) as part of our approach. Second, consider paradigm completion methods such as the work of Dreyer and Eisner (2011). This effort is closely related to our work although unlike it, we make no assumptions about the data and do not introduce any restrictions along the lines of derivation/inflectional morphology: Dreyer and Eisner (2011) limited their work to verbal paradigms and used annotated training data in addition to basic assumptions about the problem such as the size of the paradigms. In our approach, we have zero annotated information and we do not distinguish between inflectional and derivational morphology, nor do we limit ourselves to a specific part-of-speech (POS).

Vocabulary Expansion in HLT There have been diverse approaches towards dealing with out-of-vocabulary (OOV) words in ASR. In some models, the approach is to expand the lexicon by

adding new words or pronunciations. Ohtsuki et al. (2005) propose a two-run model where in the first run, the input speech is recognized by the reference vocabulary and relevant words are extracted from the vocabulary database and added thereafter to the reference vocabulary to build an expanded lexicon. Word recognition is done in the second run based on the lexicon. Lei et al. (2009) expanded the pronunciation lexicon via generating all possible pronunciations for a word before lattice generation and indexation. There are also other methods for generating abbreviations in voice search systems such as Yang et al. (2012). While all of these approaches involve lexicon expansion, they do not employ any morphological information.

In the context of MT, several researchers have addressed the problem of OOV words by relating them to known in-vocabulary (INV) words. Yang and Kirchhoff (2006) anticipated OOV words that are potentially morphologically related using phrase-based backoff models. Habash (2008) considered different techniques for vocabulary expansion online. One of their techniques learned models of morphological mapping between morphologically rich source words in Arabic that produce the same English translation. This was used to relate an OOV word to a morphologically related INV word. Another technique expanded the MT phrase tables with possible transliterations and spelling alternatives.

3 Morphology-based Vocabulary Expansion

3.1 Approach

Our approach to morphology-based vocabulary expansion consists of three steps (Figure 1). We start with a "training" corpus of (unannotated) words and generate a list of new (unseen) words that expands the vocabulary of the training corpus.

1. **Unsupervised Morphology Segmentation** The first step is to segment each word in the training corpus into sequences of prefixes, stem and suffixes, where the prefixes and suffixes are optional.[3]

2. **FST-based Morphology Expansion** We then construct new word models using the segmented stems and affixes. We explore two different techniques for morphology-based vocabulary expansion that we discuss below. The output of these models is represented as a weighted finite state machine (WFST).

3. **Reranking Models** Given that the size of the expanded vocabulary can be quite large and it may include a lot of over-generation, we rerank the expanded set of words before taking the top n words to use in downstream processes. We consider four reranking conditions which we describe below.

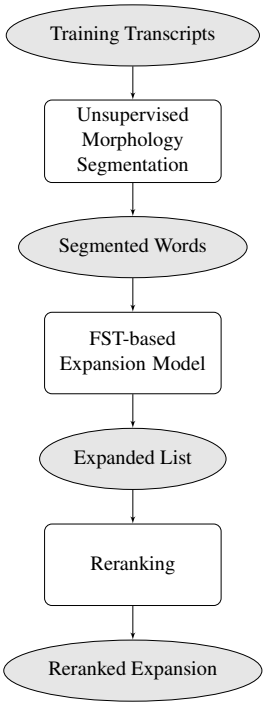

Figure 1: The flowchart of the lexicon expansion system.

3.2 Morphology Expansion Techniques

As stated above, the input to the morphology expansion step is a list of words segmented into morphemes: zero or more prefixes, one stem, and zero or more suffixes. Figure 2a presents an example of such input using English words (for clarity).

We use two different models of morphology expansion in this paper: Fixed Affix model and Bigram Affix model.

3.2.1 Fixed Affix Expansion Model

In the Fixed Affix model, we construct a set of fused prefixes from all the unique prefix sequences in the training data; and we similarly construct a

[3] In this paper, we use an off-the-shelf system for this step but plan to explore new methods in the future, such as joint segmentation and expansion.

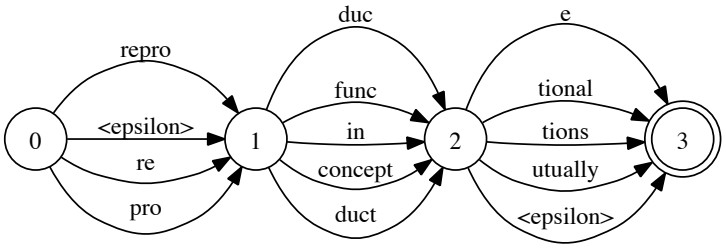
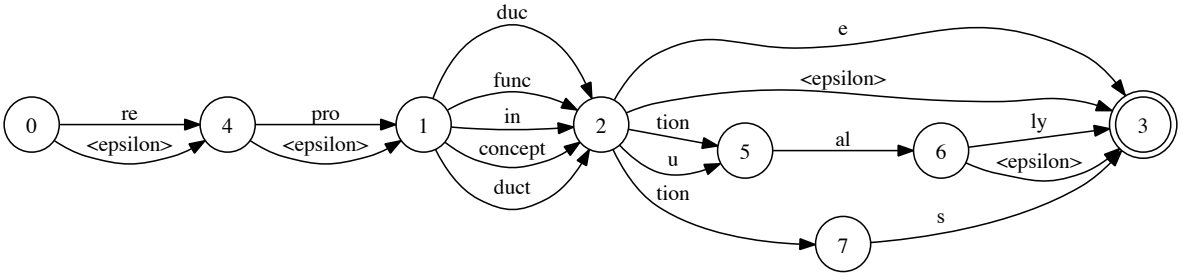
(a) Training data with morpheme boundaries. Prefixes end with and suffixes start with "+" signs.



(b) FST for the Fixed Affix expansion model



(c) FST for the Bigram Affix expansion model

Figure 2: Two models of word generation from morphologically annotated data. In our experiments, we used weighted finite state machine. We use character-based WFST in the implementation to facilitate analyzing inputs as well as word generation.

set of fused suffixes from all the unique suffix sequences in the training data. In other words, we simply pick characters from beginning of the word up to the first stem as the prefix and characters from the first suffix to the end of the word as the suffix. Everything in the middle is the stem. In this model, each word has one single prefix and one single suffix (each of which can be empty independently). The Fixed Affix model is simply the concatenation of the disjunction of all prefixes with the disjunction of all stems and the disjunction of all suffixes into one FST:

$$\textit{prefix} \rightarrow \textit{stem} \rightarrow \textit{suffix}$$

The morpheme paths in the FST are weighted to reflect their probability in the training corpus.[4] Figure 2b exemplifies a Fixed Affix model derived from the example training data in Figure 2a.

[4]We convert the probability into a cost by taking the negative of the log of the probability.

3.2.2 Bigram Affix Expansion Model

In the Bigram Affix model, we do the same for the stem as in the Fixed Affix model, but for prefixes and suffixes, we create a bigram language model in the finite state machine. The advantage of this technique is that unseen compound affixes can be generated by our model. For example, the Fixed Affix model in Figure 2b cannot generate the word *func+tion+al+ly* since the suffix *+tionally* is not seen in the training data. However, this word can be generated in the Bigram Affix model as shown in Figure 2c: there is a path passing $0 \rightarrow 4 \rightarrow 1 \rightarrow 2 \rightarrow 5 \rightarrow 6 \rightarrow 3$ in the FST that can produce this word. We expect this model to have better recall for generating new words in the language because of its affixation flexibility.

3.3 Reranking Techniques

The expanded models allow for a large number of words to be generated. We limit the number of vocabulary expansion using different thresholds after reranking or reweighing the WFSTs generated

above. We consider four reranking conditions.

3.3.1 No Reranking (NRR)

The baseline reranking option is no reranking (NRR). In this approach we use the weights in the WFST, which are based on the independent prefix/stem/suffix probabilities, to determine the ranking of the expanded vocabulary.

3.3.2 Trigraph-based Reweighting (W∘Tr)

We reweight the weights in the WFST model (Fixed or Bigram) by composing it with a *letter trigraph language model* ($W \circ \text{Tr}$). A letter trigraph LM is itself a WFST where each trigraph (a sequence of three consequent letters) has an associated weight equal to its negative log-likelihood in the training data. This reweighting allows us to model preferences of sequences of word letters seen more in the training data. For example, in a word like *producttions*, the trigraphs *ctt* and *tti* are very rare and thus decrease its probability.

3.3.3 Trigraph-based Reranking (TRR)

When we compose our initial WFST with the trigraph FST, the probability of each generated word from the new FST is equal to the product of the probability of its morphemes and the probabilities of each trigraph in that word. This basically makes the model prefer shorter words and may degrade the effect of morphology information. Instead of reweighting the WFST, we get the n-best list of generated words and rerank them using their trigraph probabilities. We will refer to this technique as TRR.

3.3.4 Reranking Morpheme Boundaries (BRR)

The last reranking technique reranks the n-best generated word list with trigraphs that are incident on the morpheme boundaries (in case of Bigram Affix model, the last prefix and first suffix). The intuition is that we already know that any morpheme that is generated from the morphology FST is already seen in the training data but the boundary for different morphemes are not guaranteed to be seen in the training data. For example, for the word *producttions*, we only take into account the trigraphs *rod*, *odu*, *ctt* and *tti* instead of all possible trigraphs. We will refer to this technique as BRR.

4 Evaluation

4.1 Evaluation Data and Tools

Evaluation Data The IARPA Babel program is a research program for developing rapid spoken detection systems for under-resourced languages (Harper, 2013). We use the IARPA Babel program limited language pack data which consists of 20 hours of telephone speech with transcription. We use six languages which are known to have rich morphology: Assamese (IARPA-babel102b-v0.5a), Bengali (IARPA-babel103b-v0.4b), Pashto (IARPA-babel104b-v0.4bY), Tagalog (IARPA-babel106-v0.2g), Turkish (IARPA-babel105b-v0.4) and Zulu (IARPA-babel206b-v0.1e). Speech annotation such as silences and hesitations are removed from transcription and all words are turned into lower-case (for languages using the Roman script – Tagalog, Turkish and Zulu). Moreover, in order to be able to perform a manual error analysis, we include a language that has rich morphology and of which the first author is a native speaker: Persian. We sampled data from the training and development set of the Persian dependency treebank (Rasooli et al., 2013) to create a comparable seventh dataset in Persian. Statistics about the datasets are shown in Table 1. We also conduct further experiments on just verbs and nouns in the data set for Persian (Persian-N and Persian V). As shown in Table 1, the training data is very small and the OOV rate is high especially in terms of types. For some languages that have richer morphology such as Turkish and Zulu, the OOV rate is much higher than other languages.

Word Generation Tools and Settings For unsupervised learning of morphology, we use Morfessor CAT-MAP (v. 0.9.2) which was shown to be a very accurate morphological analyzer for morphologically rich languages (Creutz and Lagus, 2007). In order to be able to analyze Unicode-based data, we convert each character in our dataset to some conventional ASCII character and then train Morfessor on the mapped dataset; after finishing the training, we map the data back to the original character set. We use the default setting in Morfessor for unsupervised learning.

For preparing the WFST, we use OpenFST (Riley et al., 2009). We get the top one million shortest paths (i.e., least costly paths of words) and apply our reranking models on them. It is worth pointing out that our WFSTs are character-based

Language	Training Data		Development Data			
	Type	Token	Type	Token	Type OOV%	Token OOV%
Assamese	8694	73151	7253	66184	49.57	8.28
Bengali	9460	81476	7794	70633	50.65	8.47

and thus we also have a morphological analyzer that can give all possible segmentations for a given word. By running the morphological analyzer on the OOVs, we can have the potential upper bound of OOV reduction by the system (labeled "∞" in Tables 2 and 3).

4.2 Lexicon Expansion Results

The results for lexicon expansion are shown in Table 2 for types and Table 3 for tokens.

We use the trigraph WFST as our baseline model. This model does not use any morphological information. In this case, words are generated according to the likelihood of their trigraphs, without using any information from the morphological segmentation. We call this model the trigraph WFST (Tr. WFST). We consistently have better numbers than this baseline in all of our models except for Pashto when measured by tokens. ∞ is the upper-bound OOV reduction for our expansion model: for each word in the development set, we ask if our model, without any vocabulary size restriction at all, could generate it.

The best results (again, except for Pashto) are achieved using one of the three reranking methods (reranking by trigraph probabilities or morpheme boundaries) as opposed to doing no reranking. To our surprise, the Fixed Affix model does a slightly better job in reducing out of vocabulary than the Bigram Affix model. We can also see from the results that reranking in general is very effective.

We also compare our models with the case that there is much more training data and we do not do vocabulary expansion at all. In Table 2 and Table 3, "FP" indicates the full language pack for the Babel project data which is approximately six to eight times larger than the limited pack training data, and the full training data for Persian which is approximately five times larger. We see that the larger training data outperforms our methods in all languages. However, from the results of ∞, which is the upper-bound OOV reduction by our expansion model, for some languages such as Assamese, our numbers are close to the FP results and for Zulu it is even better than FP.

We also study how OOV reduction is affected by the size of the generated vocabulary. The trends for different sizes of the lexicon expansion by Fixed Affix model that is reranked by trigraph probabilities is shown in Figure 3. As seen in the results, for languages that have richer morphology, it is harder to achieve results near to the upper bound. As an outlier, morphology does not help for Pashto. One possible reason might be that based on the results in Table 4, Morfessor does not explore morphology in Pashto as well as other languages.

Morphological Complexity As for further analysis, we can study the correlation between morphological complexity and hardness of reducing OOVs. Much work has been done in linguistics to classify languages (Sapir, 1921; Greenberg, 1960). The common wisdom is that languages are not either agglutinative or fusional, but are on a spectrum; however, no work to our knowledge places all languages (or at least the ones we worked on) on such a spectrum. We propose several metrics. First, we can consider the number of unique affixival morphemes in each language, as determined by Morfessor. As shown in Table 4 ($|pr| + |sf|$), Zulu has the most morphemes and Pashto the fewest. A second possible metric of the

Table 3: Token-based expansion results for the 50k-best list for different models. Abbreviations are the same as Table 2.

complexity of the morphology is by calculating the average number of unique prefix-suffix pairs in the training data after morpheme segmentation which is shown as $|If|$ in Table 4. Finally, a third possible metric is the number of all possible words that can be generated ($|L|$). These three metrics correlate fairly well across the languages.

The metrics we propose also correlate with commonly accepted classifications: e.g., Zulu and Turkish (highly agglutinative) have higher scores in terms of our $|pr| + |sf|$, $|If|$ and $|L|$ metrics in Table 4 than other languages. The results from full language packs in Table 3 also show that there is a reverse interaction of morphological complexity and the effect of blindly adding more data. Thus for morphologically rich languages, adding more data is less effective than for languages with poor morphology.

The size of the languages ($|L|$) suggests that we are suffering from vast overgeneration; we overgenerate because in our model any affix can attach to any stem, which is not in general true. Thus there is a lack of linguistic knowledge such as paradigm information (Stump, 2001) for each word category in our model. In other words, all morphemes are treated the same in our model which is not true in natural languages. One way to tackle this problem is through an unsupervised POS tagger. The challenge here is that fully unsupervised POS taggers (without any tag dictionary) are not very accurate (Christodoulopoulos et al., 2010). Another way is through using joint mor-

Table 4: Information about the number of unique morphemes in the Fixed Affix model for each dataset including empty affixes. $|L|$ shows the upper bound of the number of possible unique words that can be generated from the word generation model. $|If|$ is the average number of unique prefix-suffix pairs (including empty pairs) for each stem.

phology and tagging models such as Frank et al. (2013).

Error Analysis on Turkish Unfortunately for most languages we could not find an available rule-based or supervised morphological analyzer to verify the words generated by our model. The only available tool for us is a Turkish finite-state morphological analyzer (Oflazer, 1996) implemented with the Xerox FST toolkit (Beesley and Karttunen, 2003). As we can see in Table 5, the system with the largest proportion of correct generated words reranks the expansion with trigraph probabilities using a Fixed Affix model. Results also show that we are overgenerating many nonsense words that we ought to be pruning from our results. Another observation is that the recognition percentage of the morphological analyzer on INV words is much higher than on OOVs, which shows that OOVs in Turkish dataset are much harder to analyze.

Model		Precision
Tr. WFST		17.19
Fixed Affix Model	NRR	13.36
	W∘Tr	25.66
	TRR	**26.30**
	BRR	25.14

	TRR	25.39
	BRR	23.45
Development	words	89.30
	INVs	95.44
	OOVs	84.64

Table 5: Results from running a hand-crafted Turkish morphological analyzer (Oflazer, 1996) on different expansions and on the development set. Precision refers to the percentage of the words are recognized by the analyzer. The results on development are also separated into INV and OOV.

Error Analysis on Persian From the best 50k word result for Persian (Fixed Affix Model:BRR), we randomly picked 200 words and manually analyzed them. 89 words are correct (45.5%) where 55.0% of these words are from noun affixation, 23.6% from verb clitics, 9.0% from verb inflections, 5.6% from incorrect affixations that accidentally resulted in possible words, 4.5% from uninflected stems, and a few from adjective affixation. Among incorrectly generated words, 65.8% are from combining a stem of one POS with affixes from another POS (e.g., attaching a noun affix to a verb stem), 14.4% from combining a stem with affixes which are compatible with POS but not allowed for that particular stem (e.g., there is a noun suffix that can only attach to a subset of noun stems), 9.0% are from wrong affixes produced by Morfessor and others are from incorrect vowel harmony or double affixation.

In order to study the effect of vocabulary expansion more deeply, we trained a subset of all nouns and verbs in the same dataset (also shown in Table 1). Verbs in Persian have rich but more or less regular morphology, while nouns, which have many irregular cases, have rich morphology but not as rich as verbs. The results in Table 4 show that Morfessor captures these phenomena. Furthermore, our results in Table 2 and Table 3 show that our performance on OOV reduction with verbs is far superior to our performance with nouns. We also randomly picked 200 words from each of the experiments (noun and verbs) to study the degree of correctness of generated forms. For nouns, 94 words are correct and for verbs only 71 words are correct. Most verb errors are due to incorrect morpheme extraction by Morfessor. In contrast, most noun errors result from affixes that are only compatible with a subset of all possible noun stems. This suggests that if we conduct experiments using more accurate unsupervised morphology and also have a more fine-grained paradigm completion model, we might improve our performance.

5 Conclusion and Future Work

We have presented an approach to generating new words. This approach is useful for low-resource, morphologically rich languages. It provides words that can be used in HLT applications that require target-language generation in this language, such as ASR, OCR, and MT. An implementation of our approach, named BabelGUM (Babel General Unsupervised Morphology), will be publicly available. Please contact the authors for more information.

In future work we will explore the possibility of jointly performing unsupervised morphological segmentation with clustering of words into classes with similar morphological behavior. These classes will extend POS classes. We will tune the system for our purposes, namely OOV reduction.

Abstract

This study investigates on building a better Chinese word segmentation model for statistical machine translation. It aims at leveraging word boundary information, automatically learned by bilingual character-based alignments, to induce a preferable segmentation model. We propose dealing with the induced word boundaries as soft constraints to bias the continuous learning of a supervised CRFs model, trained by the treebank data (labeled), on the bilingual data (unlabeled). The induced word boundary information is encoded as a graph propagation constraint. The constrained model induction is accomplished by using posterior regularization algorithm. The experiments on a Chinese-to-English machine translation task reveal that the proposed model can bring positive segmentation effects to translation quality.

1 Introduction

Word segmentation is regarded as a critical procedure for high-level Chinese language processing tasks, since Chinese scripts are written in continuous characters without explicit word boundaries (e.g., space in English). The empirical works show that word segmentation can be beneficial to Chinese-to-English statistical machine translation (SMT) (Xu et al., 2005; Chang et al., 2008; Zhao et al., 2013). In fact most current SMT models assume that parallel bilingual sentences should be segmented into sequences of tokens that are meant to be "words" (Ma and Way, 2009). The practice in state-of-the-art MT systems is that Chinese sentences are tokenized by a monolingual supervised word segmentation model trained on the hand-annotated treebank data, e.g., Chinese treebank (CTB) (Xue et al., 2005). These models are conducive to MT to some extent, since they commonly have relatively good aggregate performance and segmentation consistency (Chang et al., 2008). But one outstanding problem is that these models may leave out some crucial segmentation features for SMT, since the output words conform to the treebank segmentation standard designed for monolingually linguistic intuition, rather than specific to the SMT task.

In recent years, a number of works (Xu et al., 2005; Chang et al., 2008; Ma and Way, 2009; Xi et al., 2012) attempted to build segmentation models for SMT based on bilingual unsegmented data, instead of monolingual segmented data. They proposed to learn gainful bilingual knowledge as golden-standard segmentation supervisions for training a bilingual unsupervised model. Frequently, the bilingual knowledge refers to the mappings of an individual English word to one or more consecutive Chinese characters, generated via statistical character-based alignment. They leverage such mappings to either constitute a Chinese word dictionary for maximum-matching segmentation (Xu et al., 2004), or form labeled data for training a sequence labeling model (Paul et al., 2011). The prior works showed that these models help to find some segmentations tailored for SMT, since the bilingual word occurrence feature can be captured by the character-based alignment (Och and Ney, 2003). However, these models tend to miss out other linguistic segmentation patterns as monolingual supervised models, and suffer from the negative effects of erroneously alignments to word segmentation.

This paper proposes an alternative Chinese Word Segmentation (CWS) model adapted to the SMT task, which seeks not only to maintain the advantages of a monolingual supervised model, having hand-annotated linguistic knowledge, but also to assimilate the relevant bilingual segmenta-

tion nature. We propose leveraging the bilingual knowledge to form learning constraints that guide a supervised segmentation model toward a better solution for SMT. Besides the bilingual motivated models, character-based alignment is also employed to achieve the mappings of the successive Chinese characters and the target language words. Instead of directly merging the characters into concrete segmentations, this work attempts to extract word boundary distributions for character-level trigrams (types) from the "chars-to-word" mappings. Furthermore, these word boundaries are encoded into a graph propagation (GP) expression, in order to widen the influence of the induced bilingual knowledge among Chinese texts. The GP expression constrains similar types having approximated word boundary distributions. Crucially, the GP expression with the bilingual knowledge is then used as side information to regularize a CRFs (conditional random fields) model's learning over treebank and bitext data, based on the posterior regularization (PR) framework (Ganchev et al., 2010). This constrained learning amounts to a jointly coupling of GP and CRFs, i.e., integrating GP into the estimation of a parametric structural model.

This paper is structured as follows: Section 2 points out the main differences with the related works of this study. Section 3 presents the details of the proposed segmentation model. Section 4 reports the experimental results of the proposed model for a Chinese-to-English MT task. The conclusion is drawn in Section 5.

2 Related Work

In the literature, many approaches have been proposed to learn CWS models for SMT. They can be put into two categories, monolingual-motivated and bilingual-motivated. The former primarily optimizes monolingual supervised models according to some predefined segmentation properties that are manually summarized from empirical MT evaluations. Chang et al. (2008) enhanced a CRFs segmentation model in MT tasks by tuning the word granularity and improving the segmentation consistence. Zhang et al. (2008) produced a better segmentation model for SMT by concatenating various corpora regardless of their different specifications. Distinct from their behaviors, this work uses automatically learned constraints instead of manually defined ones. Most importantly, the constraints have a better learning guidance since they originate from the bilingual texts. On the other hand, the bilingual-motivated CWS models typically rely on character-based alignments to generate segmentation supervisions. Xu et al. (2004) proposed to employ "chars-to-word" alignments to generate a word dictionary for maximum matching segmentation in SMT task. The works in (Ma and Way, 2009; Zhao et al., 2013) extended the dictionary extraction strategy. Ma and Way (2009) adopted co-occurrence frequency metric to iteratively optimize "candidate words" extract from the alignments. Zhao et al. (2013) attempted to find an optimal subset of the dictionary learned by the character-based alignment to maximize the MT performance. Paul et al. (2011) used the words learned from "chars-to-word" alignments to train a maximum entropy segmentation model. Rather than playing the "hard" uses of the bilingual segmentation knowledge, i.e., directly merging "char-to-word" alignments to words as supervisions, this study extracts word boundary information of characters from the alignments as soft constraints to regularize a CRFs model's learning.

The graph propagation (GP) technique provides a natural way to represent data in a variety of target domains (Belkin et al., 2006). In this technique, the constructed graph has vertices consisting of labeled and unlabeled examples. Pairs of vertices are connected by weighted edges encoding the degree to which they are expected to have the same label (Zhu et al., 2003). Many recent works, such as by Subramanya et al. (2010), Das and Petrov (2011), Zeng et al. (2013; 2014) and Zhu et al. (2014), proposed GP for inferring the label information of unlabeled data, and then leverage these GP outcomes to learn a semi-supervised scalable model (e.g., CRFs). These approaches are referred to as pipelined learning with GP. This study also works with a similarity graph, encoding the learned bilingual knowledge. But, unlike the prior pipelined approaches, this study performs a joint learning behavior in which GP is used as a learning constraint to interact with the CRFs model estimation.

One of our main objectives is to bias CRFs model's learning on unlabeled data, under a non-linear GP constraint encoding the bilingual knowledge. This is accomplished by the posterior regularization (PR) framework (Ganchev et

al., 2010). PR performs regularization on posteriors, so that the learned model itself remains simple and tractable, while during learning it is driven to obey the constraints through setting appropriate parameters. The closest prior study is constrained learning, or learning with prior knowledge. Chang et al. (2008) described constraint driven learning (CODL) that augments model learning on unlabeled data by adding a cost for violating expectations of constraint features designed by domain knowledge. Mann and McCallum (2008) and McCallum et al. (2007) proposed to employ generalized expectation criteria (GE) to specify preferences about model expectations in the form of linear constraints on some feature expectations.

3 Methodology

This work aims at building a CWS model adapted to the SMT task. The model induction is shown in Algorithm 1. The input data requires two types of training resources, segmented Chinese sentences from treebank $\mathcal{D}_l^c$ and parallel unsegmented sentences of Chinese and foreign language $\mathcal{D}_u^c$ and $\mathcal{D}_u^f$. The first step is to conduct character-based alignment over bitexts $\mathcal{D}_u^c$ and $\mathcal{D}_u^f$, where every Chinese character is an alignment target. Here, we are interested on n-to-1 alignment patterns, i.e., one target word is aligned to one or more source Chinese characters. The second step aims to collect word boundary distributions for all types, i.e., character-level trigrams, according to the n-to-1 mappings (Section 3.1). The third step is to encode the induced word boundary information into a k-nearest-neighbors (k-NN) similarity graph constructed over the entire set of types from $\mathcal{D}_l^c$ and $\mathcal{D}_u^c$ (Section 3.2). The final step trains a discriminative sequential labeling model, conditional random fields, on $\mathcal{D}_l^c$ and $\mathcal{D}_u^c$ under bilingual constraints in a graph propagation expression (Section 3.3). This constrained learning is carried out based on posterior regularization (PR) framework (Ganchev et al., 2010).

3.1 Word Boundaries Learned from Character-based Alignments

The gainful supervisions toward a better segmentation solution for SMT are naturally extracted from MT training resources, i.e., bilingual parallel data. This study employs an approximated method introduced in (Xu et al., 2004; Ma and Way, 2009; Chung and Gildea, 2009) to learn bilingual segmentation knowledge. This relies on statistical character-based alignment: first, every Chinese character in the bitexts is divided by a white space so that individual characters are regarded as special "words" or alignment targets, and second, they are connected with English words by using a statistical word aligner, e.g., GIZA++ (Och and Ney, 2003). Note that the aligner is restricted to use an n-to-1 alignment pattern. The primary idea is that consecutive Chinese characters are grouped to a candidate word, if they are aligned to the same foreign word. It is worth mentioning that prior works presented a straightforward usage for candidate words, treating them as golden segmentations, either dictionary units or labeled resources. But this study treats the induced candidate words in a different way. We propose to extract the word boundary distributions[1] for character-level trigrams (*type*)[2], as shown in Figure 1, instead of the very specific words. There are two main reasons to do so. First, it is a more general expression which can reduce the impact amplification of erroneous character alignments. Second, boundary distributions can play more flexible roles as constraints over labelings to bias the model learning.

The type-level word boundary extraction is formally described as follows. Given the ith sentence pair $\langle x_i^c, x_i^f, \mathcal{A}_i^{c\rightarrow f}\rangle$ of the aligned bilingual corpus $\mathcal{D}^{c\leftrightarrow f}$, the Chinese sentence x_i^c consisting of m characters $\{x_{i,1}^c, x_{i,2}^c, ..., x_{i,m}^c\}$, and the foreign language sentence x_i^f, consisting of

[1] The distribution is on four word boundary labels indicating the character positions in a word, i.e., **B** (begin), **M** (middle), **E** (end) and **S** (single character).

[2] A word boundary distribution corresponds to the center character of a type. In fact, it aims at reducing label ambiguities to collect boundary information of character trigrams, rather than individual characters (Altun et al., 2006).

n words $\{x^f_{i,1}, x^f_{i,2}, ..., x^f_{i,n}\}$, $\mathcal{A}^{c\to f}_i$ represents a set of alignment pairs $a_j = \langle C_j, x^f_{i,j}\rangle$ that defines connections between a few Chinese characters $C_j = \{x^c_{i,j_1}, x^c_{i,j_2}, ..., x^c_{i,j_k}\}$ and a single foreign word $x^f_{i,j}$. For an alignment $a_j = \langle C_j, x^f_{i,j}\rangle$, only the sequence of characters $C_j = \{x^c_{i,j_1}, x^c_{i,j_2}, ..., x^c_{i,j_k}\}$ $\forall d \in [1, k-1], j_{d+1} - j_d = 1$ constitutes a valid candidate word. For the whole bilingual corpus, we assign each character in the candidate words with a word boundary tag $T \in \{B, M, E, S\}$, and then count across the entire corpus to collect the tag distributions $r_i = \{r_{i,t}; t \in T\}$ for each type $x^c_{i,j-1}x^c_{i,j}x^c_{i,j+1}$.

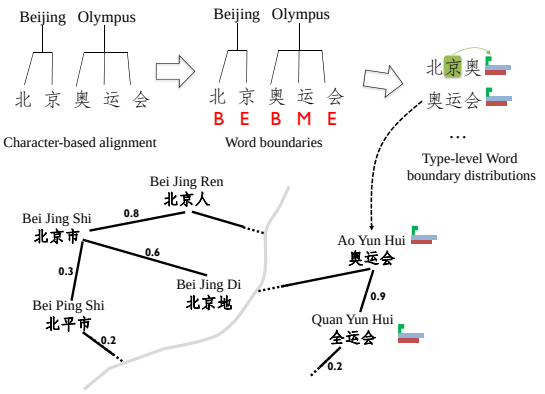

Figure 1: An example of similarity graph over character-level trigrams (types).

3.2 Constraints Encoded by Graph Propagation Expression

The previous step contributes to generate bilingual segmentation supervisions, i.e., type-level word boundary distributions. An intuitive manner is to directly leverage the induced boundary distributions as label constraints to regularize segmentation model learning, based on a constrained learning algorithm. This study, however, makes further efforts to elevate the positive effects of the bilingual knowledge via the graph propagation technique. We adopt a similarity graph to encode the learned type-level word boundary distributions. The GP expression will be defined as a PR constraint in Section 3.3 that reflects the interactions between the graph and the CRFs model. In other words, GP is integrated with estimation of parametric structural model. This is greatly different from the prior pipelined approaches (Subramanya et al., 2010; Das and Petrov, 2011; Zeng et al., 2013), where GP is run first and its propagated outcomes are then used to bias the structural model. This work seeks to capture the GP benefits during the modeling of sequential correlations.

In what follows, the graph setting and propagation expression are introduced. As in conventional GP examples (Das and Smith, 2012), a similarity graph $\mathcal{G} = (V, E)$ is constructed over N types extracted from Chinese training data, including treebank $\mathcal{D}^c_l$ and bitexts $\mathcal{D}^c_u$. Each vertex V_i has a $|T|$-dimensional estimated measure $v_i = \{v_{i,t}; t \in T\}$ representing a probability distribution on word boundary tags. The induced type-level word boundary distributions $r_i = \{r_{i,t}; t \in T\}$ are empirical measures for the corresponding M graph vertices. The edges $E \in V_i \times V_j$ connect all the vertices. Scores between pairs of graph vertices (types), w_{ij}, refer to the similarities of their syntactic environment, which are computed following the method in (Subramanya et al., 2010; Das and Petrov, 2011; Zeng et al., 2013). The similarities are measured based on co-occurrence statistics over a set of predefined features (introduced in Section 4.1). Specifically, the point-wise mutual information (PMI) values, between vertices and each feature instantiation that they have in common, are summed to sparse vectors, and their cosine distances are computed as the similarities. The nature of this similarity graph enforces that the connected types with high weights appearing in different texts should have similar word boundary distributions.

The quality (smoothness) of the similarity graph can be estimated by using a standard propagation function, as shown in Equation 1. The square-loss criterion (Zhu et al., 2003; Bengio et al., 2006) is used to formulate this function:

$$\mathcal{P}(v) = \sum_{t=1}^{T}\Bigg(\sum_{i=1}^{M}(v_{i,t} - r_{i,t})^2 + \mu\sum_{j=1}^{N}\sum_{i=1}^{N} w_{ij}(v_{i,t} - v_{j,t})^2 + \rho\sum_{i=1}^{N}(v_{i,t})^2\Bigg) \quad (1)$$

The first term in this equation refers to seed matches that compute the distances between the estimated measure v_i and the empirical probabilities r_i. The second term refers to edge smoothness that measures how vertices v_i are smoothed with respect to the graph. Two types connected by an edge with high weight should be assigned similar word boundary distributions. The third term, a ℓ_2 norm, evaluates the distribution sparsity (Das and

Smith, 2012) per vertex. Typically, the GP process amounts to an optimization process with respect to parameter v such that Equation 1 is minimized. This propagation function can be used to reflect the graph smoothness, where the higher the score, the lower the smoothness.

3.3 PR Learning with GP Constraint

Our learning problem belongs to semi-supervised learning (SSL), as the training is done on treebank labeled data $(\mathrm{X}_L, \mathrm{Y}_L) = \{(\mathrm{x}_1, \mathrm{y}_1), ..., (\mathrm{x}_l, \mathrm{y}_l)\}$, and bilingual unlabeled data $(\mathrm{X}_U) = \{\mathrm{x}_1, ..., \mathrm{x}_u\}$ where $\mathrm{x}_i = \{x^1, ..., x^m\}$ is an input word sequence and $\mathrm{y}_i = \{y^1, ..., y^m\}, y \in T$ is its corresponding label sequence. Supervised linear-chain CRFs can be modeled in a standard conditional log-likelihood objective with a Gaussian prior:

$$\mathcal{L}(\theta) = p_\theta(\mathrm{y}_i|\mathrm{x}_i) - \frac{\|\theta\|^2}{2\sigma} \tag{2}$$

The conditional probabilities p_θ are expressed as a log-linear form:

$$p_\theta(\mathrm{y}_i|\mathrm{x}_i) = \frac{\exp(\sum_{k=1}^{m} \theta^{\mathrm{T}} f(y_i^{k-1}, y_i^k, \mathrm{x}_i))}{Z_\theta(\mathrm{x}_i)} \tag{3}$$

Where $Z_\theta(\mathrm{x}_i)$ is a partition function that normalizes the exponential form to be a probability distribution, and $f(y_i^{k-1}, y_i^k, \mathrm{x}_i)$ are arbitrary feature functions.

In our setting, the CRFs model is required to learn from unlabeled data. This work employs the posterior regularization (PR) framework[3] (Ganchev et al., 2010) to bias the CRFs model's learning on unlabeled data, under a constraint encoded by the graph propagation expression. It is expected that similar types in the graph should have approximated expected taggings under the CRFs model. We follow the approach introduced by (He et al., 2013) to set up a penalty-based PR objective with GP: the CRFs likelihood is modified by adding a regularization term, as shown in Equation 4, representing the constraints:

$$\mathcal{R}_U(\theta, q) = \mathrm{KL}(q||p_\theta) + \lambda \mathcal{P}(v) \tag{4}$$

Rather than regularize CRFs model's posteriors $p_\theta(\mathcal{Y}|\mathrm{x}_i)$ directly, our model uses an auxiliary distribution $q(\mathcal{Y}|\mathrm{x}_i)$ over the possible labelings $\mathcal{Y}$ for x_i, and penalizes the CRFs marginal log-likelihood by a **KL-divergence** term[4], representing the distance between the estimated posteriors p and the desired posteriors q, as well as a **penalty** term, formed by the GP function. The hyperparameter λ is used to control the impacts of the penalty term. Note that the penalty is fired if the graph score computed based on the expected taggings given by the current CRFs model is increased vis-a-vis the previous training iteration. This nature requires that the penalty term $\mathcal{P}(v)$ should be formed as a function of posteriors q over CRFs model predictions[5], i.e., $\mathcal{P}(q)$. To state this, a mapping $\mathcal{M} : (\{1, ..., u\}, \{1, ..., m\}) \rightarrow V$ from words in the corpus to vertices in the graph is defined. We can thus decompose $v_{i,t}$ into a function of q as follows:

$$v_{i,t} = \frac{\sum_{a=1}^{u} \sum_{\substack{b=1; \\ \mathcal{M}(a,b)=V_i}}^{m} \sum_{c=1}^{T} \sum_{y \in \mathcal{Y}} \mathbf{1}(y^b = t, y^{b-1} = c) q(\mathrm{y}|\mathrm{x}_a)}{\sum_{a=1}^{u} \sum_{b=1}^{m} \mathbf{1}(\mathcal{M}(a,b) = V_i)} \tag{5}$$

The final learning objective combines the CRFs likelihood with the PR regularization term: $\mathcal{J}(\theta, q) = \mathcal{L}(\theta) + \mathcal{R}_U(\theta, q)$. This joint objective, over θ and q, can be optimized by an expectation maximization (EM) style algorithm as reported in (Ganchev et al., 2010). We start from initial parameters θ^0, estimated by supervised CRFs model training on treebank data. The E-step is to minimize $\mathcal{R}_U(\theta, q)$ over the posteriors q that are constrained to the probability simplex. Since the penalty term $\mathcal{P}(v)$ is a non-linear form, the optimization method in (Ganchev et al., 2010) via projected gradient descent on the dual is inefficient[6]. This study follows the optimization method (He et al., 2013) that uses exponentiated gradient descent (EGD) algorithm. It allows that the variable update expression, as shown in Equation 6, takes a multiplicative rather than an additive form.

$$q^{(w+1)}(\mathrm{y}|\mathrm{x}_i) = q^{(w)}(\mathrm{y}|\mathrm{x}_i) \exp(-\eta \frac{\partial \mathcal{R}}{\partial q^{(w)}(\mathrm{y}|\mathrm{x}_i)}) \tag{6}$$

where the parameter η controls the optimization rate in the E-step. With the contributions from

[3]The readers are refered to the original paper of Ganchev et al. (2010).

[4]The form of KL term: $\mathrm{KL}(q||p) = \sum_{q \in \mathcal{Y}} q(\mathrm{y}) \log \frac{q(\mathrm{y})}{p(\mathrm{y})}$.

[5]The original PR setting also requires that the penalty term should be a linear (Ganchev et al., 2010) or non-linear (He et al., 2013) function on q.

[6]According to (He et al., 2013), the dual of quadratic program implies an expensive matrix inverse.

the E-step that further encourage q and p to agree, the M-step aims to optimize the objective $\mathcal{J}(\theta, q)$ with respect to θ. The M-step is similar to the standard CRFs parameter estimation, where the gradient ascent approach still works. This EM-style approach monotonically increases $\mathcal{J}(\theta, q)$ and thus is guaranteed to converge to a local optimum.

$$\begin{aligned}\textbf{E-step:}\quad & q^{(t+1)} = \arg\min_{q} \mathcal{R}_U(\theta^{(t)}, q^{(t)}) \\ \textbf{M-step:}\quad & \theta^{(t+1)} = \arg\max_{\theta} \mathcal{L}(\theta) \\ & + \delta \sum_{i=1}^{u} \sum_{\mathrm{y} \in \mathcal{Y}} q^{(t+1)}(\mathrm{y}|\mathrm{x}_i) \log p_\theta(\mathrm{y}|\mathrm{x}_i)\end{aligned} \tag{7}$$

4 Experiments

4.1 Data and Setup

The experiments in this study evaluated the performances of various CWS models in a Chinese-to-English translation task. The influence of the word segmentation on the final translation is our main investigation. We adopted three state-of-the-art metrics, BLEU (Papineni et al., 2002), NIST (Doddington et al., 2000) and METEOR (Banerjee and Lavie, 2005), to evaluate the translation quality.

The monolingual segmented data, $\mathrm{train}_{\mathrm{TB}}$, is extracted from the Penn Chinese Treebank (CTB-7) (Xue et al., 2005), containing 51,447 sentences. The bilingual training data, $\mathrm{train}_{\mathrm{MT}}$, is formed by a large in-house Chinese-English parallel corpus (Tian et al., 2014). There are in total 2,244,319 Chinese-English sentence pairs crawled from online resources, concentrated in 5 different domains including *laws*, *novels*, *spoken*, *news* and *miscellaneous*[7]. This in-house bilingual corpus is the MT training data as well. The target-side language model is built on over 35 million monolingual English sentences, $\mathrm{train}_{\mathrm{LM}}$, crawled from online resources. The NIST evaluation campaign data, MT-03 and MT-05, are selected to comprise the MT development data, $\mathrm{dev}_{\mathrm{MT}}$, and testing data, $\mathrm{test}_{\mathrm{MT}}$, respectively.

For the settings of our model, we adopted the standard feature templates introduced by Zhao et al. (2006) for CRFs. The character-based alignment for achieving the "chars-to-word" mappings is accomplished by GIZA++ aligner (Och and Ney, 2003). For the GP, a 10-NNs similarity graph was constructed[8]. Following (Subramanya et al., 2010; Zeng et al., 2013), the features used to compute similarities between vertices were (Suppose given a type "$w_2w_3w_4$" surrounding contexts "$w_1w_2w_3w_4w_5$"): unigram (w_3), bigram (w_1w_2, w_4w_5, w_2w_4), trigram ($w_2w_3w_4$, $w_2w_4w_5$, $w_1w_2w_4$), trigram+context ($w_1w_2w_3w_4w_5$) and character classes in number, punctuation, alphabetic letter and other ($t(w_2)t(w_3)t(w_4)$). There are four hyperparameters in our model to be tuned by using the development data ($\mathrm{dev}_{\mathrm{MT}}$) among the following settings: for the graph propagation, $\mu \in \{0.2, 0.5, 0.8\}$ and $\rho \in \{0.1, 0.3, 0.5, 0.8\}$; for the PR learning, $\lambda \in \{0 \leq \lambda_i \leq 1\}$ and $\sigma \in \{0 \leq \sigma_i \leq 1\}$ where the step is 0.1. The best performed joint settings, $\mu = 0.5, \rho = 0.5, \lambda = 0.9$ and $\sigma = 0.8$, were used to measure the final performance.

The MT experiment was conducted based on a standard log-linear phrase-based SMT model. The GIZA++ aligner was also adopted to obtain word alignments (Och and Ney, 2003) over the segmented bitexts. The heuristic strategy of *grow-diag-final-and* (Koehn et al., 2007) was used to combine the bidirectional alignments for extracting phrase translations and reordering tables. A 5-gram language model with Kneser-Ney smoothing was trained with SRILM (Stolcke, 2002) on monolingual English data. Moses (Koehn et al., 2007) was used as decoder. The Minimum Error Rate Training (MERT) (Och, 2003) was used to tune the feature parameters on development data.

4.2 Various Segmentation Models

To provide a thorough analysis, the MT experiments in this study evaluated three baseline segmentation models and two off-the-shelf models, in addition to four variant models that also employ the bilingual constraints. We start from three baseline models:

- **Character Segmenter (CS)**: this model simply divides Chinese sentences into sequences of characters.
- **Supervised Monolingual Segmenter (SMS)**: this model is trained by CRFs on treebank training data ($\mathrm{train}_{\mathrm{TB}}$). The same feature templates (Zhao et al., 2006) are used. The standard four-tags (**B**, **M**, **E** and **S**) were used

[7]The in-house corpus has been manually validated, in a long process that exceeded 500 hours.

[8]We evaluated graphs with top k (from 3 to 20) nearest neighbors on development data, and found that the performance converged beyond 10-NNs.

as the labels. The stochastic gradient descent is adopted to optimize the parameters.

- **Unsupervised Bilingual Segmenter (UBS)**: this model is trained on the bitexts (trainMT) following the approach introduced in (Ma and Way, 2009). The optimal set of the model parameter values was found on $\mathrm{dev_{MT}}$ to be $k = 3, t_{AC} = 0.0$ and $t_{COOC} = 15$.

The comparison candidates also involve two popular off-the-shelf segmentation models:

- **Stanford Segmenter**: this model, trained by Chang et al. (2008), treats CWS as a binary word boundary decision task. It covers several features specific to the MT task, e.g., external lexicons and proper noun features.

- **ICTCLAS Segmenter**: this model, trained by Zhang et al. (2003), is a hierarchical HMM segmenter that incorporates parts-of-speech (POS) information into the probability models and generates multiple HMM models for solving segmentation ambiguities.

This work also evaluated four variant models[9] that perform alternative ways to incorporate the bilingual constraints based on two state-of-the-art graph-based SSL approaches.

- **Self-training Segmenters (STS)**: two variant models were defined by the approach reported in (Subramanya et al., 2010) that uses the supervised CRFs model's decodings, incorporating empirical and constraint information, for unlabeled examples as additional labeled data to retrain a CRFs model. One variant (STS-NO-GP) skips the GP step, directly decoding with type-level word boundary probabilities induced from bitexts, while the other (STS-GP-PL) runs the GP at first and then decodes with GP outcomes. The optimal hyperparameter values were found to be: STS-NO-GP ($\alpha = 0.8$) and $\eta = 0.6$) and STS-GP-PL ($\mu = 0.5, \rho = 0.3, \alpha = 0.8$ and $\eta = 0.6$).

- **Virtual Evidences Segmenters (VES)**: Two variant models based on the approach in (Zeng et al., 2013) were defined. The type-level word boundary distributions, induced by the character-based alignment (VES-NO-GP), and the graph propagation (VES-GP-PL), are regarded as virtual evidences to bias CRFs model's learning on the unlabeled data. The optimal hyperparameter values were found to be: VES-NO-GP ($\alpha = 0.7$) and VES-GP-PL ($\mu = 0.5, \rho = 0.3$ and $\alpha = 0.7$).

[9]Note that there are two variant models working with GP. To be fair, the same similarity graph settings introduced in this paper were used.

4.3 Main Results

Table 1 summarizes the final MT performance on the MT-05 test data, evaluated with ten different CWS models. In what follows, we summarized four major observations from the results. Firstly, as expected, having word segmentation does help Chinese-to-English MT. All other nine CWS models outperforms the CS baseline which does not try to identify Chinese words at all. Secondly, the other two baselines, SMS and UBS, are on a par with each other, showing less than 0.36 average performance differences on the three evaluation metrics. This outcome validated that the models, trained by either the treebank or the bilingual data, performed reasonably well. But they only capture partial segmentation features so that less gains for SMT are achieved when comparing to other sophisticated models. Thirdly, we notice that the two off-the-shelf models, Stanford and ICTCLAS, just brought minor improvements over the SMS baseline, although they are trained using richer supervisions. This behaviour illustrates that the conventional optimizations to the monolingual supervised model, e.g., accumulating more supervised data or predefined segmentation properties, are insufficient to help model for achieving better segmentations for SMT. Finally, highlighting the five models working with the bilingual constraints, most of them can achieve significant gains over the other ones without using the bilingual constraints. This strongly demonstrates that bilingually-learned segmentation knowledge does helps CWS for SMT. The models working with G-P, STS-GP-PL, VES-GP-PL and ours outperform all others. We attribute this to the role of GP in assisting the spread of bilingual knowledge on the Chinese side. Importantly, it can be observed that our model outperforms STS-GP, VES-GP, which greatly supports that joint learning of CRFs and GP can alleviate the error transfer by the pipelined models. This is one of the most crucial findings in this study. Overall, the boldface numbers in the last row illustrate that our model obtains average improvements of 1.89, 1.76 and 1.61 on BLEU,

NIST and METEOR over others.

Models	BLEU	NIST	METEOR
CS	29.38	59.85	54.07
SMS	30.05	61.33	55.95
UBS	30.15	61.56	55.39
Stanford	30.40	61.94	56.01
ICTCLAS	30.29	61.26	55.72
STS-NO-GP	31.47	62.35	56.12
STS-GP-PL	31.94	63.20	57.09
VES-NO-GP	31.98	62.63	56.59
VES-GP-PL	32.04	63.49	57.34
Our Model	**32.75**	**63.72**	**57.64**

4.4 Analysis & Discussion

This section aims to further analyze the three primary observations concluded in Section 4.3: i) word segmentation is useful to SMT; ii) the treebank and the bilingual segmentation knowledge are helpful, performing segmentation of different nature; and iii) the bilingual constraints lead to learn segmentations better tailored for SMT.

The first observation derives from the comparisons between the CS baseline and other models. Our results, showing the significant CWS benefits to SMT, are consistent with the works reported in the literature (Xu et al., 2004; Chang et al., 2008). In our experiment, two additional evidences found in the translation model are provided to further support that NO tokenization of Chinese (i.e., the CS model's output) could harm the MT system. First, the SMT phrase extraction, i.e., building "phrases" on top of the character sequences, cannot fully capture all meaningful segmentations produced by the CS model. The character based model leads to missing some useful longer phrases, and to generate many meaningless or redundant translations in the phrase table. Moreover, it is affected by translation ambiguities, caused by the cases where a Chinese character has very different meanings in different contextual environments.

The second observation shifts the emphasis to SMS and UBS, based on the treebank and the bilingual segmentation, respectively. Our results show that both segmentation patterns can bring positive effects to MT. Through analyzing both models' segmentations for $\mathrm{train}_{\mathrm{MT}}$ and $\mathrm{test}_{\mathrm{MT}}$, we attempted to get a closer inspection on the segmentation preferences and their influence on MT. Our first finding is that the segmentation consensuses between SMS and UBS are positive to MT. There have about 35% identical segmentations produced by the two models. If these identical segmentations are removed, and the experiments are rerun, the translation scores decrease (on average) by 0.50, 0.85 and 0.70 on BLEU, NIST and METEOR, respectively. Our second finding is that SMS exhibits better segmentation consistency than UBS. One representative example is the segmentations for "孤零零 (lonely)". All the outputs of SMS were "孤零零", while UBS generated three ambiguous segmentations, "孤(alone)_零零(double zero)", "孤 零(lonely)_零(zero)" and "孤(alone)_零(zero)_零(zero)". The segmentation consistency of SMS rests on the high-quality treebank data and the robust CRFs tagging model. On the other hand, the advantage of UBS is to capture the segmentations matching the aligned target words. For example, UBS grouped "国(country)_际(border)_间(between)" to a word "国 际 间(international)", rather than two words "国际(international)_间(between)" (as given by SMS), since these three characters are aligned to a single English word "international". The above analysis shows that SMS and UBS have their own merits and combining the knowledge derived from both segmentations is highly encouraged.

The third observation concerns the great impact of the bilingual constraints to the segmentation models in the MT task. The use of the bilingual constraints is the prime objective of this study. Our first contribution for this purpose is on using the word boundary distributions to capture the bilingual segmentation supervisions. This representation contributes to reduce the negative impacts of erroneous "chars-to-word" alignments. The ambiguous types (having relatively uniform boundary distribution), caused by alignment errors, cannot directly bias the model tagging preferences. Furthermore, the word boundary distributions are convenient to make up the learning constraints over the labelings among various constrained learning approaches. They have successfully played in three types of constraints for our experiments: PR penalty (Our model), decoding constraints in self-training (STS) and virtual evidences (VES). The second contribution is the use of GP, illustrated by STS-GP-PL, VES-GP-PL and

Our model. The major effect is to multiply the impacts of the bilingual knowledge through the similarity graph. The graph vertices (types)[10], without any supervisions, can learn the word boundary information from their similar types (neighborhoods) having the empirical boundary probabilities. The segmentations given by the three GP models show about 70% positive segmentation changes, affected by the unlabeled graph vertices, with respect to the ones given by the NO-GP models, STS-NO-GP and VES-NO-GP. In our opinion, the learning mechanism of our approach, joint coupling of GP and CRFs, rather than the pipelined one as the other two models, contributes to maximizing the graph smoothness effects to the CRFs estimation so that the error propagation of the pipelined approaches is alleviated.

5 Conclusion

This paper proposed a novel CWS model for the SMT task. This model aims to maintain the linguistic segmentation supervisions from treebank data and simultaneously integrate useful bilingual segmentations induced from the bitexts. This objective is accomplished by three main steps: 1) learn word boundaries from character-based alignments; 2) encode the learned word boundaries into a GP constraint; and 3) training a CRFs model, under the GP constraint, by using the PR framework. The empirical results indicate that the proposed model can yield better segmentations for SMT.

Abstract

Recent work has shown success in using neural network language models (NNLMs) as features in MT systems. Here, we present a novel formulation for a neural network *joint* model (NNJM), which augments the NNLM with a source context window. Our model is purely lexicalized and can be integrated into any MT decoder. We also present several variations of the NNJM which provide significant additive improvements.

Although the model is quite simple, it yields strong empirical results. On the NIST OpenMT12 Arabic-English condition, the NNJM features produce a gain of +3.0 BLEU on top of a powerful, feature-rich baseline which already includes a target-only NNLM. The NNJM features also produce a gain of +6.3 BLEU on top of a simpler baseline equivalent to Chiang's (2007) original Hiero implementation.

Additionally, we describe two novel techniques for overcoming the historically high cost of using NNLM-style models in MT decoding. These techniques speed up NNJM computation by a factor of 10,000x, making the model as fast as a standard back-off LM.

This work was supported by DARPA/I2O Contract No. HR0011-12-C-0014 under the BOLT program (Approved for Public Release, Distribution Unlimited). 1 Introduction

In recent years, neural network models have become increasingly popular in NLP. Initially, these models were primarily used to create n-gram neural network language models (NNLMs) for speech recognition and machine translation (Bengio et al., 2003; Schwenk, 2010). They have since been extended to translation modeling, parsing, and many other NLP tasks.

In this paper we use a basic neural network architecture and a lexicalized probability model to create a powerful MT decoding feature. Specifically, we introduce a novel formulation for a neural network joint model (NNJM), which augments an n-gram target language model with an m-word source window. Unlike previous approaches to joint modeling (Le et al., 2012), our feature can be easily integrated into any statistical machine translation (SMT) decoder, which leads to substantially larger improvements than k-best rescoring only. Additionally, we present several variations of this model which provide significant additive BLEU gains.

We also present a novel technique for training the neural network to be *self-normalized*, which avoids the costly step of posteriorizing over the entire vocabulary in decoding. When used in conjunction with a *pre-computed* hidden layer, these techniques speed up NNJM computation by a factor of 10,000x, with only a small reduction on MT accuracy.

Although our model is quite simple, we obtain strong empirical results. We show primary results on the NIST OpenMT12 Arabic-English condition. The NNJM features produce an improvement of +3.0 BLEU on top of a baseline that is already better than the 1st place MT12 result and includes

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1370–1380,
Baltimore, Maryland, USA, June 23-25 2014.

a powerful NNLM. Additionally, on top of a simpler decoder equivalent to Chiang's (2007) original Hiero implementation, our NNJM features are able to produce an improvement of +6.3 BLEU – as much as all of the other features in our strong baseline system combined.

We also show strong improvements on the NIST OpenMT12 Chinese-English task, as well as the DARPA BOLT (Broad Operational Language Translation) Arabic-English and Chinese-English conditions.

2 Neural Network Joint Model (NNJM)

Formally, our model approximates the probability of target hypothesis T conditioned on source sentence S. We follow the standard n-gram LM decomposition of the target, where each target word t_i is conditioned on the previous $n-1$ target words. To make this a *joint* model, we also condition on source context vector $\mathcal{S}_i$:

$$P(T|S) \approx \Pi_{i=1}^{|T|} P(t_i|t_{i-1}, \cdots, t_{i-n+1}, \mathcal{S}_i)$$

Intuitively, we want to define $\mathcal{S}_i$ as the window that is most relevant to t_i. To do this, we first say that each target word t_i is *affiliated* with exactly one source word at index a_i. $\mathcal{S}_i$ is then the m-word source window centered at a_i:

$$\mathcal{S}_i = s_{a_i - \frac{m-1}{2}}, \cdots, s_{a_i}, \cdots, s_{a_i + \frac{m-1}{2}}$$

This notion of *affiliation* is derived from the word alignment, but unlike word alignment, each target word must be affiliated with exactly one non-NULL source word. The affiliation heuristic is very simple:

(1) If t_i aligns to exactly one source word, a_i is the index of the word it aligns to.
(2) If t_i align to multiple source words, a_i is the index of the aligned word in the middle.[1]
(3) If t_i is unaligned, we inherit its affiliation from the closest aligned word, with preference given to the right.[2]

An example of the NNJM context model for a Chinese-English parallel sentence is given in Figure 1.

For all of our experiments we use $n = 4$ and $m = 11$. It is clear that this model is effectively an $(n+m)$-gram LM, and a 15-gram LM would be far too sparse for standard probability models such as Kneser-Ney back-off (Kneser and Ney, 1995) or Maximum Entropy (Rosenfeld, 1996). Fortunately, neural network language models are able to elegantly scale up and take advantage of arbitrarily large context sizes.

2.1 Neural Network Architecture

Our neural network architecture is almost identical to the original feed-forward NNLM architecture described in Bengio et al. (2003).

The input vector is a 14-word context vector (3 target words, 11 source words), where each word is mapped to a 192-dimensional vector using a shared mapping layer. We use two 512-dimensional hidden layers with $tanh$ activation functions. The output layer is a softmax over the entire output vocabulary.

The input vocabulary contains 16,000 source words and 16,000 target words, while the output vocabulary contains 32,000 target words. The vocabulary is selected by frequency-sorting the words in the parallel training data. Out-of-vocabulary words are mapped to their POS tag (or `OOV`, if POS is not available), and in this case $P(POS_i|t_{i-1}, \cdots)$ is used directly without further normalization. Out-of-bounds words are represented with special tokens `<src>`, `</src>`, `<trg>`, `</trg>`.

We chose these values for the hidden layer size, vocabulary size, and source window size because they seemed to work best on our data sets – larger sizes did not improve results, while smaller sizes degraded results. Empirical comparisons are given in Section 6.5.

2.2 Neural Network Training

The training procedure is identical to that of an NNLM, except that the parallel corpus is used instead of a monolingual corpus. Formally, we seek to maximize the log-likelihood of the training data:

$$L = \sum_i \log(P(x_i))$$

where x_i is the training sample, with one sample for every target word in the parallel corpus.

Optimization is performed using standard back propagation with stochastic gradient ascent (LeCun et al., 1998). Weights are randomly initialized in the range of $[-0.05, 0.05]$. We use an initial learning rate of 10^{-3} and a minibatch size of

[1] We arbitrarily round down.

[2] We have found that the affiliation heuristic is robust to small differences, such as left vs. right preference.

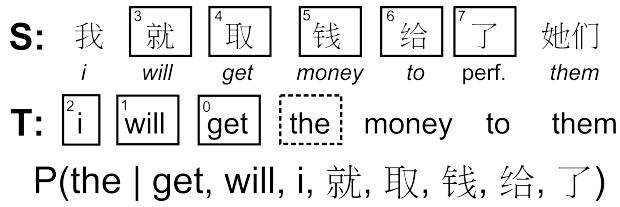

Figure 1: Context vector for target word "the", using a 3-word target history and a 5-word source window (i.e., $n = 4$ and $m = 5$). Here, "the" inherits its affiliation from "money" because this is the first aligned word to its right. The number in each box denotes the index of the word in the context vector. This indexing must be consistent across samples, but the absolute ordering does not affect results.

128.[3] At every epoch, which we define as 20,000 minibatches, the likelihood of a validation set is computed. If this likelihood is worse than the previous epoch, the learning rate is multiplied by 0.5. The training is run for 40 epochs. The training data ranges from 10-30M words, depending on the condition. We perform a basic weight update with no L2 regularization or momentum. However, we have found it beneficial to clip each weight update to the range of [-0.1, 0.1], to prevent the training from entering degenerate search spaces (Pascanu et al., 2012).

Training is performed on a single Tesla K10 GPU, with each epoch (128*20k = 2.6M samples) taking roughly 1100 seconds to run, resulting in a total training time of ∼12 hours. Decoding is performed on a CPU.

2.3 Self-Normalized Neural Network

The computational cost of NNLMs is a significant issue in decoding, and this cost is dominated by the output softmax over the entire target vocabulary. Even class-based approaches such as Le et al. (2012) require a 2-20k shortlist vocabulary, and are therefore still quite costly.

Here, our goal is to be able to use a fairly large vocabulary without word classes, and to simply avoid computing the entire output layer at decode time.[4] To do this, we present the novel technique of *self-normalization*, where the output layer scores are close to being probabilities without explicitly performing a softmax.

Formally, we define the standard softmax log likelihood as:

$$\begin{aligned} \log(P(x)) &= \log\left(\frac{e^{U_r(x)}}{Z(x)}\right) \\ &= U_r(x) - \log(Z(x)) \\ Z(x) &= \Sigma_{r'=1}^{|V|} e^{U_{r'}(x)} \end{aligned}$$

where x is the sample, U is the raw output layer scores, r is the output layer row corresponding to the observed target word, and $Z(x)$ is the softmax normalizer.

If we could guarantee that $\log(Z(x))$ were always equal to 0 (i.e., $Z(x)$ = 1) then at decode time we would only have to compute row r of the output layer instead of the whole matrix. While we cannot train a neural network with this guarantee, we can *explicitly encourage* the log-softmax normalizer to be as close to 0 as possible by augmenting our training objective function:

$$\begin{aligned} L &= \sum_i \left[\log(P(x_i)) - \alpha(\log(Z(x_i)) - 0)^2\right] \\ &= \sum_i \left[\log(P(x_i)) - \alpha \log^2(Z(x_i))\right] \end{aligned}$$

In this case, the output layer bias weights are initialized to $\log(1/|V|)$, so that the initial network is self-normalized. At decode time, we simply use $U_r(x)$ as the feature score, rather than $\log(P(x))$. For our NNJM architecture, self-normalization increases the lookup speed during decoding by a factor of ∼15x.

Table 1 shows the neural network training results with various values of the free parameter α. In all subsequent MT experiments, we use $\alpha = 10^{-1}$.

We should note that Vaswani et al. (2013) implements a method called Noise Contrastive Estimation (NCE) that is also used to train self-normalized NNLMs. Although NCE results in faster training time, it has the downside that there

[3] We do *not* divide the gradient by the minibatch size. For those who do, this is equivalent to using an initial learning rate of $10^{-3} * 128 \approx 10^{-1}$.

[4] We are not concerned with speeding up training time, as we already find GPU training time to be adequate.

Arabic BOLT Val		
α	$\log(P(x))$	$\lvert\log(Z(x))\rvert$
0	-1.82	5.02
10^{-2}	-1.81	1.35
10^{-1}	-1.83	0.68
1	-1.91	0.28

Table 1: Comparison of neural network likelihood for various α values. $\log(P(x))$ is the average log-likelihood on a held-out set. $|\log(Z(x))|$ is the mean error in log-likelihood when using $U_r(x)$ directly instead of the true softmax probability $\log(P(x))$. Note that $\alpha = 0$ is equivalent to the standard neural network objective function.

is no mechanism to control the degree of self-normalization. By contrast, our α parameter allows us to carefully choose the optimal trade-off between neural network accuracy and mean self-normalization error. In future work, we will thoroughly compare self-normalization vs. NCE.

2.4 Pre-Computing the Hidden Layer

Although self-normalization significantly improves the speed of NNJM lookups, the model is still several orders of magnitude slower than a back-off LM. Here, we present a "trick" for pre-computing the first hidden layer, which further increases the speed of NNJM lookups by a factor of 1,000x.

Note that this technique only results in a significant speedup for self-normalized, feed-forward, NNLM-style networks with *one* hidden layer. We demonstrate in Section 6.6 that using one hidden layer instead of two has minimal effect on BLEU.

For the neural network described in Section 2.1, computing the first hidden layer requires multiplying a 2689-dimensional input vector[5] with a 2689×512 dimensional hidden layer matrix. However, note that there are only 3 possible positions for each target word, and 11 for each source word. Therefore, for every word in the vocabulary, and for each position, we can pre-compute the dot product between the word embedding and the first hidden layer. These are computed offline and stored in a lookup table, which is <500MB in size.

Computing the first hidden layer now only requires 15 scalar additions for each of the 512 hidden rows – one for each word in the input vector, plus the bias. This can be reduced to just 5 scalar additions by pre-summing each 11-word source window when starting a test sentence. If our neural network has only one hidden layer and is self-normalized, the only remaining computation is 512 calls to $tanh()$ and a single 513-dimensional dot product for the final output score.[6] Thus, only ∼3500 arithmetic operations are required per n-gram lookup, compared to ∼2.8M for self-normalized NNJM without pre-computation, and ∼35M for the standard NNJM.[7]

Neural Network Speed		
Condition	lookups/sec	sec/word
Standard	110	10.9
+ Self-Norm	1500	0.8
+ Pre-Computation	1,430,000	0.0008

Table 2: Speed of the neural network computation on a single CPU thread. "lookups/sec" is the number of unique n-gram probabilities that can be computed per second. "sec/word" is the amortized cost of unique NNJM lookups in decoding, per source word.

Table 2 shows the speed of self-normalization and pre-computation for the NNJM. The decoding cost is based on a measurement of ∼1200 unique NNJM lookups per source word for our Arabic-English system.[8]

By combining self-normalization and pre-computation, we can achieve a speed of 1.4M lookups/second, which is on par with fast back-off LM implementations (Tanaka et al., 2013). We demonstrate in Section 6.6 that using the self-normalized/pre-computed NNJM results in only a very small BLEU degradation compared to the standard NNJM.

3 Decoding with the NNJM

Because our NNJM is fundamentally an n-gram NNLM with additional source context, it can easily be integrated into any SMT decoder. In this section, we describe the considerations that must be taken when integrating the NNJM into a hierarchical decoder.

[5] 2689 = 14 words × 192 dimensions + 1 bias

[6] $tanh()$ is implemented using a lookup table.

[7] $3500 \approx 5 \times 512 + 2 \times 513$; $2.8\text{M} \approx 2 \times 2689 \times 512 + 2 \times 513$; $35\text{M} \approx 2 \times 2689 \times 512 + 2 \times 513 \times 32000$. For the sake of a fair comparison, these all use one hidden layer. A second hidden layer adds 0.5M floating point operations.

[8] This does not include the cost of *duplicate* lookups within the same test sentence, which are cached.

3.1 Hierarchical Parsing

When performing hierarchical decoding with an n-gram LM, the leftmost and rightmost $n-1$ words from each constituent must be stored in the state space. Here, we extend the state space to also include the index of the affiliated source word for these edge words. This does not noticeably increase the search space. We also train a separate lower-order n-gram model, which is necessary to compute estimate scores during hierarchical decoding.

3.2 Affiliation Heuristic

For aligned target words, the normal affiliation heuristic can be used, since the word alignment is available within the rule. For unaligned words, the normal heuristic can also be used, *except* when the word is on the edge of a rule, because then the target neighbor words are not necessarily known.

In this case, we infer the affiliation from the rule structure. Specifically, if unaligned target word t is on the right edge of an arc that covers source span $[s_i, s_j]$, we simply say that t is affiliated with source word s_j. If t is on the left edge of the arc, we say it is affiliated with s_i.

4 Model Variations

Recall that our NNJM feature can be described with the following probability:

$$\Pi_{i=1}^{|T|} P(t_i | t_{i-1}, t_{i-2}, \cdots, s_{a_i}, s_{a_i-1}, s_{a_i+1}, \cdots)$$

This formulation lends itself to several natural variations. In particular, we can reverse the translation direction of the languages, as well as the direction of the language model.

We denote our original formulation as a source-to-target, left-to-right model (**S2T/L2R**). We can train three variations using target-to-source (T2S) and right-to-left (R2L) models:

S2T/R2L

$$\Pi_{i=1}^{|T|} P(t_i | t_{i+1}, t_{i+2}, \cdots, s_{a_i}, s_{a_i-1}, s_{a_i+1}, \cdots)$$

T2S/L2R

$$\Pi_{i=1}^{|S|} P(s_i | s_{i-1}, s_{i-2}, \cdots, t_{a'_i}, t_{a'_i-1}, t_{a'_i+1}, \cdots)$$

T2S/R2L

$$\Pi_{i=1}^{|S|} P(s_i | s_{i+1}, s_{i+2}, \cdots, t_{a'_i}, t_{a'_i-1}, t_{a'_i+1}, \cdots)$$

where a'_i is the target-to-source affiliation, defined analogously to a_i.

The T2S variations cannot be used in decoding due to the large target context required, and are thus only used in k-best rescoring. The S2T/R2L variant could be used in decoding, but we have not found this beneficial, so we only use it in rescoring.

4.1 Neural Network Lexical Translation Model (NNLTM)

One issue with the S2T NNJM is that the probability is computed over every *target* word, so it does not explicitly model NULL-aligned source words. In order to assign a probability to every source word during decoding, we also train a neural network lexical translation model (NNLMT).

Here, the input context is the 11-word source window centered at s_i, and the output is the target token t_{s_i} which s_i aligns to. The probability is computed over every *source* word in the input sentence. We treat NULL as a normal target word, and if a source word aligns to multiple target words, it is treated as a single concatenated token. Formally, the probability model is:

$$\Pi_{i=1}^{|S|} P(t_{s_i} | s_i, s_{i-1}, s_{i+1}, \cdots)$$

This model is trained and evaluated like our NNJM. It is easy and computationally inexpensive to use this model in decoding, since only one neural network computation must be made for each source word.

In rescoring, we also use a T2S NNLTM model computed over every target word:

$$\Pi_{i=1}^{|T|} P(s_{t_i} | t_i, t_{i-1}, t_{i+1}, \cdots)$$

5 MT System

In this section, we describe the MT system used in our experiments.

5.1 MT Decoder

We use a state-of-the-art string-to-dependency hierarchical decoder (Shen et al., 2010). Our baseline decoder contains a large and powerful set of features, which include:

- Forward and backward rule probabilities
- 4-gram Kneser-Ney LM
- Dependency LM (Shen et al., 2010)
- Contextual lexical smoothing (Devlin, 2009)
- Length distribution (Shen et al., 2010)
- Trait features (Devlin and Matsoukas, 2012)
- Factored source syntax (Huang et al., 2013)
- 7 sparse feature types, totaling 50k features (Chiang et al., 2009)
- LM adaptation (Snover et al., 2008)

We also perform 1000-best rescoring with the following features:

- 5-gram Kneser-Ney LM
- Recurrent neural network language model (RNNLM) (Mikolov et al., 2010)

Although we consider the RNNLM to be part of our baseline, we give it special treatment in the results section because we would expect it to have the highest overlap with our NNJM.

5.2 Training and Optimization

For Arabic word tokenization, we use the MADA-ARZ tokenizer (Habash et al., 2013) for the BOLT condition, and the Sakhr[9] tokenizer for the NIST condition. For Chinese tokenization, we use a simple longest-match-first lexicon-based approach.

For word alignment, we align all of the training data with both GIZA++ (Och and Ney, 2003) and NILE (Riesa et al., 2011), and concatenate the corpora together for rule extraction.

For MT feature weight optimization, we use iterative k-best optimization with an Expected-BLEU objective function (Rosti et al., 2010).

6 Experimental Results

We present MT primary results on Arabic-English and Chinese-English for the NIST OpenMT12 and DARPA BOLT conditions. We also present a set of auxiliary results in order to further analyze our features.

6.1 NIST OpenMT12 Results

Our NIST system is fully compatible with the OpenMT12 constrained track, which consists of 10M words of high-quality parallel training for Arabic, and 25M words for Chinese.[10] The Kneser-Ney LM is trained on 5B words of data from English GigaWord. For test, we use the "Arabic-To-English Original Progress Test" (1378 segments) and "Chinese-to-English Original Progress Test + OpenMT12 Current Test" (2190 segments), which consists of a mix of newswire and web data.[11] All test segments have 4 references. Our tuning set contains 5000 segments, and is a mix of the MT02-05 eval set as well as held-out parallel training.

[9] http://www.sakhr.com

[10] We also make weak use of 30M-100M words of UN data + ISI comparable corpora, but this data provides almost no benefit.

+ Other NNJMs (Resc)	49.7	32.2

Table 3: Primary results on Arabic-English and Chinese-English NIST MT12 Test Set. The first section corresponds to the top and bottom ranked systems from the evaluation, and are taken from the NIST website. The second section corresponds to results on top of our strongest baseline. The third section corresponds to results on top of a simpler baseline. Within each section, each row includes all of the features from previous rows. BLEU scores are mixed-case.

Results are shown in the second section of Table 3. On Arabic-English, the primary S2T/L2R NNJM gains +1.4 BLEU on top of our baseline, while the S2T NNLTM gains another +0.8, and the directional variations gain +0.8 BLEU more. This leads to a total improvement of +3.0 BLEU from the NNJM and its variations. Considering that our baseline is already +0.3 BLEU better than the 1st place result of MT12 and contains a strong RNNLM, we consider this to be quite an extraordinary improvement.[12]

For the Chinese-English condition, there is an improvement of +0.8 BLEU from the primary NNJM and +1.3 BLEU overall. Here, the baseline system is already +0.8 BLEU better than the

[12] Note that the official 1st place OpenMT12 result was our own system, so we can assure that these comparisons are accurate.

best MT12 system. The smaller improvement on Chinese-English compared to Arabic-English is consistent with the behavior of our baseline features, as we show in the next section.

6.2 "Simple Hierarchical" NIST Results

The baseline used in the last section is a highly-engineered research system, which uses a wide array of features that were refined over a number of years, and some of which require linguistic resources. Because of this, the baseline BLEU scores are much higher than a typical MT system – especially a real-time, production engine which must support many language pairs.

Therefore, we also present results using a simpler version of our decoder which emulates Chiang's original Hiero implementation (Chiang, 2007). Specifically, this means that we don't use dependency-based rule extraction, and our decoder only contains the following MT features: (1) rule probabilities, (2) n-gram Kneser-Ney LM, (3) lexical smoothing, (4) target word count, (5) concat rule penalty.

Results are shown in the third section of Table 3. The "Simple Hierarchical" Arabic-English system is -6.4 BLEU worse than our strong baseline, and would have ranked 10th place out of 11 systems in the evaluation. When the NNJM features are added to this system, we see an improvement of +6.3 BLEU, which would have ranked 1st place in the evaluation.

Effectively, this means that for Arabic-English, the NNJM features are equivalent to the combined improvements from the string-to-dependency model plus all of the features listed in Section 5.1.

For Chinese-English, the "Simple Hierarchical" system only degrades by -3.2 BLEU compared to our strongest baseline, and the NNJM features produce a gain of +2.1 BLEU on top of that.

6.3 BOLT Web Forum Results

DARPA BOLT is a major research project with the goal of improving translation of informal, dialectical Arabic and Chinese into English. The BOLT domain presented here is "web forum," which was crawled from various Chinese and Egyptian Internet forums by LDC. The BOLT parallel training consists of all of the high-quality NIST training, plus an additional 3 million words of translated forum data provided by LDC. The tuning and test sets consist of roughly 5000 segments each, with 2 references for Arabic and 3 for Chinese.

Results are shown in Table 4. The baseline here uses the same feature set as the strong NIST system. On Arabic, the total gain is +2.6 BLEU, while on Chinese, the gain is +1.3 BLEU.

BOLT Test		
	Ar-En	**Ch-En**
	BLEU	BLEU
Baseline (w/o RNNLM)	40.2	30.6
Baseline (w/ RNNLM)	41.3	30.9
+ S2T/L2R NNJM (Dec)	42.9	31.9
+ S2T NNLTM (Dec)	43.2	31.9
+ Other NNJMs (Resc)	43.9	32.2

Table 4: Primary results on Arabic-English and Chinese-English BOLT Web Forum. Each row includes the aggregate features from all previous rows.

6.4 Effect of k-best Rescoring Only

Table 5 shows performance when our S2T/L2R NNJM is used only in 1000-best rescoring, compared to decoding. The primary purpose of this is as a comparison to Le et al. (2012), whose model can only be used in k-best rescoring.

BOLT Test		
	Ar-En	
	Without RNNLM	**With RNNLM**
	BLEU	BLEU
Baseline	40.2	41.3
S2T/L2R NNJM (Resc)	41.7	41.6
S2T/L2R NNJM (Dec)	42.8	42.9

Table 5: Comparison of our primary NNJM in decoding vs. 1000-best rescoring.

We can see that the rescoring-only NNJM performs very well when used on top of a baseline without an RNNLM (+1.5 BLEU), but the gain on top of the RNNLM is very small (+0.3 BLEU). The gain from the decoding NNJM is large in both cases (+2.6 BLEU w/o RNNLM, +1.6 BLEU w/ RNNLM). This demonstrates that the full power of the NNJM can only be harnessed when it is used in decoding. It is also interesting to see that the RNNLM is no longer beneficial when the NNJM is used.

6.5 Effect of Neural Network Configuration

Table 6 shows results using the S2T/L2R NNJM with various configurations. We can see that reducing the source window size, layer size, or vocab size will all degrade results. Increasing the sizes beyond the default NNJM has almost no effect (102%). Also note that the target-only NNLM (i.e., Source Window=0) only obtains 33% of the improvements of the NNJM.

BOLT Test		
	Ar-En	
	BLEU	**% Gain**
"Simple Hier." Baseline	33.8	-
S2T/L2R NNJM (Dec)	38.4	100%
Source Window=7	38.3	98%
Source Window=5	38.2	96%
Source Window=3	37.8	87%
Source Window=0	35.3	33%
Layers=384x768x768	38.5	102%
Layers=192x512	38.1	93%
Layers=128x128	37.1	72%
Vocab=64,000	38.5	102%
Vocab=16,000	38.1	93%
Vocab=8,000	37.3	83%
Activation=Rectified Lin.	38.5	102%
Activation=Linear	37.3	76%

Table 6: Results with different neural network architectures. The "default" NNJM in the second row uses these parameters: SW=11, L=192x512x512, V=32,000, A=tanh. All models use a 3-word target history (i.e., 4-gram LM). "Layers" refers to the size of the word embedding followed by the hidden layers. "Vocab" refers to the size of the input and output vocabularies. "% Gain" is the BLEU gain over the baseline relative to the default NNJM.

6.6 Effect of Speedups

All previous results use a self-normalized neural network with two hidden layers. In Table 7, we compare this to using a standard network (with two hidden layers), as well as a pre-computed neural network.[13] The "Simple Hierarchical" baseline is used here because it more closely approximates a real-time MT engine. For the sake of speed, these experiments only use the S2T/L2R NNJM+S2T NNLTM.

[13]The difference in score for self-normalized vs. pre-computed is *entirely* due to two vs. one hidden layers.

Each result from Table 7 corresponds to a row in Table 2 of Section 2.4. We can see that going from the standard model to the pre-computed model only reduces the BLEU improvement from +6.4 to +6.1, while increasing the NNJM lookup speed by a factor of 10,000x.

BOLT Test		
	Ar-En	
	BLEU	**Gain**
"Simple Hier." Baseline	33.8	-
Standard NNJM	40.2	+6.4
Self-Norm NNJM	40.1	+6.3
Pre-Computed NNJM	39.9	+6.1

Table 7: Results for the standard NNs vs. self-normalized NNs vs. pre-computed NNs.

In Table 2 we showed that the cost of unique lookups for the pre-computed NNJM is only $\sim$0.001 seconds per source word. This does not include the cost of n-gram creation or cached lookups, which amount to $\sim$0.03 seconds per source word in our current implementation.[14] However, the n-grams created for the NNJM can be shared with the Kneser-Ney LM, which reduces the cost of that feature. Thus, the total cost *increase* of using the NNJM+NNLTM features in decoding is only $\sim$0.01 seconds per source word.

In future work we will provide more detailed analysis regarding the usability of the NNJM in a low-latency, high-throughput MT engine.

7 Related Work

Although there has been a substantial amount of past work in lexicalized joint models (Marino et al., 2006; Crego and Yvon, 2010), nearly all of these papers have used older statistical techniques such as Kneser-Ney or Maximum Entropy. However, not only are these techniques intractable to train with high-order context vectors, they also lack the neural network's ability to semantically generalize (Mikolov et al., 2013) and learn non-linear relationships.

A number of recent papers have proposed methods for creating neural network translation/joint models, but nearly all of these works have obtained much smaller BLEU improvements than ours. For each related paper, we will briefly con-

[14]In our decoder, roughly 95% of NNJM n-gram lookups within the same sentence are duplicates.

trast their methodology with our own and summarize their BLEU improvements using scores taken directly from the cited paper.

Auli et al. (2013) use a *fixed* continuous-space source representation, obtained from LDA (Blei et al., 2003) or a source-only NNLM. Also, their model is recurrent, so it cannot be used in decoding. They obtain +0.2 BLEU improvement on top of a target-only NNLM (25.6 vs. 25.8).

Schwenk (2012) predicts an entire target phrase at a time, rather than a word at a time. He obtains +0.3 BLEU improvement (24.8 vs. 25.1).

Zou et al. (2013) estimate context-free bilingual lexical similarity scores, rather than using a large context. They obtain an +0.5 BLEU improvement on Chinese-English (30.0 vs. 30.5).

Kalchbrenner and Blunsom (2013) implement a convolutional recurrent NNJM. They score a 1000-best list using only their model and are able to achieve the same BLEU as using all 12 standard MT features (21.8 vs 21.7). However, additive results are not presented.

The most similar work that we know of is Le et al. (2012). Le's basic procedure is to re-order the source to match the linear order of the target, and then segment the hypothesis into minimal bilingual phrase pairs. Then, he predicts each target word given the previous bilingual phrases. However, Le's formulation could only be used in k-best rescoring, since it requires long-distance reordering and a large target context.

Le's model does obtain an impressive +1.7 BLEU gain on top of a baseline without an NNLM (25.8 vs. 27.5). However, when compared to the strongest baseline which includes an NNLM, Le's best models (S2T + T2S) only obtain an +0.6 BLEU improvement (26.9 vs. 27.5). This is consistent with our rescoring-only result, which indicates that k-best rescoring is too shallow to take advantage of the power of a joint model.

Le's model also uses minimal phrases rather than being purely lexicalized, which has two main downsides: (a) a number of complex, hand-crafted heuristics are required to define phrase boundaries, which may not transfer well to new languages, (b) the effective vocabulary size is much larger, which substantially increases data sparsity issues.

We should note that our best results use six separate models, whereas all previous work only uses one or two models. However, we have demonstrated that we can obtain 50%-80% of the total improvement with only one model (S2T/L2R NNJM), and 70%-90% with only two models (S2T/L2R NNJM + S2T NNLTM). Thus, the one and two-model conditions still significantly outperform any past work.

8 Discussion

We have described a novel formulation for a neural network-based machine translation joint model, along with several simple variations of this model. When used as MT decoding features, these models are able to produce a gain of +3.0 BLEU on top of a very strong and feature-rich baseline, as well as a +6.3 BLEU gain on top of a simpler system.

Our model is remarkably simple – it requires no linguistic resources, no feature engineering, and only a handful of hyper-parameters. It also has no reliance on potentially fragile outside algorithms, such as unsupervised word clustering. We consider the simplicity to be a major advantage. Not only does this suggest that it will generalize well to new language pairs and domains, but it also suggests that it will be straightforward for others to replicate these results.

Overall, we believe that the following factors set us apart from past work and allowed us to obtain such significant improvements:

1. The ability to use the NNJM in decoding rather than rescoring.
2. The use of a large bilingual context vector, which is provided to the neural network in "raw" form, rather than as the output of some other algorithm.
3. The fact that the model is purely lexicalized, which avoids both data sparsity and implementation complexity.
4. The large size of the network architecture.
5. The directional variation models.

One of the biggest goals of this work is to quell any remaining doubts about the utility of neural networks in machine translation. We believe that there are large areas of research yet to be explored. For example, creating a new type of decoder centered around a purely lexicalized neural network model. Our short term ideas include using more interesting types of context in our input vector (such as source syntax), or using the NNJM to model syntactic/semantic structure of the target.

Low-Rank Tensors for Scoring Dependency Structures

Tao Lei, Yu Xin, Yuan Zhang, Regina Barzilay, and Tommi Jaakkola
Computer Science and Artificial Intelligence Laboratory

Abstract

Accurate scoring of syntactic structures such as head-modifier arcs in dependency parsing typically requires rich, high-dimensional feature representations. A small subset of such features is often selected manually. This is problematic when features lack clear linguistic meaning as in embeddings or when the information is blended across features. In this paper, we use tensors to map high-dimensional feature vectors into low dimensional representations. We explicitly maintain the parameters as a low-rank tensor to obtain low dimensional representations of words in their syntactic roles, and to leverage modularity in the tensor for easy training with online algorithms. Our parser consistently outperforms the Turbo and MST parsers across 14 different languages. We also obtain the best published UAS results on 5 languages.[1]

1 Introduction

Finding an expressive representation of input sentences is crucial for accurate parsing. Syntactic relations manifest themselves in a broad range of surface indicators, ranging from morphological to lexical, including positional and part-of-speech (POS) tagging features. Traditionally, parsing research has focused on modeling the direct connection between the features and the predicted syntactic relations such as head-modifier (arc) relations in dependency parsing. Even in the case of first-order parsers, this results in a high-dimensional vector representation of each arc. Discrete features, and their cross products, can be further complemented with auxiliary information about words participating in an arc, such as continuous vector representations of words. The exploding dimensionality of rich feature vectors must then be balanced with the difficulty of effectively learning the associated parameters from limited training data.

A predominant way to counter the high dimensionality of features is to manually design or select a meaningful set of feature templates, which are used to generate different types of features (McDonald et al., 2005a; Koo and Collins, 2010; Martins et al., 2013). Direct manual selection may be problematic for two reasons. First, features may lack clear linguistic interpretation as in distributional features or continuous vector embeddings of words. Second, designing a small subset of templates (and features) is challenging when the relevant linguistic information is distributed across the features. For instance, morphological properties are closely tied to part-of-speech tags, which in turn relate to positional features. These features are not redundant. Therefore, we may suffer a performance loss if we select only a small subset of the features. On the other hand, by including all the rich features, we face over-fitting problems.

We depart from this view and leverage high-dimensional feature vectors by mapping them into low dimensional representations. We begin by representing high-dimensional feature vectors as multi-way cross-products of smaller feature vectors that represent words and their syntactic relations (arcs). The associated parameters are viewed as a tensor (multi-way array) of low rank, and optimized for parsing performance. By explicitly representing the tensor in a low-rank form, we have direct control over the effective dimensionality of the set of parameters. We obtain role-dependent low-dimensional representations for words (head, modifier) that are specifically tailored for parsing accuracy, and use standard online algorithms for optimizing the low-rank tensor components.

The overall approach has clear linguistic and

[1] Our code is available at https://github.com/taolei87/RBGParser.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1381–1391,
Baltimore, Maryland, USA, June 23-25 2014.

computational advantages:

- Our low dimensional embeddings are tailored to the syntactic context of words (head, modifier). This low dimensional syntactic abstraction can be thought of as a proxy to manually constructed POS tags.
- By automatically selecting a small number of dimensions useful for parsing, we can leverage a wide array of (correlated) features. Unlike parsers such as MST, we can easily benefit from auxiliary information (e.g., word vectors) appended as features.

We implement the low-rank factorization model in the context of first- and third-order dependency parsing. The model was evaluated on 14 languages, using dependency data from CoNLL 2008 and CoNLL 2006. We compare our results against the MST (McDonald et al., 2005a) and Turbo (Martins et al., 2013) parsers. The low-rank parser achieves average performance of 89.08% across 14 languages, compared to 88.73% for the Turbo parser, and 87.19% for MST. The power of the low-rank model becomes evident in the absence of any part-of-speech tags. For instance, on the English dataset, the low-rank model trained without POS tags achieves 90.49% on first-order parsing, while the baseline gets 86.70% if trained under the same conditions, and 90.58% if trained with 12 core POS tags. Finally, we demonstrate that the model can successfully leverage word vector representations, in contrast to the baselines.

2 Related Work

Selecting Features for Dependency Parsing A great deal of parsing research has been dedicated to feature engineering (Lazaridou et al., 2013; Marton et al., 2010; Marton et al., 2011). While in most state-of-the-art parsers, features are selected manually (McDonald et al., 2005a; McDonald et al., 2005b; Koo and Collins, 2010; Martins et al., 2013; Zhang and McDonald, 2012a; Rush and Petrov, 2012a), automatic feature selection methods are gaining popularity (Martins et al., 2011b; Ballesteros and Nivre, 2012; Nilsson and Nugues, 2010; Ballesteros, 2013). Following standard machine learning practices, these algorithms iteratively select a subset of features by optimizing parsing performance on a development set. These feature selection methods are particularly promising in parsing scenarios where the optimal feature set is likely to be a small subset of the original set of candidate features. Our technique, in contrast, is suitable for cases where the relevant information is distributed across a larger set of related features.

Embedding for Dependency Parsing A lot of recent work has been done on mapping words into vector spaces (Collobert and Weston, 2008; Turian et al., 2010; Dhillon et al., 2011; Mikolov et al., 2013). Traditionally, these vector representations have been derived primarily from co-occurrences of words within sentences, ignoring syntactic roles of the co-occurring words. Nevertheless, any such word-level representation can be used to offset inherent sparsity problems associated with full lexicalization (Cirik and Şensoy, 2013). In this sense they perform a role similar to POS tags.

Word-level vector space embeddings have so far had limited impact on parsing performance. From a computational perspective, adding non-sparse vectors directly as features, including their combinations, can significantly increase the number of active features for scoring syntactic structures (e.g., dependency arc). Because of this issue, Cirik and Şensoy (2013) used word vectors only as unigram features (without combinations) as part of a shift reduce parser (Nivre et al., 2007). The improvement on the overall parsing performance was marginal. Another application of word vectors is compositional vector grammar (Socher et al., 2013). While this method learns to map word combinations into vectors, it builds on existing word-level vector representations. In contrast, we represent words as vectors in a manner that is directly optimized for parsing. This framework enables us to learn new syntactically guided embeddings while also leveraging separately estimated word vectors as starting features, leading to improved parsing performance.

Dimensionality Reduction Many machine learning problems can be cast as matrix problems where the matrix represents a set of co-varying parameters. Such problems include, for example, multi-task learning and collaborative filtering. Rather than assuming that each parameter can be set independently of others, it is helpful to assume that the parameters vary in a low dimensional subspace that has to be estimated together with the parameters. In terms of the parameter matrix, this corresponds to a low-rank assumption. Low-rank constraints are commonly used for improving

generalization (Lee and Seung, 1999; Srebro et al., 2003; Srebro et al., 2004; Evgeniou and Pontil, 2007)

A strict low-rank assumption can be restrictive. Indeed, recent approaches to matrix problems decompose the parameter matrix as a sum of low-rank and sparse matrices (Tao and Yuan, 2011; Zhou and Tao, 2011). The sparse matrix is used to highlight a small number of parameters that should vary independently even if most of them lie on a low-dimensional subspace (Waters et al., 2011; Chandrasekaran et al., 2011). We follow this decomposition while extending the parameter matrix into a tensor.

Tensors are multi-way generalizations of matrices and possess an analogous notion of rank. Tensors are increasingly used as tools in spectral estimation (Hsu and Kakade, 2013), including in parsing (Cohen et al., 2012) and other NLP problems (de Cruys et al., 2013), where the goal is to avoid local optima in maximum likelihood estimation. In contrast, we expand features for parsing into a multi-way tensor, and operate with an explicit low-rank representation of the associated parameter tensor. The explicit representation sidesteps inherent complexity problems associated with the tensor rank (Hillar and Lim, 2009). Our parameters are divided into a sparse set corresponding to manually chosen MST or Turbo parser features and a larger set governed by a low-rank tensor.

3 Problem Formulation

We will commence here by casting first-order dependency parsing as a tensor estimation problem. We will start by introducing the notation used in the paper, followed by a more formal description of our dependency parsing task.

3.1 Basic Notations

Let $A \in \mathbb{R}^{n \times n \times d}$ be a 3-dimensional tensor (a 3-way array). We denote each element of the tensor as $A_{i,j,k}$ where $i \in [n], j \in [n], k \in [d]$ and $[n]$ is a shorthand for the set of integers $\{1, 2, \cdots, n\}$. Similarly, we use $M_{i,j}$ and u_i to represent the elements of matrix M and vector u, respectively.

We define the *inner product* of two tensors (or matrices) as $\langle A, B \rangle = \text{vec}(A)^T \text{vec}(B)$, where $\text{vec}(\cdot)$ concatenates the tensor (or matrix) elements into a column vector. The *squared norm* of a tensor/matrix is denoted by $\|A\|^2 = \langle A, A \rangle$.

The *Kronecker product* of three vectors is denoted by $u \otimes v \otimes w$ and forms a rank-1 tensor such that

$$(u \otimes v \otimes w)_{i,j,k} = u_i v_j w_k.$$

Note that the vectors u, v, and w may be column or row vectors. Their orientation is defined based on usage. For example, $u \otimes v$ is a rank-1 matrix uv^T when u and v are column vectors ($u^T v$ if they are row vectors).

We say that tensor A is in Kruskal form if

$$A = \sum_{i=1}^{r} U(i,:) \otimes V(i,:) \otimes W(i,:) \qquad (1)$$

where $U, V \in \mathbb{R}^{r \times n}$, $W \in \mathbb{R}^{r \times d}$ and $U(i,:)$ is the i^{th} row of matrix U. We will directly learn a low-rank tensor A (because r is small) in this form as one of our model parameters.

3.2 Dependency Parsing

Let x be a sentence and $\mathcal{Y}(x)$ the set of possible dependency trees over the words in x. We assume that the score $S(x, y)$ of each candidate dependency tree $y \in \mathcal{Y}(x)$ decomposes into a sum of "local" scores for arcs. Specifically:

$$S(x, y) = \sum_{h \to m \in y} s(h \to m) \qquad \forall y \in \mathcal{Y}(x)$$

where $h \to m$ is the head-modifier dependency arc in the tree y. Each y is understood as a collection of arcs $h \to m$ where h and m index words in x.[2] For example, $x(h)$ is the word corresponding to h. We suppress the dependence on x whenever it is clear from context. For example, $s(h \to m)$ can depend on x in complicated ways as discussed below. The predicted parse is obtained as $\hat{y} = \arg\max_{y \in \mathcal{Y}(x)} S(x, y)$.

A key problem is how we parameterize the arc scores $s(h \to m)$. Following the MST parser (McDonald et al., 2005a) we can define rich features characterizing each head-modifier arc, compiled into a sparse binary vector $\phi_{h \to m} \in \mathbb{R}^L$ that depends on the sentence x as well as the chosen arc $h \to m$ (again, we suppress the dependence on x). Based on this feature representation, we define the score of each arc as $s_\theta(h \to m) =$

[2] Note that in the case of high-order parsing, the sum $S(x, y)$ may also include local scores for other syntactic structures, such as grandhead-head-modifier score $s(g \to h \to m)$. See (Martins et al., 2013) for a complete list of these structures.

Unigram features:		
form	form-p	form-n
lemma	lemma-p	lemma-n
pos	pos-p	pos-n
morph	bias	
Bigram features:		
pos-p, pos		
pos, pos-n		
pos, lemma		
morph, lemma		
Trigram features:		
pos-p, pos, pos-n		

Table 1: Word feature templates used by our model. pos, form, lemma and morph stand for the fine POS tag, word form, word lemma and the morphology feature (provided in CoNLL format file) of the current word. There is a bias term that is always active for any word. The suffixes -p and -n refer to the left and right of the current word respectively. For example, pos-p means the POS tag to the left of the current word in the sentence.

$\langle \theta, \phi_{h \to m} \rangle$ where $\theta \in \mathbb{R}^L$ represent adjustable parameters to be learned, and L is the number of parameters (and possible features in $\phi_{h \to m}$).

We can alternatively specify arc features in terms of rank-1 tensors by taking the Kronecker product of simpler feature vectors associated with the head (vector $\phi_h \in \mathbb{R}^n$), and modifier (vector $\phi_m \in \mathbb{R}^n$), as well as the arc itself (vector $\phi_{h,m} \in \mathbb{R}^d$). Here $\phi_{h,m}$ is much lower dimensional than the MST arc feature vector $\phi_{h \to m}$ discussed earlier. For example, $\phi_{h,m}$ may be composed of only indicators for binned arc lengths[3]. ϕ_h and ϕ_m, on the other hand, are built from features shown in Table 1. By taking the cross-product of all these component feature vectors, we obtain the full feature representation for arc $h \to m$ as a rank-1 tensor

$$\phi_h \otimes \phi_m \otimes \phi_{h,m} \in \mathbb{R}^{n \times n \times d}$$

Note that elements of this rank-1 tensor include feature combinations that are not part of the feature crossings in $\phi_{h \to m}$. In this sense, the rank-1 tensor represents a substantial feature expansion. The arc score $s_{tensor}(h \to m)$ associated with the tensor representation is defined analogously as

$$s_{tensor}(h \to m) = \langle A, \phi_h \otimes \phi_m \otimes \phi_{h,m} \rangle$$

where the adjustable parameters A also form a tensor. Given the typical dimensions of the component feature vectors, ϕ_h, ϕ_m, $\phi_{h,m}$, it is not even possible to store all the parameters in A. Indeed, in the full English training set of CoNLL-2008, the tensor involves around 8×10^{11} entries while the MST feature vector has approximately 1.5×10^7 features. To counter this feature explosion, we restrict the parameters A to have low rank.

Low-Rank Dependency Scoring We can represent a rank-r tensor A explicitly in terms of parameter matrices U, V, and W as shown in Eq. 1. As a result, the arc score for the tensor reduces to evaluating $U\phi_h$, $V\phi_m$, and $W\phi_{h,m}$ which are all r dimensional vectors and can be computed efficiently based on any sparse vectors ϕ_h, ϕ_m, and $\phi_{h,m}$. The resulting arc score $s_{tensor}(h \to m)$ is then

$$\sum_{i=1}^{r} [U\phi_h]_i [V\phi_m]_i [W\phi_{h,m}]_i \qquad (2)$$

By learning parameters U, V, and W that function well in dependency parsing, we also learn context-dependent embeddings for words and arcs. Specifically, $U\phi_h$ (for a given sentence, suppressed) is an r dimensional vector representation of the word corresponding to h as a head word. Similarly, $V\phi_m$ provides an analogous representation for a modifier m. Finally, $W\phi_{h,m}$ is a vector embedding of the supplemental arc-dependent information. The resulting embedding is therefore tied to the syntactic roles of the words (and arcs), and learned in order to perform well in parsing.

We expect a dependency parsing model to benefit from several aspects of the low-rank tensor scoring. For example, we can easily incorporate additional useful features in the feature vectors ϕ_h, ϕ_m and $\phi_{h,m}$, since the low-rank assumption (for small enough r) effectively counters the otherwise uncontrolled feature expansion. Moreover, by controlling the amount of information we can extract from each of the component feature vectors (via rank r), the statistical estimation problem does not scale dramatically with the dimensions of ϕ_h, ϕ_m and $\phi_{h,m}$. In particular, the low-rank constraint can help generalize to unseen arcs. Consider a feature $\delta(x(h) = a) \cdot \delta(x(m) =$

[3] In our current version, $\phi_{h,m}$ only contains the binned arc length. Other possible features include, for example, the label of the arc $h \to m$, the POS tags between the head and the modifier, boolean flags which indicate the occurence of in-between punctutations or conjunctions, etc.

$b) \cdot \delta(dis(x,h,m) = c)$ which is non-zero only for an arc $a \rightarrow b$ with distance c in sentence x. If the arc has not been seen in the available training data, it does not contribute to the traditional arc score $s_\theta(\cdot)$. In contrast, with the low-rank constraint, the arc score in Eq. 2 would typically be non-zero.

Combined Scoring Our parsing model aims to combine the strengths of both traditional features from the MST/Turbo parser as well as the new low-rank tensor features. In this way, our model is able to capture a wide range of information including the auxiliary features without having uncontrolled feature explosion, while still having the full accessibility to the manually engineered features that are proven useful. Specifically, we define the arc score $s_\gamma(h \rightarrow m)$ as the combination

$$\begin{aligned}
&(1-\gamma) s_{tensor}(h \rightarrow m) + \gamma s_\theta(h \rightarrow m) \\
&= (1-\gamma) \sum_{i=1}^{r} [U\phi_h]_i [V\phi_m]_i [W\phi_{h,m}]_i \\
&+ \gamma \langle \theta, \phi_{h \rightarrow m} \rangle \qquad (3)
\end{aligned}$$

where $\theta \in \mathbb{R}^L$, $U \in \mathbb{R}^{r \times n}$, $V \in \mathbb{R}^{r \times n}$, and $W \in \mathbb{R}^{r \times d}$ are the model parameters to be learned. The rank r and $\gamma \in [0,1]$ (balancing the two scores) represent hyper-parameters in our model.

4 Learning

The training set $D = \{(\hat{x}_i, \hat{y}_i)\}_{i=1}^N$ consists of N pairs, where each pair consists of a sentence x_i and the corresponding gold (target) parse y_i. The goal is to learn values for the parameters θ, U, V and W that optimize the combined scoring function $S_\gamma(x,y) = \sum_{h \rightarrow m \in y} s_\gamma(h \rightarrow m)$, defined in Eq. 3, for parsing performance. We adopt a maximum soft-margin framework for this learning problem. Specifically, we find parameters θ, U, V, W, and $\{\xi_i\}$ that minimize

$$\begin{aligned}
&C \sum_i \xi_i + \|\theta\|^2 + \|U\|^2 + \|V\|^2 + \|W\|^2 \\
&\text{s.t.} \quad S_\gamma(\hat{x}_i, \hat{y}_i) \geq S_\gamma(\hat{x}_i, y_i) + \|\hat{y}_i - y_i\|_1 - \xi_i \\
&\qquad \forall y_i \in \mathcal{Y}(\hat{x}_i),\ \forall i. \qquad (4)
\end{aligned}$$

where $\|\hat{y}_i - y_i\|_1$ is the number of mismatched arcs between the two trees, and ξ_i is a non-negative slack variable. The constraints serve to separate the gold tree from other alternatives in $\mathcal{Y}(\hat{x}_i)$ with a margin that increases with distance.

The objective as stated is not jointly convex with respect to U, V and W due to our explicit representation of the low-rank tensor. However, if we fix any two sets of parameters, for example, if we fix V and W, then the combined score $S_\gamma(x,y)$ will be a linear function of both θ and U. As a result, the objective will be jointly convex with respect to θ and U and could be optimized using standard tools. However, to accelerate learning, we adopt an online learning setup. Specifically, we use the passive-aggressive learning algorithm (Crammer et al., 2006) tailored to our setting, updating pairs of parameter sets, (θ, U), (θ, V) and (θ, W) in an alternating manner. This method is described below.

Online Learning In an online learning setup, we update parameters successively based on each sentence. In order to apply the passive-aggressive algorithm, we fix two of U, V and W (say, for example, V and W) in an alternating manner, and apply a closed-form update to the remaining parameters (here U and θ). This is possible since the objective function with respect to (θ, U) has a similar form as in the original passive-aggressive algorithm. To illustrate this, consider a training sentence x_i. The update involves finding first the best competing tree,

$$\tilde{y}_i = \arg\max_{y_i \in \mathcal{Y}(\hat{x}_i)} S_\gamma(\hat{x}_i, y_i) + \|\hat{y}_i - y_i\|_1 \qquad (5)$$

which is the tree that violates the constraint in Eq. 4 most (i.e. maximizes the loss ξ_i). We then obtain parameter increments $\Delta\theta$ and ΔU by solving

$$\begin{aligned}
&\min_{\Delta\theta,\ \Delta U,\ \xi \geq 0} \quad \frac{1}{2}\|\Delta\theta\|^2 + \frac{1}{2}\|\Delta U\|^2 + C\xi \\
&\text{s.t.} \quad S_\gamma(\hat{x}_i, \hat{y}_i) \geq S_\gamma(\hat{x}_i, \tilde{y}_i) + \|\hat{y}_i - \tilde{y}_i\|_1 - \xi
\end{aligned}$$

In this way, the optimization problem attempts to keep the parameter change as small as possible, while forcing it to achieve mostly zero loss on this single instance. This problem has a closed form solution

$$\begin{aligned}
\Delta\theta &= \min\left\{C, \frac{\text{loss}}{\gamma^2\|d\theta\|^2 + (1-\gamma)^2\|du\|^2}\right\} \gamma d\theta \\
\Delta U &= \min\left\{C, \frac{\text{loss}}{\gamma^2\|d\theta\|^2 + (1-\gamma)^2\|du\|^2}\right\} (1-\gamma) du
\end{aligned}$$

where

$$\begin{aligned}
\text{loss} &= S_\gamma(\hat{x}_i, \tilde{y}_i) + \|\hat{y}_i - \tilde{y}_i\|_1 - S_\gamma(\hat{x}_i, \hat{y}_i) \\
d\theta &= \sum_{h \to m \in \hat{y}_i} \phi_{h \to m} - \sum_{h \to m \in \tilde{y}_i} \phi_{h \to m} \\
du &= \sum_{h \to m \in \hat{y}_i} [(V\phi_m) \odot (W\phi_{h,m})] \otimes \phi_h \\
&- \sum_{h \to m \in \tilde{y}_i} [(V\phi_m) \odot (W\phi_{h,m})] \otimes \phi_h
\end{aligned}$$

where $(u \odot v)_i = u_i v_i$ is the Hadamard (element-wise) product. The magnitude of change of θ and U is controlled by the parameter C. By varying C, we can determine an appropriate step size for the online updates. The updates also illustrate how γ balances the effect of the MST component of the score relative to the low-rank tensor score. When $\gamma = 0$, the arc scores are entirely based on the low-rank tensor and $\Delta\theta = 0$. Note that ϕ_h, ϕ_m, $\phi_{h,m}$, and $\phi_{h \to m}$ are typically very sparse for each word or arc. Therefore du and $d\theta$ are also sparse and can be computed efficiently.

Initialization The alternating online algorithm relies on how we initialize U, V, and W since each update is carried out in the context of the other two. A random initialization of these parameters is unlikely to work well, both due to the dimensions involved, and the nature of the alternating updates. We consider here instead a reasonable deterministic "guess" as the initialization method.

We begin by training our model without any low-rank parameters, and obtain parameters θ. The majority of features in this MST component can be expressed as elements of the feature tensor, i.e., as $[\phi_h \otimes \phi_m \otimes \phi_{h,m}]_{i,j,k}$. We can therefore create a tensor representation of θ such that $B_{i,j,k}$ equals the corresponding parameter value in θ. We use a low-rank version of B as the initialization. Specifically, we unfold the tensor B into a matrix $B^{(h)}$ of dimensions n and nd, where $n = dim(\phi_h) = dim(\phi_m)$ and $d = dim(\phi_{h,m})$. For instance, a rank-1 tensor can be unfolded as $u \otimes v \otimes w = u \otimes \text{vec}(v \otimes w)$. We compute the top-r SVD of the resulting unfolded matrix such that $B^{(h)} = P^T S Q$. U is initialized as P. Each right singular vector $S_i Q(i,:)$ is also a matrix in $\mathbb{R}^{n \times d}$. The leading left and right singular vectors of this matrix are assigned to $V(i,:)$ and $W(i,:)$ respectively. In our implementation, we run one epoch of our model without low-rank parameters and initialize the tensor A.

Parameter Averaging The passive-aggressive algorithm regularizes the increments (e.g. $\Delta\theta$ and ΔU) during each update but does not include any overall regularization. In other words, keeping updating the model may lead to large parameter values and over-fitting. To counter this effect, we use parameter averaging as used in the MST and Turbo parsers. The final parameters are those averaged across all the iterations (cf. (Collins, 2002)). For simplicity, in our algorithm we average U, V, W and θ separately, which works well empirically.

5 Experimental Setup

Datasets We test our dependency model on 14 languages, including the English dataset from CoNLL 2008 shared tasks and all 13 datasets from CoNLL 2006 shared tasks (Buchholz and Marsi, 2006; Surdeanu et al., 2008). These datasets include manually annotated dependency trees, POS tags and morphological information. Following standard practices, we encode this information as features.

Methods We compare our model to MST and Turbo parsers on non-projective dependency parsing. For our parser, we train both a first-order parsing model (as described in Section 3 and 4) as well as a third-order model. The third order parser simply adds high-order features, those typically used in MST and Turbo parsers, into our $s_\theta(x, y) = \langle \theta, \phi(x, y) \rangle$ scoring component. The decoding algorithm for the third-order parsing is based on (Zhang et al., 2014). For the Turbo parser, we directly compare with the recent published results in (Martins et al., 2013). For the MST parser, we train and test using the most recent version of the code.[4] In addition, we implemented two additional baselines, NT-1st (first order) and NT-3rd (third order), corresponding to our model without the tensor component.

Features For the arc feature vector $\phi_{h \to m}$, we use the same set of feature templates as MST v0.5.1. For head/modifier vector ϕ_h and ϕ_m, we show the complete set of feature templates used by our model in Table 1. Finally, we use a similar set of feature templates as Turbo v2.1 for 3rd order parsing.

To add auxiliary word vector representations, we use the publicly available word vectors (Cirik

Table 2: First-order parsing (left) and high-order parsing (right) results on CoNLL-2006 datasets and the English dataset of CoNLL-2008. For our model, the experiments are ran with rank $r = 50$ and hyper-parameter $\gamma = 0.3$. To remove the tensor in our model, we ran experiments with $\gamma = 1$, corresponding to columns NT-1st and NT-3rd. The last column shows results of most accurate parsers among Nivre et al. (2006), McDonald et al. (2006), Martins et al. (2010), Martins et al. (2011a), Martins et al. (2013), Koo et al. (2010), Rush and Petrov (2012b), Zhang and McDonald (2012b) and Zhang et al. (2013).

and Şensoy, 2013), learned from raw data (Globerson et al., 2007; Maron et al., 2010). Three languages in our dataset – English, German and Swedish – have corresponding word vectors in this collection.[5] The dimensionality of this representation varies by language: English has 50 dimensional word vectors, while German and Swedish have 25 dimensional word vectors. Each entry of the word vector is added as a feature value into feature vectors ϕ_h and ϕ_m. For each word in the sentence, we add its own word vector as well as the vectors of its left and right words.

We should note that since our model parameter A is represented and learned in the low-rank form, we only have to store and maintain the low-rank projections $U\phi_h$, $V\phi_m$ and $W\phi_{h,m}$ rather than explicitly calculate the feature tensor $\phi_h \otimes \phi_m \otimes \phi_{h,m}$. Therefore updating parameters and decoding a sentence is still efficient, i.e., linear in the number of values of the feature vector. In contrast, assume we take the cross-product of the auxiliary word vector values, POS tags and lexical items of a word and its context, and add the crossed values into a normal model (in $\phi_{h \to m}$). The number of features for each arc would be at least quadratic, growing into thousands, and would be a significant impediment to parsing efficiency.

Evaluation Following standard practices, we train our full model and the baselines for 10 epochs. As the evaluation measure, we use unlabeled attachment scores (UAS) excluding punctuation. In all the reported experiments, the hyper-parameters are set as follows: $r = 50$ (rank of the tensor), $C = 1$ for first-order model and $C = 0.01$ for third-order model.

6 Results

Overall Performance Table 2 shows the performance of our model and the baselines on 14 CoNLL datasets. Our model outperforms Turbo parser, MST parser, as well as its own variants without the tensor component. The improvements of our low-rank model are consistent across languages: results for the first order parser are better on 11 out of 14 languages. By comparing NT-1st and NT-3rd (models without low-rank) with our full model (with low-rank), we obtain 0.7% absolute improvement on first-order parsing, and 0.3% improvement on third-order parsing. Our model also achieves the best UAS on 5 languages.

We next focus on the first-order model and gauge the impact of the tensor component. First, we test our model by varying the hyper-parameter γ which balances the tensor score and the traditional MST/Turbo score components. Figure 1 shows the average UAS on CoNLL test datasets after each training epoch. We can see that the improvement of adding the low-rank tensor is consistent across various choices of hyper parame-

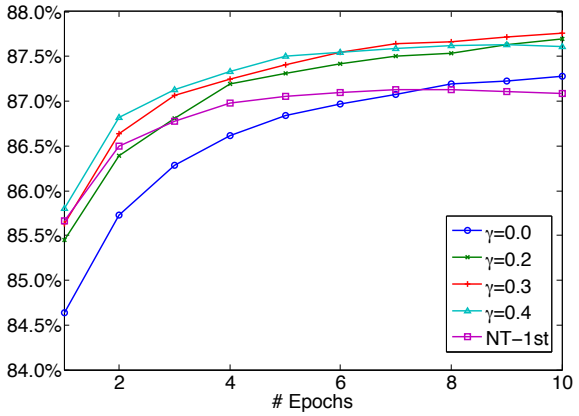

Figure 1: Average UAS on CoNLL testsets after different epochs. Our full model consistently performs better than NT-1st (its variation without tensor component) under different choices of the hyper-parameter γ.

	no word vector	with word vector
English	91.84	92.07
German	90.24	90.48
Swedish	89.86	90.38

Table 3: Results of adding unsupervised word vectors to the tensor. Adding this information yields consistent improvement for all languages.

ter γ. When training with the tensor component alone ($\gamma = 0$), the model converges more slowly. Learning of the tensor is harder because the scoring function is not linear (nor convex) with respect to parameters U, V and W. However, the tensor scoring component achieves better generalization on the test data, resulting in better UAS than NT-1st after 8 training epochs.

To assess the ability of our model to incorporate a range of features, we add unsupervised word vectors to our model. As described in previous section, we do so by appending the values of different coordinates in the word vector into ϕ_h and ϕ_m. As Table 3 shows, adding this information increases the parsing performance for all the three languages. For instance, we obtain more than 0.5% absolute improvement on Swedish.

Syntactic Abstraction without POS Since our model learns a compressed representation of feature vectors, we are interested to measure its performance when part-of-speech tags are not provided (See Table 4). The rationale is that given all other features, the model would induce representations that play a similar role to POS tags. Note that

	Our model		NT-1st	
	-POS	+wv.	-POS	+POS
English	88.89	90.49	86.70	90.58
German	82.63	85.80	78.71	88.50
Swedish	81.84	85.90	79.65	88.75

Table 4: The first three columns show parsing results when models are trained without POS tags. The last column gives the upper-bound, i.e. the performance of a parser trained with **12 Core POS tags**. The low-rank model outperforms NT-1st by a large margin. Adding word vector features further improves performance.

the performance of traditional parsers drops when tags are not provided. For example, the performance gap is 10% on German. Our experiments show that low-rank parser operates effectively in the absence of tags. In fact, it nearly reaches the performance of the original parser that used the tags on English.

Examples of Derived Projections We manually analyze low-dimensional projections to assess whether they capture syntactic abstraction. For this purpose, we train a model with only a tensor component (such that it has to learn an accurate tensor) on the English dataset and obtain low dimensional embeddings $U\phi_w$ and $V\phi_w$ for each word. The two r-dimension vectors are concatenated as an "averaged" vector. We use this vector to calculate the cosine similarity between words. Table 5 shows examples of five closest neighbors of queried words. While these lists include some noise, we can clearly see that the neighbors exhibit similar syntactic behavior. For example, "on" is close to other prepositions. More interestingly, we can consider the impact of syntactic context on the derived projections. The bottom part of Table 5 shows that the neighbors change substantially depending on the syntactic role of the word. For example, the closest words to the word "increase" are verbs in the context phrase "will increase again", while the closest words become nouns given a different phrase "an increase of".

Running Time Table 6 illustrates the impact of estimating low-rank tensor parameters on the running time of the algorithm. For comparison, we also show the NT-1st times across three typical languages. The Arabic dataset has the longest average sentence length, while the Chinese dataset

greatly	**profit**	**says**	**on**	**when**

Table 5: Five closest neighbors of the queried words (shown in bold). The upper part shows our learned embeddings group words with similar syntactic behavior. The two bottom parts of the table demonstrate that how the projections change depending on the syntactic context of the word.

	#Tok.	Len.	Train. Time (hour)	
			NT-1st	Ours
Arabic	42K	32	0.13	0.22
Chinese	337K	6	0.37	0.65
English	958K	24	1.88	2.83

Table 6: Comparison of training times across three typical datasets. The second column is the number of tokens in each data set. The third column shows the average sentence length. Both first-order models are implemented in Java and run as a single process.

has the shortest sentence length in CoNLL 2006. Based on these results, estimating a rank-50 tensor together with MST parameters only increases the running time by a factor of 1.7.

7 Conclusions

Accurate scoring of syntactic structures such as head-modifier arcs in dependency parsing typically requires rich, high-dimensional feature representations. We introduce a low-rank factorization method that enables to map high dimensional feature vectors into low dimensional representations. Our method maintains the parameters as a low-rank tensor to obtain low dimensional representations of words in their syntactic roles, and to leverage modularity in the tensor for easy training with online algorithms. We implement the approach on first-order to third-order dependency parsing. Our parser outperforms the Turbo and MST parsers across 14 languages.

Future work involves extending the tensor component to capture higher-order structures. In particular, we would consider second-order structures such as grandparent-head-modifier by increasing the dimensionality of the tensor. This tensor will accordingly be a four or five-way array. The online update algorithm remains applicable since each dimension is optimized in an alternating fashion.

CoSimRank: A Flexible & Efficient Graph-Theoretic Similarity Measure

Sascha Rothe and Hinrich Schütze
Center for Information & Language Processing
University of Munich
sascha@cis.lmu.de

Abstract

We present *CoSimRank*, a graph-theoretic similarity measure that is efficient because it can compute a single node similarity without having to compute the similarities of the entire graph. We present equivalent formalizations that show CoSimRank's close relationship to Personalized PageRank and SimRank and also show how we can take advantage of fast matrix multiplication algorithms to compute CoSimRank. Another advantage of CoSimRank is that it can be flexibly extended from basic node-node similarity to several other graph-theoretic similarity measures. In an experimental evaluation on the tasks of synonym extraction and bilingual lexicon extraction, CoSimRank is faster or more accurate than previous approaches.

1 Introduction

Graph-theoretic algorithms have been successfully applied to many problems in NLP (Mihalcea and Radev, 2011). These algorithms are often based on PageRank (Brin and Page, 1998) and other centrality measures (e.g., (Erkan and Radev, 2004)). An alternative for tasks involving similarity is SimRank (Jeh and Widom, 2002). SimRank is based on the simple intuition that nodes in a graph should be considered as similar to the extent that their neighbors are similar. Unfortunately, SimRank has time complexity $\mathcal{O}(n^3)$ (where n is the number of nodes in the graph) and therefore does not scale to the large graphs that are typical of NLP.

This paper introduces CoSimRank,[1] a new graph-theoretic algorithm for computing node similarity that combines features of SimRank and PageRank. Our key observation is that to compute the similarity of two nodes, we need not consider all other nodes in the graph as SimRank does; instead, CoSimRank starts random walks from the two nodes and computes their similarity at each time step. This offers large savings in computation time if we only need the similarities of a small subset of all n^2 node similarities.

These two cases – computing a few similarities and computing many similarities – correspond to two different representations we can compute CoSimRank on: a vector representation, which is fast for only a few similarities, and a matrix representation, which can take advantage of fast matrix multiplication algorithms.

CoSimRank can be used to compute many variations of basic node similarity – including similarity for graphs with weighted and typed edges and similarity for sets of nodes. Thus, CoSimRank has the added advantage of being a flexible tool for different types of applications.

The extension of CoSimRank to *similarity across graphs* is important for the application of bilingual lexicon extraction: given a set of correspondences between nodes in two graphs A and B (corresponding to two different languages), a pair of nodes $(a \in A, b \in B)$ is a good candidate for a translation pair if their node similarity is high. In an experimental evaluation, we show that CoSimRank is more efficient and more accurate than both SimRank and PageRank-based algorithms.

This paper is structured as follows. Section 2 discusses related work. Section 3 introduces CoSimRank. In Section 4, we compare CoSimRank and SimRank. By providing some useful extensions, we demonstrate the great flexibility of CoSimRank (Section 5). We perform an experimental evaluation of CoSimRank in Section 6. Section 7 summarizes the paper.

2 Related Work

Our work is unsupervised. We therefore do not review graph-based methods that make extensive

Baltimore, Maryland, USA, June 23-25 2014.

use of supervised learning (e.g., de Melo and Weikum (2012)).

Since the original version of *SimRank* (Jeh and Widom, 2002) has complexity $\mathcal{O}(n^4)$, many extensions have been proposed to speed up its calculation. A Monte Carlo algorithm, which is scalable to the whole web, was suggested by Fogaras and Rácz (2005). However, in an evaluation of this algorithm we found that it does not give competitive results (see Section 6). A matrix representation of SimRank called *SimFusion* (Xi et al., 2005) improves the computational complexity from $\mathcal{O}(n^4)$ to $\mathcal{O}(n^3)$. Lizorkin et al. (2010) also reduce complexity to $\mathcal{O}(n^3)$ by selecting essential node pairs and using partial sums. They also give a useful overview of SimRank, SimFusion and the Monte Carlo methods of Fogaras and Rácz (2005). A non-iterative computation for SimRank was introduced by Li et al. (2010). This is especially useful for dynamic graphs. However, all of these methods have to run SimRank on the entire graph and are not efficient enough for very large graphs. We are interested in applications that only need a fraction of all $\mathcal{O}(n^2)$ pairwise similarities. The algorithm we propose below is an order of magnitude faster in such applications because it is based on a local formulation of the similarity measure.[2]

Apart from SimRank, many other similarity measures have been proposed. Leicht et al. (2006) introduce a similarity measure that is also based on the idea that nodes are similar when their neighbors are, but that is designed for bipartite graphs. However, most graphs in NLP are not bipartite and Jeh and Widom (2002) also proposed a SimRank variant for bipartite graphs.

Another important similarity measure is cosine similarity of *Personalized PageRank* (PPR) vectors. We will refer to this measure as *PPR+cos*. Hughes and Ramage (2007) find that PPR+cos has high correlation with human similarity judgments on WordNet-based graphs. Agirre et al. (2009) use PPR+cos for WordNet and for cross-lingual studies. Like CoSimRank, PPR+cos is efficient when computing single node pair similarities; we therefore use it as one of our baselines below. This method is also used by Chang et al. (2013) for semantic relatedness. They also experimented with Euclidean distance and KL-divergence. Interestingly, a simpler method performed best when comparing with human similarity judgments. In this method only the entries corresponding to the compared nodes are used for a similarity score. Rao et al. (2008) compared PPR+cos to other graph based similarity measures like shortest-path and bounded-length random walks. PPR+cos performed best except for a new similarity measure based on commute time. We do not compare against this new measure as it uses the graph Laplacian and so cannot be computed for a single node pair.

One reason CoSimRank is efficient is that we need only compute a few iterations of the random walk. This is often true of this type of algorithm; cf. (Schütze and Walsh, 2008).

LexRank (Erkan and Radev, 2004) is similar to PPR+cos in that it combines PageRank and cosine; it initializes the sentence similarity matrix of a document using cosine and then applies PageRank to compute lexical centrality. Despite this superficial relatedness, applications like lexicon extraction that look for *similar entities* and applications that look for *central entities* are quite different.

In addition to faster versions of SimRank, there has also been work on extensions of SimRank. Dorow et al. (2009) and Laws et al. (2010) extend SimRank to edge weights, edge labels and multiple graphs. We use their Multi-Edge Extraction (MEE) algorithm as one of our baselines below. A similar graph of dependency structures was built by Minkov and Cohen (2008). They applied different similarity measures, e.g., cosine of dependency vectors or a new algorithm called *path-constrained* graph walk, on synonym extraction (Minkov and Cohen, 2012). We compare CoSimRank with their results in our experiments (see Section 6).

Some other applications of SimRank or other graph based similarity measures in NLP include work on document similarity (Li et al., 2009), the transfer of sentiment information between languages (Scheible et al., 2010) and named entity disambiguation (Han and Zhao, 2010). Hoang and Kan (2010) use SimRank for related work summarization. Muthukrishnan et al. (2010) combine link based similarity and content based similarity for document clustering and classification.

These approaches use at least one of cosine similarity, PageRank and SimRank. CoSimRank can either be interpreted as an efficient version of Sim-

[2] A reviewer suggests that CoSimRank is an efficient version of SimRank in a way analogous to SALSA's (Lempel and Moran, 2000) relationship to HITS (Kleinberg, 1999) in that different aspects of similarity are decoupled.

Rank or as a version of Personalized PageRank for similarity measurement. The novelty is that we compute similarity for vectors that are induced using a new algorithm, so that the similarity measurement is much more efficient when an application only needs a fraction of all $\mathcal{O}(n^2)$ pairwise similarities.

3 CoSimRank

We first first give an intuitive introduction of CoSimRank as a Personalized PageRank (PPR) derivative. Later on, we will give a matrix formulation to compare CoSimRank with SimRank.

3.1 Personalized PageRank

Haveliwala (2002) introduced Personalized PageRank – or topic-sensitive PageRank – based on the idea that the uniform damping vector $p^{(0)}$ can be replaced by a personalized vector, which depends on node i. We usually set $p^{(0)}(i) = e_i$, with e_i being a vector of the standard basis, i.e., the i^{th} entry is 1 and all other entries are 0. The PPR vector of node i is given by:

$$p^{(k)}(i) = dAp^{(k-1)}(i) + (1-d)p^{(0)}(i) \quad (1)$$

where A is the stochastic matrix of the Markov chain, i.e., the row normalized adjacency matrix. The damping factor $d \in (0,1)$ ensures that the computation converges. The PPR vector after k iterations is given by $p^{(k)}$.

To visualize this formula, one can imagine a random surfer starting at node i and following one of the links with probability d or jumping back to the starting node i with probability $(1-d)$. Entry i of the converged PPR vector represents the probability that the random surfer is on node i after an unlimited number of steps.

To simulate the behavior of SimRank we will simplify this equation and set the damping factor $d = 1$. We will re-add a damping factor later in the calculation.

$$p^{(k)} = Ap^{(k-1)} \quad (2)$$

Note that the personalization vector $p^{(0)}$ was eliminated, but is still present as the starting vector of the iteration.

3.2 Similarity of vectors

Let $p(i)$ be the PPR vector of node i. The cosine of two vectors u and v is computed by dividing the inner product $\langle u, v\rangle$ by the lengths of the vectors. The cosine of two PPR vectors can be used as a similarity measure for the corresponding nodes (Hughes and Ramage, 2007; Agirre et al., 2009):

$$s(i,j) = \frac{\langle p(i), p(j)\rangle}{|p(i)||p(j)|} \quad (3)$$

This measure $s(i,j)$ looks at the probability that a random walker is on a certain edge after an *unlimited number of steps*. This is potentially problematic as the example in Figure 1 shows. The PPR vectors of *suit* and *dress* will have some weight on *tailor*, which is good. However, the PPR vector of *law* will also have a non-zero weight for *tailor*. So *law* and *dress* are similar because of the node *tailor*. This is undesirable.

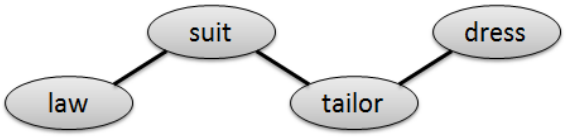

Figure 1: Graph motivating CoSimRank algorithm. Whereas PPR gives relatively high similarity to the pair (law,suit), CoSimRank assigns the pair similarity 0.

We can prevent this type of spurious similarity by *taking into account the path the random surfer took to get to a particular node*. We formalize this by defining CoSimRank $s(i,j)$ as follows:

$$s(i,j) = \sum_{k=0}^{\infty} c^k \langle p^{(k)}(i), p^{(k)}(j)\rangle \quad (4)$$

where $p^{(k)}(i)$ is the PPR vector of node i from Eq. 2 after k iterations. We compare the PPR vectors at each time step k. The sum of all similarities is the value of CoSimRank, i.e., the final similarity. We add a damping factor c, so that early meetings are more valuable than later meetings.

To compute the similarity of two vectors u and v we use the inner product $\langle\cdot,\cdot\rangle$ in Eq. 4 for two reasons:

1. This is similar to cosine similarity except that the 1-norm is used instead of the 2-norm. Since our vectors are probability vectors, we have

$$\frac{\langle p(i), p(j)\rangle}{|p(i)||p(j)|} = \langle p(i), p(j)\rangle$$

for the 1-norm.[3]

2. Without expensive normalization, we can give a simple matrix formalization of CoSimRank and compute it efficiently using fast matrix multiplication algorithms.

Later on, the following iterative computation of CoSimRank will prove useful:

$$s^{(k)}(i,j) = c^k \langle p^{(k)}(i), p^{(k)}(j) \rangle + s^{(k-1)}(i,j) \tag{5}$$

3.3 Matrix formulation

The matrix formulation of CoSimRank is:

$$\begin{aligned} S^{(0)} &= E \\ S^{(1)} &= cAA^T + S^{(0)} \\ S^{(2)} &= c^2 A^2 (A^T)^2 + S^{(1)} \\ &\dots \\ S^{(k)} &= c^k A^k (A^T)^k + S^{(k-1)} \end{aligned} \tag{6}$$

We will see in Section 5 that this formulation is the basis for a very efficient version of CoSimRank.

3.4 Convergence properties

As the PPR vectors have only positive values, we can easily see in Eq. 4 that the CoSimRank of one node pair is monotonically non-decreasing. For the dot product of two vectors, the Cauchy-Schwarz inequality gives the upper bound:

$$\langle u, v \rangle \leq \|u\| \, \|v\|$$

where $\|x\|$ is the norm of x. From Eq. 2 we get $\left\|p^{(k)}\right\|_1 = 1$, where $\|\cdot\|_1$ is the 1-norm. We also know from elementary functional analysis that the 1-norm is the biggest of all p-norms and so one has $\left\|p^{(k)}\right\| \leq 1$. It follows that CoSimRank grows more slowly than a geometric series and converges if $|c| < 1$:

$$s(i,j) \leq \sum_{k=0}^{\infty} c^k = \frac{1}{1-c}$$

If an upper bound of 1 is desired for $s(i,j)$ (instead of $1/(1-c)$), then we can use s':

$$s'(i,j) = (1-c)s(i,j)$$

[3]This type of similarity measure has also been used and investigated by Ó Séaghdha and Copestake (2008), Cha (2007), Jebara et al. (2004) (probability product kernel) and (Jaakkola et al., 1999) (Fisher kernel) among others.

4 Comparison to SimRank

The original SimRank equation can be written as follows (Jeh and Widom, 2002):

$$r(i,j) = \begin{cases} 1, & \text{if } i = j \\ \frac{c}{|N(i)||N(j)|} \sum\limits_{\substack{k \in N(i) \\ l \in N(j)}} r(k,l), & \text{else} \end{cases}$$

where $N(i)$ denotes the nodes connected to i. SimRank is computed iteratively. With A being the normalized adjacency matrix we can write SimRank in matrix formulation:

$$\begin{aligned} R^{(0)} &= E \\ R^{(k)} &= \max\{cAR^{(k-1)}A^T, R^{(0)}\} \end{aligned} \tag{7}$$

where the maximum of two matrices refers to the element-wise maximum. We will now prove by induction that the matrix formulation of CoSimRank (Eq. 6) is equivalent to:

$$S'^{(k)} = cAS'^{(k-1)}A^T + S^{(0)} \tag{8}$$

and thus very similar to SimRank (Eq. 7).

The base case $S^{(1)} = S'^{(1)}$ is trivial. Inductive step:

$$\begin{aligned} S'^{(k)} &\overset{(8)}{=} cAS'^{(k-1)}A^T + S^{(0)} \\ &= cA(c^{k-1}A^{k-1}(A^T)^{k-1} + S^{(k-2)})A^T + S^{(0)} \\ &= c^k A^k (A^T)^k + cAS^{(k-2)}A^T + S^{(0)} \\ &= c^k A^k (A^T)^k + S^{(k-1)} \overset{(6)}{=} S^{(k)} \end{aligned}$$ □

Comparing Eqs. 7 and 8, we see that SimRank and CoSimRank are very similar except that they initialize the similarities on the diagonal differently. Whereas SimRank sets each of these entries back to one at each iteration, CoSimRank adds one. Thus, when computing the two similarity measures iteratively, the diagonal element (i,i) will be set to 1 by both methods for those initial iterations for which this entry is 0 for $cAS^{(k-1)}A^T$ (i.e., before applying either max or add). The methods diverge when the entry is $\neq 0$ for the first time.

Complexity of computing all n^2 similarities. The matrix formulas of both SimRank (Eq. 7) and CoSimRank (Eq. 8) have time complexity $\mathcal{O}(n^3)$ or – if we want to take the higher efficiency of computation for sparse graphs into account – $\mathcal{O}(dn^2)$ where n is the number of nodes and d the

average degree. Space complexity is $\mathcal{O}(n^2)$ for both algorithms.

Complexity of computing $k^2 \ll n^2$ similarities. In most cases, we only want to compute k^2 similarities for k nodes. For CoSimRank, we compute the k PPR vectors in $\mathcal{O}(kdn)$ (Eq. 2) and compute the k^2 similarities in $\mathcal{O}(k^2n)$ (Eq. 5). If $d < k$, then the time complexity of CoSimRank is $\mathcal{O}(k^2n)$. If we only compute a single similarity, then the complexity is $\mathcal{O}(dn)$. In contrast, the complexity of SimRank is the same as in the all-similarities case: $\mathcal{O}(dn^2)$. It is not obvious how to design a lower-complexity version of SimRank for this case. Thus, we have reduced SimRank's cubic time complexity to a quadratic time complexity for CoSimRank or – assuming that the average degree d does not depend on n – SimRank's quadratic time complexity to linear time complexity for the case of computing few similarities.

Space complexity for computing k^2 similarities is $\mathcal{O}(kn)$ since we need only store k vectors, not the complete similarity matrix. This complexity can be exploited even for the all similarities application: If the matrix formulation cannot be used because the $\mathcal{O}(n^2)$ similarity matrix is too big for available memory, then we can compute all similarities in batches – and if desired in parallel – whose size is chosen such that the vectors of each batch still fit in memory.

In summary, CoSimRank and SimRank have similar space and time complexities for computing all n^2 similarities. For the more typical case that we only want to compute a fraction of all similarities, we have recast the global SimRank formulation as a local CoSimRank formulation. As a result, time and space complexities are much improved. In Section 6, we will show that this is also true in practice.

5 Extensions

We will show now that the basic CoSimRank algorithm can be extended in a number of ways and is thus a flexible tool for different NLP applications.

5.1 Weighted edges

The use of weighted edges was first proposed in the PageRank patent. It is straightforward and easy to implement by replacing the row normalized adjacency matrix A with an arbitrary stochastic matrix P. We can use this edge weighted PageRank for CoSimRank.

5.2 CoSimRank across graphs

We often want to compute the similarity of nodes in *two different graphs* with a known node-node correspondence; this is the scenario we are faced with in the lexicon extraction task (see Section 6). A variant of SimRank for this task was presented by Dorow et al. (2009). We will now present an equivalent method for CoSimRank. We denote the number of nodes in the two graphs U and V by $|U|$ and $|V|$, respectively. We compute PPR vectors $p \in \mathbb{R}^{|U|}$ and $q \in \mathbb{R}^{|V|}$ for each graph. Let $S^{(0)} \in \mathbb{R}^{|U| \times |V|}$ be the known node-node correspondences. The analog of CoSimRank (Eq. 4) for two graphs is then:

$$s(i,j) = \sum_{k=0}^{\infty} c^k \sum_{(u,v) \in S^{(0)}} p_u^{(k)}(i) q_v^{(k)}(j) \quad (9)$$

The matrix formulation (cf. Eq. 6) is:

$$S^{(k)} = c^k A^k S^{(0)} (B^T)^k + S^{(k-1)} \quad (10)$$

where A and B are row-normalized adjacency matrices. We can interpret $S^{(0)}$ as a change of basis. A similar approach for word embeddings was published by Mikolov et al. (2013). They call $S^{(0)}$ the translation matrix.

5.3 Typed edges

To be able to directly compare to prior work in our experiments, we also present a method to integrate a set of typed edges $\mathcal{T}$ in the CoSimRank calculation. For this we will compute a similarity matrix for each edge type τ and merge them into one matrix for the next iteration:

$$S^{(k)} = \left(\frac{c}{|\mathcal{T}|} \sum_{\tau \in \mathcal{T}} A_\tau S^{(k-1)} B_\tau^T \right) + S^{(0)} \quad (11)$$

This formula is identical to the random surfer model where two surfers only meet iff they are on the same node and used the same edge type to get there. A more strict claim would be to use the same edge type at any time of their journey:

$$S^{(k)} = \frac{c^k}{|\mathcal{T}|^k} \sum_{\tau \in \mathcal{T}^k} \left(\prod_{i=1}^{k} A_{\tau_i} \right) S^{(0)} \left(\prod_{i=0}^{k-1} B_{\tau_{k-i}}^T \right) + S^{(k-1)} \quad (12)$$

We will not use Eq. 12 due to its space complexity.

5.4 Similarity of sets of nodes

CoSimRank can also be used to compute the similarity $s(V, W)$ of two sets V and W of nodes, e.g., short text snippets. We are not including this method in our experiments, but we will give the equation here, as traditional document similarity measures (e.g., cosine similarity) perform poorly on this task although there also are known alternatives with good results (Sahami and Heilman, 2006). For a set V, the initial PPR vector is given by:

$$p_i^{(0)}(V) = \begin{cases} \frac{1}{|V|}, & \text{if } i \in V \\ 0, & \text{else} \end{cases}$$

We then reuse Eq. 4 to compute $s(V, W)$:

$$s(V, W) = \sum_{k=0}^{\infty} c^k \langle p^{(k)}(V), p^{(k)}(W) \rangle$$

In summary, modifications proposed for SimRank (weighted and typed edges, similarity across graphs) as well as modifications proposed for PageRank (sets of nodes) can also be applied to CoSimRank. This makes CoSimRank a very flexible similarity measure.

We will test the first three extensions experimentally in the next section and leave similarity of node sets for future work.

6 Experiments

We evaluate CoSimRank for the tasks of synonym extraction and bilingual lexicon extraction. We use the basic version of CoSimRank (Eq. 4) for synonym extraction and the two-graph version (Eq. 9) for lexicon extraction, both with weighted edges. Our motivation for this application is that two words that are synonyms of each other should have similar lexical neighbors and that two words that are translations of each other should have neighbors that correspond to each other; thus, in each case the nodes should be similar in the graph-theoretic sense and CoSimRank should be able to identify this similarity.

We use the English and German graphs published by Laws et al. (2010), including edge weighting and normalization. Nodes are nouns, adjectives and verbs occurring in Wikipedia. There are three types of edges, corresponding to three types of syntactic configurations extracted from the parsed Wikipedias: adjective-noun, verb-object and noun-noun coordination. Table 1 gives examples and number of nodes and edges.

Edge types

relation	entities	description	example
amod	a, v	adjective-noun	a fast car
dobj	v, n	verb-object	drive a car
ncrd	n, n	noun-noun	cars and busses

Graph statistics

nodes		nouns	adjectives	verbs
	de	34,544	10,067	2,828
	en	22,258	12,878	4,866
edges		ncrd	amod	dobj
	de	65,299	417,151	143,905
	en	288,878	686,069	510,351

Table 1: Edge types (above) and number of nodes and edges (below)

6.1 Baselines

We propose CoSimRank as an efficient algorithm for computing the similarity of nodes in a graph. Consequently, we compare against the two main methods for this task in NLP: SimRank and extensions of PageRank.

We also compare against the MEE (Multi-Edge Extraction) variant of SimRank (Dorow et al., 2009), which handles labeled edges more efficiently than SimRank:

$$S'^{(k)} = \frac{c}{|\mathcal{T}|} \sum_{\tau \in \mathcal{T}} A_\tau S^{(k-1)} B_\tau^T$$

$$S^{(k)} = \max\{S'^{(k)}, S^{(0)}\}$$

where A_τ is the row-normalized adjacency matrix for edge type τ (see edge types in Table 1).

Apart from SimRank, extensions of PageRank are the main methods for computing the similarity of nodes in graphs in NLP (e.g., Hughes and Ramage (2007), Agirre et al. (2009) and other papers discussed in related work). Generally, these methods compute the Personalized PageRank for each node (see Eq. 1). When the computation has converged, the similarity of two nodes is given by the cosine similarity of the Personalized PageRank vectors. We implemented this method for our experiments and call it PPR+cos.

6.2 Synonym Extraction

We use *TS68*, a test set of 68 synonym pairs published by Minkov and Cohen (2012) for evaluation. This gold standard lists a single word as the

	P@1	P@10	MRR
one-synonym			
PPR+cos	20.6%	52.9%	0.32
SimRank	**25.0**%	61.8%	**0.37**
CoSimRank	**25.0**%	61.8%	**0.37**
Typed CoSimRank	23.5%	**63.2**%	**0.37**
extended			
PPR+cos	32.6%	73.5%	0.48
SimRank	**45.6**%	**83.8**%	**0.59**
CoSimRank	**45.6**%	**83.8**%	**0.59**
Typed CoSimRank	44.1%	**83.8**%	**0.59**

Table 2: Results for synonym extraction on TS68. Best result in each column in bold.

correct synonym even if there are several equally acceptable near-synonyms (see Table 3 for examples). We call this the one-synonym evaluation. Three native English speakers were asked to mark synonyms, that were proposed by a baseline or by CoSimRank, i.e. ranked in the top 10. If all three of them agreed on one word as being a synonym in at least one meaning, we added this as a correct answer to the test set. We call this the "extended" evaluation (see Table 2).

Synonym extraction is run on the English graph. To calculate PPR+cos, we computed 20 iterations with a decay factor of 0.8 and used the cosine similarity with the 2-norm in the denominator to compare two vectors. For the other three methods, we also used a decay factor of 0.8 and computed 5 iterations. Recall that CoSimRank uses the simple inner product $\langle \cdot, \cdot \rangle$ to compare vectors.

Our evaluation measures are proportion of words correctly translated by word in the top position (P@1), proportion of words correctly translated by a word in one of the top 10 positions (P@10) and Mean Reciprocal Rank (MRR). CoSimRank's MRR scores of 0.37 (one-synonym) and 0.59 (extended) are the same or better than all baselines (see Table 2). CoSimRank and SimRank have the same P@1 and P@10 accuracy (although they differed on some decisions). CoSimRank is better than PPR+cos on both evaluations, but as this test set is very small, the results are not significant. Table 3 shows a sample of synonyms proposed by CoSimRank.

Minkov and Cohen (2012) tested cosine and random-walk measures on grammatical relationships (similar to our setup) as well as on cooccurrence statistics. The MRR scores for these methods range from 0.29 to 0.59. (MRR is equivalent to MAP as reported by Minkov and Cohen (2012) when there is only one correct answer.) Their best number (0.59) is better than our one-synonym result; however, they performed manual postprocessing of results – e.g., discarding words that are morphologically or semantically related to other words in the list – so our fully automatic results cannot be directly compared.

close	shut	open

Table 3: Examples for extracted synonyms. Correct synonyms according to extended evaluation in bold.

6.3 Lexicon Extraction

We evaluate lexicon extraction on TS1000, a test set of 1000 items, (Laws et al., 2010) each consisting of an English word and its German translations. For lexicon extraction, we use the same parameters as in the synonym extraction task for all four similarity measures. We use a seed dictionary of 12,630 word pairs to establish node-node correspondences between the two graphs. We remove a search keyword from the seed dictionary before calculating similarities for it, something that the architecture of CoSimRank makes easy because we can use a different seed dictionary $S^{(0)}$ for every keyword.

Both CoSimRank methods outperform SimRank significantly (see Table 4). The difference between CoSimRank with and without typed edges is not significant. (This observation was also made for SimRank on a smaller graph and test set (Laws et al., 2010).)

PPR+cos's performance at 14.8% correct translations is much lower than SimRank and CoSimRank. The disadvantage of this similarity measure is significant and even more visible on bilingual lexicon extraction than on synonym extraction (see Table 2). The reason might be that we are not comparing the whole PPR vector anymore,

	P@1	P@10
PPR+cos	14.8%†	45.7%†
SimRank MEE	48.0%†	76.0%†
CoSimRank	61.1%	**84.0%**
Typed CoSimRank	**61.4%**	83.9%

Table 4: Results for bilingual lexicon extraction (TS1000 EN → DE). Best result in each column in bold.

	synonym extraction (68 word pairs)	lexicon extraction (1000 word pairs)
PPR+cos	2,228	**2,195**
SimRank	23,423	14,418
CoSimRank	**524**	2,342
Typed CoSimRank	615	6,108

Table 5: Execution times in minutes for CoSimRank and the baselines. Best result in each column in bold.

but only entries which occur in the seed dictionary (see Eq. 9). As the seed dictionary contains 12,630 word pairs, this means that only every fourth entry of the PPR vector (the German graph has 47,439 nodes) is used for similarity calculation. This is also true for CoSimRank, but it seems that CoSimRank is more stable because we compare more than one vector.

We also experimented with the method of Fogaras and Rácz (2005). We tried a number of different ways of modifying it for weighted graphs: (i) running the random walks with the weighted adjacency matrix as Markov matrix, (ii) storing the weight (product of each edge weight) of a random walk and using it as a factor if two walks meet and (iii) a combination of both. We needed about 10,000 random walks in all three conditions. As a result, the computational time was approximately 30 minutes per test word, so this method is even slower than SimRank for our application. The accuracies P@1 and P@10 were worse in all experiments than those of CoSimRank.

6.4 Run time performance

Table 5 compares the run time performance of CoSimRank with the baselines. We ran all experiments on a 64-bit Linux machine with 64 Intel Xenon X7560 2.27Ghz CPUs and 1TB RAM. The calculated time is the sum of the time spent in user mode and the time spent in kernel mode. The actual wall clock time was significantly lower as we used up to 64 CPUs.

Compared to SimRank, CoSimRank is more than 40 times faster on synonym extraction and six times faster on lexicon extraction. SimRank is at a disadvantage because it computes all similarities in the graph regardless of the size of the test set; it is particularly inefficient on synonym extraction because the English graph contains a large number of edges (see Table 1).

Compared to PPR+cos, CoSimRank is roughly four times faster on synonym extraction and has comparable performance on lexicon extraction. We compute 20 iterations of PPR+cos to reach convergence and then calculate a single cosine similarity. For CoSimRank, we need only compute five iterations to reach convergence, but we have to compute a vector similarity in each iteration. The counteracting effects of fewer iterations and more vector similarity computations can give either CoSimRank or PPR+cos an advantage, as is the case for synonym extraction and lexicon extraction, respectively.

CoSimRank should generally be three times faster than typed CoSimRank since the typed version has to repeat the computation for each of the three types. This effect is only visible on the larger test set (lexicon extraction) because the general computation overhead is about the same on a smaller test set.

6.5 Comparison with WINTIAN

Here we address inducing a bilingual lexicon from a seed set based on grammatical relations found by a parser. An alternative approach is to induce a bilingual lexicon from Wikipedia's interwiki links (Rapp et al., 2012). These two approaches have different strengths and weaknesses; e.g., the interwiki-link-based approach does not require a seed set, but it can only be applied to comparable corpora that consist of corresponding – although not necessarily "parallel" – documents.

Despite these differences it is still interesting to compare the two algorithms. Rapp et al. (2012) kindly provided their test set to us. It contains 1000 English words and a single correct German translation for each. We evaluate on a subset we call TS774 that consists of the 774 test word pairs that are in the intersection of words covered by the

†significantly worse than CoSimRank ($\alpha = 0.05$, one-tailed Z-Test)

	P@1	P@10
Wintian	**43.8%**	55.4%†
CoSimRank	43.0%	**73.6%**

Table 6: Results for bilingual lexicon extraction (TS774 DE → EN). Best result in each column in bold.

WINTIAN Wikipedia data (Rapp et al., 2012) and words covered by our data. Most of the 226 missing word pairs are adverbs, prepositions and plural forms that are not covered by our graphs due to the construction algorithm we use: lemmatization, restriction to adjectives, nouns and verbs etc.

Table 6 shows that CoSimRank is slightly, but not significantly worse than WINTIAN on P@1 (43.0 vs 43.8), but significantly better on P@10 (73.6 vs 55.4).[4] The reason could be that CoSimRank is a more effective algorithm than WINTIAN; but the different initializations (seed set vs interwiki links) or the different linguistic representations (grammatical relations vs bag-of-words) could also be responsible.

6.6 Error Analysis

The results on TS774 can be considered conservative since only one translation is accepted as being correct. In reality other translations might also be acceptable (e.g., both *street* and *road* for *Straße*). In contrast, TS1000 accepts more than one correct translation. Additionally, TS774 was created by translating English words into German (using Google translate). We are now testing the reverse direction. So we are doomed to fail if the original English word is a less common translation of an ambiguous German word. For example, the English word *gulf* was translated by Google to *Golf*, but the most common sense of *Golf* is the sport. Hence our algorithm will incorrectly translate it back to *golf*.

As we can see in Table 7, we also face the problems discussed by Laws et al. (2010): the algorithm sometimes picks cohyponyms (which can still be seen as reasonable) and antonyms (which are clear errors).

Contrary to our intuition, the edge-typed variant of CoSimRank did not perform significantly better than the non-edge-typed version. Looking at Table 1, we see that there is only one edge type connecting adjectives. The same is true for verbs. The random surfer only has a real choice between different edge types when she is on a noun node. Combined with the fact that only the last edge type is important this has absolutely no effect for a random surfer meeting at adjectives or verbs.

Two possible solutions would be (i) to use more fine-grained edge types, (ii) to apply Eq. 12, in which the edge type of each step is important. However, this will increase the memory needed for calculation.

[4] We achieved better results for CoSimRank by optimizing the damping factor, but in this paper, we only present results for a fixed damping factor of 0.8.

7 Summary

We have presented *CoSimRank*, a new similarity measure that can be computed for a single node pair without relying on the similarities in the whole graph. We gave two different formalizations of CoSimRank: (i) a derivation from Personalized PageRank and (ii) a matrix representation that can take advantage of fast matrix multiplication algorithms. We also presented extensions of CoSimRank for a number of applications, thus demonstrating the flexibility of CoSimRank as a similarity measure.

We showed that CoSimRank is superior to SimRank in time and space complexity; and we demonstrated that CoSimRank performs better than PPR+cos on two similarity computation tasks.

Is this a wampimuk? Cross-modal mapping between distributional semantics and the visual world

Abstract

Following up on recent work on establishing a mapping between vector-based semantic embeddings of words and the visual representations of the corresponding objects from natural images, we first present a simple approach to cross-modal vector-based semantics for the task of *zero-shot learning*, in which an image of a previously unseen object is mapped to a linguistic representation denoting its word. We then introduce *fast mapping*, a challenging and more cognitively plausible variant of the zero-shot task, in which the learner is exposed to new objects and the corresponding words in very limited linguistic contexts. By combining prior linguistic and visual knowledge acquired about words and their objects, as well as exploiting the limited new evidence available, the learner must learn to associate new objects with words. Our results on this task pave the way to realistic simulations of how children or robots could use existing knowledge to bootstrap grounded semantic knowledge about new concepts.

1 Introduction

Computational models of meaning that rely on corpus-extracted context vectors, such as LSA (Landauer and Dumais, 1997), HAL (Lund and Burgess, 1996), Topic Models (Griffiths et al., 2007) and more recent neural-network approaches (Collobert and Weston, 2008; Mikolov et al., 2013b) have successfully tackled a number of lexical semantics tasks, where context vector similarity highly correlates with various indices of semantic relatedness (Turney and Pantel, 2010). Given that these models are learned from naturally occurring data using simple associative techniques, various authors have advanced the claim that they might be also capturing some crucial aspects of how humans acquire and use language (Landauer and Dumais, 1997; Lenci, 2008).

However, the models induce the meaning of words entirely from their co-occurrence with other words, without links to the external world. This constitutes a serious blow to claims of cognitive plausibility in at least two respects. One is the *grounding problem* (Harnad, 1990; Searle, 1984). Irrespective of their relatively high performance on various semantic tasks, it is debatable whether models that have no access to visual and perceptual information can capture the holistic, grounded knowledge that humans have about concepts. However, a possibly even more serious pitfall of vector models is *lack of reference*: natural language is, fundamentally, a means to communicate, and thus our words must be able to *refer* to objects, properties and events in the outside world (Abbott, 2010). Current vector models are purely language-internal, solipsistic models of meaning. Consider the very simple scenario in which visual information is being provided to an agent about the current state of the world, and the agent's task is to determine the truth of a statement similar to *There is a dog in the room*. Although the agent is equipped with a powerful context vector model, this will not suffice to successfully complete the task. The model might suggest that the concepts of *dog* and *cat* are semantically related, but it has no means to determine the visual appearance of dogs, and consequently no way to verify the truth of such a simple statement.

Mapping words to the objects they denote is such a core function of language that humans are highly optimized for it, as shown by the so-called *fast mapping* phenomenon, whereby children can learn to associate a word to an object or property by a single exposure to it (Bloom, 2000; Carey, 1978; Carey and Bartlett, 1978; Heibeck and Markman, 1987). But lack of reference is not

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1403–1414,
Baltimore, Maryland, USA, June 23-25 2014.

only a theoretical weakness: Without the ability to refer to the outside world, context vectors are arguably useless for practical goals such as learning to execute natural language instructions (Branavan et al., 2009; Chen and Mooney, 2011), that could greatly benefit from the rich network of lexical meaning such vectors encode, in order to scale up to real-life challenges.

Very recently, a number of papers have exploited advances in automated feature extraction form images and videos to enrich context vectors with visual information (Bruni et al., 2014; Feng and Lapata, 2010; Leong and Mihalcea, 2011; Regneri et al., 2013; Silberer et al., 2013). This line of research tackles the grounding problem: Word representations are no longer limited to their linguistic contexts but also encode visual information present in images associated with the corresponding objects. In this paper, we rely on the same image analysis techniques but instead focus on the reference problem: We do not aim at enriching word representations with visual information, although this might be a side effect of our approach, but we address the issue of automatically mapping objects, as depicted in images, to the context vectors representing the corresponding words. This is achieved by means of a simple neural network trained to project image-extracted feature vectors to text-based vectors through a hidden layer that can be interpreted as a cross-modal semantic space.

We first test the effectiveness of our cross-modal semantic space on the so-called *zero-shot learning* task (Palatucci et al., 2009), which has recently been explored in the machine learning community (Frome et al., 2013; Socher et al., 2013). In this setting, we assume that our system possesses linguistic and visual information for a set of concepts in the form of text-based representations of words and image-based vectors of the corresponding objects, used for vision-to-language-mapping training. The system is then provided with visual information for a previously unseen object, and the task is to associate it with a word by cross-modal mapping. Our approach is competitive with respect to the recently proposed alternatives, while being overall simpler.

The aforementioned task is very demanding and interesting from an engineering point of view. However, from a cognitive angle, it relies on strong, unrealistic assumptions: The learner is asked to establish a link between a new object and a word for which they possess a full-fledged text-based vector extracted from a billion-word corpus. On the contrary, the first time a learner is exposed to a new object, the linguistic information available is likely also very limited. Thus, in order to consider vision-to-language mapping under more plausible conditions, similar to the ones that children or robots in a new environment are faced with, we next simulate a scenario akin to fast mapping. We show that the induced cross-modal semantic space is powerful enough that sensible guesses about the correct word denoting an object can be made, even when the linguistic context vector representing the word has been created from as little as 1 sentence containing it.

The contributions of this work are three-fold. First, we conduct experiments with simple image- and text-based vector representations and compare alternative methods to perform cross-modal mapping. Then, we complement recent work (Frome et al., 2013) and show that zero-shot learning scales to a large and noisy dataset. Finally, we provide preliminary evidence that cross-modal projections can be used effectively to simulate a fast mapping scenario, thus strengthening the claims of this approach as a full-fledged, fully inductive theory of meaning acquisition.

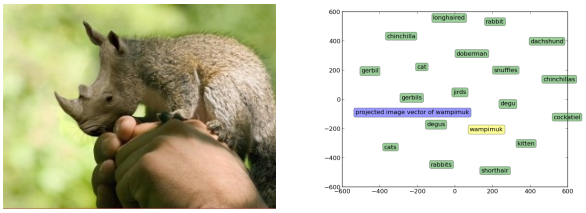
2 Related Work

The problem of establishing word reference has been extensively explored in computational simulations of cross-situational learning (see Fazly et al. (2010) for a recent proposal and extended review of previous work). This line of research has traditionally assumed artificial models of the external world, typically a set of linguistic or logical labels for objects, actions and possibly other aspects of a scene (Siskind, 1996). Recently, Yu and Siskind (2013) presented a system that induces word-object mappings from features extracted from short videos paired with sentences. Our work complements theirs in two ways. First, unlike Yu and Siskind (2013) who considered a limited lexicon of 15 items with only 4 nouns, we conduct experiments in a large search space containing a highly ambiguous set of potential target words for every object (see Section 4.1). Most importantly, by projecting visual representations of objects into a shared *semantic space*, we do not limit ourselves to establishing a link between ob-

jects and words. We induce a rich semantic representation of the multimodal concept, that can lead, among other things, to the discovery of important properties of an object even when we lack its linguistic label. Nevertheless, Yu and Siskind's system could in principle be used to initialize the vision-language mapping that we rely upon.

Closer to the spirit of our work are two very recent studies coming from the machine learning community. Socher et al. (2013) and Frome et al. (2013) focus on zero-shot learning in the vision-language domain by exploiting a shared visual-linguistic semantic space. Socher et al. (2013) learn to project unsupervised vector-based image representations onto a word-based semantic space using a neural network architecture. Unlike us, Socher and colleagues train an outlier detector to decide whether a test image should receive a known-word label by means of a standard supervised object classifier, or be assigned an unseen label by vision-to-language mapping. In our zero-shot experiments, we assume no access to an outlier detector, and thus, the search for the correct label is performed in the full concept space. Furthermore, Socher and colleagues present a much more constrained evaluation setup, where only 10 concepts are considered, compared to our experiments with hundreds or thousands of concepts.

Frome et al. (2013) use linear regression to transform vector-based image representations onto vectors representing the same concepts in linguistic semantic space. Unlike Socher et al. (2013) and the current study that adopt simple unsupervised techniques for constructing image representations, Frome et al. (2013) rely on a supervised state-of-the-art method: They feed low-level features to a deep neural network trained on a supervised object recognition task (Krizhevsky et al., 2012). Furthermore, their text-based vectors encode very rich information, such as $\vec{king} - \vec{man} + \vec{woman} = \vec{queen}$ (Mikolov et al., 2013c). A natural question we aim to answer is whether the success of cross-modal mapping is due to the high-quality embeddings or to the general algorithmic design. If the latter is the case, then these results could be extended to traditional distributional vectors bearing other desirable properties, such as high interpretability of dimensions.



(a) (b)

Figure 1: A potential *wampimuk* (a) together with its projection onto the linguistic space (b).

3 Zero-shot learning and fast mapping

"We found a cute, hairy *wampimuk* sleeping behind the tree." Even though the previous statement is certainly the first time one hears about *wampimuks*, the linguistic context already creates some visual expectations: Wampimuks probably resemble small animals (Figure 1a). This is the scenario of *zero-shot learning*. Moreover, if this is also the first linguistic encounter of that concept, then we refer to the task as *fast mapping*.

Concretely, we assume that concepts, denoted for convenience by word labels, are represented in linguistic terms by vectors in a text-based distributional semantic space (see Section 4.3). Objects corresponding to concepts are represented in visual terms by vectors in an image-based semantic space (Section 4.2). For a subset of concepts (e.g., a set of animals, a set of vehicles), we possess information related to both their linguistic and visual representations. During training, this cross-modal vocabulary is used to induce a projection function (Section 4.4), which – intuitively – represents a mapping between visual and linguistic dimensions. Thus, this function, given a visual vector, returns its corresponding linguistic representation. At test time, the system is presented with a previously unseen object (e.g., *wampimuk*). This object is projected onto the linguistic space and associated with the word label of the nearest neighbor in that space (*degus* in Figure 1b).

The fast mapping setting can be seen as a special case of the zero-shot task. Whereas for the latter our system assumes that all concepts have rich linguistic representations (i.e., representations estimated from a large corpus), in the case of the former, new concepts are assumed to be encounted in a limited linguistic context and therefore lacking rich linguistic representations. This is operationalized by constructing the text-based vector for these

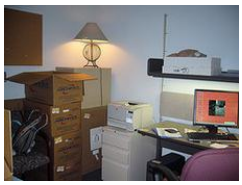


Figure 2: Images of *chair* as extracted from CIFAR-100 (left) and ESP (right).

concepts from a context of just a few occurrences. In this way, we simulate the first encounter of a learner with a concept that is new in both visual and linguistic terms.

4 Experimental Setup

4.1 Visual Datasets

CIFAR-100 The CIFAR-100 dataset (Krizhevsky, 2009) consists of 60,000 32x32 colour images (note the extremely small size) representing 100 distinct concepts, with 600 images per concept. The dataset covers a wide range of concrete domains and is organized into 20 broader categories. Table 1 lists the concepts used in our experiments organized by category.

ESP Our second dataset consists of 100K images from the ESP-Game data set, labeled through a "game with a purpose" (Von Ahn, 2006).[1] The ESP image tags form a vocabulary of 20,515 unique words. Unlike other datasets used for zero-shot learning, it covers adjectives and verbs in addition to nouns. On average, an image has 14 tags and a word appears as a tag for 70 images. Unlike the CIFAR-100 images, which were chosen specifically for image object recognition tasks (i.e., each image is clearly depicting a single object in the foreground), ESP contains a random selection of images from the Web. Consequently, objects do not appear in most images in their prototypical display, but rather as elements of complex scenes (see Figure 2). Thus, ESP constitutes a more realistic, and at the same time more challenging, simulation of how things are encountered in real life, testing the potentials of cross-modal mapping in dealing with the complex scenes that one would encounter in event recognition and caption generation tasks.

[1] http://www.cs.cmu.edu/~biglou/resources/

4.2 Visual Semantic Spaces

Image-based vectors are extracted using the unsupervised bag-of-visual-words (BoVW) representational architecture (Sivic and Zisserman, 2003; Csurka et al., 2004), that has been widely and successfully applied to computer vision tasks such as object recognition and image retrieval (Yang et al., 2007). First, low-level visual features (Szeliski, 2010) are extracted from a large collection of images and clustered into a set of "visual words". The low-level features of a specific image are then mapped to the corresponding visual words, and the image is represented by a count vector recording the number of occurrences of each visual word in it. We do not attempt any parameter tuning of the pipeline.

As low-level features, we use Scale Invariant Feature Transform (SIFT) features (Lowe, 2004). SIFT features are tailored to capture object parts and to be invariant to several image transformations such as rotation, illumination and scale change. These features are clustered into vocabularies of 5,000 (ESP) and 4,096 (CIFAR-100) visual words.[2] To preserve spatial information in the BoVW representation, we use the spatial pyramid technique (Lazebnik et al., 2006), which consists in dividing the image into several regions, computing BoVW vectors for each region and concatenating them. In particular, we divide ESP images into 16 regions and the smaller CIFAR-100 images into 4. The vectors resulting from region concatenation have dimensionality $5000 \times 16 = 80,000$ (ESP) and $4,096 \times 4 = 16,384$ (CIFAR-100), respectively. We apply Local Mutual Information (LMI, (Evert, 2005)) as weighting scheme and reduce the full co-occurrence space to 300 dimensions using the Singular Value Decomposition.

For CIFAR-100, we extract distinct visual vectors for single images. For ESP, given the size and amount of noise in this dataset, we build vectors for visual *concepts*, by normalizing and summing the BoVW vectors of all the images that have the relevant concept as a tag. Note that relevant literature (Pereira et al., 2010) has emphasized the importance of learners self-generating multiple views when faced with new objects. Thus, our multiple-image assumption should not be considered as problematic in the current setup.

[2] For selecting the size of the vocabulary size, we relied on standard settings found in the relevant literature (Bruni et al., 2014; Chatfield et al., 2011).

Category	Seen Concepts	Unseen (Test) Concepts
aquatic mammals	beaver, otter, seal, whale	dolphin
fish	ray, trout	shark
flowers	orchid, poppy, sunflower, tulip	rose
food containers	bottle, bowl, can ,plate	cup
fruit vegetable	apple, mushroom, pear	orange
household electrical devices	keyboard, lamp, telephone, television	clock
household furniture	chair, couch, table, wardrobe	bed
insects	bee, beetle, caterpillar, cockroach	butterfly
large carnivores	bear, leopard, lion, wolf	tiger
large man-made outdoor things	bridge, castle, house, road	skyscraper
large natural outdoor scenes	cloud, mountain, plain, sea	forest
large omnivores and herbivores	camel, cattle, chimpanzee, kangaroo	elephant
medium-sized mammals	fox, porcupine, possum, skunk	raccoon
non-insect invertebrates	crab, snail, spider, worm	lobster
people	baby, girl, man, woman	boy
reptiles	crocodile, dinosaur, snake, turtle	lizard
small mammals	hamster, mouse, rabbit, shrew	squirrel
vehicles 1	bicycle, motorcycle, train	bus
vehicles 2	rocket, tank, tractor	streetcar

Table 1: Concepts in our version of the CIFAR-100 data set

We implement the entire visual pipeline with VSEM, an open library for visual semantics (Bruni et al., 2013).[3]

4.3 Linguistic Semantic Spaces

For constructing the text-based vectors, we follow a standard pipeline in distributional semantics (Turney and Pantel, 2010) without tuning its parameters and collect co-occurrence statistics from the concatenation of ukWaC[4] and the Wikipedia, amounting to 2.7 billion tokens in total. Semantic vectors are constructed for a set of 30K target words (lemmas), namely the top 20K most frequent nouns, 5K most frequent adjectives and 5K most frequent verbs, and the same 30K lemmas are also employed as contextual elements. We collect co-occurrences in a symmetric context window of 20 elements around a target word. Finally, similarly to the visual semantic space, raw counts are transformed by applying LMI and then reduced to 300 dimensions with SVD.[5]

4.4 Cross-modal Mapping

The process of learning to map objects to the their word label is implemented by training a projection function $\mathrm{f}_{\mathrm{proj_{v\rightarrow w}}}$ from the visual onto the linguistic semantic space. For the learning, we use a set of N_s *seen* concepts for which we have both image-based visual representations $\mathbf{V}_s \in \mathbb{R}^{N_s \times d_v}$ and text-based linguistic representations $\mathbf{W}_s \in \mathbb{R}^{N_s \times d_w}$. The projection function is subject to an objective that aims at minimizing some cost function between the induced text-based representations $\hat{\mathbf{W}}_s \in \mathbb{R}^{N_s \times d_w}$ and the gold ones $\mathbf{W}_s$. The induced $\mathrm{f}_{\mathrm{proj_{v\rightarrow w}}}$ is then applied to the image-based representations $\mathbf{V}_u \in \mathbb{R}^{N_u \times d_v}$ of N_u unseen objects to transform them into text-based representations $\hat{\mathbf{W}}_u \in \mathbb{R}^{N_u \times d_w}$. We implement 4 alternative learning algorithms for inducing the cross-modal projection function $\mathrm{f}_{\mathrm{proj_{v\rightarrow w}}}$.

Linear Regression (lin) Our first model is a very simple linear mapping between the two modalities estimated by solving a least-squares problem. This method is similar to the one introduced by Mikolov et al. (2013a) for estimating a translation matrix, only solved analytically. In our setup, we can see the two different modalities as if they were different languages. By using least-squares regression, the projection function $\mathrm{f}_{\mathrm{proj_{v\rightarrow w}}}$ can be derived as

$$\mathrm{f}_{\mathrm{proj_{v\rightarrow w}}} = (\mathbf{V}_s^T \mathbf{V}_s)^{-1} \mathbf{V}_s^T \mathbf{W}_s \qquad (1)$$

Canonical Correlation Analysis (CCA) CCA (Hardoon et al., 2004; Hotelling, 1936) and variations thereof have been successfully used in the past for annotation of regions (Socher and Fei-Fei, 2010) and complete images (Hardoon et al., 2006; Hodosh et al., 2013). Given two paired observation matrices, in our case $\mathbf{V}_s$ and $\mathbf{W}_s$, CCA aims at capturing the linear relationship that exists between these variables. This is achieved by finding a pair of matrices, in our

[3] http://clic.cimec.unitn.it/vsem/

[4] http://wacky.sslmit.unibo.it

[5] We also experimented with the image- and text-based vectors of Socher et al. (2013), but achieved better performance with the reported setup.

case $\mathbf{C}_V \in \mathbb{R}^{d_v \times d}$ and $\mathbf{C}_W \in \mathbb{R}^{d_w \times d}$, such that the correlation between the projections of the two multidimensional variables into a common, lower-rank space is maximized. The resulting multimodal space has been shown to provide a good approximation to human concept similarity judgments (Silberer and Lapata, 2012). In our setup, after applying CCA on the two spaces $\mathbf{V}_s$ and $\mathbf{W}_s$, we obtain the two projection mappings onto the common space and thus our projection function can be derived as:

$$\mathrm{f}_{\mathrm{proj}_{\mathrm{v}\rightarrow\mathrm{w}}} = \mathbf{C}_V {\mathbf{C}_W}^{-1} \quad (2)$$

Singular Value Decomposition (SVD) SVD is the most widely used dimensionality reduction technique in distributional semantics (Turney and Pantel, 2010), and it has recently been exploited to combine visual and linguistic dimensions in the multimodal distributional semantic model of Bruni et al. (2014). SVD smoothing is also a way to infer values of unseen dimensions in partially incomplete matrices, a technique that has been applied to the task of inferring word tags of unannotated images (Hare et al., 2008). Assuming that the concept-representing rows of $\mathbf{V}_s$ and $\mathbf{W}_s$ are ordered in the same way, we apply the (k-truncated) SVD to the concatenated matrix $[\mathbf{V}_s\mathbf{W}_s]$, such that $[\hat{\mathbf{V}}_s\hat{\mathbf{W}}_\mathbf{s}] = \mathbf{U}_k\mathbf{\Sigma}_k\mathbf{Z}_k^T$ is a k-rank approximation of the original matrix.[6] The projection function is then:

$$\mathrm{f}_{\mathrm{proj}_{\mathrm{v}\rightarrow\mathrm{w}}} = \mathbf{Z}_k\mathbf{Z}_k^T \quad (3)$$

where the input is appropriately padded with 0s ($[\mathbf{V}_u\mathbf{0}_{Nu\times W}]$) and we discard the visual block of the output matrix $[\hat{\mathbf{V}}_u\hat{\mathbf{W}}_u]$.

Neural Network (NNet) The last model that we introduce is a neural network with one hidden layer. The projection function in this model can be described as:

$$\mathrm{f}_{\mathrm{proj}_{\mathrm{v}\rightarrow\mathrm{w}}} = \mathbf{\Theta}_{\mathrm{v}\rightarrow\mathrm{w}} \quad (4)$$

where $\mathbf{\Theta}_{v\rightarrow w}$ consists of the model weights $\boldsymbol{\theta}^{(1)} \in \mathbb{R}^{d_v \times h}$ and $\boldsymbol{\theta}^{(2)} \in \mathbb{R}^{h \times d_w}$ that map the input image-based vectors $\mathbf{V}_s$ first to the hidden layer and then to the output layer in order to obtain text-based vectors, i.e., $\hat{\mathbf{W}}_s = \sigma^{(2)}(\sigma^{(1)}(\mathbf{V}_s\boldsymbol{\theta}^{(1)})\boldsymbol{\theta}^{(2)})$, where $\sigma^{(1)}$ and $\sigma^{(2)}$ are the non-linear activation functions. We experimented with sigmoid, hyperbolic tangent and linear; hyperbolic tangent yielded the highest performance. The weights are estimated by minimizing the objective function

$$J(\mathbf{\Theta}_{\mathrm{v}\rightarrow\mathrm{w}}) = \frac{1}{2}(1 - sim(\mathbf{W}_s, \hat{\mathbf{W}}_s)) \quad (5)$$

where sim is some similarity function. In our experiments we used *cosine* as similarity function, so that $sim(\mathbf{A}, \mathbf{B}) = \frac{AB}{\|A\|\|B\|}$, thus penalizing parameter settings leading to a low cosine between the target linguistic representations $\mathbf{W}_s$ and those produced by the projection function $\hat{\mathbf{W}}_s$. The cosine has been widely used in the distributional semantic literature, and it has been shown to outperform Euclidean distance (Bullinaria and Levy, 2007).[7] Parameters were estimated with standard backpropagation and L-BFGS.

5 Results

Our experiments focus on the tasks of zero-shot learning (Sections 5.1 and 5.2) and fast mapping (Section 5.3). In both tasks, the projected vector of the unseen concept is labeled with the word associated to its cosine-based nearest neighbor vector in the corresponding semantic space.

For the zero-shot task we report the *accuracy* of retrieving the correct label among the top k neighbors from a semantic space populated with the *union of seen and unseen* concepts. For fast mapping, we report the *mean rank* of the correct concept among fast mapping candidates.

5.1 Zero-shot Learning in CIFAR-100

For this experiment, we use the intersection of our linguistic space with the concepts present in CIFAR-100, containing a total of 90 concepts. For each concept category, we treat all concepts but one as seen concepts (Table 1). The 71 seen concepts correspond to 42,600 distinct visual vectors and are used to induce the projection function. Table 2 reports results obtained by averaging the performance on the 11,400 distinct vectors of the 19 unseen concepts.

Our 4 models introduced in Section 4.4 are compared to a theoretically derived baseline **Chance** simulating selecting a label at random. For the neural network **NN**, we use prior knowledge

[6] We denote the right singular vectors matrix by $\mathbf{Z}$ instead of the customary $\mathbf{V}$ to avoid confusion with the visual matrix.

[7] We also experimented with the same objective function as Socher et al. (2013), however, our objective function yielded consistently better results in all experimental settings.

Model \ k	1	2	3	5	10	20
Chance	1.1	2.2	3.3	5.5	11.0	22.0
SVD	1.9	5.0	8.1	14.5	29.0	48.6
CCA	3.0	6.9	10.7	17.9	31.7	51.7
lin	2.4	6.4	10.5	18.7	33.0	55.0
NN	3.9	6.6	10.6	21.9	37.9	58.2

Table 2: Percentage accuracy among top k nearest neighbors on CIFAR-100.

about the number of concept categories to set the number of hidden units to 20 in order to avoid tuning of this parameter. For the **SVD** model, we set the number of dimensions to 300, a common choice in distributional semantics, coherent with the settings we used for the visual and linguistic spaces.

First and foremost, all 4 models outperform **Chance** by a large margin. Surprisingly, the very simple **lin** method outperforms both **CCA** and **SVD**. However, **NN**, an architecture that can capture more complex, non-linear relations in features across modalities, emerges as the best performing model, confirming on a larger scale the recent findings of Socher et al. (2013).

5.1.1 Concept Categorization

In order to gain qualitative insights into the performance of the projection process of **NN**, we attempt to investigate the role and interpretability of the *hidden layer*. We achieve this by looking at which visual concepts result in the *highest* hidden unit activation.[8] This is inspired by analogous qualitative analysis conducted in Topic Models (Griffiths et al., 2007), where "topics" are interpreted in terms of the words with the highest probability under each of them.

Table 3 presents both seen and unseen concepts corresponding to visual vectors that trigger the highest activation for a subset of hidden units. The table further reports, for each hidden unit, the "correct" unseen concept for the category of the top seen concepts, together with its rank in terms of activation of the unit. The analysis demonstrates that, although prior knowledge about categories was not explicitly used to train the network, the latter induced an organization of concepts into superordinate categories in which the hidden layer acts as a cross-modal concept categorization/organization system. When the induced projection function maps an object onto the linguistic space, the derived text vector will inherit a mixture of textual features from the concepts that activated the same hidden unit as the object. This suggests a bias towards seen concepts. Furthermore, in many cases of miscategorization, the concepts are still semantically coherent with the induced category, confirming that the projection function is indeed capturing a latent, cross-modal semantic space. A *squirrel*, although not a "*large* omnivore", is still an animal, while *butterflies* are not *flowers* but often feed on their nectar.

[8]For this post-hoc analysis, we include a sparsity parameter in the objective function of Equation 5 in order to get more interpretable results; hidden units are therefore maximally activated by a only few concepts.

Unseen Concept	Nearest Neighbors
tiger	cat, microchip, kitten, vet, pet
bike	spoke, wheel, brake, tyre, motorcycle
blossom	bud, leaf, jasmine, petal, dandelion
bakery	quiche, bread, pie, bagel, curry

Table 4: Top 5 neighbors in linguistic space after visual vector projection of 4 unseen concepts.

5.2 Zero-shot Learning in ESP

For this experiment, we focus on **NN**, the best performing model in the previous experiment. We use a set of approximately 9,500 concepts, the intersection of the ESP-based visual semantic space with the linguistic space. For tuning the number of hidden units of **NN**, we use the MEN-concrete dataset of Bruni et al. (2014). Finally, we randomly pick 70% of the concepts to induce the projection function $f_{proj_{v \rightarrow w}}$ and report results on the remaining 30%. Note that the search space for the correct label in this experiment is approximately 95 times larger than the one used for the experiment presented in Section 5.1.

Although our experimental setup differs from the one of Frome et al. (2013), thus preventing a direct comparison, the results reported in Table 5 are on a comparable scale to theirs. We note that previous work on zero-shot learning has used standard object recognition benchmarks. To the best of our knowledge, this is the first time this task has been performed on a dataset as noisy as ESP. Overall, the results suggest that cross-modal mapping could be applied in tasks where images exhibit a more complex structure, e.g., caption generation and event recognition.

	Seen Concepts	Unseen Concept	Rank of Correct Unseen Concept	CIFAR-100 Category
Unit 1	**sunflower**, **tulip**, pear	butterfly	2 (**rose**)	flowers
Unit 2	**cattle**, **camel**, **bear**	squirrel	2 (**elephant**)	large omnivores and herbivores
Unit 3	**castle**, **bridge**, **house**	bus	4 (**skyscraper**)	large man-made outdoor things
Unit 4	**man**, **girl**, **baby**	**boy**	1	people
Unit 5	**motorcycle**, **bicycle**, tractor	streetcar	2 (**bus**)	vehicles 1
Unit 6	**sea**, **plain**, **cloud**	**forest**	1	large natural outdoor scenes
Unit 7	**chair**, **couch**, **table**	**bed**	1	household furniture
Unit 8	**plate**, **bowl**, **can**	clock	3 (**cup**)	food containers
Unit 9	**apple**, **pear**, **mushroom**	**orange**	1	fruit and vegetables

Table 3: Categorization induced by the hidden layer of the **NN**; concepts belonging in the same CIFAR-100 categories, reported in the last column, are marked in bold. Example: Unit 1 receives the highest activation during training by the category *flowers* and at test time by *butterfly*, belonging to *insects*. The same unit receives the second highest activation by the "correct" test concept, the *flower rose*.

Model \ k	1	2	5	10	50
Chance	0.01	0.02	0.05	0.10	0.5
NN	0.8	1.9	5.6	9.7	30.9

Table 5: Percentage accuracy among top k nearest neighbors on ESP.

5.3 Fast Mapping in ESP

In this section, we aim at simulating a fast mapping scenario in which the learner has been just exposed to a new concept, and thus has limited linguistic evidence for that concept. We operationalize this by considering the 34 concrete concepts introduced by Frassinelli and Keller (2012), and deriving their text-based representations from just a few sentences randomly picked from the corpus. Concretely, we implement 5 models: **context 1**, **context 5**, **context 10**, **context 20** and **context full**, where the name of the model denotes the number of sentences used to construct the text-based representations. The derived vectors were reduced with the same SVD projection induced from the complete corpus. Cross-modal mapping is done via **NN**.

The zero-shot framework leads us to frame fast mapping as the task of projecting visual representations of new objects onto language space for retrieving their word labels (v $\rightarrow$ w). This mapping from visual to textual representations is arguably a more plausible task than *vice versa*. If we think about how linguistic reference is acquired, a scenario in which a learner *first* encounters a new object and *then* seeks its reference in the language of the surrounding environment (e.g., adults having a conversation, the text of a book with an illustration of an unknown object) is very natural. Furthermore, since not all new concepts in the linguistic environment refer to new objects (they might denote abstract concepts or out-of-scene objects), it seems more reasonable for the learner to be more alerted to linguistic cues about a recently-spotted new object than *vice versa*. Moreover, once the learner observes a new object, she can easily construct a full visual representation for it (and the acquisition literature has shown that humans are wired for good object segmentation and recognition (Spelke, 1994)) – the more challenging task is to scan the ongoing and very ambiguous linguistic communication for contexts that might be relevant and informative about the new object. However, fast mapping is often described in the psychological literature as the opposite task: The learner is exposed to a new word in context and has to search for the right object referring to it. We implement this second setup (w $\rightarrow$ v) by training the projection function $\mathrm{f}_{\mathrm{proj}_{\mathrm{w}\rightarrow\mathrm{v}}}$ which maps linguistic vectors to visual ones. The adaptation of **NN** is straightforward; the new objective function is derived as

$$J(\mathbf{\Theta}_{\mathrm{w}\rightarrow\mathrm{v}}) = \frac{1}{2}(1 - sim(\mathbf{V}_s, \hat{\mathbf{V}}_s)) \qquad (6)$$

where $\hat{\mathbf{V}}_s = \sigma^{(2)}(\sigma^{(1)}(\mathbf{W}_s\boldsymbol{\theta}^{(1)})\boldsymbol{\theta}^{(2)})$, $\boldsymbol{\theta}^{(1)} \in \mathbb{R}^{d_w \times h}$ and $\boldsymbol{\theta}^{(2)} \in \mathbb{R}^{h \times d_v}$.

Table 7 presents the results. Not surprisingly, performance increases with the number of sentences that are used to construct the textual representations. Furthermore, all models perform better than **Chance**, including those that are based on just **1** or **5** sentences. This suggests that the system can make reasonable inferences about object-word connections even when linguistic evidence is very scarce.

Regarding the sources of error, a qualitative analysis of predicted word labels and objects as

v→w	w→v
cooker→potato	dishwasher→ corkscrew
clarinet→ drum	potato→ corn
gorilla→ elephant	guitar→ violin
scooter→ car	scarf→ trouser

Table 6: Top-ranked concepts in cases where the gold concepts received numerically high ranks.

Context \ Mapping	v → w	w → v
Chance	17	17
context 1	12.6	14.5
context 5	8.08	13.29
context 10	7.29	13.44
context 20	6.02	12.17
context full	5.52	5.88

Table 7: Mean rank results averaged across 34 concepts when mapping an image-based vector and retrieving its linguistic neighbors (v → w) as well as when mapping a text-based vector and retrieving its visual neighbors (w → v). Lower numbers cue better performance.

presented in Table 6 suggests that both textual and visual representations, although capturing relevant "topical" or "domain" information, are not enough to single out the properties of the target concept. As an example, the textual vector of *dishwasher* contains kitchen-related dimensions such as ⟨**fridge**, **oven**, **gas**, **hob**, ..., **sink**⟩. After projecting onto the visual space, its nearest visual neighbours are the visual ones of the same-domain concepts *corkscrew* and *kettle*. The latter is shown in Figure 3a, with a *gas hob* well in evidence. As a further example, the visual vector for *cooker* is extracted from pictures such as the one in Figure 3b. Not surprisingly, when projecting it onto the linguistic space, the nearest neighbours are other kitchen-related terms, i.e., *potato* and *dishwasher*.

6 Conclusion

At the outset of this work, we considered the problem of linking purely language-based distributional semantic spaces with objects in the visual world by means of cross-modal mapping. We compared recent models for this task both on a benchmark object recognition dataset and on a more realistic and noisier dataset covering a wide range of concepts. The neural network architecture emerged as the best performing approach, and our qualitative analysis revealed that it induced a categorical organization of concepts. Most importantly, our results suggest the viability of cross-modal mapping for grounded word-meaning acquisition in a simulation of fast mapping.

Given the success of **NN**, we plan to experiment in the future with more sophisticated neural network architectures inspired by recent work in machine translation (Gao et al., 2013) and multimodal deep learning (Srivastava and Salakhutdinov, 2012). Furthermore, we intend to adopt *visual attributes* (Farhadi et al., 2009; Silberer et al., 2013) as visual representations, since they should allow a better understanding of how cross-modal mapping works, thanks to their linguistic interpretability. The error analysis in Section 5.3 suggests that automated *localization* techniques (van de Sande et al., 2011), distinguishing an object from its surroundings, might drastically improve mapping accuracy. Similarly, in the textual domain, models that extract collocates of a word that are more likely to denote conceptual properties (Kelly et al., 2012) might lead to more informative and discriminative linguistic vectors. Finally, the lack of large child-directed speech corpora constrained the experimental design of fast mapping simulations; we plan to run more realistic experiments with true nonce words and using source corpora (e.g., the Simple Wikipedia, child stories, portions of CHILDES) that contain sentences more akin to those a child might effectively hear or read in her word-learning years.

Semantic Parsing via Paraphrasing

Jonathan Berant

joberant@stanford.edu

Percy Liang
Stanford University
pliang@cs.stanford.edu

Abstract

A central challenge in semantic parsing is handling the myriad ways in which knowledge base predicates can be expressed. Traditionally, semantic parsers are trained primarily from text paired with knowledge base information. Our goal is to exploit the much larger amounts of raw text not tied to any knowledge base. In this paper, we turn semantic parsing on its head. Given an input utterance, we first use a simple method to deterministically generate a set of candidate logical forms with a canonical realization in natural language for each. Then, we use a paraphrase model to choose the realization that best paraphrases the input, and output the corresponding logical form. We present two simple paraphrase models, an *association* model and a *vector space* model, and train them jointly from question-answer pairs. Our system PARASEMPRE improves state-of-the-art accuracies on two recently released question-answering datasets.

1 Introduction

We consider the semantic parsing problem of mapping natural language utterances into logical forms to be executed on a knowledge base (KB) (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Wong and Mooney, 2007; Kwiatkowski et al., 2010). Scaling semantic parsers to large knowledge bases has attracted substantial attention recently (Cai and Yates, 2013; Berant et al., 2013; Kwiatkowski et al., 2013), since it drives applications such as question answering (QA) and information extraction (IE).

Semantic parsers need to somehow associate natural language phrases with logical predicates, e.g., they must learn that the constructions *"What does X do for a living?"*, *"What is X's profession?"*, and *"Who is X?"*, should all map to the logical predicate `Profession`. To learn these mappings, traditional semantic parsers use data which pairs natural language with the KB. However, this leaves untapped a vast amount of text not related to the KB. For instance, the utterances *"Where is ACL in 2014?"* and *"What is the location of ACL 2014?"* cannot be used in traditional semantic parsing methods, since the KB does not contain an entity `ACL2014`, but this pair clearly contains valuable linguistic information. As another reference point, out of 500,000 relations extracted by the ReVerb Open IE system (Fader et al., 2011), only about 10,000 can be aligned to Freebase (Berant et al., 2013).

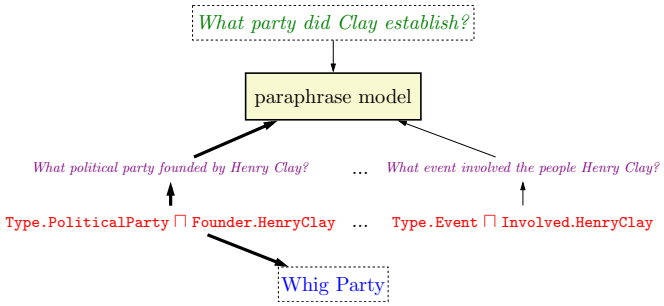

Figure 1: Semantic parsing via paraphrasing: For each candidate logical form (in red), we generate canonical utterances (in purple). The model is trained to paraphrase the input utterance (in green) into the canonical utterances associated with the correct denotation (in blue).

In this paper, we present a novel approach for semantic parsing based on paraphrasing that can exploit large amounts of text not covered by the KB (Figure 1). Our approach targets factoid questions with a modest amount of compositionality. Given an input utterance, we first use a simple deterministic procedure to construct a manageable set of candidate logical forms (ideally, we would generate canonical utterances for all possible logical forms, but this is intractable). Next, we heuris-

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1415–1425,
Baltimore, Maryland, USA, June 23-25 2014.

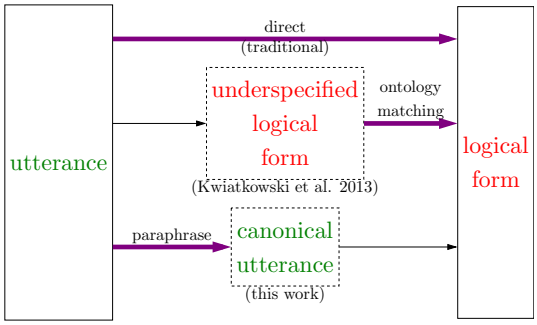

Figure 2: The main challenge in semantic parsing is coping with the *mismatch* between language and the KB. (a) Traditionally, semantic parsing maps utterances directly to logical forms. (b) Kwiatkowski et al. (2013) map the utterance to an underspecified logical form, and perform ontology matching to handle the mismatch. (c) We approach the problem in the other direction, generating canonical utterances for logical forms, and use paraphrase models to handle the mismatch.

tically generate *canonical utterances* for each logical form based on the text descriptions of predicates from the KB. Finally, we choose the canonical utterance that best paraphrases the input utterance, and thereby the logical form that generated it. We use two complementary paraphrase models: an *association model* based on aligned phrase pairs extracted from a monolingual parallel corpus, and a *vector space model*, which represents each utterance as a vector and learns a similarity score between them. The entire system is trained jointly from question-answer pairs only.

Our work relates to recent lines of research in semantic parsing and question answering. Kwiatkowski et al. (2013) first maps utterances to a domain-independent *intermediate logical form*, and then performs ontology matching to produce the final logical form. In some sense, we approach the problem from the opposite end, using an *intermediate utterance*, which allows us to employ paraphrasing methods (Figure 2). Fader et al. (2013) presented a QA system that maps questions onto simple queries against Open IE extractions, by learning paraphrases from a large monolingual parallel corpus, and performing a single paraphrasing step. We adopt the idea of using paraphrasing for QA, but suggest a more general paraphrase model and work against a formal KB (Freebase).

We apply our semantic parser on two datasets: WEBQUESTIONS (Berant et al., 2013), which contains 5,810 question-answer pairs with common questions asked by web users; and FREE917 (Cai and Yates, 2013), which has 917 questions manually authored by annotators. On WEBQUESTIONS, we obtain a relative improvement of 12% in accuracy over the state-of-the-art, and on FREE917 we match the current best performing system. The source code of our system PARASEMPRE is released at `http://www-nlp.stanford.edu/software/sempre/`.

2 Setup

Our task is as follows: Given (i) a knowledge base $\mathcal{K}$, and (ii) a training set of question-answer pairs $\{(x_i, y_i)\}_{i=1}^n$, output a semantic parser that maps new questions x to answers y via latent logical forms z. Let $\mathcal{E}$ denote a set of *entities* (e.g., `BillGates`), and let $\mathcal{P}$ denote a set of *properties* (e.g., `PlaceOfBirth`). A *knowledge base* $\mathcal{K}$ is a set of *assertions* $(e_1, p, e_2) \in \mathcal{E} \times \mathcal{P} \times \mathcal{E}$ (e.g., (`BillGates`, `PlaceOfBirth`, `Seattle`)). We use the Freebase KB (Google, 2013), which has 41M entities, 19K properties, and 596M assertions.

To query the KB, we use a logical language called *simple λ-DCS*. In simple λ-DCS, an entity (e.g., `Seattle`) is a unary predicate (i.e., a subset of $\mathcal{E}$) denoting a singleton set containing that entity. A property (which is a binary predicate) can be joined with a unary predicate; e.g., `Founded.Microsoft` denotes the entities that are Microsoft founders. In `PlaceOfBirth.Seattle` $\sqcap$ `Founded.Microsoft`, an intersection operator allows us to denote the set of Seattle-born Microsoft founders. A reverse operator reverses the order of arguments: **R**`[PlaceOfBirth].BillGates` denotes Bill Gates's birthplace (in contrast to `PlaceOfBirth.Seattle`). Lastly, `count(Founded.Microsoft)` denotes set cardinality, in this case, the number of Microsoft founders. The denotation of a logical form z with respect to a KB $\mathcal{K}$ is given by $[\![z]\!]_{\mathcal{K}}$. For a formal description of simple λ-DCS, see Liang (2013) and Berant et al. (2013).

3 Model overview

We now present the general framework for semantic parsing via paraphrasing, including the model and the learning algorithm. In Sections 4 and 5, we provide the details of our implementation.

Canonical utterance construction Given an utterance x and the KB, we construct a set of candi-

date logical forms $\mathcal{Z}_x$, and then for each $z \in \mathcal{Z}_x$ generate a small set of canonical natural language utterances $\mathcal{C}_z$. Our goal at this point is only to generate a manageable set of logical forms containing the correct one, and then generate an appropriate canonical utterance from it. This strategy is feasible in factoid QA where compositionality is low, and so the size of $\mathcal{Z}_x$ is limited (Section 4).

Paraphrasing We score the canonical utterances in $\mathcal{C}_z$ with respect to the input utterance x using a paraphrase model, which offers two advantages. First, the paraphrase model is decoupled from the KB, so we can train it from large text corpora. Second, natural language utterances often do not express predicates explicitly, e.g., the question *"What is Italy's money?"* expresses the binary predicate `CurrencyOf` with a possessive construction. Paraphrasing methods are well-suited for handling such text-to-text gaps. Our framework accommodates any paraphrasing method, and in this paper we propose an *association model* that learns to associate natural language phrases that co-occur frequently in a monolingual parallel corpus, combined with a *vector space model*, which learns to score the similarity between vector representations of natural language utterances (Section 5).

Model We define a discriminative log-linear model that places a probability distribution over pairs of logical forms and canonical utterances (c, z), given an utterance x:

$$p_\theta(c, z \mid x) = \frac{\exp\{\phi(x, c, z)^\top \theta\}}{\sum_{z' \in \mathcal{Z}_x, c' \in \mathcal{C}_z} \exp\{\phi(x, c', z')^\top \theta\}},$$

where $\theta \in \mathbb{R}^b$ is the vector of parameters to be learned, and $\phi(x, c, z)$ is a feature vector extracted from the input utterance x, the canonical utterance c, and the logical form z. Note that the candidate set of logical forms $\mathcal{Z}_x$ and canonical utterances $\mathcal{C}_x$ are constructed during the canonical utterance construction phase.

The model score decomposes into two terms:

$$\phi(x, c, z)^\top \theta = \phi_{\text{pr}}(x, c)^\top \theta_{\text{pr}} + \phi_{\text{lf}}(x, z)^\top \theta_{\text{lf}},$$

where the parameters θ_{pr} define the paraphrase model (Section 5), which is based on features extracted from text only (the input and canonical utterance). The parameters θ_{lf} correspond to semantic parsing features based on the logical form and input utterance, and are briefly described in this section.

Many existing paraphrase models introduce latent variables to describe the *derivation* of c from x, e.g., with transformations (Heilman and Smith, 2010; Stern and Dagan, 2011) or alignments (Haghighi et al., 2005; Das and Smith, 2009; Chang et al., 2010). However, we opt for a simpler paraphrase model without latent variables in the interest of efficiency.

Logical form features The parameters θ_{lf} correspond to the following features adopted from Berant et al. (2013). For a logical form z, we extract the size of its denotation $[\![z]\!]_{\mathcal{K}}$. We also add all binary predicates in z as features. Moreover, we extract a popularity feature for predicates based on the number of instances they have in $\mathcal{K}$. For Freebase entities, we extract a popularity feature based on the entity frequency in an entity linked subset of Reverb (Lin et al., 2012). Lastly, Freebase formulas have types (see Section 4), and we conjoin the type of z with the first word of x, to capture the correlation between a word (e.g., *"where"*) with the Freebase type (e.g., `Location`).

Learning As our training data consists of question-answer pairs (x_i, y_i), we maximize the log-likelihood of the correct answer. The probability of an answer y is obtained by marginalizing over canonical utterances c and logical forms z whose denotation is y. Formally, our objective function $\mathcal{O}(\theta)$ is as follows:

$$\mathcal{O}(\theta) = \sum_{i=1}^{n} \log p_\theta(y_i \mid x_i) - \lambda \|\theta\|_1,$$

$$p_\theta(y \mid x) = \sum_{z \in \mathcal{Z}_x : y = [\![z]\!]_{\mathcal{K}}} \sum_{c \in \mathcal{C}_z} p_\theta(c, z \mid x).$$

The strength λ of the L_1 regularizer is set based on cross-validation. We optimize the objective by initializing the parameters θ to zero and running AdaGrad (Duchi et al., 2010). We approximate the set of pairs of logical forms and canonical utterances with a beam of size 2,000.

4 Canonical utterance construction

We construct canonical utterances in two steps. Given an input utterance x, we first construct a set of logical forms $\mathcal{Z}_x$, and then generate canonical utterances from each $z \in \mathcal{Z}_x$. Both steps are performed with a small and simple set of deterministic rules, which suffices for our datasets, as

they consist of factoid questions with a modest amount of compositional structure. We describe these rules below for completeness. Due to its soporific effect though, we advise the reader to skim it quickly.

Candidate logical forms We consider logical forms defined by a set of templates, summarized in Table 1. The basic template is a join of a binary and an entity, where a binary can either be one property $p.e$ (#1 in the table) or two properties $p_1.p_2.e$ (#2). To handle cases of events involving multiple arguments (e.g., *"Who did Brad Pitt play in Troy?"*), we introduce the template $p.(p_1.e_1 \sqcap p_2.e_2)$ (#3), where the main event is modified by more than one entity. Logical forms can be further modified by a unary "filter", e.g., the answer to *"What composers spoke French?"* is a set of composers, i.e., a subset of all people (#4). Lastly, we handle aggregation formulas for utterances such as *"How many teams are in the NCAA?"* (#5).

To construct candidate logical forms $\mathcal{Z}_x$ for a given utterance x, our strategy is to find an entity in x and grow the logical form from that entity. As we show later, this procedure actually produces a set with better coverage than constructing logical forms recursively from spans of x, as is done in traditional semantic parsing. Specifically, for every span of x, we take at most 10 entities whose Freebase descriptions approximately match the span. Then, we join each entity e with all type-compatible[1] binaries b, and add these logical forms to $\mathcal{Z}_x$ (#1 and #2).

To construct logical forms with multiple entities (#3) we do the following: For any logical form $z = p.p_1.e_1$, where p_1 has type signature $(t_1, *)$, we look for other entities e_2 that were matched in x. Then, we add the logical form $p.(p_1.e_1 \sqcap p_2.e_2)$, if there exists a binary p_2 with a compatible type signature (t_1, t_2), where t_2 is one of e_2's types. For example, for the logical form `Character.Actor.BradPitt`, if we match the entity `Troy` in x, we obtain `Character.(Actor.BradPitt ⊓ Film.Troy)`. We further modify logical forms by intersecting with a unary filter (#4): given a formula z with some Freebase type (e.g., `People`), we look at all Freebase sub-types t (e.g., `Composer`), and check whether one of their Freebase descriptions (e.g., *"composer"*) appears in x. If so, we add the formula `Type`$.t \sqcap z$ to $\mathcal{Z}_x$. Finally, we check whether x is an aggregation formula by identifying whether it starts with phrases such as *"how many"* or *"number of"* (#5).

On WEBQUESTIONS, this results in 645 formulas per utterance on average. Clearly, we can increase the expressivity of this step by expanding the template set. For example, we could handle superlative utterances (*"What NBA player is tallest?"*) by adding a template with an `argmax` operator.

Utterance generation While mapping general language utterances to logical forms is hard, we observe that it is much easier to generate a *canonical* natural language utterances of our choice given a logical form. Table 2 summarizes the rules used to generate canonical utterances from the template $p.e$. Questions begin with a question word, are followed by the Freebase description of the expected answer type ($d(t)$), and followed by Freebase descriptions of the entity ($d(e)$) and binary ($d(p)$). To fill in auxiliary verbs, determiners, and prepositions, we parse the description $d(p)$ into one of NP, VP, PP, or NP VP. This determines the generation rule to be used.

Each Freebase property p has an explicit property p' equivalent to the reverse $\mathbf{R}[p]$ (e.g., `ContainedBy` and $\mathbf{R}$[`Contains`]). For each logical form z, we also generate using equivalent logical forms where p is replaced with $\mathbf{R}[p']$. Reversed formulas have different generation rules, since entities in these formulas are in the subject position rather than object position.

We generate the description $d(t)$ from the Freebase description of the type of z (this handles #4). For the template $p_1.p_2.e$ (#2), we have a similar set of rules, which depends on the syntax of $d(p_1)$ and $d(p_2)$ and is omitted for brevity. The template $p.(p_1.e_1 \sqcap p_2.e_2)$ (#3) is generated by appending the prepositional phrase `in` $d(e_2)$, e.g, *"What character is the character of Brad Pitt in Troy?"*. Lastly, we choose the question phrase *"How many"* for aggregation formulas (#5), and *"What"* for all other formulas.

We also generate canonical utterances using an alignment lexicon, released by Berant et al. (2013), which maps text phrases to Freebase binary predicates. For a binary predicate b mapped from text phrase $d(b)$, we generate the utterance

[1] Entities in Freebase are associated with a set of types, and properties have a type signature (t_1, t_2) We use these types to compute an expected type t for any logical form z.

#	Template	Example	Question
1	$p.e$	`Directed.TopGun`	*Who directed Top Gun?*
2	$p_1.p_2.e$	`Employment.EmployerOf.SteveBalmer`	*Where does Steve Balmer work?*
3	$p.(p_1.e_1 \sqcap p_2.e_2)$	`Character.(Actor.BradPitt` $\sqcap$ `Film.Troy)`	*Who did Brad Pitt play in Troy?*
4	`Type.`$t \sqcap z$	`Type.Composer` $\sqcap$ `SpeakerOf.French`	*What composers spoke French?*
5	`count(`z`)`	`count(BoatDesigner.NatHerreshoff)`	*How many ships were designed by Nat Herreshoff?*

Table 1: Logical form templates, where p, p_1, p_2 are Freebase properties, e, e_1, e_2 are Freebase entities, t is a Freebase type, and z is a logical form.

	$d(p)$ Categ.	Rule	Example
$p.e$	NP	`WH` $d(t)$ `has` $d(e)$ `as` NP ?	*What* ***election contest*** *has* ***George Bush*** *as* ***winner?***
	VP	`WH` $d(t)$ `(AUX)` VP $d(e)$?	*What* ***radio station serves area New-York****?*
	PP	`WH` $d(t)$ PP $d(e)$?	*What* ***beer from region Argentina****?*
	NP VP	`WH` $d(t)$ VP `the` NP $d(e)$?	*What* ***mass transportation system served*** *the* ***area Berlin****?*
$\mathbf{R}(p).e$	NP	`WH` $d(t)$ `is the` NP `of` $d(e)$?	*What* ***location*** *is the* ***place of birth*** *of* ***Elvis Presley****?*
	VP	`WH` $d(t)$ `AUX` $d(e)$ VP ?	*What* ***film*** *is* ***Brazil featured in****?*
	PP	`WH` $d(t)$ $d(e)$ PP ?	*What* ***destination Spanish steps near travel destination****?*
	NP VP	`WH` NP `is` VP `by` $d(e)$?	*What* ***structure*** *is* ***designed*** *by Herod?*

Table 2: Generation rules for templates of the form $p.e$ and $\mathbf{R}[p].e$ based on the syntactic category of the property description. Freebase descriptions for the type, entity, and property are denoted by $d(t)$, $d(e)$ and $d(p)$ respectively. The surface form of the auxiliary `AUX` is determined by the POS tag of the verb inside the VP tree.

`WH` $d(t)$ $d(b)$ $d(e)$ `?`. On the WEBQUESTIONS dataset, we generate an average of 1,423 canonical utterances c per input utterance x. In Section 6, we show that an even simpler method of generating canonical utterances by concatenating Freebase descriptions hurts accuracy by only a modest amount.

5 Paraphrasing

Once the candidate set of logical forms paired with canonical utterances is constructed, our problem is reduced to scoring pairs (c, z) based on a paraphrase model. The NLP paraphrase literature is vast and ranges from simple methods employing surface features (Wan et al., 2006), through vector space models (Socher et al., 2011), to latent variable models (Das and Smith, 2009; Wang and Manning, 2010; Stern and Dagan, 2011).

In this paper, we focus on two paraphrase models that emphasize simplicity and efficiency. This is important since for each question-answer pair, we consider thousands of canonical utterances as potential paraphrases. In contrast, traditional paraphrase detection (Dolan et al., 2004) and Recognizing Textual Entailment (RTE) tasks (Dagan et al., 2013) consider examples consisting of only a single pair of candidate paraphrases.

Our paraphrase model decomposes into an *association model* and a *vector space model*:

$$\phi_{\text{pr}}(x, c)^\top \theta_{\text{pr}} = \phi_{\text{as}}(x, c)^\top \theta_{\text{as}} + \phi_{\text{vs}}(x, c)^\top \theta_{\text{vs}}.$$

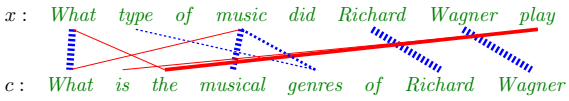

Figure 3: Token associations extracted for a paraphrase pair. Blue and dashed (red and solid) indicate positive (negative) score. Line width is proportional to the absolute value of the score.

5.1 Association model

The goal of the association model is to determine whether x and c contain phrases that are likely to be paraphrases. Given an utterance $x = \langle x_0, x_1, .., x_{n-1} \rangle$, we denote by $x_{i:j}$ the span from token i to token j. For each pair of utterances (x, c), we go through all spans of x and c and identify a set of pairs of potential paraphrases $(x_{i:j}, c_{i':j'})$, which we call *associations*. (We will describe how associations are identified shortly.) We then define features on each association; the weighted combination of these features yields a score. In this light, associations can be viewed as soft paraphrase rules. Figure 3 presents examples of associations extracted from a paraphrase pair and visualizes the learned scores. We can see that our model learns a positive score for associating *"type"* with *"genres"*, and a negative score for associating *"is"* with *"play"*.

We define associations in x and c primarily by looking up phrase pairs in a phrase table constructed using the PARALEX corpus (Fader et al., 2013). PARALEX is a large monolingual parallel

Category	Description
Assoc.	lemma($x_{i:j}$) $\wedge$ lemma($c_{i':j'}$) pos($x_{i:j}$) $\wedge$ pos($c_{i':j'}$) lemma($x_{i:j}$) = lemma($c_{i':j'}$)? pos($x_{i:j}$) = pos($c_{i':j'}$)? lemma($x_{i:j}$) and lemma($c_{i':j'}$) are synonyms? lemma($x_{i:j}$) and lemma($c_{i':j'}$) are derivations?
Deletions	Deleted lemma and POS tag

Table 3: Full feature set in the association model. $x_{i:j}$ and $c_{i':j'}$ denote spans from x and c. pos($x_{i:j}$) and lemma($x_{i:j}$) denote the POS tag and lemma sequence of $x_{i:j}$.

corpora, containing 18 million pairs of question paraphrases from `wikianswers.com`, which were tagged as having the same meaning by users. PARALEX is suitable for our needs since it focuses on *question* paraphrases. For example, the phrase *"do for a living"* occurs mostly in questions, and we can extract associations for this phrase from PARALEX. Paraphrase pairs in PARALEX are word-aligned using standard machine translation methods. We use the word alignments to construct a phrase table by applying the consistent phrase pair heuristic (Och and Ney, 2004) to all 5-grams. This results in a phrase table with approximately 1.3 million phrase pairs. We let $\mathcal{A}$ denote this set of mined candidate associations.

For a pair (x, c), we also consider as candidate associations the set $\mathcal{B}$ (represented implicitly), which contains token pairs $(x_i, c_{i'})$ such that x_i and $c_{i'}$ share the same lemma, the same POS tag, or are linked through a *derivation* link on WordNet (Fellbaum, 1998). This allows us to learn paraphrases for words that appear in our datasets but are not covered by the phrase table, and to handle nominalizations for phrase pairs such as *"Who designed the game of life?"* and *"What game designer is the designer of the game of life?"*.

Our model goes over all possible spans of x and c and constructs all possible associations from $\mathcal{A}$ and $\mathcal{B}$. This results in many poor associations (e.g., *"play"* and *"the"*), but as illustrated in Figure 3, we learn weights that discriminate good from bad associations. Table 3 specifies the full set of features. Note that unlike standard paraphrase detection and RTE systems, we use lexicalized features, firing approximately 400,000 features on WEBQUESTIONS. By extracting POS features, we obtain soft syntactic rules, e.g., the feature "`JJ N` $\wedge$ `N`" indicates that omitting adjectives before nouns is possible. Once associations are constructed, we mark tokens in x and c that were not part of any association, and extract deletion features for their lemmas and POS tags. Thus, we learn that deleting pronouns is acceptable, while deleting nouns is not.

To summarize, the association model links phrases of two utterances in multiple overlapping ways. During training, the model learns which associations are characteristic of paraphrases and which are not.

5.2 Vector space model

The association model relies on having a good set of candidate associations, but mining associations suffers from coverage issues. We now introduce a vector space (VS) model, which assigns a vector representation for each utterance, and learns a scoring function that ranks paraphrase candidates.

We start by constructing vector representations of words. We run the WORD2VEC tool (Mikolov et al., 2013) on lower-cased Wikipedia text (1.59 billion tokens), using the CBOW model with a window of 5 and hierarchical softmax. We also experiment with publicly released word embeddings (Huang et al., 2012), which were trained using both local and global context. Both result in k-dimensional vectors ($k = 50$). Next, we construct a vector $v_x \in \mathbb{R}^k$ for each utterance x by simply averaging the vectors of all content words (nouns, verbs, and adjectives) in x.

We can now estimate a paraphrase score for two utterances x and c via a weighted combination of the components of the vector representations:

$$v_x^\top W v_c = \sum_{i,j=1}^{k} w_{ij} v_{x,i} v_{c,j}$$

where $W \in \mathbb{R}^{k \times k}$ is a parameter matrix. In terms of our earlier notation, we have $\theta_{\text{vs}} = \text{vec}(W)$ and $\phi_{\text{vs}}(x, c) = \text{vec}(v_x v_c^\top)$, where vec$(\cdot)$ unrolls a matrix into a vector. In Section 6, we experiment with W equal to the identity matrix, constraining W to be diagonal, and learning a full W matrix.

The VS model can identify correct paraphrases in cases where it is hard to directly associate phrases from x and c. For example, the answer to *"Where is made Kia car?"* (from WEBQUESTIONS), is given by the canonical utterance *"What city is Kia motors a headquarters of?"*. The association model does not associate *"made"* and *"headquarters"*, but the VS model is able to determine that these utterances are semantically related. In other cases, the VS model cannot distinguish correct paraphrases from incorrect ones. For

Dataset	# examples	# word types
FREE917	917	2,036
WEBQUESTIONS	5,810	4,525

Table 4: Statistics on WEBQUESTIONS and FREE917.

example, the association model identifies that the paraphrase for *"What type of music did Richard Wagner Play?"* is *"What is the musical genres of Richard Wagner?"*, by relating phrases such as *"type of music"* and *"musical genres"*. The VS model ranks the canonical utterance *"What composition has Richard Wagner as lyricist?"* higher, as this utterance is also in the music domain. Thus, we combine the two models to benefit from their complementary nature.

In summary, while the association model aligns particular phrases to one another, the vector space model provides a soft vector-based representation for utterances.

6 Empirical evaluation

In this section, we evaluate our system on WEBQUESTIONS and FREE917. After describing the setup (Section 6.1), we present our main empirical results and analyze the components of the system (Section 6.2).

6.1 Setup

We use the WEBQUESTIONS dataset (Berant et al., 2013), which contains 5,810 question-answer pairs. This dataset was created by crawling questions through the Google Suggest API, and then obtaining answers using Amazon Mechanical Turk. We use the original train-test split, and divide the training set into 3 random 80%–20% splits for development. This dataset is characterized by questions that are commonly asked on the web (and are not necessarily grammatical), such as *"What character did Natalie Portman play in Star Wars?"* and *"What kind of money to take to Bahamas?"*.

The FREE917 dataset contains 917 questions, authored by two annotators and annotated with logical forms. This dataset contains questions on rarer topics (for example, *"What is the engine in a 2010 Ferrari California?"* and *"What was the cover price of the X-men Issue 1?"*), but the phrasing of questions tends to be more rigid compared to WEBQUESTIONS. Table 4 provides some statistics on the two datasets. Following Cai and Yates (2013), we hold out 30% of the data for the final test, and perform 3 random 80%-20% splits of the training set for development. Since we train from question-answer pairs, we collect answers by executing the gold logical forms against Freebase.

We execute λ-DCS queries by converting them into SPARQL and executing them against a copy of Freebase using the Virtuoso database engine. We evaluate our system with accuracy, that is, the proportion of questions we answer correctly. We run all questions through the Stanford CoreNLP pipeline (Toutanova and Manning, 2003; Finkel et al., 2005; Klein and Manning, 2003).

We tuned the L_1 regularization strength, developed features, and ran analysis experiments on the development set (averaging across random splits). On WEBQUESTIONS, without L_1 regularization, the number of non-zero features was 360K; L_1 regularization brings it down to 17K.

6.2 Results

We compare our system to Cai and Yates (2013) (CY13), Berant et al. (2013) (BCFL13), and Kwiatkowski et al. (2013) (KCAZ13). For BCFL13, we obtained results using the SEMPRE package[2] and running Berant et al. (2013)'s system on the datasets.

Table 5 presents results on the test set. We achieve a substantial relative improvement of 12% in accuracy on WEBQUESTIONS, and match the best results on FREE917. Interestingly, our system gets an *oracle accuracy* of 63% on WEBQUESTIONS compared to 48% obtained by BCFL13, where the oracle accuracy is the fraction of questions for which at least one logical form in the candidate set produced by the system is correct. This demonstrates that our method for constructing candidate logical forms is reasonable. To further examine this, we ran BCFL13 on the development set, allowing it to use only predicates from logical forms suggested by our logical form construction step. This improved oracle accuracy on the development set to 64.5%, but accuracy was 32.2%. This shows that the improvement in accuracy should not be attributed only to better logical form generation, but also to the paraphrase model.

We now perform more extensive analysis of our system's components and compare it to various baselines.

Component ablation We ablate the association model, the VS model, and the entire paraphrase

We omit scores for the words *"czech"* and *"republic"* since they appear in all canonical utterances for this example.

model (using only logical form features). Table 5 shows that our full system obtains highest accuracy, and that removing the association model results in a much larger degradation compared to removing the VS model.

Utterance generation Our system generates relatively natural utterances from logical forms using simple rules based on Freebase descriptions (Section 4). We now consider simply concatenating Freebase descriptions. For example, the logical form `R[PlaceOfBirth].ElvisPresley` would generate the utterance *"What location Elvis Presley place of birth?"*. Row SIMPLEGEN in Table 6 demonstrates that we still get good results in this setup. This is expected given that our paraphrase models are not sensitive to the syntactic structure of the generated utterance.

VS model Our system learns parameters for a full W matrix. We now examine results when learning parameters for a full matrix W, a diagonal matrix W, and when setting W to be the identity matrix. Table 6 (third section) illustrates that learning a full matrix substantially improves accuracy. Figure 4 gives an example for a correct paraphrase pair, where the full matrix model boosts the overall model score. Note that the full matrix assigns a high score for the phrases *"official language"* and *"speak"* compared to the simpler models, but other pairs are less interpretable.

Baselines We also compared our system to the following implemented baselines:

- JACCARD: We compute the Jaccard score between the tokens of x and c and define $\phi_{\text{pr}}(x, c)$ to be this single feature.
- EDIT: We compute the token edit distance between x and c and define $\phi_{\text{pr}}(x, c)$ to be this single feature.
- WDDC06: We re-implement 13 features from Wan et al. (2006), who obtained close to state-of-the-art performance on the Microsoft Research paraphrase corpus.[3]

Table 6 demonstrates that we improve performance over all baselines. Interestingly, JACCARD and WDDC06 obtain reasonable performance on FREE917 but perform much worse on WEBQUESTIONS. We surmise this is because questions in FREE917 were generated by annotators prompted by Freebase facts, whereas questions in WEBQUESTIONS originated independently of Freebase. Thus, word choice in FREE917 is often close to the generated Freebase descriptions, allowing simple baselines to perform well.

Error analysis We sampled examples from the development set to examine the main reasons PARASEMPRE makes errors. We notice that in many cases the paraphrase model can be further improved. For example, PARASEMPRE suggests

[3]We implement all features that do not require dependency parsing.

that the best paraphrase for *"What company did Henry Ford work for?"* is *"What written work novel by Henry Ford?"* rather than *"The employer of Henry Ford"*, due to the exact match of the word *"work"*. Another example is the question *"Where is the Nascar hall of fame?"*, where PARASEMPRE suggests that *"What hall of fame discipline has Nascar hall of fame as halls of fame?"* is the best canonical utterance. This is because our simple model allows to associate *"hall of fame"* with the canonical utterance three times. Entity recognition also accounts for many errors, e.g., the entity chosen in *"where was the gallipoli campaign waged?"* is `Galipoli` and not `GalipoliCampaign`. Last, PARASEMPRE does not handle temporal information, which causes errors in questions like *"Where did Harriet Tubman live after the civil war?"*

7 Discussion

In this work, we approach the problem of semantic parsing from a paraphrasing viewpoint. A fundamental motivation and long standing goal of the paraphrasing and RTE communities has been to cast various semantic applications as paraphrasing/textual entailment (Dagan et al., 2013). While it has been shown that paraphrasing methods are useful for question answering (Harabagiu and Hickl, 2006) and relation extraction (Romano et al., 2006), this is, to the best of our knowledge, the first paper to perform semantic parsing through paraphrasing. Our paraphrase model emphasizes simplicity and efficiency, but the framework is agnostic to the internals of the paraphrase method.

On the semantic parsing side, our work is most related to Kwiatkowski et al. (2013). The main challenge in semantic parsing is coping with the *mismatch* between language and the KB. In both Kwiatkowski et al. (2013) and this work, an intermediate representation is employed to handle the mismatch, but while they use a logical representation, we opt for a text-based one. Our choice allows us to benefit from the parallel monolingual corpus PARALEX and from word vectors trained on Wikipedia. We believe that our approach is particularly suitable for scenarios such as factoid question answering, where the space of logical forms is somewhat constrained and a few generation rules suffice to reduce the problem to paraphrasing.

Our work is also related to Fader et al. (2013), who presented a paraphrase-driven question answering system. One can view this work as a generalization of Fader et al. along three dimensions. First, Fader et al. use a KB over natural language extractions rather than a formal KB and so querying the KB does not require a generation step – they paraphrase questions to KB entries directly. Second, they suggest a particular paraphrasing method that maps a test question to a question for which the answer is already known in a single step. We propose a general paraphrasing framework and instantiate it with two paraphrase models. Lastly, Fader et al. handle queries with only one property and entity whereas we generalize to more types of logical forms.

Since our generated questions are passed to a paraphrase model, we took a very simple approach, mostly ensuring that we preserved the semantics of the utterance without striving for the most fluent realization. Research on generation (Dale et al., 2003; Reiter et al., 2005; Turner et al., 2009; Piwek and Boyer, 2012) typically focuses on generating natural utterances for human consumption, where fluency is important.

In conclusion, the main contribution of this paper is a novel approach for semantic parsing based on a simple generation procedure and a paraphrase model. We achieve state-of-the-art results on two recently released datasets. We believe that our approach opens a window of opportunity for learning semantic parsers from raw text not necessarily related to the target KB. With more sophisticated generation and paraphrase, we hope to tackle compositionally richer utterances.

Abstract

Abstract Meaning Representation (AMR) is a semantic formalism for which a growing set of annotated examples is available. We introduce the first approach to parse sentences into this representation, providing a strong baseline for future improvement. The method is based on a novel algorithm for finding a maximum spanning, connected subgraph, embedded within a Lagrangian relaxation of an optimization problem that imposes linguistically inspired constraints. Our approach is described in the general framework of structured prediction, allowing future incorporation of additional features and constraints, and may extend to other formalisms as well. Our open-source system, JAMR, is available at:
http://github.com/jflanigan/jamr

1 Introduction

Semantic parsing is the problem of mapping natural language strings into meaning representations. Abstract Meaning Representation (AMR) (Banarescu et al., 2013; Dorr et al., 1998) is a semantic formalism in which the meaning of a sentence is encoded as a rooted, directed, acyclic graph. Nodes represent concepts, and labeled directed edges represent the relationships between them–see Figure 1 for an example AMR graph. The formalism is based on propositional logic and neo-Davidsonian event representations (Parsons, 1990; Davidson, 1967). Although it does not encode quantifiers, tense, or modality, the set of semantic phenomena included in AMR were selected with natural language applications—in particular, machine translation—in mind.

In this paper we introduce JAMR, the first published system for automatic AMR parsing. The system is based on a statistical model whose parameters are trained discriminatively using annotated sentences in the AMR Bank corpus (Banarescu et al., 2013). We evaluate using the Smatch score (Cai and Knight, 2013), establishing a baseline for future work.

The core of JAMR is a two-part algorithm that first identifies *concepts* using a semi-Markov model and then identifies the *relations* that obtain between these by searching for the **maximum spanning connected subgraph** (MSCG) from an edge-labeled, directed graph representing all possible relations between the identified concepts. To solve the latter problem, we introduce an apparently novel $O(|V|^2 \log |V|)$ algorithm that is similar to the maximum spanning tree (MST) algorithms that are widely used for dependency parsing (McDonald et al., 2005). Our MSCG algorithm returns the connected subgraph with maximal sum of its edge weights from among all connected subgraphs of the input graph. Since AMR imposes additional constraints to ensure semantic well-formedness, we use Lagrangian relaxation (Geoffrion, 1974; Fisher, 2004) to augment the MSCG algorithm, yielding a tractable iterative algorithm that finds the optimal solution subject to these constraints. In our experiments, we have found this algorithm to converge 100% of the time for the constraint set we use.

The approach can be understood as an alternative to parsing approaches using graph transducers such as (synchronous) hyperedge replacement grammars (Chiang et al., 2013; Jones et al., 2012; Drewes et al., 1997), in much the same way that spanning tree algorithms are an alternative to using shift-reduce and dynamic programming algorithms for dependency parsing.[1] While a detailed

[1] To date, a graph transducer-based semantic parser has not been published, although the Bolinas toolkit (http://www.isi.edu/publications/licensed-sw/bolinas/) contains much of the necessary infrastructure.

  :ARG1 (g / visit-01
           :ARG0 b
           :ARG1 (c / city
                    :name (n / name
                             :op1 "New"
                             :op2 "York"
                             :op3 "City"))))
```

(b) AMR annotation.

Figure 1: Two equivalent ways of representing the AMR parse for the sentence, "The boy wants to visit New York City."

comparison of these two approaches is beyond the scope of this paper, we emphasize that—as has been observed with dependency parsing—a diversity of approaches can shed light on complex problems such as semantic parsing.

2 Notation and Overview

Our approach to AMR parsing represents an AMR parse as a graph $G = \langle V, E \rangle$; vertices and edges are given labels from sets L_V and L_E, respectively. G is constructed in two stages. The first stage identifies the **concepts** evoked by words and phrases in an input sentence $\boldsymbol{w} = \langle w_1, \ldots, w_n \rangle$, each w_i a member of vocabulary W. The second stage connects the concepts by adding L_E-labeled edges capturing the **relations** between concepts, and selects a root in G corresponding to the **focus** of the sentence $\boldsymbol{w}$.

Concept identification (§3) involves segmenting $\boldsymbol{w}$ into contiguous spans and assigning to each span a graph fragment corresponding to a concept from a concept set denoted F (or to $\emptyset$ for words that evoke no concept). In §5 we describe how F is constructed. In our formulation, spans are contiguous subsequences of $\boldsymbol{w}$. For example, the words "New York City" can evoke the fragment represented by

```
(c / city
  :name (n / name
           :op1 "New"
           :op2 "York"
           :op3 "City"))))
```

We use a sequence labeling algorithm to identify concepts.

The relation identification stage (§4) is similar to a graph-based dependency parser. Instead of finding the maximum-scoring tree over words, it finds the maximum-scoring connected subgraph that preserves concept fragments from the first stage, links each pair of vertices by at most one edge, and is deterministic[2] with respect to a special set of edge labels $L_E^* \subset L_E$. The set L_E^* consists of the labels ARG0–ARG5, and does not include labels such as MOD or MANNER, for example. Linguistically, the determinism constraint enforces that predicates have at most one semantic argument of each type; this is discussed in more detail in §4.

To train the parser, spans of words must be labeled with the concept fragments they evoke. Although AMR Bank does not label concepts with the words that evoke them, it is possible to build an automatic aligner (§5). The alignments are used to construct the concept lexicon and to train the concept identification and relation identification stages of the parser (§6). Each stage is a discriminatively-trained linear structured predictor with rich features that make use of part-of-speech tagging, named entity tagging, and dependency parsing.

In §7, we evaluate the parser against gold-standard annotated sentences from the AMR Bank corpus (Banarescu et al., 2013) under the Smatch score (Cai and Knight, 2013), presenting the first published results on automatic AMR parsing.

3 Concept Identification

The concept identification stage maps spans of words in the input sentence $\boldsymbol{w}$ to concept graph fragments from F, or to the empty graph fragment $\emptyset$. These graph fragments often consist of just one labeled concept node, but in some cases they are larger graphs with multiple nodes and edges.[3]

[2] By this we mean that, at each node, there is at most one outgoing edge with that label type.

[3] About 20% of invoked concept fragments are multi-concept fragments.

Concept identification is illustrated in Figure 2 using our running example, "The boy wants to visit New York City."

Let the concept lexicon be a mapping $clex : W^* \rightarrow 2^F$ that provides candidate graph fragments for sequences of words. (The construction of F and $clex$ is discussed below.) Formally, a concept labeling is (i) a segmentation of $\boldsymbol{w}$ into contiguous spans represented by boundaries $\boldsymbol{b}$, giving spans $\langle \boldsymbol{w}_{b_0:b_1}, \boldsymbol{w}_{b_1:b_2}, \ldots \boldsymbol{w}_{b_{k-1}:b_k} \rangle$, with $b_0 = 0$ and $b_k = n$, and (ii) an assignment of each phrase $\boldsymbol{w}_{b_{i-1}:b_i}$ to a concept graph fragment $c_i \in clex(\boldsymbol{w}_{b_{i-1}:b_i}) \cup \emptyset$.

Our approach scores a sequence of spans $\boldsymbol{b}$ and a sequence of concept graph fragments $\boldsymbol{c}$, both of arbitrary length k, using the following locally decomposed, linearly parameterized function:

$$score(\boldsymbol{b}, \boldsymbol{c}; \boldsymbol{\theta}) = \sum_{i=1}^{k} \boldsymbol{\theta}^\top \mathbf{f}(\boldsymbol{w}_{b_{i-1}:b_i}, b_{i-1}, b_i, c_i) \quad (1)$$

where $\mathbf{f}$ is a feature vector representation of a span and one of its concept graph fragments in context. The features are:

- **Fragment given words**: Relative frequency estimates of the probability of a concept graph fragment given the sequence of words in the span. This is calculated from the concept-word alignments in the training corpus (§5).
- **Length** of the matching span (number of tokens).
- **NER**: 1 if the named entity tagger marked the span as an entity, 0 otherwise.
- **Bias**: 1 for any concept graph fragment from F and 0 for $\emptyset$.

Our approach finds the highest-scoring $\boldsymbol{b}$ and $\boldsymbol{c}$ using a dynamic programming algorithm: the zeroth-order case of inference under a semi-Markov model (Janssen and Limnios, 1999). Let $S(i)$ denote the score of the best labeling of the first i words of the sentence, $\boldsymbol{w}_{0:i}$; it can be calculated using the recurrence:

$$S(0) = 0$$
$$S(i) = \max_{\substack{j:0 \leq j < i, \\ c \in clex(\boldsymbol{w}_{j:i}) \cup \emptyset}} \left\{ S(j) + \boldsymbol{\theta}^\top \mathbf{f}(\boldsymbol{w}_{j:i}, j, i, c) \right\}$$

The best score will be $S(n)$, and the best scoring concept labeling can be recovered using backpointers, as in typical implementations of the Viterbi algorithm. Runtime is $O(n^2)$.

$clex$ is implemented as follows. When $clex$ is called with a sequence of words, it looks up the sequence in a table that contains, for every word sequence that was labeled with a concept fragment in the training data, the set of concept fragments it was labeled with. $clex$ also has a set of rules for generating concept fragments for named entities and time expressions. It generates a concept fragment for any entity recognized by the named entity tagger, as well as for any word sequence matching a regular expression for a time expression. $clex$ returns the union of all these concept fragments.

4 Relation Identification

The relation identification stage adds edges among the concept subgraph fragments identified in the first stage (§3), creating a graph. We frame the task as a constrained combinatorial optimization problem.

Consider the fully dense labeled multigraph $D = \langle V_D, E_D \rangle$ that includes the union of all labeled vertices and labeled edges in the concept graph fragments, as well as every possible labeled edge $u \xrightarrow{\ell} v$, for all $u, v \in V_D$ and every $\ell \in L_E$.[4]

We require a subgraph $G = \langle V_G, E_G \rangle$ that respects the following constraints:

1. **Preserving**: all graph fragments (including labels) from the concept identification phase are subgraphs of G.
2. **Simple**: for any two vertices u and $v \in V_G$, E_G includes at most one edge between u and v. This constraint forbids a small number of perfectly valid graphs, for example for sentences such as "John hurt himself"; however, we see that $< 1\%$ of training instances violate the constraint. We found in preliminary experiments that including the constraint increases overall performance.[5]
3. **Connected**: G must be weakly connected (every vertex reachable from every other vertex, ignoring the direction of edges). This constraint follows from the formal definition of AMR and is never violated in the training data.
4. **Deterministic**: For each node $u \in V_G$, and for each label $\ell \in L_E^*$, there is at most one outgoing edge in E_G from u with label ℓ. As discussed in §2, this constraint is linguistically motivated.

[4] To handle numbered OP labels, we pre-process the training data to convert OPN to OP, and post-process the output by numbering the OP labels sequentially.

[5] In future work it might be treated as a soft constraint, or the constraint might be refined to specific cases.

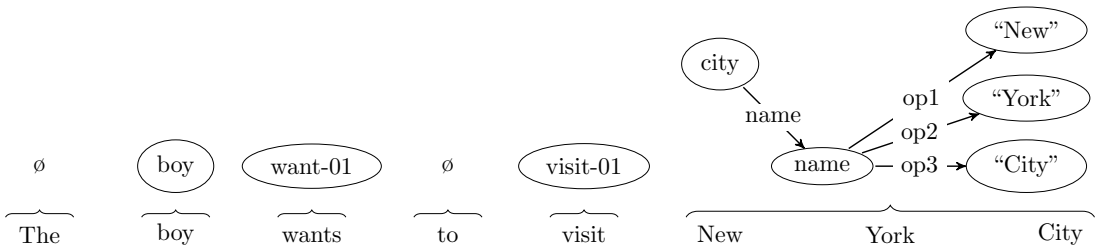

Figure 2: A concept labeling for the sentence "The boy wants to visit New York City."

One constraint we do not include is **acyclicity**, which follows from the definition of AMR. In practice, graphs with cycles are rarely produced by JAMR. In fact, none of the graphs produced on the test set violate acyclicity.

Given the constraints, we seek the maximum-scoring subgraph. We define the score to decompose by edges, and with a linear parameterization:

$$score(E_G; \boldsymbol{\psi}) = \sum_{e \in E_G} \boldsymbol{\psi}^\top \mathbf{g}(e) \qquad (2)$$

The features are shown in Table 1.

Our solution to maximizing the score in Eq. 2, subject to the constraints, makes use of (i) an algorithm that ignores constraint 4 but respects the others (§4.1); and (ii) a Lagrangian relaxation that iteratively adjusts the edge scores supplied to (i) so as to enforce constraint 4 (§4.2).

4.1 Maximum Preserving, Simple, Spanning, Connected Subgraph Algorithm

The steps for constructing a maximum preserving, simple, spanning, connected (but not necessarily deterministic) subgraph are as follows. These steps ensure the resulting graph G satisfies the constraints: the initialization step ensures the preserving constraint is satisfied, the pre-processing step ensures the graph is simple, and the core algorithm ensures the graph is connected.

1. (Initialization) Let $E^{(0)}$ be the union of the concept graph fragments' weighted, labeled, directed edges. Let V denote its set of vertices. Note that $\langle V, E^{(0)} \rangle$ is preserving (constraint 4), as is any graph that contains it. It is also simple (constraint 4), assuming each concept graph fragment is simple.
2. (Pre-processing) We form the edge set E by including just one edge from E_D between each pair of nodes:
   - For any edge $e = u \xrightarrow{\ell} v$ in $E^{(0)}$, include e in E, omitting all other edges between u and v.
   - For any two nodes u and v, include only the highest scoring edge between u and v.

   Note that without the deterministic constraint, we have no constraints that depend on the label of an edge, nor its direction. So it is clear that the edges omitted in this step could not be part of the maximum-scoring solution, as they could be replaced by a higher scoring edge without violating any constraints.

   Note also that because we have kept exactly one edge between every pair of nodes, $\langle V, E \rangle$ is simple and connected.
3. (Core algorithm) Run Algorithm 1, MSCG, on $\langle V, E \rangle$ and $E^{(0)}$. This algorithm is a (to our knowledge novel) modification of the minimum spanning tree algorithm of Kruskal (1956). Note that the directions of edges do not matter for MSCG.

Steps 1–2 can be accomplished in one pass through the edges, with runtime $O(|V|^2)$. MSCG can be implemented efficiently in $O(|V|^2 \log |V|)$ time, similarly to Kruskal's algorithm, using a disjoint-set data structure to keep track of connected components.[6] The total asymptotic runtime complexity is $O(|V|^2 \log |V|)$.

The details of MSCG are given in Algorithm 1. In a nutshell, MSCG first adds all positive edges to the graph, and then connects the graph by greedily adding the least negative edge that connects two previously unconnected components.

Theorem 1. MSCG *finds a maximum spanning, connected subgraph of* $\langle V, E \rangle$

Proof. We closely follow the original proof of correctness of Kruskal's algorithm. We first show by induction that, at every iteration of MSCG, there exists some maximum spanning, connected subgraph that contains $G^{(i)} = \langle V, E^{(i)} \rangle$:

[6] For dense graphs, Prim's algorithm (Prim, 1957) is asymptotically faster ($O(|V|^2)$). We conjecture that using Prim's algorithm instead of Kruskall's to connect the graph could improve the runtime of MSCG.

Name	Description
Label	For each $\ell \in L_E$, 1 if the edge has that label
Self edge	1 if the edge is between two nodes in the same fragment
Tail fragment root	1 if the edge's tail is the root of its graph fragment
Head fragment root	1 if the edge's head is the root of its graph fragment
Path	Dependency edge labels and parts of speech on the shortest syntactic path between any two words in the two spans
Distance	Number of tokens (plus one) between the two concepts' spans (zero if the same)
Distance indicators	A feature for each distance value, that is 1 if the spans are of that distance
Log distance	Logarithm of the distance feature plus one.
Bias	1 for any edge.

Table 1: Features used in relation identification. In addition to the features above, the following conjunctions are used (Tail and Head concepts are elements of L_V): Tail concept ∧ Label, Head concept ∧ Label, Path ∧ Label, Path ∧ Head concept, Path ∧ Tail concept, Path ∧ Head concept ∧ Label, Path ∧ Tail concept ∧ Label, Path ∧ Head word, Path ∧ Tail word, Path ∧ Head word ∧ Label, Path ∧ Tail word ∧ Label, Distance ∧ Label, Distance ∧ Path, and Distance ∧ Path ∧ Label. To conjoin the distance feature with anything else, we multiply by the distance.

input : weighted, connected graph $\langle V, E\rangle$ and set of edges $E^{(0)} \subseteq E$ to be preserved
output: maximum spanning, connected subgraph of $\langle V, E\rangle$ that preserves $E^{(0)}$

let $E^{(1)} = E^{(0)} \cup \{e \in E \mid \boldsymbol{\psi}^\top \mathbf{g}(e) > 0\}$;
create a priority queue Q containing $\{e \in E \mid \boldsymbol{\psi}^\top \mathbf{g}(e) \leq 0\}$ prioritized by scores;
$i = 1$;
while *Q nonempty and $\langle V, E^{(i)}\rangle$ is not yet spanning and connected* **do**
  $i = i + 1$;
  $E^{(i)} = E^{(i-1)}$;
  $e = \arg\max_{e' \in Q} \boldsymbol{\psi}^\top \mathbf{g}(e')$;
  remove e from Q;
  if *e connects two previously unconnected components of $\langle V, E^{(i)}\rangle$* **then**
    add e to $E^{(i)}$
  end
end
return $G = \langle V, E^{(i)}\rangle$;

Algorithm 1: MSCG algorithm.

Base case: Consider $G^{(1)}$, the subgraph containing $E^{(0)}$ and every positive edge. Take any maximum preserving spanning connected subgraph M of $\langle V, E\rangle$. We know that such an M exists because $\langle V, E\rangle$ itself is a preserving spanning connected subgraph. Adding a positive edge to M would strictly increase M's score without disconnecting M, which would contradict the fact that M is maximal. Thus M must contain $G^{(1)}$.

Induction step: By the inductive hypothesis, there exists some maximum spanning connected subgraph $M = \langle V, E_M\rangle$ that contains $G^{(i)}$.

Let e be the next edge added to $E^{(i)}$ by MSCG.

If e is in E_M, then $E^{(i+1)} = E^{(i)} \cup \{e\} \subseteq E_M$, and the hypothesis still holds.

Otherwise, since M is connected and does not contain e, $E_M \cup \{e\}$ must have a cycle containing e. In addition, that cycle must have some edge e' that is not in $E^{(i)}$. Otherwise, $E^{(i)} \cup \{e\}$ would contain a cycle, and e would not connect two unconnected components of $G^{(i)}$, contradicting the fact that e was chosen by MSCG.

Since e' is in a cycle in $E_M \cup \{e\}$, removing it will not disconnect the subgraph, i.e. $(E_M \cup \{e\}) \setminus \{e'\}$ is still connected and spanning. The score of e is greater than or equal to the score of e', otherwise MSCG would have chosen e' instead of e. Thus, $\langle V, (E_M \cup \{e\}) \setminus \{e'\}\rangle$ is a maximum spanning connected subgraph that contains $E^{(i+1)}$, and the hypothesis still holds.

When the algorithm completes, $G = \langle V, E^{(i)}\rangle$ is a spanning connected subgraph. The maximum spanning connected subgraph M that contains it cannot have a higher score, because G contains every positive edge. Hence G is maximal. □

4.2 Lagrangian Relaxation

If the subgraph resulting from MSCG satisfies constraint 4 (deterministic) then we are done. Otherwise we resort to Lagrangian relaxation (LR). Here we describe the technique as it applies to our task, referring the interested reader to Rush and Collins (2012) for a more general introduction to Lagrangian relaxation in the context of structured prediction problems.

In our case, we begin by encoding a graph $G = \langle V_G, E_G\rangle$ as a binary vector. For each edge e in the fully dense multigraph D, we associate a bi-

nary variable $z_e = \mathbf{1}\{e \in E_G\}$, where $\mathbf{1}\{P\}$ is the indicator function, taking value 1 if the proposition P is true, 0 otherwise. The collection of z_e form a vector $\mathbf{z} \in \{0,1\}^{|E_D|}$.

Determinism constraints can be encoded as a set of linear inequalities. For example, the constraint that vertex u has no more than one outgoing ARG0 can be encoded with the inequality:

$$\sum_{v \in V} \mathbf{1}\{u \xrightarrow{\text{ARG0}} v \in E_G\} = \sum_{v \in V} z_{u \xrightarrow{\text{ARG0}} v} \leq 1.$$

All of the determinism constraints can collectively be encoded as one system of inequalities:

$$\mathbf{A}\mathbf{z} \leq \mathbf{b},$$

with each row $\mathbf{A}_i$ in A and its corresponding entry b_i in $\mathbf{b}$ together encoding one constraint. For the previous example we have a row $\mathbf{A}_i$ that has 1s in the columns corresponding to edges outgoing from u with label ARG0 and 0's elsewhere, and a corresponding element $b_i = 1$ in $\mathbf{b}$.

The score of graph G (encoded as $\mathbf{z}$) can be written as the objective function $\boldsymbol{\phi}^\top \mathbf{z}$, where $\phi_e = \boldsymbol{\psi}^\top \mathbf{g}(e)$. To handle the constraint $\mathbf{A}\mathbf{z} \leq \mathbf{b}$, we introduce multipliers $\boldsymbol{\mu} \geq 0$ to get the Lagrangian relaxation of the objective function:

$$L_{\boldsymbol{\mu}}(\mathbf{z}) = \max_{\mathbf{z}} (\boldsymbol{\phi}^\top \mathbf{z} + \boldsymbol{\mu}^\top (\mathbf{b} - \mathbf{A}\mathbf{z})),$$

$$\mathbf{z}^*_{\boldsymbol{\mu}} = \arg\max_{\mathbf{z}} L_{\boldsymbol{\mu}}(\mathbf{z}).$$

And the dual objective:

$$L(\mathbf{z}) = \min_{\boldsymbol{\mu} \geq \mathbf{0}} L_{\boldsymbol{\mu}}(\mathbf{z}),$$

$$\mathbf{z}^* = \arg\max_{\mathbf{z}} L(\mathbf{z}).$$

Conveniently, $L_{\boldsymbol{\mu}}(\mathbf{z})$ decomposes over edges:

$$\begin{aligned} L_{\boldsymbol{\mu}}(\mathbf{z}) &= \max_{\mathbf{z}} (\boldsymbol{\phi}^\top \mathbf{z} + \boldsymbol{\mu}^\top (\mathbf{b} - \mathbf{A}\mathbf{z})) \\ &= \max_{\mathbf{z}} (\boldsymbol{\phi}^\top \mathbf{z} - \boldsymbol{\mu}^\top \mathbf{A}\mathbf{z}) \\ &= \max_{\mathbf{z}} ((\boldsymbol{\phi} - \mathbf{A}^\top \boldsymbol{\mu})^\top \mathbf{z}). \end{aligned}$$

So for any $\boldsymbol{\mu}$, we can find $\mathbf{z}^*_\mu$ by assigning edges the new Lagrangian adjusted weights $\boldsymbol{\phi} - \mathbf{A}^\top \boldsymbol{\mu}$ and reapplying the algorithm described in §4.1. We can find $\mathbf{z}^*$ by projected subgradient descent, by starting with $\boldsymbol{\mu} = \mathbf{0}$, and taking steps in the direction:

$$-\frac{\partial L_{\boldsymbol{\mu}}}{\partial \boldsymbol{\mu}}(\mathbf{z}^*_{\boldsymbol{\mu}}) = \mathbf{A}\mathbf{z}^*_{\boldsymbol{\mu}}.$$

If any components of $\boldsymbol{\mu}$ are negative after taking a step, they are set to zero.

$L(\mathbf{z})$ is an upper bound on the unrelaxed objective function $\boldsymbol{\phi}^\top \mathbf{z}$, and is equal to it if and only if the constraints $A\mathbf{z} \leq \mathbf{b}$ are satisfied. If $L(\mathbf{z}^*) = \boldsymbol{\phi}^\top \mathbf{z}^*$, then $\mathbf{z}^*$ is also the optimal solution to the constrained solution. Otherwise, there exists a duality gap, and Lagrangian relaxation has failed. In that case we still return the subgraph encoded by $\mathbf{z}^*$, even though it might violate one or more constraints. Techniques from integer programming such as branch-and-bound or cutting-planes methods could be used to find an optimal solution when LR fails (Das et al., 2012), but we do not use these techniques here. In our experiments, with a stepsize of 1 and max number of steps as 500, Lagrangian relaxation succeeds 100% of the time in our data.

4.3 Focus Identification

In AMR, one node must be marked as the focus of the sentence. We notice this can be accomplished within the relation identification step: we add a special concept node `root` to the dense graph D, and add an edge from `root` to every other node, giving each of these edges the label FOCUS. We require that `root` have at most one outgoing FOCUS edge. Our system has two feature types for this edge: the concept it points to, and the shortest dependency path from a word in the span to the root of the dependency tree.

5 Automatic Alignments

In order to train the parser, we need alignments between sentences in the training data and their annotated AMR graphs. More specifically, we need to know which spans of words invoke which concept fragments in the graph. To do this, we built an automatic aligner and tested its performance on a small set of alignments we annotated by hand.

The automatic aligner uses a set of rules to greedily align concepts to spans. The list of rules is given in Table 2. The aligner proceeds down the list, first aligning named-entities exactly, then fuzzy matching named-entities, then date-entities, etc. For each rule, an entire pass through the AMR graph is done. The pass considers every concept in the graph and attempts to align a concept fragment rooted at that concept if the rule can apply. Some rules only apply to a particular type of concept fragment, while others can apply to any concept. For example, rule 1 can apply to any NAME concept and its OP children. It searches the sentence

for a sequence of words that exactly matches its OP children and aligns them to the NAME and OP children fragment.

Concepts are considered for alignment in the order they are listed in the AMR annotation (left to right, top to bottom). Concepts that are not aligned in a particular pass may be aligned in subsequent passes. Concepts are aligned to the first matching span, and alignments are mutually exclusive. Once aligned, a concept in a fragment is never realigned.[7] However, more concepts can be attached to the fragment by rules 8–14.

We use WordNet to generate candidate lemmas, and we also use a fuzzy match of a concept, defined to be a word in the sentence that has the longest string prefix match with that concept's label, if the match length is ≥ 4. If the match length is < 4, then the concept has no fuzzy match. For example the fuzzy match for ACCUSE-01 could be "accusations" if it is the best match in the sentence. WordNet lemmas and fuzzy matches are only used if the rule explicitly uses them. All tokens and concepts are lowercased before matches or fuzzy matches are done.

On the 200 sentences of training data we aligned by hand, the aligner achieves 92% precision, 89% recall, and 90% F_1 for the alignments.

6 Training

We now describe how to train the two stages of the parser. The training data for the concept identification stage consists of (X, Y) pairs:

- **Input:** X, a sentence annotated with named entities (person, organization, location, misciscellaneous) from the Illinois Named Entity Tagger (Ratinov and Roth, 2009), and part-of-speech tags and basic dependencies from the Stanford Parser (Klein and Manning, 2003; de Marneffe et al., 2006).
- **Output:** Y, the sentence labeled with concept subgraph fragments.

The training data for the relation identification stage consists of (X, Y) pairs:

[7] As an example, if "North Korea" shows up twice in the AMR graph and twice in the input sentence, then the first "North Korea" concept fragment listed in the AMR gets aligned to the first "North Korea" mention in the sentence, and the second fragment to the second mention (because the first span is already aligned when the second "North Korea" concept fragment is considered, so it is aligned to the second matching span).

1. **(Named Entity)** Applies to `name` concepts and their `opn` children. Matches a span that exactly matches its `opn` children in numerical order.

2. **(Fuzzy Named Entity)** Applies to `name` concepts and their `opn` children. Matches a span that matches the fuzzy match of each child in numerical order.

3. **(Date Entity)** Applies to `date-entity` concepts and their `day`, `month`, `year` children (if exist). Matches any permutation of day, month, year, (two digit or four digit years), with or without spaces.

4. **(Minus Polarity Tokens)** Applies to − concepts, and matches "no", "not", "non."

5. **(Single Concept)** Applies to any concept. Strips off trailing '-[0-9]+' from the concept (for example `run-01` → `run`), and matches any exact matching word or WordNet lemma.

6. **(Fuzzy Single Concept)** Applies to any concept. Strips off trailing '-[0-9]+', and matches the fuzzy match of the concept.

7. **(U.S.)** Applies to `name` if its `op1` child is `united` and its `op2` child is `states`. Matches a word that matches "us", "u.s." (no space), or "u. s." (with space).

8. **(Entity Type)** Applies to concepts with an outgoing `name` edge whose head is an aligned fragment. Updates the fragment to include the unaligned concept. Ex: `continent` in `(continent :name (name :op1 "Asia"))` aligned to "asia."

9. **(Quantity)** Applies to `.*-quantity` concepts with an outgoing `unit` edge whose head is aligned. Updates the fragment to include the unaligned concept. Ex: `distance-quantity` in `(distance-quantity :unit kilometer)` aligned to "kilometres."

10. **(Person-Of, Thing-Of)** Applies to `person` and `thing` concepts with an outgoing `.*-of` edge whose head is aligned. Updates the fragment to include the unaligned concept. Ex: `person` in `(person :ARG0-of strike-02)` aligned to "strikers."

11. **(Person)** Applies to `person` concepts with a single outgoing edge whose head is aligned. Updates the fragment to include the unaligned concept. Ex: `person` in `(person :poss (country :name (name :op1 "Korea")))`

12. **(Goverment Organization)** Applies to concepts with an incoming `ARG.*-of` edge whose tail is an aligned `government-organization` concept. Updates the fragment to include the unaligned concept. Ex: `govern-01` in `(government-organization :ARG0-of govern-01)` aligned to "government."

13. **(Minus Polarity Prefixes)** Applies to − concepts with an incoming `polarity` edge whose tail is aligned to a word beginning with "un", "in", or "il." Updates the fragment to include the unaligned concept. Ex: − in `(employ-01 :polarity -)` aligned to "unemployment."

14. **(Degree)** Applies to concepts with an incoming `degree` edge whose tail is aligned to a word ending is "est." Updates the fragment to include the unaligned concept. Ex: `most` in `(large :degree most)` aligned to "largest."

Table 2: Rules used in the automatic aligner.

- **Input:** X, the sentence labeled with graph fragments, as well as named enties, POS tags, and basic dependencies as in concept identification.
- **Output:** Y, the sentence with a full AMR parse.[8]

Alignments are used to induce the concept labeling for the sentences, so no annotation beyond the automatic alignments is necessary.

We train the parameters of the stages separately using AdaGrad (Duchi et al., 2011) with the perceptron loss function (Rosenblatt, 1957; Collins, 2002). We give equations for concept identification parameters $\boldsymbol{\theta}$ and features $\mathbf{f}(X, Y)$. For a sentence of length k, and spans $\boldsymbol{b}$ labeled with a sequence of concept fragments $\boldsymbol{c}$, the features are:

$$\mathbf{f}(X, Y) = \sum_{i=1}^{k} \mathbf{f}(\boldsymbol{w}_{b_{i-1}:b_i}, b_{i-1}, b_i, c_i)$$

To train with AdaGrad, we process examples in the training data $((X^1, Y^1), \ldots, (X^N, Y^N))$ one at a time. At time t, we decode (§3) to get $\hat{Y}^t$ and compute the subgradient:

$$\mathbf{s}^t = \mathbf{f}(X^t, \hat{Y}^t) - \mathbf{f}(X^t, Y^t)$$

We then update the parameters and go to the next example. Each component i of the parameter vector gets updated like so:

$$\theta_i^{t+1} = \theta_i^t - \frac{\eta}{\sqrt{\sum_{t'=1}^{t} s_i^{t'}}} s_i^t$$

η is the learning rate which we set to 1. For relation identification training, we replace $\boldsymbol{\theta}$ and $\mathbf{f}(X, Y)$ in the above equations with $\boldsymbol{\psi}$ and

$$\mathbf{g}(X, Y) = \sum_{e \in E_G} \mathbf{g}(e).$$

We ran AdaGrad for ten iterations for concept identification, and five iterations for relation identification. The number of iterations was chosen by early stopping on the development set.

7 Experiments

We evaluate our parser on the newswire section of LDC2013E117 (deft-amr-release-r3-proxy.txt). Statistics about this corpus and our train/dev./test splits are given in Table 3.

[8]Because the alignments are automatic, some concepts may not be aligned, so we cannot compute their features. We remove the unaligned concepts and their edges from the full AMR graph for training. Thus some graphs used for training may in fact be disconnected.

Split	Document Years	Sentences	Tokens
Train	1995-2006	4.0k	79k
Dev.	2007	2.1k	40k
Test	2008	2.1k	42k

Table 3: Train/dev./test split.

Train			Test		
P	R	F_1	P	R	F_1
.92	.90	.91	.90	.79	.84

Table 4: Concept identification performance.

For the performance of concept identification, we report precision, recall, and F_1 of labeled spans using the induced labels on the training and test data as a gold standard (Table 4). Our concept identifier achieves 84% F_1 on the test data. Precision is roughly the same between train and test, but recall is worse on test, implicating unseen concepts as a significant source of errors on test data.

We evaluate the performance of the full parser using Smatch v1.0 (Cai and Knight, 2013), which counts the precision, recall and F_1 of the concepts and relations together. Using the full pipeline (concept identification and relation identification stages), our parser achieves 58% F_1 on the test data (Table 5). Using gold concepts with the relation identification stage yields a much higher Smatch score of 80% F_1. As a comparison, AMR Bank annotators have a consensus inter-annotator agreement Smatch score of 83% F_1. The runtime of our system is given in Figure 3.

The large drop in performance of 22% F_1 when moving from gold concepts to system concepts suggests that joint inference and training for the two stages might be helpful.

8 Related Work

Our approach to relation identification is inspired by graph-based techniques for non-projective syntactic dependency parsing. Minimum spanning tree algorithms—specifically, the optimum branching algorithm of Chu and Liu (1965) and Edmonds (1967)—were first used for dependency parsing by McDonald et al. (2005). Later ex-

tensions allow for *higher-order* (non–edge-local) features, often making use of relaxations to solve the NP-hard optimization problem. Mcdonald and Pereira (2006) incorporated second-order features, but resorted to an approximate algorithm. Others have formulated the problem as an integer linear program (Riedel and Clarke, 2006; Martins et al., 2009). TurboParser (Martins et al., 2013) uses AD^3 (Martins et al., 2011), a type of augmented Lagrangian relaxation, to integrate third-order features into a CLE backbone. Future work might extend JAMR to incorporate additional linguistically motivated constraints and higher-order features.

The task of concept identification is similar in form to the problem of Chinese word segmentation, for which semi-Markov models have successfully been used to incorporate features based on entire spans (Andrew, 2006).

While all semantic parsers aim to transform natural language text to a formal representation of its meaning, there is wide variation in the meaning representations and parsing techniques used. Space does not permit a complete survey, but we note some connections on both fronts.

Interlinguas (Carbonell et al., 1992) are an important precursor to AMR. Both formalisms are intended for use in machine translation, but AMR has an admitted bias toward the English language.

First-order logic representations (and extensions using, e.g., the λ-calculus) allow variable quantification, and are therefore more powerful. In recent research, they are often associated with combinatory categorial grammar (Steedman, 1996). There has been much work on statistical models for CCG parsing (Zettlemoyer and Collins, 2005; Zettlemoyer and Collins, 2007; Kwiatkowski et al., 2010, *inter alia*), usually using chart-based dynamic programming for inference.

Natural language interfaces for querying databases have served as another driving application (Zelle and Mooney, 1996; Kate et al., 2005; Liang et al., 2011, *inter alia*). The formalisms used here are richer in logical expressiveness than AMR, but typically use a smaller set of concept types—only those found in the database.

In contrast, semantic dependency parsing—in which the vertices in the graph correspond to the words in the sentence—is meant to make semantic parsing feasible for broader textual domains. Alshawi et al. (2011), for example, use shift-reduce parsing to map sentences to natural logical form.

AMR parsing also shares much in common with tasks like semantic role labeling and frame-semantic parsing (Gildea and Jurafsky, 2002; Punyakanok et al., 2008; Das et al., 2014, *inter alia*). In these tasks, predicates are often disambiguated to a canonical word sense, and roles are filled by spans (usually syntactic constituents). They consider each predicate separately, and produce a disconnected set of shallow predicate-argument structures. AMR, on the other hand, canonicalizes both predicates and arguments to a common concept label space. JAMR reasons about all concepts jointly to produce a unified representation of the meaning of an entire sentence.

9 Conclusion

We have presented the first published system for automatic AMR parsing, and shown that it provides a strong baseline based on the Smatch evaluation metric. We also present an algorithm for finding the maximum, spanning, connected subgraph and show how to incorporate extra constraints with Lagrangian relaxation. Our feature-based learning setup allows the system to be easily extended by incorporating new feature sources.

Abstract

We present an approach for learning context-dependent semantic parsers to identify and interpret time expressions. We use a Combinatory Categorial Grammar to construct compositional meaning representations, while considering contextual cues, such as the document creation time and the tense of the governing verb, to compute the final time values. Experiments on benchmark datasets show that our approach outperforms previous state-of-the-art systems, with error reductions of 13% to 21% in end-to-end performance.

1 Introduction

Time expressions present a number of challenges for language understanding systems. They have rich, compositional structure (e.g., "2nd Friday of July"), can be easily confused with non-temporal phrases (e.g., the word "May" can be a month name or a verb), and can vary in meaning in different linguistic contexts (e.g., the word "Friday" refers to different dates in the sentences "We met on *Friday*" and "We will meet on *Friday*"). Recovering the meaning of time expressions is therefore challenging, but provides opportunities to study context-dependent language use. In this paper, we present the first context-dependent semantic parsing approach for learning to identify and interpret time expressions, addressing all three challenges.

Existing state-of-the-art methods use hand-engineered rules for reasoning about time expressions (Strötgen and Gertz, 2013). This includes both *detection*, identifying a phrase as a time expression, and *resolution*, mapping such a phrase into a standardized time value. While rule-based approaches provide a natural way to express expert knowledge, it is relatively difficult to encode preferences between similar competing hypotheses and provide prediction confidence. Recently, methods for learning probabilistic semantic parsers have been shown to address such limitations (Angeli et al., 2012; Angeli and Uszkoreit, 2013). However, these approaches do not account for any surrounding linguistic context and were mainly evaluated with gold standard mentions.

We propose to use a context-dependent semantic parser for both detection and resolution of time expressions. For both tasks, we make use of a hand-engineered Combinatory Categorial Grammar (CCG) to construct a set of meaning representations that identify the time being described. For example, this grammar maps the phrase "2nd Friday of July" to the meaning representation $intersect(nth(2, friday), july)$, which encodes the set of all such days. Detection is then performed with a binary classifier to prune the set of text spans that can be parsed with the grammar (e.g., to tell that "born in *2000*" has a time expression but "a 2000 piece puzzle" does not). For resolution, we consider mentions sequentially and use a log-linear model to select the most likely meaning for each. This choice depends on contextual cues such as previous time expressions and the tense of the governing verb (e.g., as required to correctly resolve cases like "We should meet on the *2nd Friday of July*").

Such an approach provides a good balance between hand engineering and learning. For the relatively closed-class time expressions, we demonstrate that it is possible to engineer a high quality CCG lexicon. We take a data-driven approach for grammar design, preferring a grammar with high coverage even if it results in parsing ambiguities. We then learn a model to accurately select between competing parses and incorporate signals from the surrounding context, both more difficult to model with deterministic rules.

For both problems, we learn from TimeML an-

[*] Work conducted at the University of Washington.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1437–1447,
Baltimore, Maryland, USA, June 23-25 2014.

notations (Pustejovsky et al., 2005), which mark mentions and the specific times they reference. Training the detector is a supervised learning problem, but resolution is more challenging, requiring us to reason about latent parsing and context-dependent decisions.

We evaluate performance in two domains: the TempEval-3 corpus of newswire text (Uzzaman et al., 2013) and the WikiWars corpus of Wikipedia history articles (Mazur and Dale, 2010). On these benchmark datasets, we present new state-of-the-art results, with error reductions of up to 28% for the detection task and 21% for the end-to-end task.

2 Formal Overview

Time Expressions We follow the TIMEX3 standard (Pustejovsky et al., 2005) for defining time expressions within documents. Let a document $D = \langle w_1, \ldots, w_n \rangle$ be a sequence of n words w_i and a mention $m = (i, j)$ indicate start and end indices for a phrase $\langle w_i, \ldots, w_j \rangle$ in D. Define a time expression $e = (t, v)$ to include both a temporal type t and value v.[1] The temporal type $t \in \{\text{Date, Time, Duration, Set}\}$ can take one of four possible values, indicating if the expression e is a date (e.g., "January 10, 2014"), time (e.g., "11:59 pm"), duration (e.g., "6 months"), or set (e.g., "every year"). The value v is an extension of the ISO 8601 standard, which encodes the time that mention m refers to in the context provided by document D. For example, in a document written on Tuesday, January 7, 2014, "Friday," "three days later," and "January 10th" would all resolve to the value 2014-01-10. The time values are similarly defined for a wide range of expressions, such as underspecified dates (e.g., XXXX-01-10 for "Janunary 10th" when the year is not inferable from context) and durations (P2D for "two days").

Tasks Our goal is to find all time expressions in an input document. We divide the problem into two parts: detection and resolution. The *detection* problem is to take an input document D and output a mention set $M = \{m_i \mid i = 1 \ldots n\}$ of phrases in D that describe time expressions. The *resolution* problem (often also called *normalization*) is, given a document D and a set of mentions M, to map each $m \in M$ to the referred time expression e. This paper addresses both of these tasks.

Approach We learn separate, but related, models for detection and resolution. For both tasks, we define the space of possible compositional meaning representations $\mathcal{Z}$, where each $z \in \mathcal{Z}$ defines a unique time expression e. We use a log-linear CCG (Steedman, 1996; Clark and Curran, 2007) to rank possible meanings $z \in \mathcal{Z}$ for each mention m in a document D, as described in Section 4. Both detection (Section 5) and resolution (Section 6) rely on the semantic parser to identify likely mentions and resolve them within context. For learning we assume access to TimeML data containing documents labeled with time expressions. Each document D has a set $\{(m_i, e_i) | i = 1 \ldots n\}$, where each mention m_i marks a phrase that resolves to the time expression e_i.

Evaluation We evaluate performance (Section 8) for both newswire text and Wikipedia articles. We compare to the state-of-the-art systems for end-to-end resolution (Strötgen and Gertz, 2013) and resolution given gold mentions (Bethard, 2013b), both of which do not use any machine learning techniques.

3 Representing Time

We use simply typed lambda calculus to represent time expressions. Our representation draws heavily from the representation proposed by Angeli et al. (2012), who introduced semantic parsing for this task. There are five primitive types: duration d, sequence s, range r, approximate reference a, and numeral n, as described below. Table 1 lists the available constants for each type.

Duration A period of time. Each duration is a multiple of one of a closed set of possible base durations (e.g., $hour$, day, and $quarter$), which we refer to as its granularity. Table 1 includes the complete set of base durations used.

Range A specific interval of time, following an interval-based theory of time (Allen, 1981). The interval length is one of the base durations, which is the granularity of the range. Given two ranges R and R', we say that $R \subseteq R'$ if the endpoints of R lie on or within R'.

Sequence A set of ranges with identical granularity. The granularity of the sequence is that of its members. For example, $thursday$, which has a

[1] Time expressions also have optional modifier values for non-TIMEX properties (e.g., the modifier would contain $EARLY$ for the phrase "*early march*"). We do recover these modifiers but omit them from the discussion since they are not part of the official evaluation metrics.

Type	Primitive Constants
Duration	*second*, *minute*, *hour*, *timeofday*, *day*, *month*, *season*, *quarter*, *weekend*, *week*, *year*, *decade*, *century* , *temp_d*
Sequence	*monday*, *tuesday*, *wednesday*, *thursday*, *friday*, *saturday*, *sunday*, *january*, *february*, *march*, *april*, *may*, *june*, *july*, *august*, *september*, *october*, *november*, *december*, *winter*, *spring*, *summer*, *fall*, *night*, *morning*, *afternoon*, *evening*
Range	*ref_time*
Approximate reference	*present*, *future*, *past*, *unknown*
Numeral	*1*, *2*, *3*, *1999*, *2000*, *2001*, ...

Table 1: The types and primitive logical constants supported by the logical language for time.

day granularity, denotes the set of all day-granular ranges enclosing specific Thursdays. Given a range R and sequence S, we say that $R \in S$ if R is a member of S. Given two sequences S and S' we say that $S \subseteq S'$ if $R \in S$ implies $R \in S'$.

Approximate Reference An approximate time relative to the reference time. For example, $past$ and $future$. To handle mentions such as "a while," we add the constant $unknown$.

Numeral An integer, for example, 5 or 1990. Numerals are used to denote specific ranges, such as the year 2001, or to modify a duration's length.

Functions We also allow for functional types, for example $\langle s, r \rangle$ is assigned to a function that maps from sequences to ranges. Table 2 lists all supported functions with example mentions.

Context Dependent Constants To mark places where context-dependent choices will need to be made during resolution, we use two placeholder constants. First, ref_time denotes the mention reference time, which is later set to either the document time or a previously resolved mention. Second, $temp\_d$ is used in the $shift$ function to determine its return granularity, as described in Table 2, and is later replaced with the granularity of either the first or second argument of the enclosing $shift$ function. Section 4.3 describes how these decisions are made.

4 Parsing Time Expressions

We define a three-step derivation to resolve mentions to their TIMEX3 value. First, we use a CCG to generate an initial logical form for the mention. Next, we apply a set of operations that modify the initial logical form, as appropriate for its context. Finally, the logical form is resolved to a TIMEX3 value using a deterministic process.

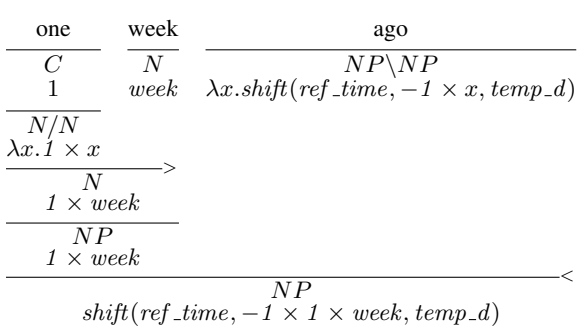

Figure 1: A CCG parse tree for the mention "one week ago." The tree includes forward (>) and backward (<) application, as well as two type-shifting operations

4.1 Combinatory Categorial Grammars

CCG is a linguistically motivated categorial formalism for modeling a wide range of language phenomena (Steedman, 1996; Steedman, 2000). A CCG is defined by a lexicon and a set of combinators. The lexicon pairs words with categories and the combinators define how to combine categories to create complete parse trees.

For example, Figure 1 shows a CCG parse tree for the phrase "one week ago." The parse tree is read top to bottom, starting from assigning categories to words using the lexicon. The lexical entry ago $\vdash NP\backslash NP : \lambda x.shift(ref\_time, -1 \times x, temp\_d)$ for the word "ago" pairs it with a category that has syntactic type $NP\backslash NP$ and semantics $\lambda x.shift(ref\_time, -1 \times x, temp\_d)$. Each intermediate parse node is then constructed by applying one of a small set of binary or unary operations (Steedman, 1996; Steedman, 2000), which modify both the syntax and semantics. We use backward (<) and forward (>) application and several unary type-shifting rules to handle number combinations. For example, in Figure 1 the category of the span "one week" is combined with the category of "ago" using backward application (<). Parsing concludes with a logical form representing the meaning of the complete mention.

Hand Engineered Lexicon To parse time expressions, we use a CCG lexicon that includes 287 manually designed entries, along with automatically generated entries such as numbers and common formats of dates and times. Figure 2 shows example entries from our lexicon.

Function	Description	Example
Operations on durations.		
$\times_{\langle n,\langle d,d\rangle\rangle}$	Given a duration D and a numeral N, return a duration D' that is N times longer than D.	"after *three days* of questioning" $3 \times day$
$some_{\langle d,d\rangle}$	Given a duration D, returns D', s.t. D' is the result of $D \times n$ for some $n > 1$.	"he left for *a few days*" $some(day)$
$seq_{\langle d,s\rangle}$	Given a duration D, generate a sequence S, s.t. S includes all ranges of type D.	"went to *last year*'s event" $previous(seq(year), ref\_time)$
Operations for extracting a specific range from a sequence.		
$this_{\langle s,\langle r,r\rangle\rangle}$	Given a sequence S and a range R, returns the range $R' \in S$, s.t. there exists a range R'' where $R \subseteq R''$ and $R' \subseteq R''$, and the length of R'' is minimal.	"a meeting *this friday*" $this(friday, ref\_time)$
$next_{\langle s,\langle r,r\rangle\rangle}$ $previous_{\langle s,\langle r,r\rangle\rangle}$	Given a sequence S and a range R, returns the range $R' \in S$ that is the one after/before $this(S, R)$.	"arriving *next month*" $next(seq(month), ref\_time)$
$nearest\_forward_{\langle s,\langle r,r\rangle\rangle}$ $nearest\_backward_{\langle s,\langle r,r\rangle\rangle}$	Given a sequence S and a range R, returns the range $R' \in S$ that is closest to R in the forward/backward direction.	"during *the coming weekend*" $nearest\_forward(seq(weekend), ref\_time)$
Operations for sequences.		
$nth_{\langle n,\langle s,\langle s,s\rangle\rangle\rangle}$ $nth_{\langle n,\langle s,s\rangle\rangle}$	Given a number N, a sequence S and a sequence S', returns a sequence $S'' \subseteq S$ s.t. for each $Q \in S''$ there exists $P \in S'$ and Q is the N-th entry in S that is a sub-interval of P. For the two-argument version, we use heuristics to infer the third argument by determining a sequence of higher granularity that is likely to contain the second argument.	"until *the second quarter of the year*" $nth(2, seq(quarter), seq(year))$
$intersect_{\langle s,\langle s,s\rangle\rangle}$	Given sequences S, S', where the duration of entries in S is shorter than these in S', return a sequence $S'' \subseteq S$, where for each $R \in S''$ there exists $R' \in S'$ s.t. $R \subseteq R'$.	"starts on *June 28*" $intersect(june, nth(28, seq(day), seq(month)))$
$shift_{\langle r,\langle d,\langle d,r\rangle\rangle\rangle}$	Given a range R, a duration D, and a duration G, return the range R', s.t. the starting point of R' is moved by the length of D. R' is converted to represent a range of granularity G by expanding if G has larger granularity, and is undefined if G has smaller granularity.	"*a week ago*, we went home" $shift(ref\_time, -1 \times 1 \times week, temp\_d)$
Operations on numbers.		
$\times_{\langle n,\langle n,n\rangle\rangle}$	Given two numerals, N' and N'', returns a numeral N''' representing their product $N' \times N''$.	"the battle lasted for *one hundred days*" $1 \times 100 \times day$
$+_{\langle n,\langle n,n\rangle\rangle}$	Given two numerals, N' and N'', returns a numeral N''' representing their sum $N' + N''$.	"open *twenty four hours*" $(20 + 4) \times hour$
Operations to mark sequences for specific TIMEX3 type annotations.		
$every_{\langle s,s\rangle}$	Given a sequence S, returns a sequence with SET temporal type.	"one dose *each day*" $every(seq(day))$
$bc_{\langle s,s\rangle}$	Convert a year to BC.	"during *five hundred BC*" $bc(nth(500, seq(year)))$

Table 2: Functional constants used to build logical expressions for representing time.

Manually Designed Entries:

several $\vdash NP/N : \lambda x.some(x)$
this $\vdash NP/N : \lambda x.this(x, ref\_time)$
each $\vdash NP/N : \lambda x.every(x)$
before $\vdash N\backslash NP/NP :$
$\lambda x.\lambda y.shift(x, -1 \times y, temp\_d)$
year $\vdash N : year$
wednesday $\vdash N : wednesday$
'20s $\vdash N : nth(192, seq(decade))$
yesterday $\vdash N : shift(ref\_time, -1 \times day, temp\_d)$

Automatically Generated Entries:

1992 $\vdash N : nth(1992, seq(year))$
nineteen ninety two $\vdash N : nth(1992, seq(year))$
09:30 $\vdash N : intersect(nth(10, seq(hour), seq(day)),$
$nth(31, seq(minute), seq(hour)))$
3rd $\vdash N\backslash N :$
$\lambda x.intersect(x, nth(3, seq(day), seq(month)))$

Figure 2: Example lexical entries.

4.2 Context-dependent Operations

To correctly resolve mentions to TIMEX3 values, the system must account for contextual information from various sources, including previous mentions in the document, the document creation time, and the sentence containing the mention. We consider three types of context operations, each takes as input a logical form z', modifies it and returns a new logical form z. Each context-dependent parse y specifies one operator of each type, which are applied to the logical form constructed by the CCG grammar, to produce the final, context-dependent logical form LF(y).

Reference Time Resolution The logical constant ref_time is replaced by either dct, representing the document creation time, or $last\_range$, the last r-typed mention resolved in the document. For example, consider the mention "the following year", which is represented using the logical form $next(seq(year), ref\_time)$. Within the sentence "*1998* was colder than *the following year*", the resolution of "the following year" depends on the previous mention "1998". In contrast, in "*The following year* will be warmer", its resolution depends on the document creation time.

Directionality Resolution If z' is s-typed we modify it to $nearest\_forward(z', ref\_time)$, $nearest\_backward(z', ref\_time)$, or z'. For example, given the sentence "...will be launched in *april*", the mention "april", and its logical form $april$, we would like to resolve it to the coming April, and therefore modify it to $nearest\_forward(april, ref\_time)$.

Shifting Granularity Every occurrence of the logical constant $temp\_d$, which is used as an argument to the function *shift* (see Table 2), is replaced with the granularity of either the first argument, the origin of the shift, or the second argument, the delta of the shift. This determines the final granularity of the output. For example, if the reference time is 2002-01, the mention "two years earlier" would resolve to either a month (since the reference time is of $month$ granularity) or a year (since the delta is of $year$ granularity).

4.3 Resolving Logical Forms

For a context-dependent parse y, we compute the TIMEX3 value TM(y) from the logical form $z =$ LF(y) with a deterministic step that performs a single traversal of z. Each primitive logical constant from Table 1 contributes to setting part of the TIMEX3 value (for example, specifying the day of the week) and the functional constants in Table 2 dictate transformations on the TIMEX3 values (for example, shifting forward or backward in time).[2]

5 Detection

The detection problem is to take an input document D and output a mention set $M = \{m_i \mid i = 1, \ldots, n\}$, where each mention m_i indexes a specific phrase in D that delimits a time expression.

Algorithm The detection algorithm considers all phrases that our CCG grammar Λ (Section 4) can parse, uses a learned classifier to further filter this set, and finally resolves conflicts between any overlapping predictions. We use a CKY algorithm to efficiently determine which phrases the CCG grammar can parse and only allow logical forms for which there exists some context in which they would produce a valid time expression, e.g. ruling out $intersect(monday, tuesday)$. Finally, we build the set M of non-overlapping mentions using a step similar to non-maximum suppression: the mentions are sorted by length (longest first) and iteratively added to M, as long as they do not overlap with any mention already in M.

Filtering Model Given a mention m, its document D, a feature function ϕ, the CCG lexicon Λ, and feature weights θ, we use a logistic regression model to define the probability distribution:

$$P(t|m, D; \Lambda, \theta) = \frac{e^{\theta \cdot \phi(m,D,\Lambda)}}{1 + e^{\theta \cdot \phi(m,D,\Lambda)}}$$

where t indicates whether m is a time expression.

Features We use three types of indicator features that test properties of the words in and around the potential mention m.

Context tokens Indicate the presence of a set of manually specified tokens near the mention. These include quotations around the mention, the word "old" after the mention, and prepositions of time (such as "in", "until", and "during") before.

Part of speech Indicators that pair each word with its part of speech, as assigned by the Stanford tagger (Toutanova et al., 2003).

Lexical group Each lexical entry belongs to one of thirteen manually defined lexical groups which cluster entries that contribute to the final time expression similarly. These groups include numbers, days of the week, months, seasons, etc. For each group, we include a feature indicating whether the parse includes a lexical entry from that group.

Determiner dependency Indicates the presence of a determiner in the mention and whether its parent in the dependency tree (generated by the Stanford parser (de Marneffe et al., 2006)) also resides within the mention.

Learning Finally, we construct the training data by considering all spans that (1) the CCG temporal grammar can parse and (2) are not strict subspans of an annotated mention. All spans that exactly matched the gold labels are used as positive examples and all others are negatives. Given this relaxed data, we learn the feature weights θ with L1-regularization. We set the probability threshold for detecting a time expression by optimizing the F1 score over the training data.

6 Resolution

The resolution problem is to, given a document D and a set of mentions M, map each $m \in M$ to the correct time expression e. Section 4 defined

[2] The full details are beyond the scope of this paper, but an implementation is available on the author's website.

the space of possible time expression that can be constructed for an input mention m in the context of a document D. In general, there will be many different possible derivations, and we will learn a model for selecting the best one.

Model Let y be a context-dependent CCG parse, which includes a parse tree TR(y), a set of context operations CNTX(y) applied to the logical form at the root of the tree, a final context-dependent logical form LF(y) and a TIMEX3 value TM(y). Define $\phi(m, D, y) \in \mathbb{R}^d$ to be a d-dimensional *feature–vector* representation and $\theta \in \mathbb{R}^d$ to be a parameter vector. The probability of a parse y for mention m and document D is:

$$P(y|m, D; \theta, \Lambda) = \frac{e^{\theta \cdot \phi(m,D,y)}}{\sum_{y'} e^{\theta \cdot \phi(m,D,y')}}$$

The inference problem at test time requires finding the best resolution by solving $y^*(m, D) = \arg\max_y P(y|m, D; \theta, \Lambda)$, where the final output TIMEX3 value is TM($y^*(m, D)$).

Inference We find the best context-dependent parse y by enumeration, as follows. We first parse the input mention m with a CKY-style algorithm, following previous work (Zettlemoyer and Collins, 2005). Due to the short length of time expressions and the manually constructed lexicon, we can perform exact inference. Given a parse, we then enumerate all possible outcomes for the context resolution operators. In practice, there are never more than one hundred possibilities.

Features The resolution features test properties of the linguistic context surrounding the mention m, relative to the context-dependent CCG parse y.

Governor verb We define the governor verb to be the nearest ancestor verb in the dependency parse of any token in m. We include features indicating the concatenation of the part-of-speech of the governor verb, its auxiliary verb if present, and the selected direction resolution operator (see Section 4.2). This feature helps to distinguish "They met on *Friday*" from "They will meet on *Friday*."

Temporal offset If the final logical form $LF(y)$ is a range, we define t to be the time difference between TM(y) and the reference time. For example, if the reference time is 2000-01-10 and the mention resolves to 2000-01-01, then t is -9 days. This feature indicates one of eleven bucketed values for t, including same day, less than a week, less than a month, etc. It allows the model to encode the likely temporal progression of a narrative. This feature is ignored if the granularity of TM(y) or the reference time is greater than a year.

Shift granularity The logical constant *shift* (Table 2) takes three arguments: the origin (range), the delta (duration), and the output granularity (duration). This indicator feature is the concatenation of each argument's granularity for every *shift* in $LF(y)$. It allows the model to determine whether "a year ago" refers to a year or a day.

Reference type Let r denote whether the reference time is the document creation time dct or the last range $last\_range$. Let g_l and g_r denote the granularities of $LF(y)$ and the reference time, respectively. We include features indicating the concatenations: $r{+}g_l$, $r{+}g_r$, and $r{+}g_l{+}g_r$. Additionally, we include features indicating the concatenation of r with each lexical entry used in the parse $TR(y)$. These features allow the model to encode preferences in selecting the correct reference time.

Fine-grained type These features indicate the fine-grained type of $TM(y)$, such as day of the month or week of the year. We also include a feature indicating the concatenation of each of these features with the direction resolution operator that was used. These features allow the model to represent, for example, that minutes of the year are less likely than days of the month.

Intersections These features indicate the concatenation of the granularities of any two sequences that appear as arguments to an $intersect$ constant.

Learning To estimate the model parameters θ we assume access to a set of training examples $\{(m_i, d_i, e_i) : i = 1, \ldots, n\}$, where each mention m_i is paired with a document d_i and a TIMEX3 value e_i. We use the AdaGrad algorithm (Duchi et al., 2011) to optimize the conditional, marginal log-likelihood of the data. For each mention, we marginalize over all possible context-dependent parses, using the predictions from the model on the previous gold mentions to fill in missing context, where necessary. After parameter estimation, we set a probability threshold for retaining a resolved time expression by optimizing value F1 (see Section 8) over the training data.

7 Related Work

Semantic parsers map sentences to logical representations of their underlying meaning, e.g., Zelle

and Mooney (1996), Zettlemoyer and Collins (2005), and Wong and Mooney (2007). Recently, research in this area has focused on learning for various forms of relatively weak but easily gathered supervision. This includes learning from question-answer pairs (Clarke et al., 2010; Liang et al., 2011; Kwiatkowski et al., 2013), from conversational logs (Artzi and Zettlemoyer, 2011), with distant supervision (Krishnamurthy and Mitchell, 2012; Cai and Yates, 2013), and from sentences paired with system behavior (Goldwasser and Roth, 2011; Chen and Mooney, 2011; Artzi and Zettlemoyer, 2013b). Recently, Angeli et al. introduced the idea of learning semantic parsers to resolve time expressions (Angeli et al., 2012) and showed that the approach can generalize to multiple languages (Angeli and Uszkoreit, 2013). Similarly, Bethard demonstrated that a hand-engineered semantic parser is also effective (Bethard, 2013b). However, these approaches did not use the semantic parser for detection and did not model linguistic context during resolution.

We build on a number of existing algorithmic ideas, including using CCGs to build meaning representations (Zettlemoyer and Collins, 2005; Zettlemoyer and Collins, 2007; Kwiatkowski et al., 2010; Kwiatkowski et al., 2011), building derivations to transform the output of the CCG parser based on context (Zettlemoyer and Collins, 2009), and using weakly supervised parameter updates (Artzi and Zettlemoyer, 2011; Artzi and Zettlemoyer, 2013b). However, we are the first to use a semantic parsing grammar within a mention detection algorithm, thereby avoiding the need to represent the meaning of complete sentences, and the first to develop a context-dependent model for semantic parsing of time expressions.

Time expressions have been extensively studied as part of the TimeEx task, including 9 teams who competed in the 2013 TempEval-3 competition (Uzzaman et al., 2013). This line of work builds on ideas from TimeBank (Pustejovsky et al., 2003) and a number of different formal models for temporal reasoning, e.g. Allen (1983), Moens and Steedman (1988). In 2013, HeidelTime (Strötgen and Gertz, 2013) was the top performing system. It used deterministic rules defined over regular expressions to perform both detection and resolution, and will provide a comparison system for our evaluation in Section 9. In general, many different rule-based systems, e.g. NavyTime (Chambers, 2013) and SUTime (Chang and Manning, 2012), and learning systems, e.g. ClearTK (Bethard, 2013a) and MANTime (Filannino et al., 2013), did well for detection. However, rule-based approaches dominated in resolution; none of the top performers attempted to learn to do resolution. Our approach is a hybrid of rule based and learning, by using latent-variable learning techniques to estimate CCG parsing and context resolution models from the provided data.

8 Experimental Setup

Data We evaluate performance on the TempEval-3 (Uzzaman et al., 2013) and WikiWars (Mazur and Dale, 2010) datasets. Figure 3 shows summary statistics for both datasets. For the TempEval-3 corpus, we use the given training and testing set splits. Since the training set has lower inter-annotator agreement than the testing set (Uzzaman et al., 2013), we manually corrected all of the mistakes we found in the training data.[3] The original training set is denoted Dev* and the corrected Dev. We report (1) cross-validation development results on Dev*, (2) cross-validation development and ablation results for Dev, and (3) held-out test results after training with Dev. For WikiWars, we randomly assigned the data to include 17 training documents (2,228 time expressions) and 5 test documents (363 time expressions). We use cross-validation on the training data for development. All cross-validation experiments used 10 folds.

Implementation Our system was implemented using the open source University of Washington Semantic Parsing Framework (Artzi and Zettlemoyer, 2013a). We used LIBLINEAR (Fan et al., 2008) to learn the detection model.

Parameter Settings We use the same set of parameters for both datasets, chosen based on development experiments. For detection, we set the regularization parameter to 10 with a stopping crite-

[3]We modified the annotations for 18% of the mentions. This relabeled corpus is available on the author's website.

rion of 0.01. For resolution, we set the learning rate to 0.25 and ran AdaGrad for 5 iterations. All features are initialized to have zero weights.

Evaluation Metrics We use the official TempEval-3 scoring script and report the standard metrics. We report *detection precision, recall* and *F1* with relaxed and strict metrics; a gold mention is considered detected for the relaxed metric if any of the output candidates overlap with it and is detected for the strict metric if the extent of any output candidates matches exactly. For resolution, we report *value accuracy*, measuring correctness of time expressions detected according to the relaxed metric. We also report *value precision, recall,* and *F1*, which score an expression as correct if it is both correctly detected (relaxed) and resolved. For end-to-end performance, value F1 is the primary metric. Finally, we report accuracy and F1 for temporal types, as defined in Section 2, for the TempEval dataset (WikiWars does not include type labels).

Comparison Systems We compare our system primarily to HeidelTime (Strötgen and Gertz, 2013), which is state of the art in the end-to-end task. For the TempEval-3 dataset, we also compare to two other strong participants of the shared task. These include NavyTime (Chambers, 2013), which had the top relaxed detection score, and ClearTK (Bethard, 2013a), which had the top strict detection score and type F1 score. We also include a comparison with Bethard's synchronous context free grammar (SCFG) (Bethard, 2013b), which is state-of-the-art in the task of resolution with gold mention boundaries.

System	Dev*	Dev	Test
This work	**81.8**	**90.1**	**82.6**
SCFG	77.0	81.6	78.9

Figure 6: TempEval-3 gold mention value accuracy.

9 Results

End-to-end results Figure 4 shows development and test results for TempEval-3. Figure 5 shows these numbers for WikiWars. In both datasets, we achieve state-of-the-art test scores. For detection, we show up to 3-point improvements in strict and relaxed F1 scores. These numbers outperform all systems participating in the shared task, which used a variety of techniques including hand-engineered rules, CRF tagging models, and SVMs. For resolution, we show up to 4-point improvements in the value F1 score, also outperforming participating systems, all of which used hand-engineered rules for resolution.

Gold Mentions Figure 6 reports development and test results with gold mentions.[4] Our approach outperforms the state of the art, SCFG (Bethard, 2013b), which also used a hand engineered grammar, but did not use machine learning techniques.

[4]These numbers vary slightly from those reported; we did not count the document creation times as mentions.

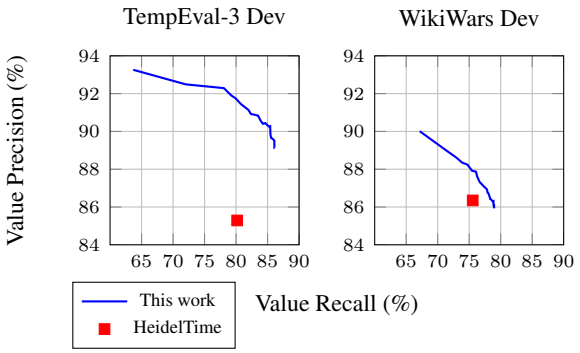

Figure 7: Value precision vs. recall for 10-fold cross validation on TempEval-3 Dev and WikiWars Dev.

Precision vs. Recall Our probabilistic model of time expression resolution allows us to easily tradeoff precision and recall for end-to-end performance by varying the resolution probability threshold. Figure 7 shows the precision vs. recall of the resolved values from 10-fold cross validation of TempEval-3 Dev and WikiWars Dev. We are able to achieve precision at or above 90% with reasonable recall, nearly 70% for WikiWars and over 85% for TempEval-3.

Ablation Study Figures 4-5 also show comparisons for our system with no context. We ablate the ability to refer to the context during resolution by removing contextual information from the resolution features and only allowing the document creation time to be the reference time.

We see an interesting asymmetry in the effect of modeling context across the two domains. We find that context is much more important in WikiWars (19 point difference) than in TempEval (2 point difference). This result reaffirms the difference in domains that Strötgen and Gertz (2012) noted during the development of HeidelTime: history articles have narrative structure that moves back and forth through time while newspaper text typically describes events happening near the document creation time. This difference helps us to understand why previous learning systems have been able to ignore context and perform well on newswire text.

Error Analysis To investigate the source of error, we compute oracle results for resolving gold mentions over the TempEval-3 Dev dataset. We found that our system produces a correct candidate derivation for 96% of the mentions.

We also manually categorized all resolution errors for end-to-end performance with 10-fold cross validation of the TempEval-3 Dev dataset, shown in Figure 8. The lexicon allows for effective parsing, contributing to only 2% of the overall errors. However, context is more challenging. The three largest categories, responsible for 64.7% of the errors, were incorrect use of the context operators. More expressive modeling will be required to fully capture the complex pragmatics involved in understanding time expressions.

Error description	%
Wrong directionality context operator	34.6
Wrong reference time context operator	15.7
Wrong shifting granularity context operator	14.4
Requires joint reasoning with events	9.2
Cascading error due to wrong detection	7.8
CCG parse error	2.0
Other error	16.3

Figure 8: Resolution errors from 10-fold cross validation of the TempEval-3 Dev dataset.

10 Conclusion

We presented the first context-dependent semantic parsing system to detect and resolve time expressions. Both models used a Combinatory Categorial Grammar (CCG) to construct a set of possible temporal meaning representations. This grammar defined the possible phrases for detection and the inputs to a context-dependent reasoning step that was used to construct the output time expression during resolution. Experiments demonstrated that our approach outperforms state-of-the-art systems.

In the future, we aim to develop joint models for reasoning about events and time expressions, including detection and resolution of temporal relations. We are also interested in testing coverage in new domains and investigating techniques for semi-supervised learning and learning with noisy data. We hypothesize that semantic parsing techniques could help in all of these settings, providing a unified mechanism for compositional analysis within temporal understanding problems.

Abstract

We present a novel technique for semantic frame identification using distributed representations of predicates and their syntactic context; this technique leverages automatic syntactic parses and a generic set of word embeddings. Given labeled data annotated with frame-semantic parses, we learn a model that projects the set of word representations for the syntactic context around a predicate to a low dimensional representation. The latter is used for semantic frame identification; with a standard argument identification method inspired by prior work, we achieve state-of-the-art results on FrameNet-style frame-semantic analysis. Additionally, we report strong results on PropBank-style semantic role labeling in comparison to prior work.

1 Introduction

Distributed representations of words have proved useful for a number of tasks. By providing richer representations of meaning than what can be encompassed in a discrete representation, such approaches have successfully been applied to tasks such as sentiment analysis (Socher et al., 2011), topic classification (Klementiev et al., 2012) or word-word similarity (Mitchell and Lapata, 2008).

We present a new technique for semantic **frame** identification that leverages distributed word representations. According to the theory of frame semantics (Fillmore, 1982), a semantic frame represents an event or scenario, and possesses frame elements (or semantic **roles**) that participate in the event. Most work on frame-semantic parsing has usually divided the task into two major subtasks: *frame identification*, namely the disambiguation of a given predicate to a frame, and *argument identification* (or semantic role labeling), the analysis of words and phrases in the sentential context that satisfy the frame's semantic roles (Das et al., 2010; Das et al., 2014).[1] Here, we focus on the first subtask of frame identification for given predicates; we use our novel method (§3) in conjunction with a standard argument identification model (§4) to perform full frame-semantic parsing.

We present experiments on two tasks. First, we show that for frame identification on the FrameNet corpus (Baker et al., 1998; Fillmore et al., 2003), we outperform the prior state of the art (Das et al., 2014). Moreover, for full frame-semantic parsing, with the presented frame identification technique followed by our argument identification method, we report the best results on this task to date. Second, we present results on PropBank-style semantic role labeling (Palmer et al., 2005; Meyers et al., 2004; Màrquez et al., 2008), that approach strong baselines, and are on par with prior state of the art (Punyakanok et al., 2008).

2 Overview

Early work in frame-semantic analysis was pioneered by Gildea and Jurafsky (2002). Subsequent work in this area focused on either the FrameNet or PropBank frameworks, and research on the latter has been more popular. Since the CoNLL 2004-2005 shared tasks (Carreras and Màrquez,

[*]The majority of this research was carried out during an internship at Google.

[1]There are exceptions, wherein the task has been modeled using a pipeline of three classifiers that perform frame identification, a binary stage that classifies candidate arguments, and argument identification on the filtered candidates (Baker et al., 2007; Johansson and Nugues, 2007).

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1448–1458,
Baltimore, Maryland, USA, June 23-25 2014.

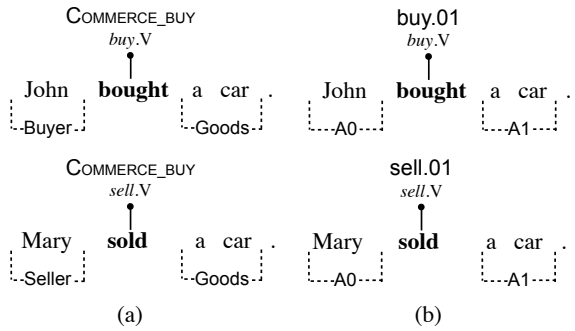

Figure 1: Example sentences with frame-semantic analyses. FrameNet annotation conventions are used in (a) while (b) denotes PropBank conventions.

2004; Carreras and Màrquez, 2005) on PropBank semantic role labeling (SRL), it has been treated as an important NLP problem. However, research has mostly focused on argument analysis, skipping the frame disambiguation step, and its interaction with argument identification.

2.1 Frame-Semantic Parsing

Closely related to SRL, frame-semantic parsing consists of the resolution of predicate sense into a frame, and the analysis of the frame's arguments. Work in this area exclusively uses the FrameNet full text annotations. Johansson and Nugues (2007) presented the best performing system at SemEval 2007 (Baker et al., 2007), and Das et al. (2010) improved performance, and later set the current state of the art on this task (Das et al., 2014). We briefly discuss FrameNet, and subsequently PropBank annotation conventions here.

FrameNet The FrameNet project (Baker et al., 1998) is a lexical database that contains information about words and phrases (represented as lemmas conjoined with a coarse part-of-speech tag) termed as lexical units, with a set of semantic frames that they could evoke. For each frame, there is a list of associated frame elements (or roles, henceforth), that are also distinguished as core or non-core.[2] Sentences are annotated using this universal frame inventory. For example, consider the pair of sentences in Figure 1(a). COMMERCE_BUY is a frame that can be evoked by morphological variants of the two example lexical units *buy*.V and *sell*.V. Buyer, Seller and Goods are some example roles for this frame.

[2]Additional information such as finer distinction of the coreness properties of roles, the relationship between frames, and that of roles are also present, but we do not leverage that information in this work.

PropBank The PropBank project (Palmer et al., 2005) is another popular resource related to semantic role labeling. The PropBank corpus has verbs annotated with sense frames and their arguments. Like FrameNet, it also has a lexical database that stores type information about verbs, in the form of sense frames and the possible semantic roles each frame could take. There are modifier roles that are shared across verb frames, somewhat similar to the non-core roles in FrameNet. Figure 1(b) shows annotations for two verbs "bought" and "sold", with their lemmas (akin to the lexical units in FrameNet) and their verb frames buy.01 and sell.01. Generic core role labels (of which there are seven, namely A0-A5 and AA) for the verb frames are marked in the figure.[3] A key difference between the two annotation systems is that PropBank uses a local frame inventory, where frames are predicate-specific. Moreover, role labels, although few in number, take specific meaning for each verb frame. Figure 1 highlights this difference: while both *sell*.V and *buy*.V are members of the same frame in FrameNet, they evoke different frames in PropBank. In spite of this difference, nearly identical statistical models could be employed for both frameworks.

Modeling In this paper, we model the frame-semantic parsing problem in two stages: **frame identification** and **argument identification**. As mentioned in §1, these correspond to a frame disambiguation stage,[4] and a stage that finds the various arguments that fulfill the frame's semantic roles within the sentence, respectively. This resembles the framework of Das et al. (2014), who solely focus on FrameNet corpora, unlike this paper. The novelty of this paper lies in the frame identification stage (§3). Note that this two-stage approach is unusual for the PropBank corpora when compared to prior work, where the vast majority of published papers have not focused on the verb frame disambiguation problem at all, only focusing on the role labeling stage (see the overview paper of Màrquez et al. (2008) for example).

[3]NomBank (Meyers et al., 2004) is a similar resource for nominal predicates, but we do not consider it in our experiments.

[4]For example in PropBank, the lexical unit *buy*.V has three verb frames and in sentential context, we want to disambiguate its frame. (Although PropBank never formally uses the term lexical unit, we adopt its usage from the frame semantics literature.)

2.2 Distributed Frame Identification

We present a model that takes word embeddings as input and learns to identify semantic frames. A word embedding is a distributed representation of meaning where each word is represented as a vector in $\mathbb{R}^n$. Such representations allow a model to share meaning between similar words, and have been used to capture semantic, syntactic and morphological content (Collobert and Weston, 2008; Turian et al., 2010, *inter alia*). We use word embeddings to represent the syntactic context of a particular predicate instance as a vector. For example, consider the sentence "He runs the company." The predicate *runs* has two syntactic dependents – a subject and direct object (but no prepositional phrases or clausal complements). We could represent the syntactic context of *runs* as a vector with blocks for all the possible dependents warranted by a syntactic parser; for example, we could assume that positions $0 \ldots n$ in the vector correspond to the subject dependent, $n{+}1 \ldots 2n$ correspond to the clausal complement dependent, and so forth. Thus, the context is a vector in $\mathbb{R}^{nk}$ with the embedding of *He* at the subject position, the embedding of *company* in direct object position and zeros everywhere else. Given input vectors of this form for our training data, we learn a matrix that maps this high dimensional and sparse representation into a lower dimensional space. Simultaneously, the model learns an embedding for all the possible labels (i.e. the frames in a given lexicon). At inference time, the predicate-context is mapped to the low dimensional space, and we choose the nearest frame label as our classification. We next describe this model in detail.

3 Frame Identification with Embeddings

We continue using the example sentence from §2.2: "He runs the company." where we want to disambiguate the frame of *runs* in context. First, we extract the words in the syntactic context of *runs*; next, we concatenate their word embeddings as described in §2.2 to create an initial vector space representation. Subsequently, we learn a mapping from this initial representation into a low-dimensional space; we also learn an embedding for each possible frame label in the same low-dimensional space. The goal of learning is to make sure that the correct frame label is as close as possible to the mapped context, while competing frame labels are farther away.

Formally, let x represent the actual sentence with a marked predicate, along with the associated syntactic parse tree; let our initial representation of the predicate context be $g(x)$. Suppose that the word embeddings we start with are of dimension n. Then g is a function from a parsed sentence x to $\mathbb{R}^{nk}$, where k is the number of possible syntactic context types. For example g selects some important positions relative to the predicate, and reserves a block in its output space for the embedding of words found at that position. Suppose g considers clausal complements and direct objects. Then $g : X \rightarrow \mathbb{R}^{2n}$ and for the example sentence it has zeros in positions $0 \ldots n$ and the embedding of the word *company* in positions $n{+}1 \ldots 2n$.

$$g(x) = [0, \ldots, 0, \text{embedding of } \textit{company}].$$

Section 3.1 describes the context positions we use in our experiments. Let the low dimensional space we map to be $\mathbb{R}^m$ and the learned mapping be $M : \mathbb{R}^{nk} \rightarrow \mathbb{R}^m$. The mapping M is a linear transformation, and we learn it using the WSABIE algorithm (Weston et al., 2011). WSABIE also learns an embedding for each frame label (y, henceforth). In our setting, this means that each frame corresponds to a point in $\mathbb{R}^m$. If we have F possible frames we can store those parameters in an $F \times m$ matrix, one m-dimensional point for each frame, which we will refer to as the linear mapping Y. Let the lexical unit (the lemma conjoined with a coarse POS tag) for the marked predicate be ℓ. We denote the frames that associate with ℓ in the frame lexicon[5] and our training corpus as F_ℓ. WSABIE performs gradient-based updates on an objective that tries to minimize the distance between $M(g(x))$ and the embedding of the correct label $Y(y)$, while maintaining a large distance between $M(g(x))$ and the other possible labels $Y(\bar{y})$ in the confusion set F_ℓ. At disambiguation time, we use a simple dot product similarity as our distance metric, meaning that the model chooses a label by computing the $\text{argmax}_y s(x, y)$ where $s(x, y) = M(g(x)) \cdot Y(y)$, where the argmax iterates over the possible frames $y \in F_\ell$ if ℓ was seen in the lexicon or the training data, or $y \in F$, if it was unseen.[6] Model learning is performed using the margin ranking loss function as described in

[5]The frame lexicon stores the frames, corresponding semantic roles and the lexical units associated with the frame.

[6]This disambiguation scheme is similar to the one adopted by Das et al. (2014), but they use unlemmatized words to define their confusion set.

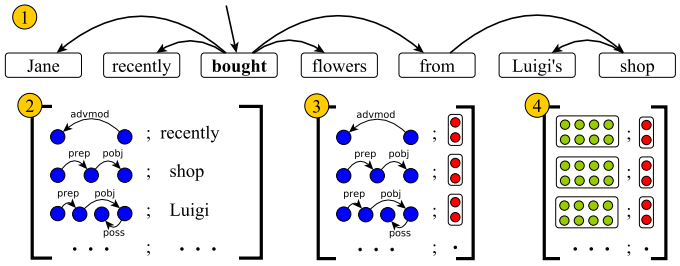

Figure 2: Context representation extraction for the embedding model. Given a dependency parse (1) the model extracts all words matching a set of paths from the frame evoking predicate and its direct dependents (2). The model computes a composed representation of the predicate instance by using distributed vector representations for words (3) – the (red) vertical embedding vectors for each word are concatenated into a long vector. Finally, we learn a linear transformation function parametrized by the context blocks (4).

Weston et al. (2011), and in more detail in section 3.2.

Since WSABIE learns a single mapping from $g(x)$ to $\mathbb{R}^m$, parameters are shared between different words and different frames. So for example "He *runs* the company" could help the model disambiguate "He *owns* the company." Moreover, since $g(x)$ relies on word embeddings rather than word identities, information is shared between words. For example "*He* runs *the company*" could help us to learn about "*She* runs *a corporation*".

3.1 Context Representation Extraction

In principle $g(x)$ could be any feature function, but we performed an initial investigation of two particular variants. In both variants, our representation is a block vector where each block corresponds to a syntactic position relative to the predicate, and each block's values correspond to the embedding of the word at that position.

Direct Dependents The first context function we considered corresponds to the examples in §3. To elaborate, the positions of interest are the labels of the direct dependents of the predicate, so k is the number of labels that the dependency parser can produce. For example, if the label on the edge between *runs* and *He* is nsubj, we would put the embedding of *He* in the block corresponding to nsubj. If a label occurs multiple times, then the embeddings of the words below this label are averaged.

Unfortunately, using only the direct dependents can miss a lot of useful information. For example, topicalization can place discriminating information farther from the predicate. Consider "He *runs* the *company*." vs. "It was the *company* that he *runs*." In the second sentence, the discriminating word, *company* dominates the predicate *runs*. Similarly, predicates in embedded clauses may have a distant agent which cannot be captured using direct dependents. Consider "*The athlete ran* the marathon." vs. "*The athlete* prepared himself for three months to *run* the marathon." In the second example, for the predicate *run*, the agent *The athlete* is not a direct dependent, but is connected via a longer dependency path.

Dependency Paths To capture more relevant context, we developed a second context function as follows. We scanned the training data for a given task (either the PropBank or the FrameNet domains) for the dependency paths that connected the gold predicates to the gold semantic arguments. This set of dependency paths were deemed as possible positions in the initial vector space representation. In addition, akin to the first context function, we also added all dependency labels to the context set. Thus for this context function, the block cardinality k was the sum of the number of scanned gold dependency path types and the number of dependency labels. Given a predicate in its sentential context, we therefore extract only those context words that appear in positions warranted by the above set. See Figure 2 for an illustration of this process.

We performed initial experiments using context extracted from 1) direct dependents, 2) dependency paths, and 3) both. For all our experiments, setting 3) which concatenates the direct dependents and dependency path always dominated the other two, so we only report results for this setting.

3.2 Learning

We model our objective function following Weston et al. (2011), using a weighted approximate-rank pairwise loss, learned with stochastic gradient descent. The mapping from $g(x)$ to the low dimensional space $\mathbb{R}^m$ is a linear transformation, so the model parameters to be learnt are the matrix $M \in \mathbb{R}^{nk \times m}$ as well as the embedding of each possible frame label, represented as another matrix $Y \in \mathbb{R}^{F \times m}$ where there are F frames in total. The training objective function minimizes:

$$\sum_x \sum_{\bar{y}} L\big(rank_y(x)\big) \max(0, \gamma + s(x,y) - s(x,\bar{y})).$$

where x, y are the training inputs and their corresponding correct frames, and $\bar{y}$ are negative frames, γ is the margin. Here, $rank_y(x)$ is the rank of the positive frame y relative to all the negative frames:

$$rank_y(x) = \sum_{\bar{y}} I(s(x,y) \leq \gamma + s(x,\bar{y})),$$

and $L(\eta)$ converts the rank to a weight. Choosing $L(\eta) = C\eta$ for any positive constant C optimizes the mean rank, whereas a weighting such as $L(\eta) = \sum_{i=1}^{\eta} 1/i$ (adopted here) optimizes the top of the ranked list, as described in (Usunier et al., 2009). To train with such an objective, stochastic gradient is employed. For speed the computation of $rank_y(x)$ is then replaced with a sampled approximation: sample N items $\bar{y}$ until a violation is found, i.e. $\max(0, \gamma + s(x,\bar{y}) - s(x,y))) > 0$ and then approximate the rank with $(F-1)/N$, see Weston et al. (2011) for more details on this procedure. For the choices of the stochastic gradient learning rate, margin (γ) and dimensionality (m), please refer to §5.4-§5.5.

Note that an alternative approach could learn only the matrix M, and then use a k-nearest neighbor classifier in $\mathbb{R}^m$, as in Weinberger and Saul (2009). The advantage of learning an embedding for the frame labels is that at inference time we need to consider only the set of labels for classification rather than all training examples. Additionally, since we use a frame lexicon that gives us the possible frames for a given predicate, we usually only consider a handful of candidate labels. If we used all training examples for a given predicate for finding a nearest-neighbor match at inference time, we would have to consider many more candidates, making the process very slow.

4 Argument Identification

Here, we briefly describe the argument identification model used in our frame-semantic parsing experiments, post frame identification. Given x, the sentence with a marked predicate, the argument identification model assumes that the predicate frame y has been disambiguated. From a frame lexicon, we look up the set of semantic roles $\mathcal{R}_y$ that associate with y. This set also contains the null role $r_\emptyset$. From x, a rule-based candidate argument extraction algorithm extracts a set of spans $\mathcal{A}$ that could potentially serve as the overt[7] arguments $\mathcal{A}_y$ for y (see §5.4-§5.5 for the details of the candidate argument extraction algorithms).

[7]By overtness, we mean the non-null instantiation of a semantic role in a frame-semantic parse.

• starting word of a	• POS of the starting word of a
• ending word of a	• POS of the ending word of a
• head word of a	• POS of the head word of a
• bag of words in a	• bag of POS tags in a
• a bias feature	• voice of the predicate use
• word cluster of a's head	
• word cluster of a's head conjoined with word cluster of the predicate*	
• dependency path between a's head and the predicate	
• the set of dependency labels of the predicate's children	
• dependency path conjoined with the POS tag of a's head	
• dependency path conjoined with the word cluster of a's head	
• position of a with respect to the predicate (*before, after, overlap or identical*)	
• whether the subject of the predicate is missing (*missingsubj*)	
• *missingsubj*, conjoined with the dependency path	
• *missingsubj*, conjoined with the dependency path from the verb dominating the predicate to a's head	

Table 1: Argument identification features. The span in consideration is termed a. Every feature in this list has two versions, one conjoined with the given role r and the other conjoined with both r and the frame y. The feature with a * superscript is only conjoined with the role to reduce its sparsity.

Learning Given training data of the form $\langle\langle x^{(i)}, y^{(i)}, \mathcal{M}^{(i)}\rangle\rangle_{i=1}^{N}$, where,

$$\mathcal{M} = \{(r,a\} : r \in \mathcal{R}_y, a \in \mathcal{A} \cup \mathcal{A}_y\}, \quad (1)$$

a set of tuples that associates each role r in $\mathcal{R}_y$ with a span a according to the gold data. Note that this mapping associates spans with the null role $r_\emptyset$ as well. We optimize the following log-likelihood to train our model:

$$\max_{\boldsymbol{\theta}} \sum_{i=1}^{N} \sum_{j=1}^{|\mathcal{M}^{(i)}|} \log p_{\boldsymbol{\theta}}\big((r,a)_j | x, y, \mathcal{R}_y\big) - C\|\boldsymbol{\theta}\|_2^2$$

where $p_{\boldsymbol{\theta}}$ is a log-linear model normalized over the set $\mathcal{R}_y$, with features described in Table 1. We set $C = 1.0$ and use L-BFGS (Liu and Nocedal, 1989) for training.

Inference Although our learning mechanism uses a local log-linear model, we perform inference globally on a per-frame basis by applying hard structural constraints. Following Das et al. (2014) and Punyakanok et al. (2008) we use the log-probability of the local classifiers as a score in an integer linear program (ILP) to assign roles subject to hard constraints described in §5.4 and §5.5. We use an off-the-shelf ILP solver for inference.

5 Experiments

In this section, we present our experiments and the results achieved. We evaluate our novel frame identification approach in isolation and also conjoined with argument identification resulting in full frame-semantic structures; before presenting our model's performance we first focus on the datasets, baselines and the experimental setup.

5.1 Data

We evaluate our models on both FrameNet- and PropBank-style structures. For FrameNet, we use the full-text annotations in the FrameNet 1.5 release[8] which was used by Das et al. (2014, §3.2). We used the same test set as Das et al. containing 23 documents with 4,458 predicates. Of the remaining 55 documents, 16 documents were randomly chosen for development.[9]

For experiments with PropBank, we used the Ontonotes corpus (Hovy et al., 2006), version 4.0, and only made use of the Wall Street Journal documents; we used sections 2-21 for training, section 24 for development and section 23 for testing. This resembles the setup used by Punyakanok et al. (2008). All the verb frame files in Ontonotes were used for creating our frame lexicon.

5.2 Frame Identification Baselines

For comparison, we implemented a set of baseline models, with varying feature configurations. The baselines use a log-linear model that models the following probability at training time:

$$p(y|x,\ell) = \frac{e^{\boldsymbol{\psi}\cdot\mathbf{f}(y,x,\ell)}}{\sum_{\bar{y}\in F_\ell} e^{\boldsymbol{\psi}\cdot\mathbf{f}(\bar{y},x,\ell)}} \quad (2)$$

At test time, this model chooses the best frame as $\text{argmax}_y \boldsymbol{\psi}\cdot\mathbf{f}(y,x,\ell)$ where argmax iterates over the possible frames $y \in F_\ell$ if ℓ was seen in the lexicon or the training data, or $y \in F$, if it was unseen, like the disambiguation scheme of §3. We train this model by maximizing L_2 regularized log-likelihood, using L-BFGS; the regularization constant was set to 0.1 in all experiments.

For comparison with our model from §3, which we call WSABIE EMBEDDING, we implemented two baselines with the log-linear model. Both the baselines use features very similar to the input representations described in §3.1. The first one computes the direct dependents and dependency paths as described in §3.1 but conjoins them with the word identity rather than a word embedding. Additionally, this model uses the un-conjoined words as backoff features. This would be a standard NLP approach for the frame identification problem, but is surprisingly competitive with the state of the art. We call this baseline LOG-LINEAR WORDS. The second baseline, tries to decouple the WSABIE training from the embedding input, and trains a log linear model using the embeddings. So the second baseline has the same input representation as WSABIE EMBEDDING but uses a log-linear model instead of WSABIE. We call this model LOG-LINEAR EMBEDDING.

5.3 Common Experimental Setup

We process our PropBank and FrameNet training, development and test corpora with a shift-reduce dependency parser that uses the Stanford conventions (de Marneffe and Manning, 2013) and uses an arc-eager transition system with beam size of 8; the parser and its features are described by Zhang and Nivre (2011). Before parsing the data, it is tagged with a POS tagger trained with a conditional random field (Lafferty et al., 2001) with the following emission features: word, the word cluster, word suffixes of length 1, 2 and 3, capitalization, whether it has a hyphen, digit and punctuation. Beyond the bias transition feature, we have two cluster features for the left and right words in the transition. We use Brown clusters learned using the algorithm of Uszkoreit and Brants (2008) on a large English newswire corpus for cluster features. We use the same word clusters for the argument identification features in Table 1.

We learn the initial embedding representations for our frame identification model (§3) using a deep neural language model similar to the one proposed by Bengio et al. (2003). We use 3 hidden layers each with 1024 neurons and learn a 128-dimensional embedding from a large corpus containing over 100 billion tokens. In order to speed up learning, we use an unnormalized output layer and a hinge-loss objective. The objective tries to ensure that the correct word scores higher than a random incorrect word, and we train with mini-batch stochastic gradient descent.

5.4 Experimental Setup for FrameNet

Hyperparameters For our frame identification model with embeddings, we search for the WSABIE hyperparameters using the development data.

Table 3: Full structure prediction results for FrameNet; this reports frame and argument identification performance jointly. We skip LOG-LINEAR EMBEDDING because it underperforms all other models by a large margin.

We search for the stochastic gradient learning rate in $\{\underline{0.0001}, 0.001, 0.01\}$, the margin $\gamma \in \{0.001, \underline{0.01}, 0.1, 1\}$ and the dimensionality of the final vector space $m \in \{\underline{256}, 512\}$, to maximize the frame identification accuracy of *ambiguous* lexical units; by ambiguous, we imply lexical units that appear in the training data or the lexicon with more than one semantic frame. The underlined values are the chosen hyperparameters used to analyze the test data.

Argument Candidates The candidate argument extraction method used for the FrameNet data, (as mentioned in §4) was adapted from the algorithm of Xue and Palmer (2004) applied to dependency trees. Since the original algorithm was designed for verbs, we added a few extra rules to handle non-verbal predicates: we added 1) the predicate itself as a candidate argument, 2) the span ranging from the sentence position to the right of the predicate to the rightmost index of the subtree headed by the predicate's head; this helped capture cases like "a *few* months" (where *few* is the predicate and months is the argument), and 3) the span ranging from the leftmost index of the subtree headed by the predicate's head to the position immediately before the predicate, for cases like "your gift *to* Goodwill" (where *to* is the predicate and your gift is the argument).[10]

Frame Lexicon In our experimental setup, we scanned the XML files in the "frames" directory of the FrameNet 1.5 release, which lists all the frames, the corresponding roles and the associated lexical units, and created a frame lexicon to be used in our frame and argument identification models. We noted that this renders every lexical unit as *seen*; in other words, at frame disambiguation time on our test set, for all instances, we only had to score the frames in F_ℓ for a predicate with lexical unit ℓ (see §3 and §5.2). We call this setup FULL LEXICON. While comparing with prior state of the art on the same corpus, we noted that Das et al. (2014) found several unseen predicates at test time.[11] For fair comparison, we took the lexical units for the predicates that Das et al. considered as seen, and constructed a lexicon with only those; training instances, if any, for the unseen predicates under Das et al.'s setup were thrown out as well. We call this setup SEMAFOR LEXICON.[12] We also experimented on the set of unseen instances used by Das et al.

ILP constraints For FrameNet, we used three ILP constraints during argument identification (§4). 1) each span could have only one role, 2) each core role could be present only once, and 3) all overt arguments had to be non-overlapping.

[10] Note that Das et al. (2014) describe the state of the art in FrameNet-based analysis, but their argument identification strategy considered all possible dependency subtrees in a parse, resulting in a much larger search space.

[11] Instead of using the frame files, Das et al. built a frame lexicon from FrameNet's exemplars and the training corpus.

[12] We got Das et al.'s seen predicates from the authors.

Table 5: Full frame-structure prediction results for Propbank. This is a metric that takes into account frames and arguments together. See §5.7 for more details.

5.5 Experimental Setup for PropBank

Hyperparameters As in §5.4, we made a hyperparameter sweep in the same space. The chosen learning rate was 0.01, while the other values were $\gamma = 0.01$ and $m = 512$. Ambiguous lexical units were used for this selection process.

Argument Candidates For PropBank we use the algorithm of Xue and Palmer (2004) applied to dependency trees.

Frame Lexicon For the PropBank experiments we scanned the frame files for propositions in Ontonotes 4.0, and stored possible core roles for each verb frame. The lexical units were simply the verb associating with the verb frames. There were no unseen verbs at test time.

ILP constraints We used the constraints of Punyakanok et al. (2008).

5.6 FrameNet Results

Table 2 presents accuracy results on frame identification.[13] We present results on all predicates, ambiguous predicates seen in the lexicon or the training data, and rare ambiguous predicates that appear ≤ 11 times in the training data. The WSABIE EMBEDDING model from §3 performs significantly better than the LOG-LINEAR WORDS baseline, while LOG-LINEAR EMBEDDING underperforms in every metric. For the SEMAFOR LEXICON setup, we also compare with the state of the art from Das et al. (2014), who used a semi-supervised learning method to improve upon a supervised latent-variable log-linear model. For unseen predicates from the Das et al. system, we perform better as well. Finally, for the FULL LEXICON setting, the absolute accuracy numbers are even better for our best model. Table 3 presents results on the full frame-semantic parsing task (measured by a reimplementation of the SemEval 2007 shared task evaluation script) when our argument identification model (§4) is used after frame identification. We notice similar trends as in Table 2, and our results outperform the previously published best results, setting a new state of the art.

[13] We do not report partial frame accuracy that has been reported by prior work.

Table 6: Argument only evaluation (semantic role labeling metrics) using the CoNLL 2005 shared task evaluation script (Carreras and Màrquez, 2005). Results from Punyakanok et al. (2008) are taken from Table 11 of that paper.

5.7 PropBank Results

Table 4 shows frame identification results on the PropBank data. On the development set, our best model performs with the highest accuracy on all and ambiguous predicates, but performs worse on rare ambiguous predicates. On the test set, the LOG-LINEAR WORDS baseline performs best by a very narrow margin. See §6 for a discussion.

Table 5 presents results where we measure precision, recall and F_1 for frames and arguments together; this strict metric penalizes arguments for mismatched frames, like in Table 3. We see the same trend as in Table 4. Finally, Table 6 presents SRL results that measures argument performance only, irrespective of the frame; we use the evaluation script from CoNLL 2005 (Carreras and Màrquez, 2005). We note that with a better frame identification model, our performance on SRL improves in general. Here, too, the embedding model barely misses the performance of the best baseline, but we are at par and sometimes better than the single parser setting of a state-of-the-art SRL system (Punyakanok et al., 2008).[14]

[14] The last row of Table 6 refers to a system which used the

6 Discussion

For FrameNet, the WSABIE EMBEDDING model we propose strongly outperforms the baselines on all metrics, and sets a new state of the art. We believe that the WSABIE EMBEDDING model performs better than the LOG-LINEAR EMBEDDING baseline (that uses the same input representation) because the former setting allows examples with different labels and confusion sets to share information; this is due to the fact that all labels live in the same label space, and a single projection matrix is shared across the examples to map the input features to this space. Consequently, the WSABIE EMBEDDING model can share more information between different examples in the training data than the LOG-LINEAR EMBEDDING model. Since the LOG-LINEAR WORDS model always performs better than the LOG-LINEAR EMBEDDING model, we conclude that the primary benefit does not come from the input embedding representation.[15]

On the PropBank data, we see that the LOG-LINEAR WORDS baseline has roughly the same performance as our model on most metrics: slightly better on the test data and slightly worse on the development data. This can be partially explained with the significantly larger training set size for PropBank, making features based on words more useful. Another important distinction between PropBank and FrameNet is that the latter shares frames between multiple lexical units. The effect of this is clearly observable from the "Rare" column in Table 4. WSABIE EMBEDDING performs poorly in this setting while LOG-LINEAR EMBEDDING performs well. Part of the explanation has to do with the specifics of WSABIE training. Recall that the WSABIE EMBEDDING model needs to estimate the label location in $\mathbb{R}^m$ for each frame. In other words, it must estimate 512 parameters based on at most 10 training examples. However, since the input representation is shared across all frames, every other training example from all the lexical units affects the optimal estimate, since they all modify the joint parameter matrix M. By contrast, in the log-linear models each label has its own set of parameters, and they interact only via the normalization constant. The LOG-LINEAR WORDS model does not have this entanglement, but cannot share information between words. For PropBank, these drawbacks and benefits balance out and we see similar performance for LOG-LINEAR WORDS and LOG-LINEAR EMBEDDING. For FrameNet, estimating the label embedding is not as much of a problem because even if a lexical unit is rare, the potential frames can be frequent. For example, we might have seen the SENDING frame many times, even though *telex*.V is a rare lexical unit.

In comparison to prior work on FrameNet, even our baseline models outperform the previous state of the art. A particularly interesting comparison is between our LOG-LINEAR WORDS baseline and the supervised model of Das et al. (2014). They also use a log-linear model, but they incorporate a latent variable that uses WordNet (Fellbaum, 1998) to get lexical-semantic relationships and smooths over frames for ambiguous lexical units. It is possible that this reduces the model's power and causes it to over-generalize. Another difference is that when training the log-linear model, they normalize over all frames, while we normalize over the allowed frames for the current lexical unit. This would tend to encourage their model to expend more of its modeling power to rule out possibilities that will be pruned out at test time.

7 Conclusion

We have presented a simple model that outperforms the prior state of the art on FrameNet-style frame-semantic parsing, and performs at par with one of the previous-best single-parser systems on PropBank SRL. Unlike Das et al. (2014), our model does not rely on heuristics to construct a similarity graph and leverage WordNet; hence, in principle it is generalizable to varying domains, and to other languages. Finally, we presented results on PropBank-style semantic role labeling with a system that included the task of automatic verb frame identification, in tune with the FrameNet literature; we believe that such a system produces more interpretable output, both from the perspective of human understanding as well as downstream applications, than pipelines that are oblivious to the verb frame, only focusing on argument analysis.

Table 7: List of files used as development set for the FrameNet 1.5 corpus.

A Development Data

Table 7 features a list of the 16 randomly selected documents from the FrameNet 1.5 corpus, which we used for development. The resultant development set consists of roughly 4,500 predicates. We use the same test set as in Das et al. (2014), containing 23 documents and 4,458 predicates.

A Sense-Based Translation Model for Statistical Machine Translation

Deyi Xiong and **Min Zhang***

Abstract

The sense in which a word is used determines the translation of the word. In this paper, we propose a sense-based translation model to integrate word senses into statistical machine translation. We build a broad-coverage sense tagger based on a nonparametric Bayesian topic model that automatically learns sense clusters for words in the source language. The proposed sense-based translation model enables the decoder to select appropriate translations for source words according to the inferred senses for these words using maximum entropy classifiers. Our method is significantly different from previous word sense disambiguation reformulated for machine translation in that the latter neglects word senses in nature. We test the effectiveness of the proposed sense-based translation model on a large-scale Chinese-to-English translation task. Results show that the proposed model substantially outperforms not only the baseline but also the previous reformulated word sense disambiguation.

1 Introduction

One of very common phenomena in language is that a plenty of words have multiple meanings. In the context of machine translation, such different meanings normally produce different target translations. Therefore a natural assumption is that word sense disambiguation (WSD) may contribute to statistical machine translation (SMT) by providing appropriate word senses for target translation selection with context features (Carpuat and Wu, 2005).

This assumption, however, has not been empirically verified in the early days. Carpuat and Wu (2005) adopt a standard formulation of WSD: predicting word senses that are defined on an ontology for ambiguous words. As they apply WSD to Chinese-to-English translation, they predict word senses from a Chinese ontology HowNet and project the predicted senses to English glosses provided by HowNet. These glosses, used as the sense predictions of their WSD system, are integrated into a word-based SMT system either to substitute for translation candidates of their translation model or to postedit the output of their SMT system. They report that WSD degenerates the translation quality of SMT.

In contrast to the standard WSD formulation, Vickrey et al. (2005) reformulate the task of WSD for SMT as predicting possible target translations rather than senses for ambiguous source words. They show that such a reformulated WSD can improve the accuracy of a simplified word translation task.

Following this WSD reformulation for SMT, Chan et al. (2007) integrate a state-of-the-art WSD system into a hierarchical phrase-based system (Chiang, 2005). Carpuat and Wu (2007) also use this reformulated WSD and further adapt it to multi-word phrasal disambiguation. They both report that the redefined WSD can significantly improve SMT.

Although this reformulated WSD has proved helpful for SMT, one question is not answered yet: are pure word senses useful for SMT? The early WSD for SMT (Carpuat and Wu, 2005) uses projected word senses while the reformulated WSD sidesteps word senses. In this paper we would like to re-investigate this question by resorting to word sense induction (WSI) that is related to but different from WSD.[1] We use

[1] We will discuss the relation and difference between WSI and WSD in Section 2.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1459–1469,
Baltimore, Maryland, USA, June 23-25 2014.

WSI to obtain word senses for large-scale data. With these word senses, we study in particular: 1) whether word senses can be directly integrated to SMT to improve translation quality and 2) whether WSI-based model can outperform the reformulated WSD in the context of SMT.

In order to incorporate word senses into SMT, we propose a sense-based translation model that is built on maximum entropy classifiers. We use a nonparametric Bayesian topic model based WSI to infer word senses for source words in our training, development and test set. We collect training instances from the sense-tagged training data to train the proposed sense-based translation model. Specially,

- Instead of predicting target translations for ambiguous source words as the previous reformulated WSD does, we first predict word senses for ambiguous source words. The predicted word senses together with other context features are then used to predict possible target translations for these words.

- Instead of using word senses defined by a prespecified sense inventory as the standard WSD does, we incorporate word senses that are automatically learned from data into our sense-based translation model.

We integrate the proposed sense-based translation model into a state-of-the-art SMT system and conduct experiments on Chines-to-English translation using large-scale training data. Results show that automatically learned word senses are able to improve translation quality and the sense-based translation model is better than the previous reformulated WSD.

The remainder of this paper proceeds as follows. Section 2 introduces how we obtain word senses for our large-scale training data via a WSI-based broad-coverage sense tagger. Section 3 presents our sense-based translation model. Section 4 describes how we integrate the sense-based translation model into SMT. Section 5 elaborates our experiments on the large-scale Chinese-to-English translation task. Section 6 introduces related studies and highlights significant differences from them. Finally, we conclude in Section 7 with future directions.

2 WSI-Based Broad-Coverage Sense Tagger

In order to obtain word senses for any source words, we build a broad-coverage sense tagger that relies on the nonparametric Bayesian model based word sense induction. We first describe WSI, especially WSI based on the Hierarchical Dirichlet Process (HDP) (Teh et al., 2004), a nonparametric version of Latent Dirichlet Allocation (LDA) (Blei et al., 2003). We then elaborate how we use the HDP-based WSI to predict sense clusters and to annotate source words in our training/development/test sets with these sense clusters.

2.1 Word Sense Induction

Before we introduce WSI, we differentiate **word type** from **word token**. A word type refers to a unique word as a vocabulary entry while a word token is an occurrence of a word type. Take the first sentence of this paragraph as an example, it has 11 word tokens but 9 word types as there are two word tokens of the word type "we" and two tokens of the word type "word".

Word sense induction is a task of automatically inducing the underlying senses of word tokens given the surrounding contexts where the word tokens occur. The biggest difference from word sense disambiguation lies in that WSI does not rely on a predefined sense inventory. Such a prespecified list of senses is normally assumed by WSD which predicts senses of word tokens using this given inventory. From this perspective, WSI can be treated as a clustering problem while WSD a classification one.

Various clustering algorithms, such as k-means, have been previously used for WSI. Recently, we have also witnessed that WSI is cast as a topic modeling problem where the sense clusters of a word type are considered as underlying topics (Brody and Lapata, 2009; Yao and Durme, 2011; Lau et al., 2012). We follow this line to tailor a topic modeling framework to induce word senses for our large-scale training data.

In the topic-based WSI, surrounding context of a word token is considered as a **pseudo document** of the corresponding word type. A pseudo document is composed of either a bag of neighboring words of a word token, or the Part-to-Speech tags of neighboring words, or other contextual information elements. In this paper, we define a pseudo

document as $\pm N$ neighboring words centered on a given word token. Table 1 shows examples of pseudo documents for a Chinese word "wǎngluò" (network). These two pseudo documents are extracted from a sentence listed in the first row of Table 1. Here we set $N = 5$. We can extract as many pseudo documents as the number of word tokens of a given word type that occur in training data. The collection of all these extracted pseudo documents of the given word type forms a corpus. We can induce topics on this corpus for each pseudo document via topic modeling approaches.

Figure 1(a) shows the LDA-based WSI for a given word type W. The outer plate represents replicates of pseudo documents which consist of N neighboring words centered on the tokens of the given word type W. $w_{j,i}$ is the i-th word of the j-th pseudo document of the given word type W. $s_{j,i}$ is the sense assigned to the word $w_{j,i}$. The conventional topic distribution θ_j for the j-th pseudo document is taken as the the distribution over senses for the given word type W. The LDA generative process for sense induction is as follows: 1) for each pseudo document D_j, draw a per-document sense distribution θ_j from a Dirichlet distribution Dir(α); 2) for each item $w_{j,i}$ in the pseudo document D_j, 2.1) draw a sense cluster $s_{j,i} \sim$ Multinomial(θ_j); and 2.2) draw a word $w_{j,i} \sim \varphi_{s_{j,i}}$ where $\varphi_{s_{j,i}}$ is the distribution of sense $s_{j,i}$ over words drawn from a Dirichlet distribution Dir(β).

As LDA needs to manually specify the number of senses (topics), a better idea is to let the training data automatically determine the number of senses for each word type. Therefore we resort to the HDP, a natural nonparametric generalization of LDA, for the inference of both sense clusters and the number of sense clusters following Lau et al. (2012) and Yao and Durme (2011). The HDP for WSI is shown in Figure 1(b). The HDP generative process for word sense induction is as follows: 1) sample a base distribution G_0 from a Dirichlet process DP(γ, H) with a concentration parameter γ and a base distribution H; 2) for each pseudo document D_j, sample a distribution $G_j \sim$ DP(α_0, G_0); 3) for each item $w_{j,i}$ in the pseudo document D_j, 3.1) sample a sense cluster $s_{j,i} \sim G_j$; and 3.2) sample a word $w_{j,i} \sim \varphi_{s_{j,i}}$. Here G_0 is a global distribution over sense clusters that are shared by all G_j. G_j is a per-document sense distribution over these sense clusters, which has its own document-specific proportions of these sense clusters. The hyperparameter γ, α_0 in the HDP are both concentration parameters which control the variability of senses in the global distribution G_0 and document-specific distribution G_j.

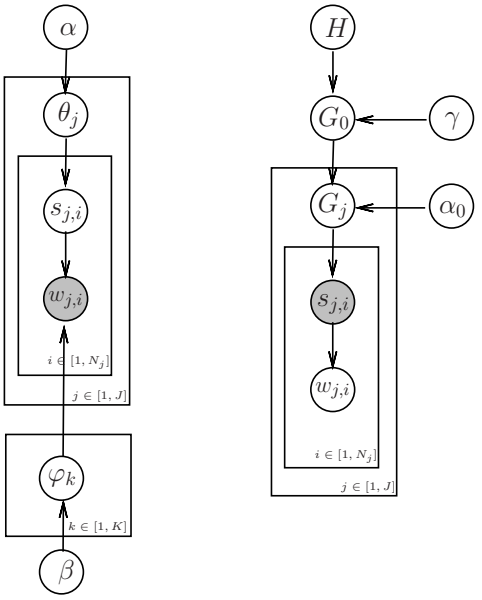

Figure 1: Graphical model representations of (a) Latent Dirichlet Allocation for WSI, (b) Hierarchical Dirichlet Process for WSI.

The HDP/LDA-based WSI complies with the distributional hypothesis that states that words occurring in the same contexts tend to have similar meanings. We want to extend this hypothesis to machine translation by building sense-based translation model upon the HDP-based word sense induction: words with the same meanings tend to be translated in the same way.

2.2 Word Sense Tagging

We adopt the HDP-based WSI to automatically predict word senses and use these predicted senses to annotate source words. We individually build a HDP-based WSI model per word type and train these models on the training data. The sense for a word token is defined as the most probable sense according to the per-document sense distribution G_j estimated for the corresponding pseudo document that represents the surrounding context of the word token. In particular, we take the following steps.

tā tíxǐng wǒguó wǎngluò yùnyíng zhě zhùyì fángfàn hēikè gōngjī ， quèbǎo wǎngluò ānquán 。
Pseudo Documents for word “wǎngluò”
tā tíxǐng wǒguó wǎngluò yùnyíng zhě zhùyì fángfàn hēikè fángfàn hēikè gōngjī ， quèbǎo wǎngluò ānquán 。

Table 1: Examples of pseudo documents extracted from a Chinese sentence (written in Chinese Pinyin).

- **Data preprocessing** We preprocess the source side of our bilingual training data as well as development and test set by removing stop words and rare words.
- **Training Data Sense Annotation** From the preprocessed training data, we extract all possible pseudo documents for each source word type. The collection of these extracted pseudo documents is used as a corpus to train a HDP-based WSI model for the source word type. In this way, we can train as many HDP-based WSI models as the number of word types kept after preprocessing. The sense with the highest probability output by the HDP-based WSI model for each pseudo document is used as the sense cluster to label the corresponding word token.
- **Test/Dev Data Sense Annotation** From the preprocessed test data, we can also extract pseudo documents for each source word type that occur in the test/dev set. Using the trained HDP-based WSI model that correspond to the source word type in question, we can obtain the best sense assignment for each pseudo document of the word type, which in turn is used to annotate the corresponding word token in the test/dev data.

3 Sense-Based Translation Model

In this section we present our sense-based translation model and describe the features that we use as well as the training process of this model.

3.1 Model

The sense-based translation model estimates the probability that a source word c is translated into a target phrase $\tilde{e}$ given contextual information, including word senses that are obtained using the HDP-based WSI as described in the last section. We allow the target phrase $\tilde{e}$ to be either a phrase of length up to 3 words or NULL so that we can capture both multi-word and null translations. The essential component of the model is a maximum entropy (MaxEnt) based classifier that is used to predict the translation probability $p(\tilde{e}|\mathcal{C}(c))$. The MaxEnt classifier can be formulated as follows.

$$p(\tilde{e}|\mathcal{C}(c)) = \frac{exp(\sum_i \theta_i h_i(\tilde{e}, \mathcal{C}(c)))}{\sum_{\tilde{e}'} exp(\sum_i \theta_i h_i(\tilde{e}', \mathcal{C}(c)))} \quad (1)$$

where h_is are binary features, θ_is are weights of these features, $\mathcal{C}(c)$ is the surrounding context of c.

We define two groups of binary features: 1) **lexicon features** and 2) **sense features**. All these features take the following form.

$$h(\tilde{e}, \mathcal{C}(c)) = \begin{cases} 1, & \text{if } \tilde{e} = \square \text{ and } \mathcal{C}(c).\mu = \nu \\ 0, & \text{else} \end{cases} \quad (2)$$

where $\square$ is a placeholder for a possible target translation (up to 3 words or NULL), μ is the name of a contextual (lexicon or sense) feature for the source word c, and the symbol ν represents the value of the feature μ.

We extract both the lexicon and sense features from a $\pm k$-word window centered on the word c. The lexicon features are defined as the preceding k words, the succeeding k words and the word c itself: $\{c_{-k}, ..., c_{-1}, c, c_1, ..., c_k\}$. The sense features are defined as the predicted senses for these words: $\{s_{c_{-k}}, ..., s_{c_{-1}}, s_c, s_{c_1}, ..., s_{c_k}\}$.

As we also use these neighboring words to predict word senses in the HDP-based WSI, the information provided by the lexicon and sense features may overlap. This is not a issue for the MaxEnt classifier as it can deal with arbitrary overlapping features (Berger et al., 1996). One may also wonder whether the sense features can contribute to SMT new information that can NOT be obtained from the lexicon features. First, we believe that the senses induced by the HDP-based WSI provide a different view of data than that of the lexicon features. Second, the sense features contain semantic distributional information learned by the HDP across contexts where lexical words occur. Third, we empirically investigate this doubt by comparing two MaxEnt-based translation models

in Section 5. One model only uses the lexicon features while the other integrates both the lexicon and sense features. The former model can be considered as a reformulated WSD for SMT as we described in Section 1.

Given a source sentence $\{c_i\}_1^I$, the proposed sense-based translation model M_s can be denoted as

$$M_s = \prod_{c_i \in \mathcal{W}} (\tilde{e_i}|\mathcal{C}(c_i)) \quad (3)$$

where $\mathcal{W}$ is a set of words for which we build MaxEnt classifiers (see the next subsection for the discussion on how we build MaxEnt classifiers for our sense-based translation model).

3.2 Training

The training of the proposed sense-based translation model is a process of estimating the feature weights θs in the equation (1). There are two strategies that we can use to obtain these weights. We can either build an all-in-one MaxEnt classifier that integrates all source word types c and their possible target translations $\tilde{e}$ or build multiple MaxEnt classifiers. If we train the all-in-one classifier, we have to predict millions of classes (target translations of length up to 3 words). This is normally intractable in practice. Therefore we take the second strategy: building multiple MaxEnt classifiers with one classifier per source word type.

In order to train these classifiers, we have to collect training events from our word-aligned bilingual training data where source words are annotated with their corresponding sense clusters predicted by the HDP-based WSI as described in Section 2. A training event for a source word c consists of all contextual elements in the form of $\mathcal{C}(c).\mu = \nu$ defined in the last subsection and the target translation $\tilde{e}$. Using these collected events, we can train our multiple classifiers. In practice, we do not build MaxEnt classifiers for source words that occur less than 10 times in the training data and run the MaxEnt toolkit in a parallel manner in order to expedite the training process.

4 Decoding with Sense-Based Translation Model

The sense-based translation model described above is integrated into the log-linear translation model of SMT as a sense-based knowledge source. The weight of this model is tuned by the minimum error rate training (MERT) (Och, 2003) together with other models such as the language model.

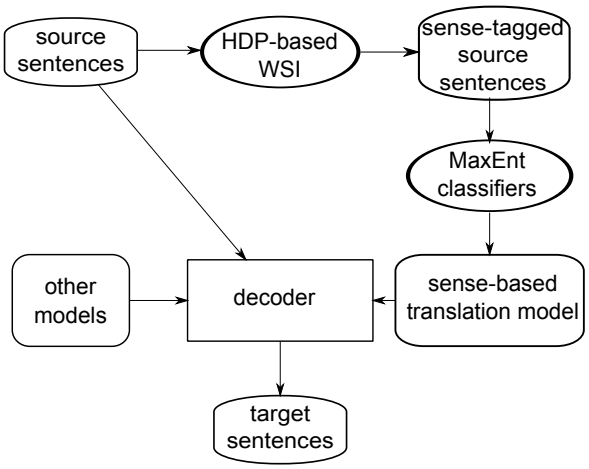

Figure 2: Architecture of SMT system with the sense-based translation model.

Figure 2 shows the architecture of the SMT system enhanced with the sense-based translation model. Before we translate a source sentence, we use the HDP-based WSI models trained on the training data to predict senses for word tokens occurring in the source sentence as discussed in Section 2.2. Note that the HDP-based WSI does not predict senses for all words due to the following two reasons.

- We do not train HDP-based WSI models for word types for which we extract more than T pseudo documents.[2]
- In the test/dev set, there are some words that are unseen in the training data. These unseen words, of course, do not have their HDP-based WSI models.

For these words, we set a default sense (i.e. $s_c = s_1$).

Sense tagging on test sentences can be done in a preprocessing step. Once we get sense clusters for word tokens in test sentences, we load pre-trained MaxEnt classifiers of the corresponding word types. During decoding, we keep word alignments for each translation rule. Whenever a new source word c is translated, we find its translation $\tilde{e}$ via the kept word alignments. We then calculate the translation probability $p(\tilde{e}|\mathcal{C}(c))$ according to the equation (1) using the corresponding loaded classifier. In this way, we can easily calculate the sense-based translation model score.

[2] we set $T = 20,000$.

5 Experiments

In this section, we carried out a series of experiments on Chinese-to-English translation using large-scale bilingual training data. In order to build the proposed sense-based translation model, we annotated the source part of the bilingual training data with word senses induced by the HDP-based WSI. With the trained sense-based translation model, we would like to investigate the following two questions:

- Do word senses automatically induced by the HDP-based WSI improve translation quality?
- Does the sense-based translation model outperform the reformulated WSD for SMT?

5.1 Setup

Our baseline system is a state-of-the-art SMT system which adapts Bracketing Transduction Grammars (Wu, 1997) to phrasal translation and equips itself with a maximum entropy based reordering model (Xiong et al., 2006). We used LDC corpora LDC2004E12, LDC2004T08, LDC2005T10, LDC2003E14, LDC2002E18, LDC2005T06, LDC2003E07, LDC2004T07 as our bilingual training data which consists of 3.84M bilingual sentences, 109.5M English word tokens and 96.9M Chinese word tokens. We ran Giza++ on the training data in two directions and applied the "grow-diag-final" refinement rule (Koehn et al., 2003) to obtain word alignments. From the word-aligned data, we extracted weighted phrase pairs to generate our phrase table. We trained a 5-gram language model on the Xinhua section of the English Gigaword corpus (306 million words) using the SRILM toolkit (Stolcke, 2002) with the modified Kneser-Ney smoothing (Chen and Goodman, 1996).

We trained our HDP-based WSI models via the C++ HDP toolkit[3] (Wang and Blei, 2012). We set the hyperparameters $\gamma = 0.1$ and $\alpha_0 = 1.0$ following Lau et al. (2012).We extracted pseudo documents from a $\pm$10-word window centered on the corresponding word token for each word type following Brody and Lapata (2009). As described in Section 2.2, we preprocessed the source part of our bilingual training data by removing stop words and infrequent words that occurs less than 10 times in the training data. From the preprocessed data, we extracted pseudo documents for each word type to train a HDP-based WSI model per word type. Note that we do not build WSI models for highly frequent words that occur more than 20,000 times in order to expedite the HDP training process.

We trained our MaxEnt classifiers with the off-the-shelf MaxEnt tool.[4] We performed 100 iterations of the L-BFGS algorithm implemented in the training toolkit on the collected training events from the sense-annotated data as described in Section 3.2. We set the Gaussian prior to 1 to avoid overfitting. On average, we obtained 346 classes (target translations) per source word type with the maximum number of classes being 256,243. It took an average of 57.5 seconds for training a Maxent classifier.

We used the NIST MT03 evaluation test data as our development set, and the NIST MT05 as the test set. We evaluated translation quality with the case-insensitive BLEU-4 (Papineni et al., 2002) and NIST (Doddington, 2002). In order to alleviate the impact of MERT (Och, 2003) instability, we followed the suggestion of Clark et al. (2011) to run MERT three times and report average BLEU/NIST scores over the three runs for all our experiments.

	Training	Test
# Word Types	67,723	4,348
# Total Pseudo Documents	27.73M	11,777
# Avg Pseudo Documents	427.79	2.71
# Total Senses	271,770	24,162
# Avg Senses	4.01	5.56

Table 2: Statistics of the HDP-based word sense induction on the training and test data.

5.2 Statistics and Examples of Word Senses

Before we present our experiment results of the sense-based translation model, we study some statistics of the HDP-based WSI on the training and test data. We show these statistics in Table 2. There are 67,723 and 4,348 unique word types in the training and test data after the preprocessing step. For these word types, we extract 27.73M and 11,777 pseudo documents from the training and test set respectively. On average, there are 427.79

System	BLEU(%)	NIST
STM (±5w)	34.64	9.4346
STM (±10w)	**34.76**	**9.5114**
STM (±15w)	-	-

Table 4: Experiment results of the sense-based translation model (STM) with lexicon and sense features extracted from a window of size varying from ±5 to ±15 words on the development set.

pseudo documents per word type in the training data and 2.71 in the test set. The HDP-based WSI learns 271,770 word senses in total using the pseudo documents collected from the training data and infers 24,162 word senses using the pseudo documents extracted from the test set. There are 4.01 different senses per word type in the training data and 5.56 in the test set on average.

Table 3 illustrates six different senses of the word "运营 (operate)" learned by the HDP-based WSI in the training data. We also show the most probable 10 words for each sense cluster. Sense s_1 represents the operations of company or organization, sense s_2 denotes country/institution/internation operations, sense s_3 refers to market operations, sense s_4 corresponds to business operations, sense s_5 to public facility operations, and finally s_6 to economy operations.

5.3 Impact of Window Size k used in MaxEnt Classifiers

Our first group of experiments were conducted to investigate the impact of the window size k on translation performance in terms of BLEU/NIST on the development set. We extracted both the lexicon and sense features from a $\pm k$-word window for our MaxEnt classifiers. We varied k from 5 to 15. Experiment results are shown in Table 4. We achieve the best performance when $k = 10$. This suggests that a ±10-word window context is sufficient for predicting target translations for ambiguous source words. We therefore set $k = 10$ for all experiments thereafter.

5.4 Effect of the Sense-Based Translation Model

Our second group of experiments were carried out to investigate whether the sense-base translation model is able to improve translation quality by comparing the system enhanced with our sense-based translation model against the baseline. We also studied the impact of word senses induced by the HDP-based WSI on translation performance by enforcing the sense-based translation model to use only sense features. Table 5 shows the experiment results. From the table, we can observe that

System	BLEU(%)	NIST
Base	33.53	9.0561
STM (sense)	34.15	9.2596
STM (sense+lexicon)	34.73	9.4184

Table 5: Experiment results of the sense-based translation model (STM) against the baseline.

System	BLEU(%)	NIST
Base	33.53	9.0561
Reformulated WSD	34.16	9.3820
STM	34.73	9.4184

Table 6: Comparison results of the sense-based translation model vs. the reformulated WSD for SMT.

- Our sense-based translation model achieves a substantial improvement of 1.2 BLEU points over the baseline. This indicates that the sense-based translation model is able to help select correct translations for ambiguous source words.
- If we only integrate sense features into the sense-based translation model, we can still outperform the baseline by 0.62 BLEU points. This suggests that automatically induced word senses alone are indeed useful for machine translation.

5.5 Comparison to Word Sense Disambiguation

As we mentioned in Section 3.1, our sense-based translation model can be degenerated to a reformulated WSD model for SMT if we only use lexicon features in MaxEnt classifiers. This allows us to directly compare our method against the reformulated WSD for SMT. Table 6 shows the comparison result.

From the table, we can find that the sense-based translation model outperforms the reformulated WSD by 0.57 BLEU points. This suggests that the HDP-based word sense induction is better than the reformulated WSD in the context of SMT. Furthermore, as the reformulated WSD is a degenerated version of our sense-based translation model which only uses the lexicon features,

s_1	s_2	s_3

the sense features used in our model do provide new information that can not be obtained by the lexicon features.

6 Related Work

In this section we introduce previous studies that are related to our work. For ease of comparison, we roughly divide them into 4 categories: 1) WSD for SMT, 2) topic-based WSI, 3) topic model for SMT and 4) lexical selection.

WSD for SMT As we mentioned in Section 1, WSD has been successfully reformulated and adapted to SMT (Vickrey et al., 2005; Carpuat and Wu, 2007; Chan et al., 2007). Rather than predicting word senses for ambiguous words, the reformulated WSD directly predicts target translations for source words with context information. Our sense-based translation model also predicts target translations for SMT. The significant difference is that we predict word senses automatically learned from data and incorporate these predicted senses into SMT. Our experiments show that such word senses are able to improve translation quality.

Topic-based WSI Topic-based WSI can be considered as the foundation of our work as we use it to obtain broad-coverage word senses to annotate our large-scale training data. Brody and Lapata (2009)'s work is the first attempt to approach WSI via topic modeling. They adapt LDA to word sense induction by building one topic model per word type. According to them, there are 3 significant differences between topic-based WSI and generic topic modeling.

- First, the goal of topic-based WSI is to divide contexts of a word type into different categories, each representing a sense cluster. However generic topic models aim at topic distributions of documents.
- Second, generic topic modeling explores whole documents for topic inference while topic-based WSI uses much smaller units in a document (e.g., surrounding words of a target word) for word sense induction.
- Finally, the number of induced word senses in WSI is usually less than 10 while the number of inferred topics in generic topic modeling is tens or hundreds.

As LDA-based WSI needs to manually specify the number of word senses, Yao and Durme (2011) propose HDP-based WSI that is capable of

determining the number of senses for each word type according to training data. Lau et al. (2012) adopt the HDP-based WSI for novel sense detection and empirically show that the HDP-based WSI is better than the LDA-based WSI. We follow them to set the hyperparameters of HDP for training and incorporate automatically induced word senses into SMT in our work.

Topic model for SMT Generic topic models are also explored for SMT. Zhao and Xing (2007) propose a bilingual topic model and integrate a topic-specific lexicon translation model into SMT. Tam et al. (2007) also explore a bilingual topic model for translation and language model adaptation. Foster and Kunh (2007) introduce a mixture model approach for translation model adaptation. Xiao et al. (2012) propose a topic-based similarity model for rule selection in hierarchical phrase-based translation. Xiong and Zhang (2013) employ a sentence-level topic model to capture coherence for document-level machine translation. The difference between our work and these previous studies on topic model for SMT lies in that we adopt topic-based WSI to obtain word senses rather than generic topics and integrate induced word senses into machine translation.

Lexical selection Our work is also related to lexical selection in SMT where appropriate target lexical items for source words are selected by a statistical model with context information (Bangalore et al., 2007; Mauser et al., 2009). The reformulated WSD discussed before can also be considered as a lexical selection model. The significant difference from these studies is that we perform lexical selection using automatically induced word senses by the HDP on the source side.

7 Conclusion

We have presented a sense-based translation model that integrates word senses into machine translation. We capitalize on the broad-coverage word sense induction system that is built on the nonparametric Bayesian HDP to learn sense clusters for words in the source language. We generate pseudo documents for word tokens in the training/test data for the HDP-based WSI system to infer topics. The most probable topic inferred for a pseudo document is taken as the sense of the corresponding word token. We incorporate these learned word senses as translation evidences into maximum entropy classifiers which form the foundation of the proposed sense-based translation model.

We carried out a series of experiments to validate the effectiveness of the sense-based translation by comparing the model against the baseline and the previous reformulated WSD. Our experiment results show that

- The sense-based translation model is able to substantially improve translation quality in terms of both BLEU and NIST.
- The sense-based translation model is also better than the previous reformulated WSD for SMT.
- Word senses automatically induced by the HDP-based WSI on large-scale training data are very useful for machine translation. To the best of our knowledge, this is the first attempt to empirically verify the positive impact of word senses on translation quality.

Comparing with macro topics of documents inferred by LDA with bag of words from the whole documents, word senses inferred by the HDP-based WSI can be considered as micro topics. In the future, we would like to explore both the micro and macro topics for machine translation. Additionally, we also want to induce sense clusters for words in the target language so that we can build sense-based language model and integrate it into SMT. We would like to investigate whether automatically learned senses of proceeding words are helpful for predicting succeeding words.

Abstract

This study proposes a word alignment model based on a recurrent neural network (RNN), in which an unlimited alignment history is represented by recurrently connected hidden layers. We perform unsupervised learning using noise-contrastive estimation (Gutmann and Hyvärinen, 2010; Mnih and Teh, 2012), which utilizes artificially generated negative samples. Our alignment model is directional, similar to the generative IBM models (Brown et al., 1993). To overcome this limitation, we encourage agreement between the two directional models by introducing a penalty function that ensures word embedding consistency across two directional models during training. The RNN-based model outperforms the feed-forward neural network-based model (Yang et al., 2013) as well as the IBM Model 4 under Japanese-English and French-English word alignment tasks, and achieves comparable translation performance to those baselines for Japanese-English and Chinese-English translation tasks.

1 Introduction

Automatic word alignment is an important task for statistical machine translation. The most classical approaches are the probabilistic IBM models 1-5 (Brown et al., 1993) and the HMM model (Vogel et al., 1996). Various studies have extended those models. Yang et al. (2013) adapted the Context-Dependent Deep Neural Network for HMM (CD-DNN-HMM) (Dahl et al., 2012), a type of feed-forward neural network (FFNN)-based model, to the HMM alignment model and achieved state-of-the-art performance. However, the FFNN-based model assumes a first-order Markov dependence for alignments.

Recurrent neural network (RNN)-based models have recently demonstrated state-of-the-art performance that outperformed FFNN-based models for various tasks (Mikolov et al., 2010; Mikolov and Zweig, 2012; Auli et al., 2013; Kalchbrenner and Blunsom, 2013; Sundermeyer et al., 2013). An RNN has a hidden layer with recurrent connections that propagates its own previous signals. Through the recurrent architecture, RNN-based models have the inherent property of modeling long-span dependencies, e.g., long contexts, in input data. We assume that this property would fit with a word alignment task, and we propose an RNN-based word alignment model. Our model can maintain and arbitrarily integrate an alignment history, e.g., bilingual context, which is longer than the FFNN-based model.

The NN-based alignment models are supervised models. Unfortunately, it is usually difficult to prepare word-by-word aligned bilingual data. Yang et al. (2013) trained their model from word alignments produced by traditional unsupervised probabilistic models. However, with this approach, errors induced by probabilistic models are learned as correct alignments; thus, generalization capabilities are limited. To solve this problem, we apply noise-contrastive estimation (NCE) (Gutmann and Hyvärinen, 2010; Mnih and Teh, 2012) for unsupervised training of our RNN-based model without gold standard alignments or pseudo-oracle alignments. NCE artificially generates bilingual sentences through samplings as pseudo-negative samples, and then trains the model such that the scores of the original bilingual sentences are higher than those of the sampled bilingual sentences.

Our RNN-based alignment model has a direc-

Baltimore, Maryland, USA, June 23-25 2014.

tion, such as other alignment models, i.e., from f (source language) to e (target language) and from e to f. It has been proven that the limitation may be overcome by encouraging two directional models to agree by training them concurrently (Matusov et al., 2004; Liang et al., 2006; Graça et al., 2008; Ganchev et al., 2008). The motivation for this stems from the fact that model and generalization errors by the two models differ, and the models must complement each other. Based on this motivation, our directional models are also simultaneously trained. Specifically, our training encourages word embeddings to be consistent across alignment directions by introducing a penalty term that expresses the difference between embedding of words into an objective function. This constraint prevents each model from overfitting to a particular direction and leads to global optimization across alignment directions.

This paper presents evaluations of Japanese-English and French-English word alignment tasks and Japanese-to-English and Chinese-to-English translation tasks. The results illustrate that our RNN-based model outperforms the FFNN-based model (up to +0.0792 F1-measure) and the IBM Model 4 (up to +0.0703 F1-measure) for the word alignment tasks. For the translation tasks, our model achieves up to 0.74% gain in BLEU as compared to the FFNN-based model, which matches the translation qualities of the IBM Model 4.

2 Related Work

Various word alignment models have been proposed. These models are roughly clustered into two groups: generative models, such as those proposed by Brown et al. (1993), Vogel et al. (1996), and Och and Ney (2003), and discriminative models, such as those proposed by Taskar et al. (2005), Moore (2005), and Blunsom and Cohn (2006).

2.1 Generative Alignment Model

Given a source language sentence $f_1^J = f_1, ..., f_J$ and a target language sentence $e_1^I = e_1, ..., e_I$, f_1^J is generated by e_1^I via the alignment $a_1^J = a_1, ..., a_J$. Each a_j is a hidden variable indicating that the source word f_j is aligned to the target word e_{a_j}. Usually, a "null" word e_0 is added to the target language sentence and a_1^J may contain $a_j = 0$, which indicates that f_j is not aligned to any target word. The probability of generating the sentence f_1^J from e_1^I is defined as

$$p(f_1^J|e_1^I) = \sum_{a_1^J} p(f_1^J, a_1^J|e_1^I). \quad (1)$$

The IBM Models 1 and 2 and the HMM model decompose it into an alignment probability p_a and a lexical translation probability p_t as

$$p(f_1^J, a_1^J|e_1^I) = \prod_{j=1}^{J} p_a(a_j|a_{j-1}, j)p_t(f_j|e_{a_j}). \quad (2)$$

The three models differ in their definition of alignment probability. For example, the HMM model uses an alignment probability with a first-order Markov property: $p_a(a_j|a_j - a_{j-1})$. In addition, the IBM models 3-5 are extensions of these, which consider the fertility and distortion of each translated word.

These models are trained using the expectation-maximization algorithm (Dempster et al., 1977) from bilingual sentences without word-level alignments (unlabeled training data). Given a specific model, the best alignment (Viterbi alignment) of the sentence pair (f_1^J, e_1^I) can be found as

$$\hat{a}_1^J = \underset{a_1^J}{\operatorname{argmax}}\, p(f_1^J, a_1^J|e_1^I). \quad (3)$$

For example, the HMM model identifies the Viterbi alignment using the Viterbi algorithm.

2.2 FFNN-based Alignment Model

As an instance of discriminative models, we describe an FFNN-based word alignment model (Yang et al., 2013), which is our baseline. An FFNN learns a hierarchy of nonlinear features that can automatically capture complex statistical patterns in input data. Recently, FFNNs have been applied successfully to several tasks, such as speech recognition (Dahl et al., 2012), statistical machine translation (Le et al., 2012; Vaswani et al., 2013), and other popular natural language processing tasks (Collobert and Weston, 2008; Collobert et al., 2011).

Yang et al. (2013) have adapted a type of FFNN, i.e., CD-DNN-HMM (Dahl et al., 2012), to the HMM alignment model. Specifically, the lexical translation and alignment probability in Eq. 2 are computed using FFNNs as

$$s_{NN}(a_1^J|f_1^J, e_1^I) = \prod_{j=1}^{J} t_a(a_j - a_{j-1}|c(e_{a_{j-1}})) \cdot t_{lex}(f_j, e_{a_j}|c(f_j), c(e_{a_j})), \quad (4)$$

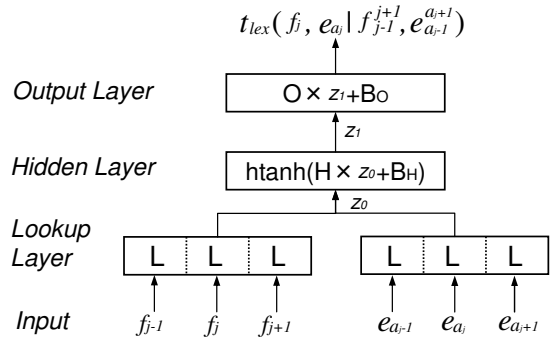

Figure 1: FFNN-based model for computing a lexical translation score of (f_j, e_{a_j})

where t_a and t_{lex} are an alignment score and a lexical translation score, respectively, s_{NN} is a score of alignments a_1^J, and "c(a word w)" denotes a context of word w. Note that the model uses nonprobabilistic scores rather than probabilities because normalization over all words is computationally expensive. The model finds the Viterbi alignment using the Viterbi algorithm, similar to the classic HMM model. Note that alignments in the FFNN-based model are also governed by first-order Markov dynamics because an alignment score depends on the previous alignment a_{j-1}.

Figure 1 shows the network structure with one hidden layer for computing a lexical translation probability $t_{lex}(f_j, e_{a_j}|c(f_j), c(e_{a_j}))$. The model consists of a lookup layer, a hidden layer, and an output layer, which have weight matrices. The model receives a source and target word with their contexts as inputs, which are words in a predefined window (the window size is three in Figure 1). First, the lookup layer converts each input word into its word embedding by looking up its corresponding column in the embedding matrix (L), and then concatenates them. Let V_f (or V_e) be a set of source words (or target words) and M be a predetermined embedding length. L is a $M \times (|V_f| + |V_e|)$ matrix[1]. Word embeddings are dense, low dimensional, and real-valued vectors that can capture syntactic and semantic properties of the words (Bengio et al., 2003). The concatenation (z_0) is then fed to the hidden layer to capture nonlinear relations. Finally, the output layer receives the output of the hidden layer (z_1) and computes a lexical translation score.

[1]We add a special token $\langle unk \rangle$ to handle unknown words and $\langle null \rangle$ to handle null alignments to V_f and V_e

The computations in the hidden and output layer are as follows[2]:

$$z_1 = f(H \times z_0 + B_H), \quad (5)$$

$$t_{lex} = O \times z_1 + B_O, \quad (6)$$

where H, B_H, O, and B_O are $|z_1| \times |z_0|$, $|z_1| \times 1$, $1 \times |z_1|$, and 1×1 matrices, respectively, and $f(x)$ is an activation function. Following Yang et al. (2013), a "hard" version of the hyperbolic tangent, htanh(x)[3], is used as $f(x)$ in this study.

The alignment model based on an FFNN is formed in the same manner as the lexical translation model. Each model is optimized by minimizing the following ranking loss with a margin using stochastic gradient descent (SGD)[4], where gradients are computed by the back-propagation algorithm (Rumelhart et al., 1986):

$$loss(\theta) = \sum_{(\boldsymbol{f},\boldsymbol{e}) \in T} \max\{0, 1 - s_\theta(\boldsymbol{a}^+|\boldsymbol{f}, \boldsymbol{e}) + s_\theta(\boldsymbol{a}^-|\boldsymbol{f}, \boldsymbol{e})\}, \quad (7)$$

where θ denotes the weights of layers in the model, T is a set of training data, $\boldsymbol{a}^+$ is the gold standard alignment, $\boldsymbol{a}^-$ is the incorrect alignment with the highest score under θ, and s_θ denotes the score defined by Eq. 4 as computed by the model under θ.

3 RNN-based Alignment Model

This section proposes an RNN-based alignment model, which computes a score for alignments a_1^J using an RNN:

$$s_{NN}(a_1^J|f_1^J, e_1^I) = \prod_{j=1}^{J} t_{RNN}(a_j|a_1^{j-1}, f_j, e_{a_j}), \quad (8)$$

where t_{RNN} is the score of an alignment a_j. The prediction of the j-th alignment a_j depends on all preceding alignments a_1^{j-1}. Note that the proposed model also uses nonprobabilistic scores, similar to the FFNN-based model.

The RNN-based model is illustrated in Figure 2. The model consists of a lookup layer, a hidden layer, and an output layer, which have weight

[2]Consecutive l hidden layers can be used: $z_l = f(H_l \times z_{l-1} + B_{H_l})$. For simplicity, this paper describes the model with 1 hidden layer.

[3]htanh$(x) = -1$ for $x < -1$, htanh$(x) = 1$ for $x > 1$, and htanh$(x) = x$ for others.

[4]In our experiments, we used a mini-batch SGD instead of a plain SGD.

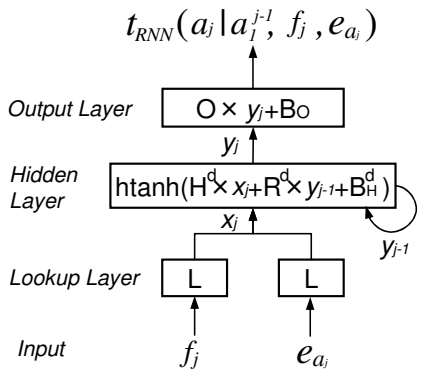

Figure 2: RNN-based alignment model

matrices L, $\{H^d, R^d, B^d_H\}$, and $\{O, B_O\}$, respectively. Each matrix in the hidden layer (H^d, R^d, and B^d_H) depends on alignment, where d denotes the jump distance from a_{j-1} to a_j: $d = a_j - a_{j-1}$. In our experiments, we merge distances that are greater than 8 and less than -8 into the special "$\geq$8" and "$\leq$-8" distances, respectively. Specifically, the hidden layer has weight matrices $\{H^{\leq -8}, H^{-7}, \cdots, H^{7}, H^{\geq 8}, R^{\leq -8}, R^{-7}, \cdots, R^{7}, R^{\geq 8}, B^{\leq -8}_H, B^{-7}_H, \cdots, B^{7}_H, B^{\geq 8}_H\}$ and computes y_j using the corresponding matrices of the jump distance d.

The Viterbi alignment is determined using the Viterbi algorithm, similar to the FFNN-based model, where the model is sequentially applied from f_1 to f_J[5]. When computing the score of the alignment between f_j and e_{a_j}, the two words are input to the lookup layer. In the lookup layer, each of these words is converted to its word embedding, and then the concatenation of the two embeddings (x_j) is fed to the hidden layer in the same manner as the FFNN-based model. Next, the hidden layer receives the output of the lookup layer (x_j) and that of the previous hidden layer (y_{j-1}). The hidden layer then computes and outputs the nonlinear relations between them. Note that the weight matrices used in this computation are embodied by the specific jump distance d. The output of the hidden layer (y_j) is copied and fed to the output layer and the next hidden layer. Finally, the output layer computes the score of a_j ($t_{RNN}(a_j|a_1^{j-1}, f_j, e_{a_j})$) from the output of the hidden layer (y_j). Note that the FFNN-based model consists of two components: one is for lexical translation and the other is for alignment. The proposed RNN produces a single score that is constructed in the hidden layer by employing the distance-dependent weight matrices.

Specifically, the computations in the hidden and output layer are as follows:

$$y_j = f(H^d \times x_j + R^d \times y_{j-1} + B^d_H), \quad (9)$$

$$t_{RNN} = O \times y_j + B_O, \quad (10)$$

where H^d, R^d, B^d_H, O, and B_O are $|y_j| \times |x_j|$, $|y_j| \times |y_{j-1}|$, $|y_j| \times 1$, $1 \times |y_j|$, and 1×1 matrices, respectively. Note that $|y_{j-1}| = |y_j|$. $f(x)$ is an activation function, which is a hard hyperbolic tangent, i.e., htanh(x), in this study.

As described above, the RNN-based model has a hidden layer with recurrent connections. Under the recurrence, the proposed model compactly encodes the entire history of previous alignments in the hidden layer configuration y_i. Therefore, the proposed model can find alignments by taking advantage of the long alignment history, while the FFNN-based model considers only the last alignment.

4 Training

During training, we optimize the weight matrices of each layer (i.e., L, H^d, R^d, B^d_H, O, and B_O) following a given objective using a mini-batch SGD with batch size D, which converges faster than a plain SGD (D = 1). Gradients are computed by the back-propagation through time algorithm (Rumelhart et al., 1986), which unfolds the network in time (j) and computes gradients over time steps. In addition, an $l2$ regularization term is added to the objective to prevent the model from overfitting the training data.

The RNN-based model can be trained by a supervised approach, similar to the FFNN-based model, where training proceeds based on the ranking loss defined by Eq. 7 (Section 2.2). However, this approach requires gold standard alignments. To overcome this drawback, we propose an unsupervised method using NCE, which learns from unlabeled training data.

4.1 Unsupervised Learning

Dyer et al. (2011) presented an unsupervised alignment model based on contrastive estimation (CE) (Smith and Eisner, 2005). CE seeks to discriminate observed data from its neighborhood,

[5]Strictly speaking, we cannot apply the dynamic programming forward-backward algorithm (i.e., the Viterbi algorithm) due to the long alignment history of y_i. Thus, the Viterbi alignment is computed approximately using heuristic beam search.

which can be viewed as pseudo-negative samples. Dyer et al. (2011) regarded all possible alignments of the bilingual sentences, which are given as training data (T), and those of the full translation search space (Ω) as the observed data and its neighborhood, respectively.

We introduce this idea to a ranking loss with margin as

$$loss(\theta) = \max\Bigg\{0, 1 - \sum_{(\boldsymbol{f}^+, \boldsymbol{e}^+) \in T} \mathrm{E}_{\Phi}[s_\theta(\boldsymbol{a}|\boldsymbol{f}^+, \boldsymbol{e}^+)] + \sum_{(\boldsymbol{f}^+, \boldsymbol{e}^-) \in \Omega} \mathrm{E}_{\Phi}[s_\theta(\boldsymbol{a}|\boldsymbol{f}^+, \boldsymbol{e}^-)]\Bigg\}, \quad (11)$$

where Φ is a set of all possible alignments given $(\boldsymbol{f}, \boldsymbol{e})$, $\mathrm{E}_{\Phi}[s_\theta]$ is the expected value of the scores s_θ on Φ, $\boldsymbol{e}^+$ denotes a target language sentence in the training data, and $\boldsymbol{e}^-$ denotes a pseudo-target language sentence. The first expectation term is for the observed data, and the second is for the neighborhood.

However, the computation for Ω is prohibitively expensive. To reduce computation, we employ NCE, which uses randomly sampled sentences from all target language sentences in Ω as $\boldsymbol{e}^-$, and calculate the expected values by a beam search with beam width W to truncate alignments with low scores. In our experiments, we set W to 100. In addition, the above criterion is converted to an online fashion as

$$loss(\theta) = \sum_{\boldsymbol{f}^+ \in T} \max\Bigg\{0, 1 - \mathrm{E}_{\mathrm{GEN}}[s_\theta(\boldsymbol{a}|\boldsymbol{f}^+, \boldsymbol{e}^+)] + \frac{1}{N} \sum_{\boldsymbol{e}^-} \mathrm{E}_{\mathrm{GEN}}[s_\theta(\boldsymbol{a}|\boldsymbol{f}^+, \boldsymbol{e}^-)]\Bigg\}, \quad (12)$$

where $\boldsymbol{e}^+$ is a target language sentence aligned to $\boldsymbol{f}^+$ in the training data, i.e., $(\boldsymbol{f}^+, \boldsymbol{e}^+) \in T$, $\boldsymbol{e}^-$ is a randomly sampled pseudo-target language sentence with length $|\boldsymbol{e}^+|$, and N denotes the number of pseudo-target language sentences per source sentence $\boldsymbol{f}^+$. Note that $|\boldsymbol{e}^+| = |\boldsymbol{e}^-|$. GEN is a subset of all possible word alignments Φ, which is generated by beam search.

In a simple implementation, each $\boldsymbol{e}^-$ is generated by repeating a random sampling from a set of target words (V_e) $|\boldsymbol{e}^+|$ times and lining them up sequentially. To employ more discriminative negative samples, our implementation samples each word of $\boldsymbol{e}^-$ from a set of the target words that co-occur with $f_i \in \boldsymbol{f}^+$ whose probability is above a threshold C under the IBM Model 1 incorporating l_0 prior (Vaswani et al., 2012). The IBM Model 1 with l_0 prior is convenient for reducing translation candidates because it generates more sparse alignments than the standard IBM Model 1.

4.2 Agreement Constraints

Both of the FFNN-based and RNN-based models are based on the HMM alignment model, and they are therefore asymmetric, i.e., they can represent one-to-many relations from the target side. Asymmetric models are usually trained in each alignment direction. The model proposed by Yang et al. (2013) is no exception. However, it has been demonstrated that encouraging directional models to agree improves alignment performance (Matusov et al., 2004; Liang et al., 2006; Graça et al., 2008; Ganchev et al., 2008).

Inspired by their work, we introduce an agreement constraint to our learning. The constraint concretely enforces agreement in word embeddings of both directions. The proposed method trains two directional models concurrently based on the following objective by incorporating a penalty term that expresses the difference between word embeddings:

$$\operatorname*{argmin}_{\theta_{FE}} \big\{loss(\theta_{FE}) + \alpha\|\theta_{L_{EF}} - \theta_{L_{FE}}\|\big\}, \quad (13)$$

$$\operatorname*{argmin}_{\theta_{EF}} \big\{loss(\theta_{EF}) + \alpha\|\theta_{L_{FE}} - \theta_{L_{EF}}\|\big\}, \quad (14)$$

where θ_{FE} (or θ_{EF}) denotes the weights of layers in a source-to-target (or target-to-source) alignment model, θ_L denotes weights of a lookup layer, i.e., word embeddings, and α is a parameter that controls the strength of the agreement constraint. $\|\theta\|$ indicates the norm of θ. 2-norm is used in our experiments. Equations 13 and 14 can be applied to both supervised and unsupervised approaches. Equations 7 and 12 are substituted into $loss(\theta)$ in supervised and unsupervised learning, respectively. The proposed constraint penalizes overfitting to a particular direction and enables two directional models to optimize across alignment directions globally.

Our unsupervised learning procedure is summarized in Algorithm 1. In Algorithm 1, line 2 randomly samples D bilingual sentences $(\mathbf{f}^+, \mathbf{e}^+)^D$ from training data T. Lines 3-1 and 3-2 generate N pseudo-negative samples for each $\mathbf{f}^+$ and $\mathbf{e}^+$ based on the translation candidates of $\mathbf{f}^+$ and $\mathbf{e}^+$ found by the IBM Model 1 with l_0 prior,

$IBM1$ (Section 4.1). Lines 4-1 and 4-2 update the weights in each layer following a given objective (Sections 4.1 and 4.2). Note that θ^t_{FE} and θ^t_{EF} are concurrently updated in each iteration, and θ^t_{EF} (or θ^t_{FE}) is employed to enforce agreement between word embeddings when updating θ^t_{FE} (or θ^t_{EF}).

5 Experiment

5.1 Experimental Data

We evaluated the alignment performance of the proposed models with two tasks: Japanese-English word alignment with the Basic Travel Expression Corpus ($BTEC$) (Takezawa et al., 2002) and French-English word alignment with the Hansard dataset ($Hansards$) from the 2003 NAACL shared task (Mihalcea and Pedersen, 2003). In addition, we evaluated the end-to-end translation performance of three tasks: a Chinese-to-English translation task with the FBIS corpus ($FBIS$), the IWSLT 2007 Japanese-to-English translation task ($IWSLT$) (Fordyce, 2007), and the NTCIR-9 Japanese-to-English patent translation task ($NTCIR$) (Goto et al., 2011)[6].

Table 1 shows the sizes of our experimental datasets. Note that the development data was not used in the alignment tasks, i.e., $BTEC$ and $Hansards$, because the hyperparameters of the alignment models were set by preliminary small-scale experiments. The $BTEC$ data is the first 9,960 sentence pairs in the training data for $IWSLT$, which were annotated with word alignment (Goh et al., 2010). We split these pairs into the first 9,000 for training data and the remaining 960 as test data. All the data in $BTEC$ is word-aligned, and the training data in $Hansards$ is unlabeled data. In $FBIS$, we used the NIST02 evaluation data as the development data, and the NIST03 and 04 evaluation data as test data ($NIST03$ and $NIST04$).

[6]We did not evaluate the translation performance on the Hansards data because the development data is very small and performance is unreliable.

5.2 Comparing Methods

We evaluated the proposed RNN-based alignment models against two baselines: the IBM Model 4 and the FFNN-based model with one hidden layer. The IBM Model 4 was trained by previously presented model sequence schemes (Och and Ney, 2003): $1^5H^53^54^5$, i.e., five iterations of the IBM Model 1 followed by five iterations of the HMM Model, etc., which is the default setting for GIZA++ ($IBM4$). For the FFNN-based model, we set the word embedding length M to 30, the number of units of a hidden layer $|z_1|$ to 100, and the window size of contexts to 5. Hence, $|z_0|$ is 300 ($30 \times 5 \times 2$). Following Yang et al. (2013), the FFNN-based model was trained by the supervised approach described in Section 2.2 ($FFNN_s$).

For the RNN-based models, we set M to 30 and the number of units of each recurrent hidden layer $|y_j|$ to 100. Thus, $|x_j|$ is 60 (30×2). The number of units of each layer of the FFNN-based and RNN-based models and M were set through preliminary experiments. To demonstrate the effectiveness of the proposed learning methods, we evaluated four types of RNN-based models: RNN_s, RNN_{s+c}, RNN_u, and RNN_{u+c}, where "*s*/*u*" denotes a supervised/unsupervised model and "$+c$" indicates that the agreement constraint was used.

In training all the models except $IBM4$, the weights of each layer were initialized first. For the weights of a lookup layer L, we preliminarily trained word embeddings for the source and target language from each side of the training data. We then set the word embeddings to L to avoid falling into local minima. Other weights were randomly initialized to $[-0.1, 0.1]$. For the pretraining, we

Table 2: Word alignment performance (F1-measure)

used the RNNLM Toolkit [7] (Mikolov et al., 2010) with the default options. We mapped all words that occurred less than five times to the special token $\langle unk \rangle$. Next, each weight was optimized using the mini-batch SGD, where batch size D was 100, learning rate was 0.01, and an l_2 regularization parameter was 0.1. The training stopped after 50 epochs. The other parameters were set as follows: W, N and C in the unsupervised learning were 100, 50, and 0.001, respectively, and α for the agreement constraint was 0.1.

In the translation tasks, we used the Moses phrase-based SMT systems (Koehn et al., 2007). All Japanese and Chinese sentences were segmented by ChaSen[8] and the Stanford Chinese segmenter[9], respectively. In the training, long sentences with over 40 words were filtered out. Using the SRILM Toolkits (Stolcke, 2002) with modified Kneser-Ney smoothing, we trained a 5-gram language model on the English side of each training data for $IWSLT$ and $NTCIR$, and a 5-gram language model on the Xinhua portion of the English Gigaword corpus for $FBIS$. The SMT weighting parameters were tuned by MERT (Och, 2003) in the development data.

5.3 Word Alignment Results

Table 2 shows the alignment performance by the F1-measure. Hereafter, $MODEL(R)$ and $MODEL(I)$ denote the $MODEL$ trained from gold standard alignments and word alignments found by the IBM Model 4, respectively. In $Hansards$, all models were trained from randomly sampled 100 K data[10]. We evaluated the word alignments produced by first applying each model in both directions and then combining the alignments using the "grow-diag-final-and" heuristic (Koehn et al., 2003). The significance test on word alignment performance was performed by the sign test with a 5% significance level. "+" in Table 2 indicates that the comparisons are significant over corresponding baselines, $IBM4$ and $FFNN_s(R/I)$.

In Table 2, RNN_{u+c}, which includes all our proposals, i.e., the RNN-based model, the unsupervised learning, and the agreement constraint, achieves the best performance for both $BTEC$ and $Hansards$. The differences from the baselines are statistically significant.

Table 2 shows that $RNN_s(R/I)$ outperforms $FFNN_s(R/I)$, which is statistically significant in $BTEC$. These results demonstrate that capturing the long alignment history in the RNN-based model improves the alignment performance. We discuss the difference of the RNN-based model's effectiveness between language pairs in Section 6.1. Table 2 also shows that $RNN_{s+c}(R/I)$ and RNN_{u+c} achieve significantly better performance than $RNN_s(R/I)$ and RNN_u in both tasks, respectively. This indicates that the proposed agreement constraint is effective in training better models in both the supervised and unsupervised approaches.

In $BTEC$, RNN_u and RNN_{u+c} significantly outperform $RNN_s(I)$ and $RNN_{s+c}(I)$, respectively. The performance of these models is comparable with $Hansards$. This indicates that our unsupervised learning benefits our models because the supervised models are adversely affected by errors in the automatically generated training data. This is especially true when the quality of training data, i.e., the performance of $IBM4$, is low.

5.4 Machine Translation Results

Table 3 shows the translation performance by the case sensitive BLEU4 metric[11] (Papineni et al., 2002). Table 3 presents the average BLEU of three different MERT runs. In $NTCIR$ and $FBIS$, each alignment model was trained from the ran-

[8] http://chasen-legacy.sourceforge.jp/

[9] http://nlp.stanford.edu/software/segmenter.shtml

[10] Due to high computational cost, we did not use all the training data. Scaling up to larger datasets will be addressed in future work.

[11] We used mteval-v13a.pl as the evaluation tool (http://www.itl.nist.gov/iad/mig/tests/mt/2009/).

Alignment	$IWSLT$	$NTCIR$	$FBIS$	
			$NIST03$	$NIST04$
$IBM4_{all}$	46.47	27.91	25.90	28.34
$IBM4$		27.25	25.41	27.65
$FFNN_s$(I)	46.38	27.05	25.45	27.61
RNN_s(I)	46.43	27.24	25.47	27.56
RNN_{s+c}(I)	46.51	27.12	25.55	27.73
RNN_u	47.05*	27.79*	25.76*	27.91*
RNN_{u+c}	46.97*	27.76*	25.84*	28.20*

Table 3: Translation performance (BLEU4(%))

domly sampled 100 K data, and then a translation model was trained from all the training data that was word-aligned by the alignment model. In addition, for a detailed comparison, we evaluated the SMT system where the IBM Model 4 was trained from all the training data ($IBM4_{all}$). The significance test on translation performance was performed by the bootstrap method (Koehn, 2004) with a 5% significance level. "*" in Table 3 indicates that the comparisons are significant over both baselines, i.e., $IBM4$ and $FFNN_s(I)$.

Table 3 also shows that better word alignment does not always result in better translation, which has been discussed previously (Yang et al., 2013). However, RNN_u and RNN_{u+c} outperform $FFNN_s(I)$ and $IBM4$ in all tasks. These results indicate that our proposals contribute to improving translation performance[12]. In addition, Table 3 shows that these proposed models are comparable to $IBM4_{all}$ in $NTCIR$ and $FBIS$ even though the proposed models are trained from only a small part of the training data.

6 Discussion

6.1 Effectiveness of RNN-based Alignment Model

Figure 3 shows word alignment examples from $FFNN_s$ and RNN_s, where solid squares indicate the gold standard alignments. Figure 3 (a) shows that RRN_s adequately identifies complicated alignments with long distances compared to $FFNN_s$ (e.g., jaggy alignments of "have you been learning" in Fig 3 (a)) because RNN_s captures alignment paths based on long alignment history, which can be viewed as phrase-level alignments, while $FFNN_s$ employs only the last alignment.

In French-English word alignment, the most

[12]We also confirmed the effectiveness of our models on the NIST05 and NTCIR-10 evaluation data.

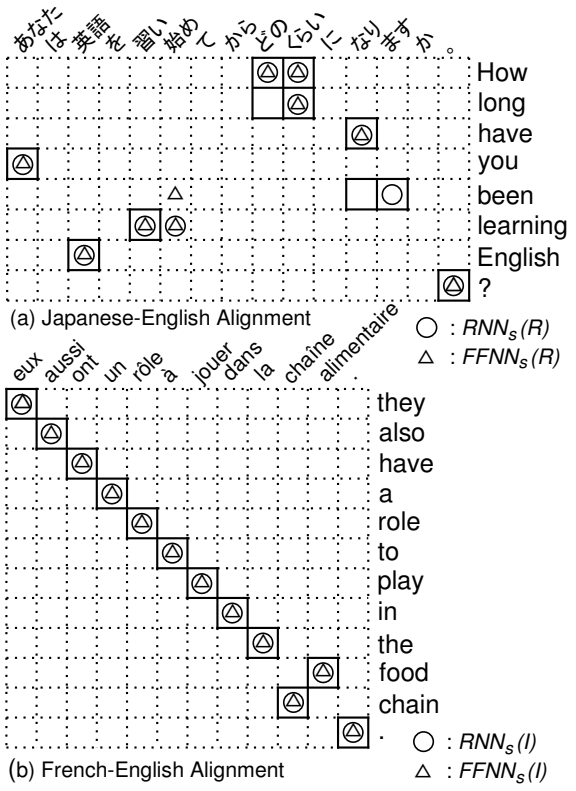

Figure 3: Word alignment examples

Alignment	40 K	9 K	1 K
$IBM4$	0.5467	0.4859	0.4128
RNN_{u+c}	0.6004	0.5562	0.4842
$RNN_{s+c}(R)$	-	0.8921	0.6063

Table 4: Word alignment performance on $BTEC$ with various sized training data

valuable clues are located locally because English and French have similar word orders and their alignment has more one-to-one mappings than Japanese-English word alignment (Figure 3). Figure 3 (b) shows that both RRN_s and $FFNN_s$ work for such simpler alignments. Therefore, the RNN-based model has less effect on French-English word alignment than Japanese-English word alignment, as indicated in Table 2.

6.2 Impact of Training Data Size

Table 4 shows the alignment performance on $BTEC$ with various training data sizes, i.e., training data for $IWSLT$ (40 K), training data for $BTEC$ (9 K), and the randomly sampled 1 K data from the $BTEC$ training data. Note that $RNN_{s+c}(R)$ cannot be trained from the 40 K data because the 40 K data does not have gold standard

Alignment	$BTEC$	$Hansards$
$FFNN_s$(I)	0.4770	0.9020
$FFNN_{s+c}$(I)	0.4854^+	0.9085^+
$FFNN_u$	0.5105^+	0.9026
$FFNN_{u+c}$	0.5313^+	0.9144^+
$FFNN_s$(R)	0.8224	-
$FFNN_{s+c}$(R)	0.8367^+	-

Table 5: Word alignment performance of various FFNN-based models (F1-measure)

word alignments.

Table 4 demonstrates that the proposed RNN-based model outperforms $IBM4$ trained from the unlabeled 40 K data by employing either the 1 K labeled data or the 9 K unlabeled data, which is less than 25% of the training data for $IBM4$. Consequently, the SMT system using RNN_{u+c} trained from a small part of training data can achieve comparable performance to that using $IBM4$ trained from all training data, which is shown in Table 3.

6.3 Effectiveness of Unsupervised Learning/Agreement Constraints

The proposed unsupervised learning and agreement constraints can be applied to any NN-based alignment model. Table 5 shows the alignment performance of the FFNN-based models trained by our supervised/unsupervised approaches (s/u) with and without our agreement constraints. In Table 5, "+c" denotes that the agreement constraint was used, and "+" indicates that the comparison with its corresponding baseline, i.e., $FFNN_s$(I/R), is significant in the sign test with a 5% significance level.

Table 5 shows that $FFNN_{s+c}$(R/I) and $FFNN_{u+c}$ achieve significantly better performance than $FFNN_s$(R/I) and $FFNN_u$, respectively, in both $BTEC$ and $Hansards$. In addition, $FFNN_u$ and $FFNN_{u+c}$ significantly outperform $FFNN_s$(I) and $FFNN_{s+c}$(I), respectively, in $BTEC$. The performance of these models is comparable in $Hansards$. These results indicate that the proposed unsupervised learning and agreement constraint benefit the FFNN-based model, similar to the RNN-based model.

7 Conclusion

We have proposed a word alignment model based on an RNN, which captures long alignment history through recurrent architectures. Furthermore, we proposed an unsupervised method for training our model using NCE and introduced an agreement constraint that encourages word embeddings to be consistent across alignment directions. Our experiments have shown that the proposed model outperforms the FFNN-based model (Yang et al., 2013) for word alignment and machine translation, and that the agreement constraint improves alignment performance.

In future, we plan to employ contexts composed of surrounding words (e.g., $c(f_j)$ or $c(e_{a_j})$ in the FFNN-based model) in our model, even though our model implicitly encodes such contexts in the alignment history. We also plan to enrich each hidden layer in our model with multiple layers following the success of Yang et al. (2013), in which multiple hidden layers improved the performance of the FFNN-based model. In addition, we would like to prove the effectiveness of the proposed method for other datasets.

Abstract

Bidirectional models of word alignment are an appealing alternative to post-hoc combinations of directional word aligners. Unfortunately, most bidirectional formulations are NP-Hard to solve, and a previous attempt to use a relaxation-based decoder yielded few exact solutions (6%). We present a novel relaxation for decoding the bidirectional model of DeNero and Macherey (2011). The relaxation can be solved with a modified version of the Viterbi algorithm. To find optimal solutions on difficult instances, we alternate between incrementally adding constraints and applying optimality-preserving coarse-to-fine pruning. The algorithm finds provably exact solutions on 86% of sentence pairs and shows improvements over directional models.

1 Introduction

Word alignment is a critical first step for building statistical machine translation systems. In order to ensure accurate word alignments, most systems employ a post-hoc symmetrization step to combine directional word aligners, such as IBM Model 4 (Brown et al., 1993) or hidden Markov model (HMM) based aligners (Vogel et al., 1996). Several authors have proposed bidirectional models that incorporate this step directly, but decoding under many bidirectional models is NP-Hard and finding exact solutions has proven difficult.

In this paper, we describe a novel Lagrangian-relaxation based decoder for the bidirectional model proposed by DeNero and Macherey (2011), with the goal of improving search accuracy. In that work, the authors implement a dual decomposition-based decoder for the problem, but are only able to find exact solutions for around 6% of instances.

Our decoder uses a simple variant of the Viterbi algorithm for solving a relaxed version of this model. The algorithm makes it easy to re-introduce constraints for difficult instances, at the cost of increasing run-time complexity. To offset this cost, we employ optimality-preserving coarse-to-fine pruning to reduce the search space. The pruning method utilizes lower bounds on the cost of valid bidirectional alignments, which we obtain from a fast, greedy decoder.

The method has the following properties:

- It is based on a novel relaxation for the model of DeNero and Macherey (2011), solvable with a variant of the Viterbi algorithm.
- To find optimal solutions, it employs an efficient strategy that alternates between adding constraints and applying pruning.
- Empirically, it is able to find exact solutions on 86% of sentence pairs and is significantly faster than general-purpose solvers.

We begin in Section 2 by formally describing the directional word alignment problem. Section 3 describes a preliminary bidirectional model using full agreement constraints and a Lagrangian relaxation-based solver. Section 4 modifies this model to include adjacency constraints. Section 5 describes an extension to the relaxed algorithm to explicitly enforce constraints, and Section 6 gives a pruning method for improving the efficiency of the algorithm.

Experiments compare the search error and accuracy of the new bidirectional algorithm to several directional combiners and other bidirectional algorithms. Results show that the new relaxation is much more effective at finding exact solutions and is able to produce comparable alignment accuracy.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1481–1490,
Baltimore, Maryland, USA, June 23-25 2014.

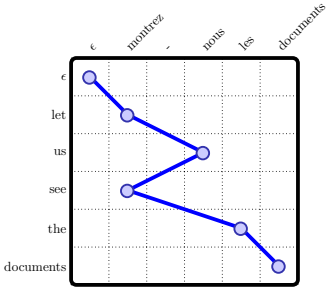

Figure 1: An example $\mathbf{e}\rightarrow\mathbf{f}$ directional alignment for the sentences `let us see the documents` and `montrez - nous les documents`, with $I = 5$ and $J = 5$. The indices $i \in [I]_0$ are rows, and the indices $j \in [J]_0$ are columns. The HMM alignment shown has transitions $x(0,1,1) = x(1,2,3) = x(3,3,1) = x(1,4,4) = x(4,5,5) = 1$.

Notation We use lower- and upper-case letters for scalars and vectors, and script-case for sets e.g. $\mathcal{X}$. For vectors, such as $v \in \{0,1\}^{(\mathcal{I}\times\mathcal{J})\cup\mathcal{J}}$, where $\mathcal{I}$ and $\mathcal{J}$ are finite sets, we use the notation $v(i,j)$ and $v(j)$ to represent elements of the vector. Define $d = \delta(i)$ to be the indicator vector with $d(i) = 1$ and $d(i') = 0$ for all $i' \neq i$. Finally define the notation $[J]$ to refer to $\{1 \dots J\}$ and $[J]_0$ to refer to $\{0 \dots J\}$.

2 Background

The focus of this work is on the word alignment decoding problem. Given a sentence $\mathbf{e}$ of length $|\mathbf{e}| = I$ and a sentence $\mathbf{f}$ of length $|\mathbf{f}| = J$, our goal is to find the best bidirectional alignment between the two sentences under a given objective function. Before turning to the model of interest, we first introduce directional word alignment.

2.1 Word Alignment

In the $\mathbf{e}\rightarrow\mathbf{f}$ word alignment problem, each word in $\mathbf{e}$ is aligned to a word in $\mathbf{f}$ or to the null word ϵ. This alignment is a mapping from each index $i \in [I]$ to an index $j \in [J]_0$ (where $j = 0$ represents alignment to ϵ). We refer to a single word alignment as a *link*.

A first-order HMM alignment model (Vogel et al., 1996) is an HMM of length $I + 1$ where the hidden state at position $i \in [I]_0$ is the aligned index $j \in [J]_0$, and the transition score takes into account the previously aligned index $j' \in [J]_0$.[1] Formally, define the set of possible HMM alignments as $\mathcal{X} \subset \{0,1\}^{([I]_0\times[J]_0)\cup([I]\times[J]_0\times[J]_0)}$ with

$$\mathcal{X} = \begin{cases} x : x(0,0) = 1, \\ x(i,j) = \sum_{j'=0}^{J} x(j',i,j) & \forall i \in [I], j \in [J]_0, \\ x(i,j) = \sum_{j'=0}^{J} x(j,i+1,j') & \forall i \in [I-1]_0, j \in [J]_0 \end{cases}$$

where $x(i,j) = 1$ indicates that there is a link between index i and index j, and $x(j',i,j) = 1$ indicates that index $i-1$ aligns to index j' and index i aligns to j. Figure 1 shows an example member of $\mathcal{X}$.

The constraints of $\mathcal{X}$ enforce *backward* and *forward* consistency respectively. If $x(i,j) = 1$, backward consistency enforces that there is a transition from $(i-1,j')$ to (i,j) for some $j' \in [J]_0$, whereas forward consistency enforces a transition from (i,j) to $(i+1,j')$ for some $j' \in [J]_0$. Informally the constraints "chain" together the links.

The HMM objective function $f : \mathcal{X} \rightarrow \mathbb{R}$ can be written as a linear function of x

$$f(x;\theta) = \sum_{i=1}^{I}\sum_{j=0}^{J}\sum_{j'=0}^{J} \theta(j',i,j)x(j',i,j)$$

where the vector $\theta \in \mathbb{R}^{[I]\times[J]_0\times[J]_0}$ includes the transition and alignment scores. For a generative model of alignment, we might define $\theta(j',i,j) = \log(p(\mathbf{e}_i|\mathbf{f}_j)p(j|j'))$. For a discriminative model of alignment, we might define $\theta(j',i,j) = w \cdot \phi(i,j',j,\mathbf{f},\mathbf{e})$ for a feature function ϕ and weights w (Moore, 2005; Lacoste-Julien et al., 2006).

Now reverse the direction of the model and consider the $\mathbf{f}\rightarrow\mathbf{e}$ alignment problem. An $\mathbf{f}\rightarrow\mathbf{e}$ alignment is a binary vector $y \in \mathcal{Y}$ where for each $j \in [J]$, $y(i,j) = 1$ for exactly one $i \in [I]_0$. Define the set of HMM alignments $\mathcal{Y} \subset \{0,1\}^{([I]_0\times[J]_0)\cup([I]_0\times[I]_0\times[J])}$ as

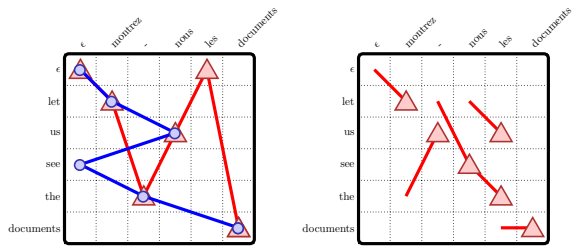
$$\mathcal{Y} = \begin{cases} y : y(0,0) = 1, \\ y(i,j) = \sum_{i'=0}^{I} y(i',i,j) & \forall i \in [I]_0, j \in [J], \\ y(i,j) = \sum_{i'=0}^{I} y(i,i',j+1) & \forall i \in [I]_0, j \in [J-1]_0 \end{cases}$$

Similarly define the objective function

$$g(y;\omega) = \sum_{j=1}^{J}\sum_{i=0}^{I}\sum_{i'=0}^{I} \omega(i',i,j)y(i',i,j)$$

with vector $\omega \in \mathbb{R}^{[I]_0\times[I]_0\times[J]}$.

[1] Our definition differs slightly from other HMM-based aligners in that it does not track the last ϵ alignment.



(a) (b)

Figure 2: (a) An example alignment pair (x, y) satisfying the full agreement conditions. The x alignment is represented with circles and the y alignment with triangles. (b) An example $\mathbf{f}\rightarrow\mathbf{e}$ alignment $y \in \mathcal{Y}'$ with relaxed forward constraints. Note that unlike an alignment from $\mathcal{Y}$ multiple words may be aligned in a column and words may transition from non-aligned positions.

Note that for both of these models we can solve the optimization problem exactly using the standard Viterbi algorithm for HMM decoding. The first can be solved in $O(IJ^2)$ time and the second in $O(I^2J)$ time.

3 Bidirectional Alignment

The directional bias of the $\mathbf{e}\rightarrow\mathbf{f}$ and $\mathbf{f}\rightarrow\mathbf{e}$ alignment models may cause them to produce differing alignments. To obtain the best single alignment, it is common practice to use a post-hoc algorithm to merge these directional alignments (Och et al., 1999). First, a directional alignment is found from each word in $\mathbf{e}$ to a word $\mathbf{f}$. Next an alignment is produced in the reverse direction from $\mathbf{f}$ to $\mathbf{e}$. Finally, these alignments are merged, either through intersection, union, or with an interpolation algorithm such as grow-diag-final (Koehn et al., 2003).

In this work, we instead consider a bidirectional alignment model that jointly considers both directional models. We begin in this section by introducing a simple bidirectional model that enforces *full* agreement between directional models and giving a relaxation for decoding. Section 4 loosens this model to *adjacent* agreement.

3.1 Enforcing Full Agreement

Perhaps the simplest post-hoc merging strategy is to retain the intersection of the two directional models. The analogous bidirectional model enforces *full* agreement to ensure the two alignments select the same non-null links i.e.

$$x^*, y^* = \arg\max_{x\in\mathcal{X}, y\in\mathcal{Y}} f(x) + g(y) \text{ s.t.}$$
$$x(i,j) = y(i,j) \quad \forall i \in [I], j \in [J]$$

We refer to the optimal alignments for this problem as x^* and y^*.

Unfortunately this bidirectional decoding model is NP-Hard (a proof is given in Appendix A). As it is common for alignment pairs to have $|\mathbf{f}|$ or $|\mathbf{e}|$ over 40, exact decoding algorithms are intractable in the worst-case.

Instead we will use Lagrangian relaxation for this model. At a high level, we will remove a subset of the constraints from the original problem and replace them with Lagrange multipliers. If we can solve this new problem efficiently, we may be able to get optimal solutions to the original problem. (See the tutorial by Rush and Collins (2012) describing the method.)

There are many possible subsets of constraints to consider relaxing. The relaxation we use preserves the agreement constraints while relaxing the Markov structure of the $\mathbf{f}\rightarrow\mathbf{e}$ alignment. This relaxation will make it simple to later re-introduce constraints in Section 5.

We relax the forward constraints of set $\mathcal{Y}$. Without these constraints the y links are no longer chained together. This has two consequences: (1) for index j there may be any number of indices i, such that $y(i,j) = 1$, (2) if $y(i',i,j) = 1$ it is no longer required that $y(i', j-1) = 1$. This gives a set $\mathcal{Y}'$ which is a superset of $\mathcal{Y}$

$$\mathcal{Y}' = \left\{ \begin{array}{l} y : y(0,0) = 1, \\ y(i,j) = \sum_{i'=0}^{I} y(i',i,j) \quad \forall i \in [I]_0, j \in [J] \end{array} \right.$$

Figure 2(b) shows a possible $y \in \mathcal{Y}'$ and a valid unchained structure.

To form the Lagrangian dual with relaxed forward constraints, we introduce a vector of Lagrange multipliers, $\lambda \in \mathbb{R}^{[I-1]_0 \times [J]_0}$, with one multiplier for each original constraint. The Lagrangian dual $L(\lambda)$ is defined as

$$\max_{\substack{x\in\mathcal{X}, y\in\mathcal{Y}', \\ x(i,j)=y(i,j)}} f(x) + \sum_{i=1}^{I}\sum_{j=0}^{J}\sum_{i'=0}^{I} y(i',i,j)\omega(i',i,j) \quad (1)$$
$$- \sum_{i=0}^{I}\sum_{j=0}^{J-1} \lambda(i,j)\left(y(i,j) - \sum_{i'=0}^{I} y(i,i',j+1)\right)$$
$$= \max_{\substack{x\in\mathcal{X}, y\in\mathcal{Y}', \\ x(i,j)=y(i,j)}} f(x) + \sum_{i=1}^{I}\sum_{j=0}^{J}\sum_{i'=0}^{I} y(i',i,j)\omega'(i',i,j) \quad (2)$$
$$= \max_{\substack{x\in\mathcal{X}, y\in\mathcal{Y}', \\ x(i,j)=y(i,j)}} f(x) + \sum_{i=1}^{I}\sum_{j=0}^{J} y(i,j) \max_{i'\in[I]_0} \omega'(i',i,j) \quad (3)$$
$$= \max_{\substack{x\in\mathcal{X}, y\in\mathcal{Y}', \\ x(i,j)=y(i,j)}} f(x) + g'(y;\omega,\lambda) \quad (4)$$

Line 2 distributes the λ's and introduces a modified potential vector ω' defined as

$$\omega'(i', i, j) = \omega(i', i, j) - \lambda(i, j) + \lambda(i', j-1)$$

for all $i' \in [I]_0, i \in [I]_0, j \in [J]$. Line 3 utilizes the relaxed set $\mathcal{Y}'$ which allows each $y(i,j)$ to select the best possible previous link $(i', j-1)$. Line 4 introduces the modified directional objective

$$g'(y; \omega, \lambda) = \sum_{i=1}^{I} \sum_{j=0}^{J} y(i,j) \max_{i' \in [I]_0} \omega'(i', i, j)$$

The Lagrangian dual is guaranteed to be an upper bound on the optimal solution, i.e. for all λ, $L(\lambda) \geq f(x^*) + g(y^*)$. Lagrangian relaxation attempts to find the tighest possible upper bound by minimizing the Lagrangian dual, $\min_\lambda L(\lambda)$, using subgradient descent. Briefly, subgradient descent is an iterative algorithm, with two steps. Starting with $\lambda = 0$, we iteratively

1. Set (x, y) to the $\arg\max$ of $L(\lambda)$.
2. Update $\lambda(i,j)$ for all $i \in [I-1]_0, j \in [J]_0$,

$$\lambda(i,j) \leftarrow \lambda(i,j) - \eta_t \big(y(i,j) - \sum_{i'=0}^{I} y(i, i', j+1)\big)$$

.

where $\eta_t > 0$ is a step size for the t'th update. If at any iteration of the algorithm the forward constraints are satisfied for (x, y), then $f(x) + g(y) = f(x^*) + g(x^*)$ and we say this gives a *certificate of optimality* for the underlying problem.

To run this algorithm, we need to be able to efficiently compute the (x, y) pair that is the $\arg\max$ of $L(\lambda)$ for any value of λ. Fortunately, since the y alignments are no longer constrained to valid transitions, we can compute these alignments by first picking the best $\mathbf{f} \rightarrow \mathbf{e}$ transitions for each possible link, and then running an $\mathbf{e} \rightarrow \mathbf{f}$ Viterbi-style algorithm to find the bidirectional alignment.

The $\max$ version of this algorithm is shown in Figure 3. It consists of two steps. We first compute the score for each $y(i,j)$ variable. We then use the standard Viterbi update for computing the x variables, adding in the score of the $y(i,j)$ necessary to satisfy the constraints.

procedure VITERBIFULL(θ, ω')
  Let π, ρ be dynamic programming charts.
  $\rho[i,j] \leftarrow \max_{i' \in [I]_0} \omega'(i', i, j) \; \forall \, i \in [I], j \in [J]_0$
  $\pi[0,0] \leftarrow \sum_{j=1}^{J} \max\{0, \rho[0,j]\}$
  for $i \in [I], j \in [J]_0$ in order **do**
    $\pi[i,j] \leftarrow \max_{j' \in [J]_0} \theta(j', i, j) + \pi[i-1, j']$
    if j $\neq 0$ **then** $\pi[i,j] \leftarrow \pi[i,j] + \rho[i,j]$
  return $\max_{j \in [J]_0} \pi[I,j]$

Figure 3: Viterbi-style algorithm for computing $L(\lambda)$. For simplicity the algorithm shows the $\max$ version of the algorithm, $\arg\max$ can be computed with back-pointers.

4 Adjacent Agreement

Enforcing full agreement can be too strict an alignment criteria. DeNero and Macherey (2011) instead propose a model that allows near matches, which we call *adjacent* agreement. Adjacent agreement allows links from one direction to agree with adjacent links from the reverse alignment for a small penalty. Figure 4(a) shows an example of a valid bidirectional alignment under adjacent agreement.

In this section we formally introduce adjacent agreement, and propose a relaxation algorithm for this model. The key algorithmic idea is to extend the Viterbi algorithm in order to consider possible adjacent links in the reverse direction.

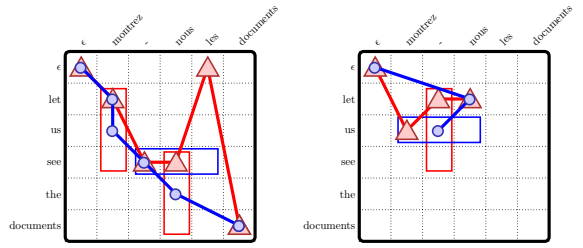
4.1 Enforcing Adjacency

Define the adjacency set $\mathcal{K} = \{-1, 0, 1\}$. A bidirectional alignment satisfies adjacency if for all $i \in [I], j \in [J]$,

- If $x(i,j) = 1$, it is required that $y(i+k, j) = 1$ for exactly one $k \in \mathcal{K}$ (i.e. either above, center, or below). We indicate which position with variables $z^{\updownarrow}_{i,j} \in \{0,1\}^{\mathcal{K}}$
- If $x(i,j) = 1$, it is allowed that $y(i, j+k) = 1$ for any $k \in \mathcal{K}$ (i.e. either left, center, or right) and all other $y(i, j') = 0$. We indicate which positions with variables $z^{\leftrightarrow}_{i,j} \in \{0,1\}^{\mathcal{K}}$

Formally for $x \in \mathcal{X}$ and $y \in \mathcal{Y}$, the pair (x, y) is feasible if there exists a z from the set $\mathcal{Z}(x,y) \subset \{0,1\}^{\mathcal{K}^2 \times [I] \times [J]}$ defined as

$$\mathcal{Z}(x,y) = \left\{ \begin{array}{ll} z : \forall i \in [I], j \in [J] & \\ z^{\updownarrow}_{i,j} \in \{0,1\}^{\mathcal{K}}, & z^{\leftrightarrow}_{i,j} \in \{0,1\}^{\mathcal{K}} \\ x(i,j) = \sum_{k \in \mathcal{K}} z^{\updownarrow}_{i,j}(k), & \sum_{k \in \mathcal{K}} z^{\leftrightarrow}_{i,j}(k) = y(i,j), \\ z^{\updownarrow}_{i,j}(k) \leq y(i+k, j) & \forall k \in \mathcal{K} : i + k > 0, \\ x(i,j) \geq z^{\leftrightarrow}_{i,j-k}(k) & \forall k \in \mathcal{K} : j + k > 0 \end{array} \right.$$



(a) (b)

Figure 4: (a) An alignment satisfying the adjacency constraints. Note that $x(2,1) = 1$ is allowed because of $y(1,1) = 1$, $x(4,3) = 1$ because of $y(3,3)$, and $y(3,1)$ because of $x(3,2)$. (b) An adjacent bidirectional alignment in progress. Currently $x(2,2) = 1$ with $z^{\updownarrow}(-1) = 1$ and $z^{\leftrightarrow}(-1) = 1$. The last transition was from $x(1,3)$ with $z^{\leftrightarrow\prime}(-1) = 1, z^{\leftrightarrow\prime}(0) = 1, z^{\updownarrow\prime}(0) = 1$.

Additionally adjacent, non-overlapping matches are assessed a penalty α calculated as

$$h(z) = \sum_{i=1}^{I} \sum_{j=1}^{J} \sum_{k \in \mathcal{K}} \alpha |k| (z^{\updownarrow}_{i,j}(k) + z^{\leftrightarrow}_{i,j}(k))$$

where $\alpha \leq 0$ is a parameter of the model. The example in Figure 4(a) includes a 3α penalty.

Adding these penalties gives the complete adjacent agreement problem

$$\arg\max_{\substack{z \in \mathcal{Z}(x,y) \\ x \in \mathcal{X}, y \in \mathcal{Y}}} f(x) + g(y) + h(z)$$

Next, apply the same relaxation from Section 3.1, i.e. we relax the forward constraints of the $\mathbf{f} \rightarrow \mathbf{e}$ set. This yields the following Lagrangian dual

$$L(\lambda) = \max_{\substack{z \in \mathcal{Z}(x,y) \\ x \in \mathcal{X}, y \in \mathcal{Y}'}} f(x) + g'(y; \omega, \lambda) + h(z)$$

Despite the new constraints, we can still compute $L(\lambda)$ in $O(IJ(I+J))$ time using a variant of the Viterbi algorithm. The main idea will be to consider possible adjacent settings for each link. Since each $z^{\updownarrow}_{i,j}$ and $z^{\leftrightarrow}_{i,j}$ only have a constant number of settings, this does not increase the asymptotic complexity of the algorithm.

Figure 5 shows the algorithm for computing $L(\lambda)$. The main loop of the algorithm is similar to Figure 3. It proceeds row-by-row, picking the best alignment $x(i,j) = 1$. The major change is that the chart π also stores a value $z \in \{0,1\}^{\mathcal{K} \times \mathcal{K}}$ representing a possible $z^{\updownarrow}_{i,j}, z^{\leftrightarrow}_{i,j}$ pair. Since we have

procedure VITERBIADJ(θ, ω')
$\rho[i,j] \leftarrow \max_{i' \in [I]_0} \omega'(i', i, j) \; \forall \, i \in [I], j \in [J]_0$
$\pi[0,0] \leftarrow \sum_{j=1}^{J} \max\{0, \rho[0,j]\}$
for $i \in [I], j \in [J]_0, z^{\updownarrow}, z^{\leftrightarrow} \in \{0,1\}^{|\mathcal{K}|}$ **do**
$\pi[i,j,z] \leftarrow$
$\max_{\substack{j' \in [J]_0, \\ z' \in \mathcal{N}(z, j-j')}} \theta(j', i, j) + \pi[i-1, j', z']$
$+ \sum_{k \in \mathcal{K}} z^{\leftrightarrow}(k)(\rho[i, j+k] + \alpha|k|)$
$+ z^{\updownarrow}(k)\alpha|k|$
return $\max_{j \in [J]_0, z \in \{0,1\}^{|\mathcal{K}| \times |\mathcal{K}|}} \pi[I, j, z]$

Figure 5: Modified Viterbi algorithm for computing the adjacent agreement $L(\lambda)$.

the proposed $z_{i,j}$ in the inner loop, we can include the scores of the adjacent y alignments that are in neighboring columns, as well as the possible penalty for matching $x(i,j)$ to a $y(i+k,j)$ in a different row. Figure 4(b) gives an example setting of z.

In the dynamic program, we need to ensure that the transitions between the z's are consistent. The vector z' indicates the y links adjacent to $x(i-1, j')$. If j' is near to j, z' may overlap with z and vice-versa. The transition set $\mathcal{N}$ ensures these indicators match up

$$\mathcal{N}(z, k') = \left\{ z' : \begin{array}{l} (z^{\updownarrow}(-1) \wedge k' \in \mathcal{K}) \Rightarrow z^{\leftrightarrow\prime}(k'), \\ (z^{\updownarrow\prime}(1) \wedge k' \in \mathcal{K}) \Rightarrow z^{\leftrightarrow}(-k'), \\ \sum_{k \in \mathcal{K}} z^{\updownarrow}(k) = 1 \end{array} \right.$$

5 Adding Back Constraints

In general, it can be shown that Lagrangian relaxation is only guaranteed to solve a linear programming relaxation of the underlying combinatorial problem. For difficult instances, we will see that this relaxation often does not yield provably exact solutions. However, it is possible to "tighten" the relaxation by re-introducing constraints from the original problem.

In this section, we extend the algorithm to allow incrementally re-introducing constraints. In particular we track which constraints are most often violated in order to explicitly enforce them in the algorithm.

Define a binary vector $p \in \{0,1\}^{[I-1]_0 \times [J]_0}$ where $p(i,j) = 1$ indicates a previously relaxed constraint on link $y(i,j)$ that should be reintroduced into the problem. Let the new partially

constrained Lagrangian dual be defined as

$$L(\lambda; p) = \max_{\substack{z \in \mathcal{Z}(x,y) \\ x \in \mathcal{X}, y \in \mathcal{Y}'}} f(x) + g'(y; \omega, \lambda) + h(z)$$

$$y(i,j) = \sum_{i'} y(i, i', j+1) \quad \forall i, j : p(i,j) = 1$$

If $p = \vec{1}$, the problem includes all of the original constraints, whereas $p = \vec{0}$ gives our original Lagrangian dual. In between we have progressively more constrained variants.

In order to compute the $\arg\max$ of this optimization problem, we need to satisfy the constraints within the Viterbi algorithm. We augment the Viterbi chart with a count vector $d \in \mathcal{D}$ where $\mathcal{D} \subset \mathbb{Z}^{||p||_1}$ and $d(i,j)$ is a count for the (i,j)'th constraint, i.e. $d(i,j) = y(i,j) - \sum_{i'} y(i', i, j)$. Only solutions with count 0 at the final position satisfy the active constraints. Additionally define a helper function $[\cdot]_{\mathcal{D}}$ as the projection from $\mathbb{Z}^{[I-1]_0 \times [J]} \rightarrow \mathcal{D}$, which truncates dimensions without constraints.

Figure 6 shows this constrained Viterbi relaxation approach. It takes p as an argument and enforces the active constraints. For simplicity, we show the full agreement version, but the adjacent agreement version is similar. The main new addition is that the inner loop of the algorithm ensures that the count vector d is the sum of the counts of its children d' and $d - d'$.

Since each additional constraint adds a dimension to d, adding constraints has a multiplicative impact on running time. Asymptotically the new algorithm requires $O(2^{||p||_1} IJ(I+J))$ time. This is a problem in practice as even adding a few constraints can make the problem intractable. We address this issue in the next section.

procedure CONSVITERBIFULL(θ, ω', p)
 for $i \in [I], j \in [J]_0, i' \in [I]$ **do**
  $d \leftarrow |\delta(i,j) - \delta(i', j-1)|_{\mathcal{D}}$
  $\rho[i,j,d] \leftarrow \omega'(i', i, j)$
 for $j \in [J], d \in \mathcal{D}$ **do**
  $\pi[0,0,d] \leftarrow \max_{d' \in \mathcal{D}} \pi[0,0,d'] + \rho[0,j,d-d']$
 for $i \in [I], j \in [J]_0, d \in \mathcal{D}$ **do**
  if j = 0 **then**
   $\pi[i,j,d] \leftarrow \max_{j' \in [J]_0} \theta(j', i, j) + \pi[i-1, j', d]$
  else
   $\pi[i,j,d] \leftarrow \max_{j' \in [J]_0, d' \in \mathcal{D}} \theta(j', i, j) + \pi[i-1, j', d'] + \rho[i, j, d-d']$
 return $\max_{j \in [J]_0} \pi[I, j, \mathbf{0}]$

Figure 6: Constrained Viterbi algorithm for finding partially-constrained, full-agreement alignments. The argument p indicates which constraints to enforce.

6 Pruning

Re-introducing constraints can lead to an exponential blow-up in the search space of the Viterbi algorithm. In practice though, many alignments in this space are far from optimal, e.g. aligning a common word like `the` to `nous` instead of `les`. Since Lagrangian relaxation re-computes the alignment many times, it would be preferable to skip these links in later rounds, particularly after re-introducing constraints.

In this section we describe an optimality preserving coarse-to-fine algorithm for pruning. Approximate coarse-to-fine pruning algorithms are widely used within NLP, but exact pruning is less common. Our method differs in that it only eliminates non-optimal transitions based on a lower-bound score. After introducing the pruning method, we present an algorithm to make this method effective in practice by producing high-scoring lower bounds for adjacent agreement.

6.1 Thresholding Max-Marginals

Our pruning method is based on removing transitions with low max-marginal values. Define the max-marginal value of an $\mathbf{e} \rightarrow \mathbf{f}$ transition in our Lagrangian dual as

$$M(j', i, j; \lambda) = \max_{\substack{z \in \mathcal{Z}(x,y), \\ x \in \mathcal{X}, y \in \mathcal{Y}'}} f(x) + g'(y; \lambda) + h(z) \quad \text{s.t. } x(j', i, j) = 1$$

where M gives the value of the best dual alignment that transitions from $(i-1, j')$ to (i, j). These max-marginals can be computed by running a forward-backward variant of any of the algorithms described thus far.

We make the following claim about max-marginal values and any lower-bound score

Lemma 1 (Safe Pruning). *For any valid constrained alignment $x \in \mathcal{X}, y \in \mathcal{Y}, z \in \mathcal{Z}(x,y)$ and for any dual vector $\lambda \in \mathbb{R}^{[I-1]_0 \times [J]_0}$, if there exists a transition j', i, j with max-marginal value $M(j', i, j; \lambda) < f(x) + g(y) + h(z)$ then the transition will not be in the optimal alignment, i.e. $x^*(j', i, j) = 0$.*

This lemma tells us that we can prune transitions whose dual max-marginal value falls below

a threshold without pruning possibly optimal transitions. Pruning these transitions can speed up Lagrangian relaxation without altering its properties.

Furthermore, the threshold is determined by any feasible lower bound on the optimal score, which means that better bounds can lead to more pruning.

6.2 Finding Lower Bounds

Since the effectiveness of pruning is dependent on the lower bound, it is crucial to be able to produce high-scoring alignments that satisfy the agreement constraints. Unfortunately, this problem is non-trivial. For instance, taking the union of directional alignments does not guarantee a feasible solution; whereas taking the intersection is trivially feasible but often not high-scoring.

To produce higher-scoring feasible bidirectional alignments we introduce a greedy heuristic algorithm. The algorithm starts with any feasible alignment (x, y, z). It runs the following greedy loop:

1. Repeat until there exists no $x(i, 0) = 1$ or $y(0, j) = 1$, or there is no score increase.
   (a) For each $i \in [I], j \in [J]_0, k \in \mathcal{K}$: $x(i, 0) = 1$, check if $x(i, j) \leftarrow 1$ and $y(i, j + k) \leftarrow 1$ is feasible, remember score.
   (b) For each $i \in [I]_0, j \in [J], k \in \mathcal{K}$: $y(0, j) = 1$, check if $y(i, j) \leftarrow 1$ and $x(i + k, j) \leftarrow 1$ is feasible, remember score.
   (c) Let (x, y, z) be the highest-scoring feasible solution produced.

This algorithm produces feasible alignments with monotonically increasing score, starting from the intersection of the alignments. It has run-time of $O(IJ(I + J))$ since each inner loop enumerates IJ possible updates and assigns at least one index a non-zero value, limiting the outer loop to $I + J$ iterations.

In practice we initialize the heuristic based on the intersection of x and y at the current round of Lagrangian relaxation. Experiments show that running this algorithm significantly improves the lower bound compared to just taking the intersection, and consequently helps pruning significantly.

7 Related Work

The most common techniques for bidirectional alignment are post-hoc combinations, such as union or intersection, of directional models, (Och et al., 1999), or more complex heuristic combiners such as grow-diag-final (Koehn et al., 2003).

Several authors have explored explicit bidirectional models in the literature. Cromieres and Kurohashi (2009) use belief propagation on a factor graph to train and decode a one-to-one word alignment problem. Qualitatively this method is similar to ours, although the model and decoding algorithm are different, and their method is not able to provide certificates of optimality.

A series of papers by Ganchev et al. (2010), Graca et al. (2008), and Ganchev et al. (2008) use posterior regularization to constrain the posterior probability of the word alignment problem to be symmetric and bijective. This work acheives state-of-the-art performance for alignment. Instead of utilizing posteriors our model tries to decode a single best one-to-one word alignment.

A different approach is to use constraints at training time to obtain models that favor bidirectional properties. Liang et al. (2006) propose agreement-based learning, which jointly learns probabilities by maximizing a combination of likelihood and agreement between two directional models.

General linear programming approaches have also been applied to word alignment problems. Lacoste-Julien et al. (2006) formulate the word alignment problem as quadratic assignment problem and solve it using an integer linear programming solver.

Our work is most similar to DeNero and Macherey (2011), which uses dual decomposition to encourage agreement between two directional HMM aligners during decoding time.

8 Experiments

Our experimental results compare the accuracy and optimality of our decoding algorithm to directional alignment models and previous work on this bidirectional model.

Data and Setup The experimental setup is identical to DeNero and Macherey (2011). Evaluation is performed on a hand-aligned subset of the NIST 2002 Chinese-English dataset (Ayan and Dorr, 2006). Following past work, the first 150 sentence pairs of the training section are used for evaluation. The potential parameters θ and ω are set based on unsupervised HMM models trained on the LDC FBIS corpus (6.2 million words).

Table 1: Experimental results for model accuracy of bilingual alignment. Column *time* is the mean time per sentence pair in seconds; *cert* is the percentage of sentence pairs solved with a certificate of optimality; *exact* is the percentage of sentence pairs solved exactly. Results are grouped by sentence length. The percentage of sentence pairs in each group is shown in parentheses.

Training is performed using the agreement-based learning method which encourages the directional models to overlap (Liang et al., 2006). This directional model has been shown produce state-of-the-art results with this setup (Haghighi et al., 2009).

Baselines We compare the algorithm described in this paper with several baseline methods. DIR includes post-hoc combinations of the $\mathbf{e}\rightarrow\mathbf{f}$ and $\mathbf{f}\rightarrow\mathbf{e}$ HMM-based aligners. Variants include union, intersection, and grow-diag-final. D&M is the dual decomposition algorithm for bidirectional alignment as presented by DeNero and Macherey (2011) with different final combinations. LR is the Lagrangian relaxation algorithm applied to the adjacent agreement problem without the additional constraints described in Section 5. CONS is our full Lagrangian relaxation algorithm including incremental constraint addition. ILP uses a highly-optimized general-purpose integer linear programming solver to solve the lattice with the constraints described (Gurobi Optimization, 2013).

Implementation The main task of the decoder is to repeatedly compute the $\arg\max$ of $L(\lambda)$. To speed up decoding, our implementation fully instantiates the Viterbi lattice for a problem instance. This approach has several benefits: each iteration can reuse the same lattice structure; max-marginals can be easily computed with a general forward-backward algorithm; pruning corresponds to removing lattice edges; and adding constraints can be done through lattice intersection. For consistency, we implement each baseline (except for D&M) through the same lattice.

Parameter Settings We run 400 iterations of the subgradient algorithm using the rate schedule $\eta_t = 0.95^{t'}$ where t' is the count of updates for which the dual value did not improve. Every 10 iterations we run the greedy decoder to compute a lower bound. If the gap between our current dual value $L(\lambda)$ and the lower bound improves significantly we run coarse-to-fine pruning as described in Section 6 with the best lower bound. For CONS, if the algorithm does not find an optimal solution we run 400 more iterations and incrementally add the 5 most violated constraints every 25 iterations.

Model	Combiner	alignment			phrase pair

D&M	union	63.3	81.5	29.1	63.2	44.9	52.5
	intersection	77.5	75.1	23.6	57.1	53.6	55.3
	grow-diag	65.6	80.6	28.0	60.2	47.4	53.0
CONS		72.5	74.9	26.4	53.0	52.4	52.7

Table 2: Alignment accuracy and phrase pair extraction accuracy for directional and bidirectional models. `Prec` is the precision. `Rec` is the recall. `AER` is alignment error rate and `F1` is the phrase pair extraction F1 score.

Results Our first set of experiments looks at the model accuracy and the decoding time of various methods that can produce optimal solutions. Results are shown in Table 1. D&M is only able to find the optimal solution with certificate on 6% of instances. The relaxation algorithm used in this work is able to increase that number to 54.7%. With incremental constraints and pruning, we are able to solve over 86% of sentence pairs including many longer and more difficult pairs. Additionally the method finds these solutions with only a small increase in running time over Lagrangian relaxation, and is significantly faster than using an ILP solver.

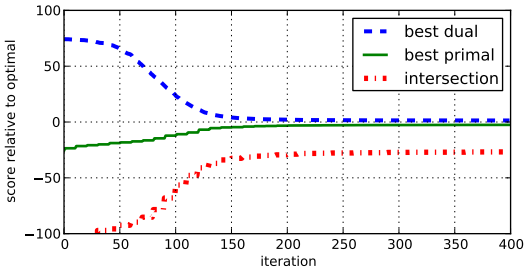
Next we compare the models in terms of alignment accuracy. Table 2 shows the precision, recall and alignment error rate (AER) for word alignment. We consider union, intersection and grow-diag-final as combination procedures. The combination procedures are applied to D&M in the case when the algorithm does not converge. For CONS, we use the optimal solution for the 86% of instances that converge and the highest-scoring greedy solution for those that do not. The proposed method has an AER of 26.4, which outperforms each of the directional models. However, although CONS achieves a higher model score than D&M, it performs worse in accuracy. Ta-

	1-20	21-40	41-60	all
# cons.	20.0	32.1	39.5	35.9

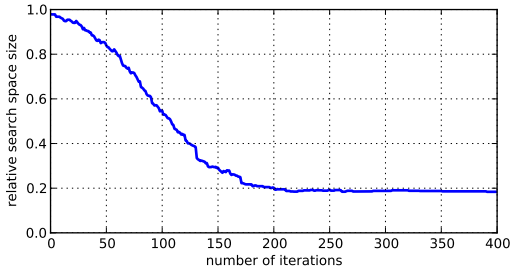
Table 3: The average number of constraints added for sentence pairs where Lagrangian relaxation is not able to find an exact solution.

ble 2 also compares the models in terms of phrase-extraction accuracy (Ayan and Dorr, 2006). We use the phrase extraction algorithm described by DeNero and Klein (2010), accounting for possible links and ϵ alignments. CONS performs better than each of the directional models, but worse than the best D&M model.

Finally we consider the impact of constraint addition, pruning, and use of a lower bound. Table 3 gives the average number of constraints added for sentence pairs for which Lagrangian relaxation alone does not produce a certificate. Figure 7(a) shows the average over all sentence pairs of the best dual and best primal scores. The graph compares the use of the greedy algorithm from Section 6.2 with the simple intersection of x and y. The difference between these curves illustrates the benefit of the greedy algorithm. This is reflected in Figure 7(b) which shows the effectiveness of coarse-to-fine pruning over time. On average, the pruning reduces the search space of each sentence pair to 20% of the initial search space after 200 iterations.



(a) The best dual and the best primal score, relative to the optimal score, averaged over all sentence pairs. The `best primal` curve uses a feasible greedy algorithm, whereas the `intersection` curve is calculated by taking the intersection of x and y.



(b) A graph showing the effectiveness of coarse-to-fine pruning. Relative search space size is the size of the pruned lattice compared to the initial size. The plot shows an average over all sentence pairs.

Figure 7

9 Conclusion

We have introduced a novel Lagrangian relaxation algorithm for a bidirectional alignment model that uses incremental constraint addition and coarse-to-fine pruning to find exact solutions. The algorithm increases the number of exact solution found on the model of DeNero and Macherey (2011) from 6% to 86%.

Unfortunately despite achieving higher model score, this approach does not produce more accurate alignments than the previous algorithm. This suggests that the adjacent agreement model may still be too constrained for this underlying task. Implicitly, an approach with fewer exact solutions may allow for useful violations of these constraints. In future work, we hope to explore bidirectional models with soft-penalties to explicitly permit these violations.

A Proof of NP-Hardness

We can show that the bidirectional alignment problem is NP-hard by reduction from the traveling salesman problem (TSP). A TSP instance with N cities has distance $c(i', i)$ for each $(i', i) \in [N]^2$. We can construct a sentence pair in which $I = J = N$ and ϵ-alignments have infinite cost.

$$\begin{aligned}
\omega(i', i, j) &= -c(i', i) && \forall i' \in [N]_0, i \in [N], j \in [N] \\
\theta(j', i, j) &= 0 && \forall j' \in [N]_0, i \in [N], j \in [N] \\
\omega(i', 0, j) &= -\infty && \forall i' \in [N]_0, j \in [N] \\
\theta(j', i, 0) &= -\infty && \forall j' \in [N]_0, i \in [N]
\end{aligned}$$

Every bidirectional alignment with finite objective score must align exactly one word in e to each word in f, encoding a permutation a. Moreover, each possible permutation has a finite score: the negation of the total distance to traverse the N cities in order a under distance c. Therefore, solving such a bidirectional alignment problem would find a minimal Hamiltonian path of the TSP encoded in this way, concluding the reduction.

Abstract

In this paper, we propose a novel recursive recurrent neural network (R^2NN) to model the end-to-end decoding process for statistical machine translation. R^2NN is a combination of recursive neural network and recurrent neural network, and in turn integrates their respective capabilities: (1) new information can be used to generate the next hidden state, like recurrent neural networks, so that language model and translation model can be integrated naturally; (2) a tree structure can be built, as recursive neural networks, so as to generate the translation candidates in a bottom up manner. A semi-supervised training approach is proposed to train the parameters, and the phrase pair embedding is explored to model translation confidence directly. Experiments on a Chinese to English translation task show that our proposed R^2NN can outperform the state-of-the-art baseline by about 1.5 points in BLEU.

1 Introduction

Deep Neural Network (DNN), which essentially is a multi-layer neural network, has re-gained more and more attentions these years. With the efficient training methods, such as (Hinton et al., 2006), DNN is widely applied to speech and image processing, and has achieved breakthrough results (Kavukcuoglu et al., 2010; Krizhevsky et al., 2012; Dahl et al., 2012).

Applying DNN to natural language processing (NLP), representation or embedding of words is usually learnt first. Word embedding is a dense, low dimensional, real-valued vector. Each dimension of the vector represents a latent aspect of the word, and captures its syntactic and semantic properties (Bengio et al., 2006). Word embedding is usually learnt from large amount of monolingual corpus at first, and then fine tuned for special distinct tasks. Collobert et al. (2011) propose a multi-task learning framework with DNN for various NLP tasks, including part-of-speech tagging, chunking, named entity recognition, and semantic role labelling. Recurrent neural networks are leveraged to learn language model, and they keep the history information circularly inside the network for arbitrarily long time (Mikolov et al., 2010). Recursive neural networks, which have the ability to generate a tree structured output, are applied to natural language parsing (Socher et al., 2011), and they are extended to recursive neural tensor networks to explore the compositional aspect of semantics (Socher et al., 2013).

DNN is also introduced to Statistical Machine Translation (SMT) to learn several components or features of conventional framework, including word alignment, language modelling, translation modelling and distortion modelling. Yang et al. (2013) adapt and extend the CD-DNN-HMM (Dahl et al., 2012) method to HMM-based word alignment model. In their work, bilingual word embedding is trained to capture lexical translation information, and surrounding words are utilized to model context information. Auli et al. (2013) propose a joint language and translation model, based on a recurrent neural network. Their model predicts a target word, with an unbounded history of both source and target words. Liu et al. (2013) propose an additive neural network for SMT decoding. Word embedding is used as the input to learn translation confidence score, which is combined with commonly used features in the conventional log-linear model. For distortion modeling, Li et al. (2013) use recursive auto encoders to make full use of the entire merging phrase pairs, going beyond the boundary words with a maximum entropy classifier (Xiong et al., 2006).

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1491–1500,
Baltimore, Maryland, USA, June 23-25 2014.

Different from the work mentioned above, which applies DNN to components of conventional SMT framework, in this paper, we propose a novel R^2NN to model the end-to-end decoding process. R^2NN is a combination of recursive neural network and recurrent neural network. In R^2NN, new information can be used to generate the next hidden state, like recurrent neural networks, and a tree structure can be built, as recursive neural networks. To generate the translation candidates in a commonly used bottom-up manner, recursive neural networks are naturally adopted to build the tree structure. In recursive neural networks, all the representations of nodes are generated based on their child nodes, and it is difficult to integrate additional global information, such as language model and distortion model. In order to integrate these crucial information for better translation prediction, we combine recurrent neural networks into the recursive neural networks, so that we can use global information to generate the next hidden state, and select the better translation candidate.

We propose a three-step semi-supervised training approach to optimizing the parameters of R^2NN, which includes recursive auto-encoding for unsupervised pre-training, supervised local training based on the derivation trees of forced decoding, and supervised global training using early update strategy. So as to model the translation confidence for a translation phrase pair, we initialize the phrase pair embedding by leveraging the sparse features and recurrent neural network. The sparse features are phrase pairs in translation table, and recurrent neural network is utilized to learn a smoothed translation score with the source and target side information. We conduct experiments on a Chinese-to-English translation task to test our proposed methods, and we get about 1.5 BLEU points improvement, compared with a state-of-the-art baseline system.

The rest of this paper is organized as follows: Section 2 introduces related work on applying DNN to SMT. Our R^2NN framework is introduced in detail in Section 3, followed by our three-step semi-supervised training approach in Section 4. Phrase pair embedding method using translation confidence is elaborated in Section 5. We introduce our conducted experiments in Section 6, and conclude our work in Section 7.

2 Related Work

Yang et al. (2013) adapt and extend CD-DNN-HMM (Dahl et al., 2012) to word alignment. In their work, initial word embedding is firstly trained with a huge mono-lingual corpus, then the word embedding is adapted and fine tuned bilingually in a context-depended DNN HMM framework. Word embeddings capturing lexical translation information and surrounding words modeling context information are leveraged to improve the word alignment performance. Unfortunately, the better word alignment result generated by this model, cannot bring significant performance improvement on a end-to-end SMT evaluation task.

To improve the SMT performance directly, Auli et al. (2013) extend the recurrent neural network language model, in order to use both the source and target side information to scoring translation candidates. In their work, not only the target word embedding is used as the input of the network, but also the embedding of the source word, which is aligned to the current target word. To tackle the large search space due to the weak independence assumption, a lattice algorithm is proposed to rerank the n-best translation candidates, generated by a given SMT decoder.

Liu et al. (2013) propose an additive neural network for SMT decoding. RNNLM (Mikolov et al., 2010) is firstly used to generate the source and target word embeddings, which are fed into a one-hidden-layer neural network to get a translation confidence score. Together with other commonly used features, the translation confidence score is integrated into a conventional log-linear model. The parameters are optimized with development data set using mini-batch conjugate sub-gradient method and a regularized ranking loss.

DNN is also brought into the distortion modeling. Going beyond the previous work using boundary words for distortion modeling in BTG-based SMT decoder, Li et al. (2013) propose to apply recursive auto-encoder to make full use of the entire merged blocks. The recursive auto-encoder is trained with reordering examples extracted from word-aligned bilingual sentences. Given the representations of the smaller phrase pairs, recursive auto-encoder can generate the representation of the parent phrase pair with a re-ordering confidence score. The combination of reconstruction error and re-ordering error is used to be the objective function for the model training.

3 Our Model

In this section, we leverage DNN to model the end-to-end SMT decoding process, using a novel recursive recurrent neural network (R^{2}NN), which is different from the above mentioned work applying DNN to components of conventional SMT framework. R^{2}NN is a combination of recursive neural network and recurrent neural network, which not only integrates the conventional global features as input information for each combination, but also generates the representation of the parent node for the future candidate generation.

In this section, we briefly recall the recurrent neural network and recursive neural network in Section 3.1 and 3.2, and then we elaborate our R^{2}NN in detail in Section 3.3.

3.1 Recurrent Neural Network

Recurrent neural network is usually used for sequence processing, such as language model (Mikolov et al., 2010). Commonly used sequence processing methods, such as Hidden Markov Model (HMM) and n-gram language model, only use a limited history for the prediction. In HMM, the previous state is used as the history, and for n-gram language model (for example n equals to 3), the history is the previous two words. Recurrent neural network is proposed to use unbounded history information, and it has recurrent connections on hidden states, so that history information can be used circularly inside the network for arbitrarily long time.

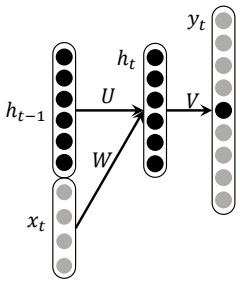

Figure 1: Recurrent neural network

As shown in Figure 1, the network contains three layers, an input layer, a hidden layer, and an output layer. The input layer is a concatenation of h_{t-1} and x_t, where h_{t-1} is a real-valued vector, which is the history information from time 0 to $t-1$. x_t is the embedding of the input word at time t. Word embedding x_t is integrated with previous history h_{t-1} to generate the current hidden layer, which is a new history vector h_t. Based on h_t, we can predict the probability of the next word, which forms the output layer y_t. The new history h_t is used for the future prediction, and updated with new information from word embedding x_t recurrently.

3.2 Recursive Neural Network

In addition to the sequential structure above, tree structure is also usually constructed in various NLP tasks, such as parsing and SMT decoding. To generate a tree structure, recursive neural networks are introduced for natural language parsing (Socher et al., 2011). Similar with recurrent neural networks, recursive neural networks can also use unbounded history information from the sub-tree rooted at the current node. The commonly used binary recursive neural networks generate the representation of the parent node, with the representations of two child nodes as the input.

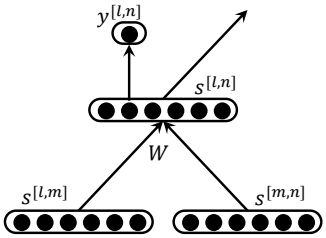

Figure 2: Recursive neural network

As shown in Figure 2, $s^{[l,m]}$ and $s^{[m,n]}$ are the representations of the child nodes, and they are concatenated into one vector to be the input of the network. $s^{[l,n]}$ is the generated representation of the parent node. $y_{[l,n]}$ is the confidence score of how plausible the parent node should be created. l, m, n are the indexes of the string. For example, for nature language parsing, $s^{[l,n]}$ is the representation of the parent node, which could be a NP or VP node, and it is also the representation of the whole sub-tree covering from l to n.

3.3 Recursive Recurrent Neural Network

Word embedding x_t is integrated as new input information in recurrent neural networks for each prediction, but in recursive neural networks, no additional input information is used except the two representation vectors of the child nodes. However, some global information , which cannot be generated by the child representations, is crucial

for SMT performance, such as language model score and distortion model score. So as to integrate such global information, and also keep the ability to generate tree structure, we combine the recurrent neural network and the recursive neural network to be a recursive recurrent neural network (R^{2}NN).

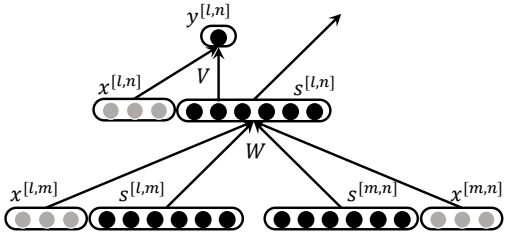

Figure 3: Recursive recurrent neural network

As shown in Figure 3, based on the recursive network, we add three input vectors $x^{[l,m]}$ for child node $[l,m]$, $x^{[m,n]}$ for child node $[m,n]$, and $x^{[l,n]}$ for parent node $[l,n]$. We call them recurrent input vectors, since they are borrowed from recurrent neural networks. The two recurrent input vectors $x^{[l,m]}$ and $x^{[m,n]}$ are concatenated as the input of the network, with the original child node representations $s^{[l,m]}$ and $s^{[m,n]}$. The recurrent input vector $x^{[l,n]}$ is concatenated with parent node representation $s^{[l,n]}$ to compute the confidence score $y^{[l,n]}$.

The input, hidden and output layers are calculated as follows:

$$\hat{x}^{[l,n]} = x^{[l,m]} \bowtie s^{[l,m]} \bowtie x^{[m,n]} \bowtie s^{[m,n]} \quad (1)$$

$$s_j^{[l,n]} = f(\sum_i \hat{x}_i^{[l,n]} w_{ji}) \quad (2)$$

$$y^{[l,n]} = \sum_j (s^{[l,n]} \bowtie x^{[l,n]})_j v_j \quad (3)$$

where $\bowtie$ is a concatenation operator in Equation 1 and Equation 3, and f is a non-linear function, here we use $HTanh$ function, which is defined as:

$$HTanh(x) = \begin{cases} -1, & x < -1 \\ x, & -1 \leq x \geq 1 \\ 1, & x > 1 \end{cases} \quad (4)$$

Figure 4 illustrates the R^{2}NN architecture for SMT decoding. For a source sentence "laizi faguo he eluosi de", we first split it into phrases "laizi", "faguo he eluosi" and "de". We then check whether translation candidates can be found in the translation table for each span, together with the phrase pair embedding and recurrent input vector (global features). We call it the rule matching phase. For a translation candidate of the span node $[l,m]$, the black dots stand for the node representation $s^{[l,m]}$, while the grey dots for recurrent input vector $x^{[l,m]}$. Given $s^{[l,m]}$ and $x^{[l,m]}$ for matched translation candidates, conventional CKY decoding process is performed using R^{2}NN. R^{2}NN can combine the translation pairs of child nodes, and generate the translation candidates for parent nodes with their representations and plausible scores. Only the n-best translation candidates are kept for upper combination, according to their plausible scores.

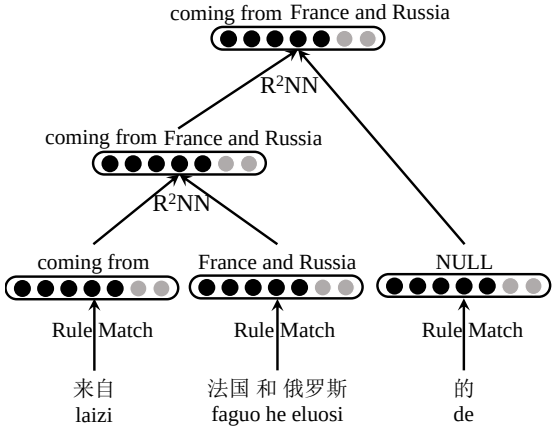

Figure 4: R^{2}NN for SMT decoding

We extract phrase pairs using the conventional method (Och and Ney, 2004). The commonly used features, such as translation score, language model score and distortion score, are used as the recurrent input vector x. During decoding, recurrent input vectors x for internal nodes are calculated accordingly. The difference between our model and the conventional log-linear model includes:

- R^{2}NN is not linear, while the conventional model is a linear combination.
- Representations of phrase pairs are automatically learnt to optimize the translation performance, while features used in conventional model are hand-crafted.
- History information of the derivation can be recorded in the representation of internal nodes, while conventional model cannot.

Liu et al. (2013) apply DNN to SMT decoding, but not in a recursive manner. A feature is learnt via a one-hidden-layer neural network, and the embedding of words in the phrase pairs are used as the input vector. Our model generates the representation of a translation pair based on its child nodes. Li et al. (2013) also generate the representation of phrase pairs in a recursive way. In their work, the representation is optimized to learn a distortion model using recursive neural network, only based on the representation of the child nodes. Our R^{2}NN is used to model the end-to-end translation process, with recurrent global information added. We also explore phrase pair embedding method to model translation confidence directly, which is introduced in Section 5.

In the next two sections, we will answer the following questions: (a) how to train the model, and (b) how to generate the initial representations of translation pairs.

4 Model Training

In this section, we propose a three-step training method to train the parameters of our proposed R^{2}NN, which includes unsupervised pre-training using recursive auto-encoding, supervised local training on the derivation tree of forced decoding, and supervised global training using early update training strategy.

4.1 Unsupervised Pre-training

We adopt the Recursive Auto Encoding (RAE) (Socher et al., 2011) for our unsupervised pre-training. The main idea of auto encoding is to initialize the parameters of the neural network, by minimizing the information lost, which means, capturing as much information as possible in the hidden states from the input vector.

As shown in Figure 5, RAE contains two parts, an encoder with parameter W, and a decoder with parameter W'. Given the representations of child nodes s_1 and s_2, the encoder generates the representation of parent node s. With the parent node representation s as the input vector, the decoder reconstructs the representation of two child nodes s_1' and s_2'. The loss function is defined as following so as to minimize the information lost:

$$L_{RAE}(s_1, s_2) = \frac{1}{2}(\|s_1 - s_1'\|^2 + \|s_2 - s_2'\|^2) \quad (5)$$

where $\|\cdot\|$ is the Euclidean norm.

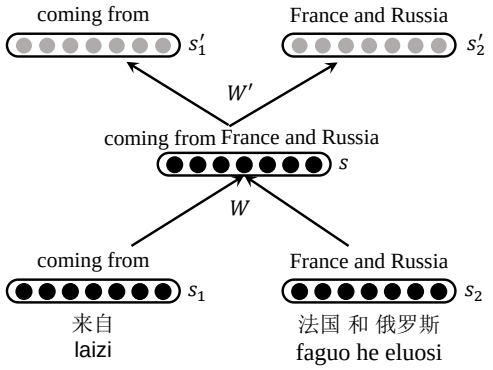

Figure 5: Recursive auto encoding for unsupervised pre-training

The training samples for RAE are phrase pairs $\{s_1, s_2\}$ in translation table, where s_1 and s_2 can form a continuous partial sentence pair in the training data. When RAE training is done, only the encoding model W will be fine tuned in the future training phases.

4.2 Supervised Local Training

We use contrastive divergence method to fine tune the parameters W and V. The loss function is the commonly used ranking loss with a margin, and it is defined as follows:

$$L_{SLT}(W, V, s^{[l,n]}) = max(0, 1 - y_{oracle}^{[l,n]} + y_t^{[l,n]}) \quad (6)$$

where $s^{[l,n]}$ is the source span. $y_{oracle}^{[l,n]}$ is the plausible score of a oracle translation result. $y_t^{[l,n]}$ is the plausible score for the best translation candidate given the model parameters W and V. The loss function aims to learn a model which assigns the good translation candidate (the oracle candidate) higher score than the bad ones, with a margin 1.

Translation candidates generated by forced decoding (Wuebker et al., 2010) are used as oracle translations, which are the positive samples. Forced decoding performs sentence pair segmentation using the same translation system as decoding. For each sentence pair in the training data, SMT decoder is applied to the source side, and any candidate which is not the partial sub-string of the target sentence is removed from the n-best list during decoding. From the forced decoding result, we can get the ideal derivation tree in the decoder's search space, and extract positive/oracle translation candidates.

4.3 Supervised Global Training

The supervised local training uses the n-odes/samples in the derivation tree of forced decoding to update the model, and the trained model tends to over-fit to local decisions. In this subsection, a supervised global training is proposed to tune the model according to the final translation performance of the whole source sentence.

Actually, we can update the model from the root of the decoding tree and perform back propagation along the tree structure. Due to the inexact search nature of SMT decoding, search errors may inevitably break theoretical properties, and the final translation results may be not suitable for model training. To handle this problem, we use early update strategy for the supervised global training. Early update is testified to be useful for SMT training with large scale features (Yu et al., 2013). Instead of updating the model using the final translation results, early update approach optimizes the model, when the oracle translation candidate is pruned from the n-best list, meaning that, the model is updated once it performs a unrecoverable mistake. Back propagation is performed along the tree structure, and the phrase pair embeddings of the leaf nodess are updated.

The loss function for supervised global training is defined as follows:

$$L_{SGT}(W, V, s^{[l,n]}) = -\log(\frac{\sum_{y^{[l,n]}_{oracle}} \exp(y^{[l,n]}_{oracle})}{\sum_{t \in nbest} \exp(y^{[l,n]}_{t})}) \quad (7)$$

where $y^{[l,n]}_{oracle}$ is the model score of a oracle translation candidate for the span $[l, n]$. Oracle translation candidates are candidates get from forced decoding. If the span $[l, n]$ is not the whole source sentence, there may be several oracle translation candidates, otherwise, there is only one, which is exactly the target sentence. There are much fewer training samples than those for supervised local training, and it is not suitable to use ranking loss for global training any longer. We use negative log-likelihood to penalize all the other translation candidates except the oracle ones, so as to leverage all the translation candidates as training samples.

5 Phrase Pair Embedding

The next question is how to initialize the phrase pair embedding in the translation table, so as to generate the leaf nodes of the derivation tree. There are more phrase pairs than mono-lingual words, but bilingual corpus is much more difficult to acquire, compared with monolingual corpus.

Embedding	#Data	#Entry	#Parameter
Word	1G	500K	$20 \times 500K$
Word Pair	7M	$(500K)^2$	$20 \times (500K)^2$
Phrase Pair	7M	$(500K)^4$	$20 \times (500K)^4$

Table 1: The relationship between the size of training data and the number of model parameters. The numbers for word embedding is calculated on English Giga-Word corpus version 3. For word pair and phrase pair embedding, the numbers are calculated on IWSLT 2009 dialog training set. The word count of each side of phrase pairs is limited to be 2.

Table 1 shows the relationship between the size of training data and the number of model parameters. For word embedding, the training size is 1G bits, and we may have 500K terms. For each term, we have a vector with length 20 as parameters, so there are $20 \times 500K$ parameters totally. But for source-target word pair, we may only have 7M bilingual corpus for training (taking IWSLT data set as an example), and there are $20 \times (500K)^2$ parameters to be tuned. For phrase pairs, the situation becomes even worse, especially when the limitation of word count in phrase pairs is relaxed. It is very difficult to learn the phrase pair embedding brute-forcedly as word embedding is learnt (Mikolov et al., 2010; Collobert et al., 2011), since we may not have enough training data.

A simple approach to construct phrase pair embedding is to use the average of the embeddings of the words in the phrase pair. One problem is that, word embedding may not be able to model the translation relationship between source and target phrases at phrase level, since some phrases cannot be decomposed. For example, the meaning of "hot dog" is not the composition of the meanings of the words "hot" and "dog". In this section, we split the phrase pair embedding into two parts to model the translation confidence directly: translation confidence with sparse features and translation confidence with recurrent neural network. We first get two translation confidence vectors separately using sparse features and recurrent neural network, and then concatenate them to be the phrase pair embedding. We call it translation confidence based phrase pair embedding (TCBPPE).

5.1 Translation Confidence with Sparse Features

Large scale feature training has drawn more attentions these years (Liang et al., 2006; Yu et al., 2013). Instead of integrating the sparse features directly into the log-linear model, we use them as the input to learn a phrase pair embedding. For the top 200,000 frequent translation pairs, each of them is a feature in itself, and a special feature is added for all the infrequent ones.

The one-hot representation vector is used as the input, and a one-hidden-layer network generates a confidence score. To train the neural network, we add the confidence scores to the conventional log-linear model as features. Forced decoding is utilized to get positive samples, and contrastive divergence is used for model training. The neural network is used to reduce the space dimension of sparse features, and the hidden layer of the network is used as the phrase pair embedding. The length of the hidden layer is empirically set to 20.

5.2 Translation Confidence with Recurrent Neural Network

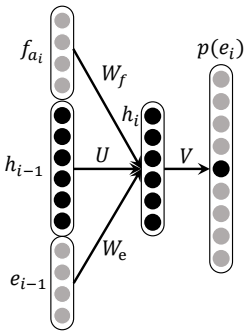

Figure 6: Recurrent neural network for translation confidence

We use recurrent neural network to generate two smoothed translation confidence scores based on source and target word embeddings. One is source to target translation confidence score and the other is target to source. These two confidence scores are defined as:

$$T_{S2T}(s,t) = \sum_i \log p(e_i|e_{i-1}, f_{a_i}, h_i) \quad (8)$$

$$T_{T2S}(s,t) = \sum_j \log p(f_j|f_{j-1}, e_{\hat{a}_j}, h_j) \quad (9)$$

where, f_{a_i} is the corresponding target word aligned to e_i, and it is similar for $e_{\hat{a}_j}$. $p(e_i|e_{i-1}, f_{a_i}, h_i)$ is produced by a recurrent network as shown in Figure 6. The recurrent neural network is trained with word aligned bilingual corpus, similar as (Auli et al., 2013).

6 Experiments and Results

In this section, we conduct experiments to test our method on a Chinese-to-English translation task. The evaluation method is the case insensitive IBM BLEU-4 (Papineni et al., 2002). Significant testing is carried out using bootstrap re-sampling method proposed by (Koehn, 2004) with a 95% confidence level.

6.1 Data Setting and Baseline

The data is from the IWSLT 2009 dialog task. The training data includes the BTEC and SLDB training data. The training data contains 81k sentence pairs, 655K Chinese words and 806K English words. The language model is a 5-gram language model trained with the target sentences in the training data. The test set is development set 9, and the development set comprises both development set 8 and the Chinese DIALOG set.

The training data for monolingual word embedding is Giga-Word corpus version 3 for both Chinese and English. Chinese training corpus contains 32M sentences and 1.1G words. English training data contains 8M sentences and 247M terms. We only train the embedding for the top 100,000 frequent words following (Collobert et al., 2011). With the trained monolingual word embedding, we follow (Yang et al., 2013) to get the bilingual word embedding using the IWSLT bilingual training data.

Our baseline decoder is an in-house implementation of Bracketing Transduction Grammar (BTG) (Wu, 1997) in CKY-style decoding with a lexical reordering model trained with maximum entropy (Xiong et al., 2006). The features of the baseline are commonly used features as standard BTG decoder, such as translation probabilities, lexical weights, language model, word penalty and distortion probabilities. All these commonly used features are used as recurrent input vector x in our R^{2}NN.

6.2 Translation Results

As we mentioned in Section 5, constructing phrase pair embeddings from word embeddings may be not suitable. Here we conduct experiments to ver-

ify it. We first train the source and target word embeddings separately using large monolingual data, following (Collobert et al., 2011). Using monolingual word embedding as the initialization, we fine tune them to get bilingual word embedding (Yang et al., 2013).

The word embedding based phrase pair embedding (WEPPE) is defined as:

$$Epp_{web}(s,t) = \sum_i E_{wms}(s_i) \bowtie \sum_j E_{wbs}(s_j) \bowtie \sum_k E_{wmt}(t_k) \bowtie \sum_l E_{wbt}(t_l) \quad (10)$$

where $\bowtie$ is a concatenation operator. s and t are the source and target phrases. $E_{wms}(s_i)$ and $E_{wmt}(t_k)$ are the monolingual word embeddings, and $E_{wbs}(s_i)$ and $E_{wbt}(t_k)$ are the bilingual word embeddings. Here the length of the word embedding is also set to 20. Therefore, the length of the phrase pair embedding is $20 \times 4 = 80$.

We compare our phrase pair embedding methods and our proposed R^{2}NN with baseline system, in Table 2. We can see that, our R^{2}NN models with WEPPE and TCBPPE are both better than the baseline system. WEPPE cannot get significant improvement, while TCBPPE does, compared with the baseline result. TCBPPE is much better than WEPPE.

Setting	Development	Test
Baseline	46.81	39.29
WEPPE+R^{2}NN	47.23	39.92
TCBPPE+R^{2}NN	48.70 $\uparrow$	40.81 $\uparrow$

Table 2: Translation results of our proposed R^{2}NN Model with two phrase embedding methods, compared with the baseline. Setting "WEPPE+R^{2}NN" is the result with word embedding based phrase pair embedding and our R^{2}NN Model, and "TCBPPE+R^{2}NN" is the result of translation confidence based phrase pair embedding and our R^{2}NN Model. The results with $\uparrow$ are significantly better than the baseline.

Word embedding can model translation relationship at word level, but it may not be powerful to model the phrase pair respondents at phrasal level, since the meaning of some phrases cannot be decomposed into the meaning of words. And also, translation task is difference from other NLP tasks, that, it is more important to model the translation confidence directly (the confidence of one target phrase as a translation of the source phrase), and our TCBPPE is designed for such purpose.

6.3 Effects of Global Recurrent Input Vector

In order to compare R^{2}NN with recursive network for SMT decoding, we remove the recurrent input vector in R^{2}NN to test its effect, and the results are shown in Table 3. Without the recurrent input vectors, R^{2}NN degenerates into recursive neural network (RNN).

Setting	Development	Test
WEPPE+R^{2}NN	47.23	40.81
WEPPE+RNN	37.62	33.29
TCBPPE+R^{2}NN	48.70	40.81
TCBPPE+RNN	45.11	37.33

Table 3: Experimental results to test the effects of recurrent input vector. WEPPE /TCBPPE+RNN are the results removing recurrent input vectors with WEPPE /TCBPPE.

From Table 3 we can find that, the recurrent input vector is essential to SMT performance. When we remove it from R^{2}NN, WEPPE based method drops about 10 BLEU points on development data and more than 6 BLEU points on test data. TCBPPE based method drops about 3 BLEU points on both development and test data sets. When we remove the recurrent input vectors, the representations of recursive network are generated with the child nodes, and it does not integrate global information, such as language model and distortion model, which are crucial to the performance of SMT.

6.4 Sparse Features and Recurrent Network Features

To test the contributions of sparse features and recurrent network features, we first remove all the recurrent network features to train and test our R^{2}NN model, and then remove all the sparse features to test the contribution of recurrent network features.

Setting	Development	Test
TCBPPE+R^{2}NN	48.70	40.81
SF+R^{2}NN	48.23	40.19
RNN+R^{2}NN	47.89	40.01

Table 4: Experimental results to test the effects of sparse features and recurrent network features.

The results are shown in Table 6.4. From the results, we can find that, sparse features are more effective than the recurrent network features a little bit. The sparse features can directly model the translation correspondence, and they may be more effective to rank the translation candidates, while recurrent neural network features are smoothed lexical translation confidence.

7 Conclusion and Future Work

In this paper, we propose a Recursive Recurrent Neural Network(R^2NN) to combine the recurrent neural network and recursive neural network. Our proposed R^2NN cannot only integrate global input information during each combination, but also can generate the tree structure in a recursive way. We apply our model to SMT decoding, and propose a three-step semi-supervised training method. In addition, we explore phrase pair embedding method, which models translation confidence directly. We conduct experiments on a Chinese-to-English translation task, and our method outperforms a state-of-the-art baseline about 1.5 points BLEU.

From the experiments, we find that, phrase pair embedding is crucial to the performance of SMT. In the future, we will explore better methods for phrase pair embedding to model the translation equivalent between source and target phrases. We will apply our proposed R^2NN to other tree structure learning tasks, such as natural language parsing.

Predicting Instructor's Intervention in MOOC forums

Snigdha Chaturvedi **Dan Goldwasser** **Hal Daumé III**
Department of Computer Science,
University of Maryland, College Park, Maryland
{snigdhac, goldwas1, hal}@umiacs.umd.edu

Abstract

Instructor intervention in student discussion forums is a vital component in Massive Open Online Courses (MOOCs), where personalized interaction is limited. This paper introduces the problem of predicting instructor interventions in MOOC forums. We propose several prediction models designed to capture unique aspects of MOOCs, combining course information, forum structure and posts content. Our models abstract contents of individual posts of threads using latent categories, learned jointly with the binary intervention prediction problem. Experiments over data from two *Coursera* MOOCs demonstrate that incorporating the structure of threads into the learning problem leads to better predictive performance.

1 Introduction

Ubiquitous computing and easy access to high bandwidth internet have reshaped the *modus operandi* in distance education towards Massive Open Online Courses (MOOCs). Courses offered by ventures such as Coursera and Udacity now impart inexpensive and high-quality education from field-experts to thousands of learners across geographic and cultural barriers.

Even as the MOOC model shows exciting possibilities, it presents a multitude of challenges that must first be negotiated to completely realize its potential. MOOCs platforms have been especially criticized on grounds of lacking a personalized educational experience (Edmundson, 2012). Unlike traditional classrooms, the predominant mode of interaction between students and instructors in MOOCs is via online discussion forums. Ideally, forum discussions can help make up for the lack of direct interaction, by enabling students to ask questions and clarify doubts. However, due to huge class sizes, even during the short duration of a course, MOOCs witness a very large number of threads on these forums. Owing to extremely skewed ratios of students to instructional staff, it can be prohibitively time-consuming for the instructional staff to manually follow all threads of a forum. Hence there is a pressing need for automatically *curating* the discussions for the instructors.

In this paper, we focus on identifying situations in which instructor (used interchangeably with "instructional staff" in this paper) intervention is warranted. Using existing forum posts and interactions, we frame this as a binary prediction problem of identifying instructor's intervention in forum threads. Our initial analysis revealed that instructors usually intervene on threads discussing students' issues close to a quiz or exam. They also take interest in grading issues and logistics problems. There are multiple cues specific to the MOOC setting, which when combined with the rich lexical information present in the forums, can yield useful predictive models.

Analyzing forum-postings contents and bringing the most pertinent content to the instructor's attention would help instructors receive timely feedback and design interventions as needed. From the students' perspective, the problem is evident from an examination of existing forum content, indicating that if students want instructor's input on some issues, the only way for them to get his/her attention is by 'up-voting' their votes. Fig. 1 provides some examples of this behavior. This is clearly an inefficient solution.

Our main technical contribution is introducing three different models addressing the task of predicting instructor interventions. The first uses a logistic regression model that primarily incorporates high level information about threads and posts. However, forum threads have structure which is not leveraged our initial model. We present two

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1501–1511,
Baltimore, Maryland, USA, June 23-25 2014.

"The problem summary: Anyone else having problems viewing the video lecture...very choppy. If you are also experiencing this issue; please upvote this post."
"I read that by up-voting threads and posts you can get the instructors' attention faster."
"Its is very bad to me that I achieved 10 marks in my 1st assignment and now 9 marks in my 2nd assignment, now I won't get certificate, please Course staff it is my appeal to change the passing scheme or please be lenient. Please upvote my post so that staff take this problem under consideration."

Figure 1: Sample posts that showing students desiring instructor's attention have to resolve to the inefficient method of getting their posts upvoted.

additional structured models. Both models assume that posts of a thread structure it in form of a story or a "chain of events." For example, an opening post of a thread might pose a question and the following posts can then answer or comment on the question. Our second and third models tap this linear 'chain of events' behavior by assuming that individual posts belong to latent categories which represent their textual content at an abstract level and that an instructor's decision to reply to a post is based on this chain of events (represented by the latent categories). We present two different ways of utilizing this 'chain of events' behavior for predicting instructor's intervention which can be either simply modeled as the 'next step' is this chain of events (*Linear Chain Markov Model*) or as a decision globally depending on the entire chain (*Global Chain Model*). Our experiments on two different datasets reveal that using the latent post categories helps in better prediction.

Our contributions can be summarized as:

- We motivate and introduce the important problem of predicting instructor intervention in MOOC forums
- We present two chain based models that incorporate thread structure.
- We show the utility of modeling thread structure, and the value of lexical and domain specific knowledge for the prediction task

2 Related Work

To the best of our knowledge, the problem of predicting instructor's intervention in MOOC forums has not been addressed yet. Prior work deals with analyzing general online discussion forums of social media sites (Kleinberg, 2013): such as predicting comment volume (Backstrom et al., 2013; De Choudhury et al., 2009; Wang et al., 2012; Tsagkias et al., 2009; Yano and Smith, 2010; Artzi et al., 2012) and rate of content diffusion (Kwak et al., 2010; Lerman and Ghosh, 2010; Bakshy et al., 2011; Romero et al., 2011; Artzi et al., 2012) and also question answering (Chaturvedi et al., 2014).

Wang et al. (2007) incorporate thread structure of conversations using features in email threads while Goldwasser and Daumé III (2014) use latent structure, aimed to identify relevant dialog segments, for predicting objections during courtroom deliberations. Other related work include speech act recognition in emails and forums but at a sentence level (Jeong et al., 2009), and using social network analysis to improve message classification into pre-determined types (Fortuna et al., 2007). Discussion forums data has also been used to address other interesting challenges such as extracting chatbox knowledge for use in general online forums (Huang et al., 2007) and automatically extracting answers from discussion forums (Catherine et al., 2013), subjectivity analysis of online forums (Biyani et al., 2013). Most of these methods use ideas similar to ours: identifying that threads (or discussions) have an underlying structure and that messages belong to categories. However, they operate in a different domain, which makes their goals and methods different from ours.

Our work is most closely related to that of Backstrom et al. (2013) which introduced the re-entry prediction task —predicting whether a user who has participated in a thread will later contribute another comment to it. While seemingly related, their prediction task, focusing on users who have already commented on a thread, and their algorithmic approach are different than ours. Our work is also very closely related to that of Wang et al. (2013) who predict solvedness —which predicts if there is a solution to the original problem posted in the thread. Like us, they believe that category of posts can assist in the prediction task, however, possibly owing to the complexity of general discussion forums, they had to manually create and annotate data with a sophisticated taxonomy. We do not make such assumptions.

The work presented in (Gómez et al., 2008;

Liben-Nowell and Kleinberg, 2008; Kumar et al., 2010; Golub and Jackson, 2010; Wang et al., 2011; Aumayr et al., 2011) discuss characterizing threads using reply-graphs (often trees) and learning this structure. However, this representation is not natural for the MOOC domain where discussions are relatively more focused on the thread topic and are better organized using sections within the forums.

Although most prior work focuses on discussion forums of social media sites such as Twitter or Facebook, where the dynamics of interaction is very different from MOOCs, a small number of recent work address the unique MOOC setting.

Stump et al. (2013) propose a framework for categorizing forum posts by designing a taxonomy and annotating posts manually to assist general forum analysis. Our model learns categories in a data-driven manner guided by the binary supervision (intervention decision) and serves a different purpose. Nevertheless, in Sec. 4.3 we compare the categories learnt by our models with those proposed by Stump et al. (2013).

Apart from this, recent works have looked into interesting challenges in this domain such as better peer grading models (Piech et al., 2013), code review (Huang et al., 2013; Nguyen et al., 2014), improving student engagement (Anderson et al., 2014) and understanding how students learn and code (Piech et al., 2012; Kizilcec et al., 2013; Ramesh et al., 2013).

3 Intervention Prediction Models

In this section, we explain our models in detail.

3.1 Problem Setting

In our description it is assumed that a discussion board is organized into multiple forums (representing topics such as "Assignment", "Study Group" etc.). A forum consists of multiple threads. Each thread (t) has a title and consists of multiple posts (p_i). Individual posts do not have a title and the number of posts varies dramatically from one thread to another. We address the problem of predicting if the course instructor would intervene on a thread, t. The instructor's decision to intervene, r, equals 0 when the instructor doesn't reply to the thread and 1 otherwise. The individual posts are not assumed to be labeled with any category and the only supervision given to the model during training is in form of intervention decision.

3.2 Logistic Regression (LR)

Our first attempt at solving this problem involved training a logistic regression for the binary prediction task which models $P(r|t)$.

3.2.1 Feature Engineering

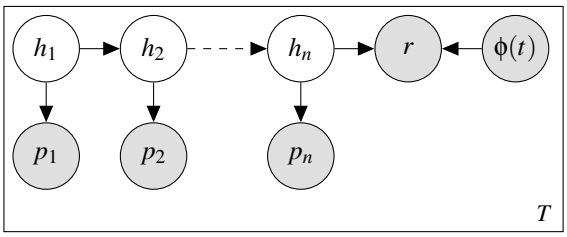
Our logistic regression model uses the following two types of features: *Thread only features* and *Aggregated post features*. 'Thread only features' capture information about the thread such as when, where, by who was the thread posted and lexical features based on the title of the thread. While these features provide a high-level information about the thread, it is also important to analyze the contents of the posts of the thread. In order to maintain a manageable feature space, we compress the features from posts and represent them using our 'Aggregated post features'.

Thread only features:

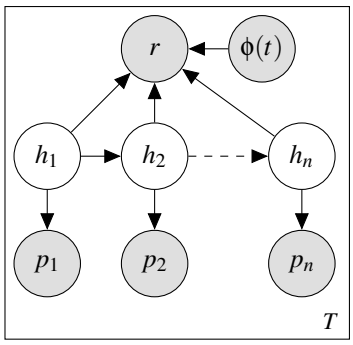
1. a binary feature indicating if the thread was started by an anonymous user
2. three binary features indicating whether the thread was marked as approved, unresolved or deleted (respectively)
3. forum id in which the thread was posted
4. time when the thread was started
5. time of last posting on the thread
6. total number of posts in the thread
7. a binary feature indicating if the thread title contains the words *lecture* or *lectures*
8. a binary feature indicating if the thread title contains the words *assignment*, *quiz*, *grade*, *project*, *exam* (and their plural forms)

Aggregated post features:

9. sum of number of votes received by the individual posts
10. mean and variance of the posting times of individual posts in the thread
11. mean of time difference between the posting times of individual posts and the closest course landmark. A course landmark is the deadline of an assignment, exam or project.
12. sum of count of occurrences of assessment related words e.g. *grade*, *exam*, *assignment*, *quiz*, *reading*, *project* etc. in the posts
13. sum of count of occurrences of words indicating technical problems e.g. *problem*, *error*
14. sum of count of occurrences of thread conclusive words like *thank you* and *thank*
15. sum of count of occurrences of *request*, *submit*, *suggest*



(a) Linear Chain Markov Model (LCMM)



(b) Global Chain Model (GCM)

Figure 2: Diagrams of the Linear Chain Markov Model (LCMM) and the Global Chain Model (GCM). p_i, r and $\phi(t)$ are observed and h_i are the latent variables. p_i and h_i represent the posts of the thread and their latent categories respectively; r represents the instructor's intervention and $\phi(t)$ represent the non-structural features used by the logistic regression model.

We had also considered and dropped (because of no performance gain) other features about identity of the user who started the thread, number of distinct participants in the thread (an important feature used by Backstrom et al. (2013)), binary feature indicating if the first and the last posts were by the same user, average number of words in the thread's posts, lexical features capturing references to the instructors in the posts etc.

3.3 Linear Chain Markov Model (LCMM)

The logistic regression model is good at exploiting the thread level features but not the content of individual posts. The 'Aggregated post features' attempt to capture this information but since the number of posts in a thread is variable, these features relied on aggregated values. We believe that considering aggregate values is not sufficient for the task in hand. As noted before, posts of a thread are not independent of each other. Instead, they are arranged chronologically such that a post is published in reply to the preceding posts and this might effect an instructor's decision to reply. For example, consider a thread that starts with a question. The following posts will be students' attempt to answer the question or raise further concerns or comment on previous posts. The instructor's post, though a future event, will be a part of this process.

For every thread, t, in the dataset:

1. Choose a start state, h_1, and emit the first post, p_1.
2. For every subsequent post, $p_i \ \forall \ i \ \in \{2 \dots n\}$:
   (a) Transition from h_{i-1} to h_i.
   (b) Emit post p_i.
3. Generate the instructor's intervention decision, r, using the last state h_n and non-structural features, $\phi(t)$.

Figure 3: Instructor's intervention decision process for the Linear Chain Markov Model.

We, therefore, propose to model this complete process using a linear chain markov model shown in Fig. 2a. The model abstractly represents the information from individual posts (p_i) using latent categories (h_i). The intervention decision, r, is the last step in the chain and thus incorporates information from the individual posts. It also depends on the thread level features: 'Thread only features' and the 'Aggregated post features' jointly represented by $\phi(t)$ (also referred to as the non-structural features). This process is explained in Fig. 3.

We use hand-crafted features to model the dynamics of the generative process. Whenever a latent state emits a post or transits to another latent state (or to the final intervention decision state), emission and transition features get fired which are then multiplied by respective weights to compute a thread's 'score':

$$f_w(t, p) = \max_h [\mathbf{w} \cdot \boldsymbol{\phi}(\boldsymbol{p}, \boldsymbol{r}, \boldsymbol{h}, \boldsymbol{t})] \qquad (1)$$

Note that the non-structural features, $\phi(t)$, also contribute to the final score.

3.3.1 Learning and Inference

During training we maximize the combined scores of all threads in the dataset using a generic EM style algorithm. The supervision in this model is provided only in form of the observed intervention decision, r and the post categories, h_i are hid-

den. The model uses the pseudocode shown in Algorithm 1 to iteratively refine the weight vectors. In each iteration, the model first uses viterbi algorithm to decode thread sequences with the current weights w_t to find optimal highest scoring latent state sequences that agree with the observed intervention state ($r = r'$). In the next step, given the latent state assignments from the previous step, a structured perceptron algorithm (Collins, 2002) is used to update the weights w_{t+1} using weights from the previous step, w_t, initialization.

Algorithm 1 Training algorithm for LCMM

1: **Input:** Labeled data $D = \{(t, p, r)_i\}$
2: **Output:** Weights w
3: **Initialization:** Set w_j randomly, $\forall j$
4: **for** $t : 1$ to N **do**
5: $\hat{h_i} = \arg\max_h[\mathbf{w_t} \cdot \boldsymbol{\phi(p, r, h, t)}]$ such that $r = r_i \forall i$
6: w_{t+1} = StructuredPerceptron$(t, p, \hat{h}, r)$
7: **end for**
8: return w

While testing, we use the learned weights and viterbi decoding to compute the intervention state and the best scoring latent category sequence.

3.3.2 Feature Engineering

In addition to the 'Thread Only Features' and the 'Aggregated post features', $\phi(t)$ (Sec. 3.2.1, this model uses the following emission and transition features:

Post Emission Features:

1. $\phi(p_i, h_i)$ = count of occurrences of question words or question marks in p_i if the state is h_i; 0 otherwise.
2. $\phi(p_i, h_i)$ = count of occurrences of thank words (*thank you* or *thanks*) in p_i if the state is h_i; 0 otherwise.
3. $\phi(p_i, h_i)$ = count of occurrences of greeting words (e.g. *hi*, *hello*, *good morning*, *welcome* etc) in p_i if the state is h_i; 0 otherwise.
4. $\phi(p_i, h_i)$ = count of occurrences of assessment related words (e.g. *grade*, *exam*, *assignment*, *quiz*, *reading*, *project* etc.) in p_i if the state is h_i; 0 otherwise.
5. $\phi(p_i, h_i)$ = count of occurrences of *request*, *submit* or *suggest* in p_i if the state is h_i; 0 otherwise.
6. $\phi(p_i, h_i)$ = log(course duration/$t(p_i)$) if the state is h_i; 0 otherwise. Here $t(p_i)$ is the difference between the posting time of p_i and the closest course landmark (assignment or project deadline or exam).
7. $\phi(p_i, p_{i-1}, h_i)$ = difference between posting times of p_i and p_{i-1} normalized by course duration if the state is h_i; 0 otherwise.

Transition Features:

1. $\phi(h_{i-1}, h_i) = 1$ if previous state is h_{i-1} and current state is h_i; 0 otherwise.
2. $\phi(h_{i-1}, h_i, p_i, p_{i-1})$ = cosine similarity between p_{i-1} and p_i if previous state is h_{i-1} and current state is h_i; 0 otherwise.
3. $\phi(h_{i-1}, h_i, p_i, p_{i-1})$ = length of p_i if previous state is h_{i-1}, p_{i-1} has non-zero question words and current state is h_i; 0 otherwise.
4. $\phi(h_n, r) = 1$ if last post's state is h_n and intervention decision is r; 0 otherwise.
5. $\phi(h_n, r, p_n) = 1$ if last post's state is h_n, p_n has non-zero question words and intervention decision is r; 0 otherwise.
6. $\phi(h_n, r, p_n)$ = log(course duration/$t(p_n)$) if last post's state is h_n and intervention decision is r; 0 otherwise. Here $t(p_n)$ is the difference between the posting time of p_n and the closest course landmark (assignment or project deadline or exam).

3.4 Global Chain Model (GCM)

In this model we propose another way of incorporating the chain structure of a thread. Like the previous model, this model also assumes that posts belong to latent categories. It, however, doesn't model the instructor's intervention decision as a step in the thread generation process. Instead, it assumes that instructor's decision to intervene is dependent on all the posts in the threads, modeled using the latent post categories. This model is shown in Fig. 2b. Assuming that p represents posts of thread t, h represents the latent category assignments, r represents the intervention decision; feature vector, $\boldsymbol{\phi(p, r, h, t)}$, is extracted for each thread and using the weight vector, $\mathbf{w}$, this model defines a decision function, similar to what is shown in Equation 1.

3.4.1 Learning and Inference

Similar to the traditional maximum margin based Support Vector Machine (SVM) formulation, our model's objective function is defined as:

$$\min_w \frac{\lambda}{2}||\mathbf{w}||^2 + \sum_j^T l(-r_j f_w(t_j, p_j)) \quad (2)$$

where λ is the regularization coefficient, t_j is the j^{th} thread with intervention decision r_j and p_j are the posts of this thread. $\mathbf{w}$ is the weight vector, $l(\cdot)$ is the squared hinge loss function and $f_w(t_j, p_j)$ is defined in Equation 1.

Replacing the term $f_w(t_j, p_j)$ with the contents of Equation 1 in the minimization objective above, reveals the key difference from the traditional SVM formulation - the objective function has a maximum term inside the global minimization problem making it non-convex.

We, therefore, employ the optimization algorithm presented in (Chang et al., 2010) to solve this problem. Exploiting the semi-convexity property (Felzenszwalb et al., 2010), the algorithm works in two steps, each executed iteratively. In the first step, it determines the latent variable assignments for positive examples. The algorithm then performs two step iteratively - first it determines the structural assignments for the negative examples, and then optimizes the fixed objective function using a cutting plane algorithm. Once this process converges for negative examples, the algorithm reassigns values to the latent variables for positive examples, and proceeds to the second step. The algorithm stops once a local minimum is reached. A somewhat similar approach, which uses the Convex-Concave Procedure (CCCP) is presented by (Yu and Joachims, 2009).

At test time, given a thread, t, and it posts, p, we use the learned weights to compute $f_w(t, p)$ and classify it as belonging to the positive class (instructor intervenes) if $f_w(t, p) \geq 0$.

3.4.2 Feature Engineering

The feature set used by this model is very similar to the features used by the previous model. In addition to the non-structural features used by the logistic regression model (Sec. 3.2.1), it uses all the Post Emission features and the three transition features represented by $\phi(h_{i-1}, h_i)$ and $\phi(h_{i-1}, h_i, p_i, p_{i-1})$ as described in Sec. 3.3.2.

4 Empirical Evaluation

This section describes our experiments.

4.1 Datasets and Evaluation Measure

For our experiments, we have used the forum content of two MOOCs from different domains (science and humanities), offered by *Coursera*[1], a leading education technology company. Both courses were taught by professors from the University of Maryland, College Park.

Genes and the Human Condition (From Behavior to Biotechnology) (GHC) dataset. [2] This course was attended by 30,000 students and the instructional staff comprised of 2 instructors, 3 Teaching Assistants and 56 technical support staff. The discussion forum of this course consisted of 980 threads composed of about 3,800 posts.

Women and the Civil Rights Movement (WCR) dataset. [3] The course consisted of a classroom of about 14,600 students, 1 instructor, 6 Teaching Assistants and 49 support staff. Its discussion forum consisted of 800 threads and 3,900 posts.

We evaluate our models on held-out test sets. For the GHC dataset, the test set consisted of 186 threads out of which the instructor intervened on 24 while, for the WCR dataset, the instructor intervened on 21 out of 155 threads.

Also, it was commonly observed that after an instructor intervenes on a thread, its posting and/or viewing behavior increases. We, therefore, only consider the student posts until the instructor's first intervention. Care was also taken to not use features that increased/decreased disproportionately because of the instructor's intervention such as number of views or votes of a thread.

In our evaluation we approximate instructor's 'should reply' instances with those where the instructor indeed replied. Unlike general forum users, we believe that the correlation between the two scenarios is quite high for instructors. It is their responsibility to reply, and by choosing to a MOOC, they have 'bought in' to the idea of forum participation. The relatively smaller class sizes of these two MOOCs also ensured that most threads were manually reviewed, thus reducing instances of 'missed' threads while retaining the posting behavior and content of a typical MOOC.

4.2 Experimental Results

Since the purpose of solving this problem is to identify the threads which should be brought to the notice of the instructors, we measure the performance of our models using F-measure of the positive class. The values of various parameters were selected using 10-fold Cross Validation on

[1] https://www.coursera.org/

[2] https://www.coursera.org/course/genes

[3] https://www.coursera.org/course/womencivilrights

Model	Genes and the Human Condition (GHC)			Women and the Civil Rights (WCR)		
	P	R	F	P	R	F
LR	44.44	16.67	24.24	66.67	15.38	25.00
J48	45.50	20.80	28.55	25.00	23.10	24.01
LCMM	33.33	29.17	31.11	42.86	23.08	**30.00**
GCM	60.00	25.00	**35.29**	50.00	18.52	27.03

Table 1: Held-out test set performances of chain models, LCMM and GCM, are better than that of the unstructured models, LR and J48.

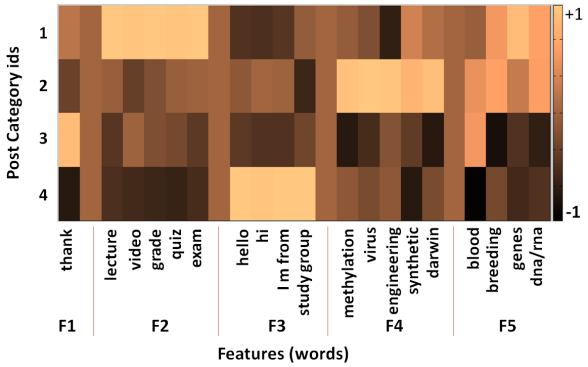


Figure 4: Visualization of lexical contents of the categories learnt by our model from the GHC dataset. Each row is a category and each column represents a feature vector. Bright cream color represents high values while lower values are represented by darker shades. Dark beige columns are used to better separate the five feature clusters, F1-F5, which represent words that are common in thanking, logistics-related, introductory, syllabus related and miscellaneous posts respectively. Categories 1,2,3 and 4 are dominated by F2, F4, F1 and F3 respectively indicating a semantic segregation of posts by our model's categories.

the training set. Table 1 presents the performances of the proposed models on the held-out test sets. We also report performance of a decision tree (J48) on the test sets for sake of comparison.

We can see that the chain based models, Linear Chain Markov Model (LCMM) and Global Chain Model (GCM), outperform the unstructured models, namely Logistic regression (LR) and Decision Trees (J48). This validates our hypothesis that using the post structure results in better modeling of instructor's intervention.

The table also reveals that GCM yields high precision and low recall values, which is possibly due to the model being more conservative owing to information from all posts of the thread.

4.3 Visual Exploration of Categories

Our chain based models assume that posts belong to different (latent) categories and use these categories to make intervention predictions. Since this process of discovering categories is data driven, it would be interesting to examine the contents of these categories. Fig. 4 presents a heat map of lexical content of categories identified by LCMM from the GHC dataset. The value of H (number of categories) was set to be 4 and was predetermined during the model selection procedure. Each row of the heat map represents a category and the columns represent values of individual features, $f(w, c)$, defined as: $f(w, c) = \frac{C(w,c)}{<C(w,c)>}$ where, $C(w, c)$ is total count of occurrences of a word, w, in all posts assigned to category, c and $< C(w, c) >$ represents its expected count based on its frequency in the dataset. While the actual size of vocabulary is huge, we use only a small subset of words in our feature vector for this visualization. These feature values, after normalization, are represented in the heat map using colors ranging from bright cream (high value) to dark black (low value). The darker the shade of a cell, the lower is the value represented by it.

For visual convenience, the features are manually clustered into five groups (F1 to F5) each separated by a dark beige colored column in the heat map. The first column of the heat map represents the F1 group which consists of words like *thank you, thanks* etc. These words are characteristic of posts that mark either the conclusion of a resolved thread or are posted towards the end of the course. Rows corresponding to the category 3 in Table 2 show two examples of such posts. Similarly, F2 represents the features related to logistics of the course and F3 captures introductory posts by new students. Finally, F4 contains words that are closely related to the subfield of gene and human conditions and would appear in posts that discuss specific aspects or chapters of the course con-

tents, while F5 contains general buzz words that would appear frequently in any biology course.

Analyzing individual rows of the heat map, we can see that out of F1 to F4, Categories 1, 2, 3 and 4 are dominated by logistics (F2), course content related (F4), thank you (F1) and introductory posts (F3) respectively, represented by bright colors in their respective rows. We also observe similar correlations while examining the columns of the heat map. Also, F5, which contains words common to the gene and human health domain, is scattered across multiple categories. For example, *dna/rna* and *breeding* are sufficiently frequent in category 1 as well as 2.

Table 2 gives examples of representative posts from the four clusters. Due to space constraints, we show only part of the complete post. We can see that these examples agree with our observations from the heat map.

Furthermore, as noted in Sec. 2, we compare the semantics of clusters learnt by our models with those proposed by Stump et al. (2013) even though the two categorizations are not directly comparable. Nevertheless, generally speaking, our category 1 corresponds to Stump et al. (2013)'s *Course structure/policies* and category 2 corresponds to *Content*. Interestingly, categories 3 and 4, which represent valedictory and introductory posts, correspond to a single *Social/affective* from the previous work.

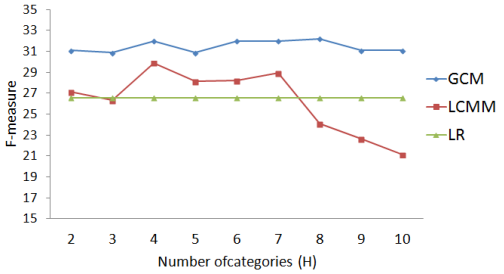
We can, therefore, conclude that the model, indeed splits the posts into categories that look semantically coherent to the human eyes.

4.4 Choice of Number of Categories

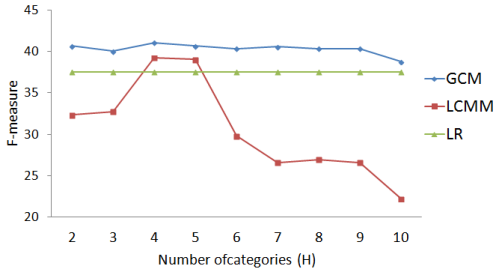
Our chain based models, assigning forum posts to latent categories, are parameterized with H, the number of categories. We therefore, study the sensitivity of our models to this parameter. Fig. 5, plots the 10-fold cross validation performance of the models with increasing values of H for the two datasets. Interestingly, the sensitivity of the two models to the value of H is very different.

The LCMM model's performance fluctuates as the value of H increases. The initial performance improvement might be due to an increase in the expressive power of the model. Performance peaks at $H = 4$ and then decreases, perhaps owing to over-fitting of the data.

In contrast, GCM performance remains steady for various values of H which might be attributed



(a) Genes and the Human Condition dataset



(b) Women and the Civil Rights Movement dataset

Figure 5: Cross validation performances of the two models with increasing number of categories.

to the explicit regularization coefficient which helps combat over-fitting, by encouraging zero weights for unnecessary categories.

4.5 How important are linguistic features?

We now focus on the structure independent features and experiment with their predictive value, according to types. We divide the features used by the LR into the following categories:[4]

- Full: set of all features (feature no. 1 to 15)
- lexical: based on content of thread titles and posts (feature no. 7 to 8 and 12 to 13)
- landmark: based on course landmarks (e.g, exams, quizzes) information (feature no. 11)
- MOOCs-specific: features specific to the MOOCs domain (lexical + landmark features)
- post: based only on aggregated posts information (feature no. 9 to 15)
- temporal: based on posting time patterns (feature no. 4, 5 and 10)

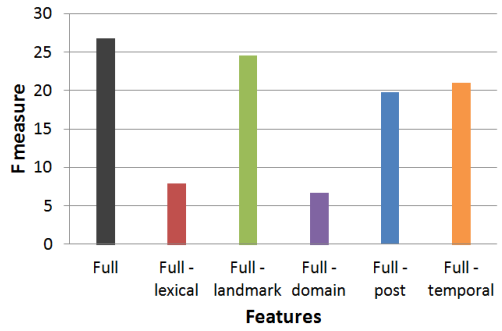
Fig. 6 shows 10-fold cross validation F-measure of the positive class for LR when different types of features are excluded from the full set.

The figure reveals that the MOOCs-specific features (purple bar) are important for both the datasets indicating a need for designing specialized models for forums analysis in this domain.

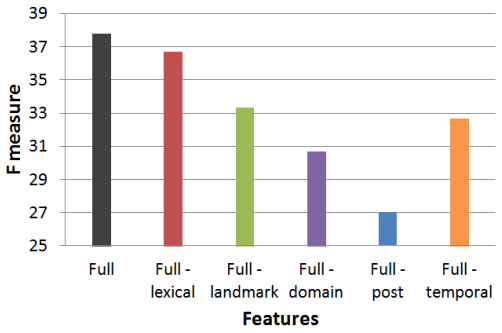
[4]Please refer to Sec 3.2.1 for description of the feature id.

Category	Example posts
1	'I'm having some issues with video playback. I have downloaded the videos to my laptop...'
1	'There was no mention of the nuclear envelope in the Week One lecture, yet it was in the quiz. Is this a mistake?'
2	'DNA methylation is a crucial part of normal development of organisms and cell differentiation in higher organisms...'
2	'In the lecture, she said there are...I don't see how tumor-suppressor genes are a cancer group mutation.'
3	'Thank you very much for a most enjoyable and informative course.'
3	'Great glossary! Thank you!'
4	'Hello everyone, I'm ... from the Netherlands. I'm a life science student.
4	'Hi, my name is ... this is my third class with coursera'

Table 2: Representative posts from the four categories learnt by our model. Due to space and privacy concerns we omit some parts of the text, indicated by ". . . ".



(a) Genes and the Human Condition dataset



(b) Women and the Civil Rights Movement dataset

Figure 6: Cross validation performances of the various feature types for the two datasets.

Also, lexical features (red bar) and post features (blue bar) have pretty dramatic effects in GHC and WCR data respectively.

Interestingly, removing the landmark feature set (green bar) causes a considerable drop in predictive performance, even though it consists of only one feature. Other temporal features (orange bar) also turn out to be important for the prediction. From a separate instructor activity vs time graph (not shown due to space constraints), we observed that instructors tend to get more active as the course progresses and their activity level also increases around quizzes/exams deadlines.

We can, therefore, conclude that all feature types are important and that lexical as well as MOOC specific analysis is necessary for modeling instructor's intervention.

5 Conclusion

One of the main challenges in MOOCs is managing student-instructor interaction. The massive scale of these courses rules out any form of personalized interaction, leaving instructors with the need to go over the forum discussions, gauge student reactions and selectively respond when appropriate. This time consuming and error prone task stresses the need for methods and tools supplying this actionable information automatically.

This paper takes a first step in that direction, and formulates the novel problem of predicting instructor intervention in MOOC discussion forums. Our main technical contribution is to construct predictive models combining information about forum post content and posting behavior with information about the course and its landmarks.

We propose three models for addressing the task. The first, a logistic regression model is trained on thread level and aggregated post features. The other two models take thread structure into account when making the prediction. These models assume that posts can be represented by categories which characterize post content at an abstract level, and treat category assignments as latent variables organized according to, and influenced by, the forum thread structure.

Our experiments on forum data from two different *Coursera* MOOCs show that utilizing thread structure is important for predicting instructor's behavior. Furthermore, our qualitative analysis shows that our latent categories are semantically coherent to human eye.

Abstract

It is very import for Chinese language processing with the aid of an efficient input method engine (IME), of which pinyin-to-Chinese (PTC) conversion is the core part. Meanwhile, though typos are inevitable during user pinyin inputting, existing IMEs paid little attention to such big inconvenience. In this paper, motivated by a key equivalence of two decoding algorithms, we propose a joint graph model to globally optimize PTC and typo correction for IME. The evaluation results show that the proposed method outperforms both existing academic and commercial IMEs.

1 Introduction

1.1 Chinese Input Method

The daily life of Chinese people heavily depends on Chinese input method engine (IME), no matter whether one is composing an E-mail, writing an article, or sending a text message. However, every Chinese word inputted into computer or cellphone cannot be typed through one-to-one mapping of key-to-letter inputting directly, but has to go through an IME as there are thousands of Chinese characters for inputting while only 26 letter keys are available in the keyboard. An IME is an essential software interface that maps Chinese characters into English letter combinations. An efficient IME will largely improve the user experience of Chinese information processing.

Nowadays most of Chinese IMEs are pinyin based. Pinyin is originally designed as the phonetic symbol of a Chinese character (based on the standard modern Chinese, mandarin) , using Latin letters as its syllable notation. For example, the pinyin of the Chinese character "爱"(love) is "ài". Most characters usually have unique pinyin representations, while a few Chinese characters may be pronounced in several different ways, so they may have multiple pinyin representations. The advantage of pinyin IME is that it only adopts the pronunciation perspective of Chinese characters so that it is simple and easy to learn. But there are only less than 500 pinyin syllables in standard modern Chinese, compared with over 6,000 commonly used Chinese characters, which leads to serious ambiguities for pinyin-to-character mapping. Modern pinyin IMEs mostly use a "*sentence-based*" decoding technique (Chen and Lee, 2000) to alleviate the ambiguities. "*Sentence based*" means that IME generates a sequence of Chinese characters upon a sequence of pinyin inputs with respect to certain statistical criteria.

1.2 Typos and Chinese Spell Checking

Written in Chinese characters but not alphabets, spell checking for Chinese language is quite different from the same task for other languages. Since Chinese characters are entered via IME, those user-made typos do not immediately lead to spelling errors. When a user types a wrong letter, IME will be very likely to fail to generate the expected Chinese character sequence. Normally, the user may immediately notice the inputting error and then make corrections, which usually means doing a bunch of extra operations like cursor

movement, deletion and re-typing. Thus there are two separated sub-tasks for Chinese spell checking: 1. *typo checking* for user typed pinyin sequences which should be a built-in module in IME, and 2. *spell checking* for Chinese texts in its narrow sense, which is typically a module of word processing applications (Yang et al., 2012b). These two terms are often confused especially in IME related works such as (Chen and Lee, 2000) and (Wu et al., 2009).

Pinyin typos have always been a serious problem for Chinese pinyin IMEs. The user may fail to input the completely right pinyin simply because he/she is a dialect speaker and does not know the exact pronunciation for the expected character. This may be a very common situation since there are about seven quite different dialects in Chinese, among which being spoken languages, six are far different from the standard modern Chinese, mandarin. With the boom of smart-phones, pinyin typos worsen due to the limited size of soft keyboard, and the lack of physical feedback on the touch screen. However, existing practical IMEs only provide small patches to deal with typos such as *Fuzzy Pinyin* (Wu and Chen, 2004) and other language specific errors (Zheng et al., 2011b).

Typo checking and correction has an important impact on IME performance. When IME fails to correct a typo and generate the expected sentence, the user will have to take much extra effort to move the cursor back to the mistyped letter and correct it, which leads to very poor user experience (Jia and Zhao, 2013).

2 Related Works

The very first approach for Chinese input with typo correction was made by (Chen and Lee, 2000), which was also the initial attempt of "sentence-based" IME. The idea of "statistical input method" was proposed by modeling PTC conversion as a hidden Markov model (HMM), and using Viterbi (Viterbi, 1967) algorithm to decode the sequence. They solved the typo correction problem by decomposing the conditional probability $P(H|P)$ of Chinese character sequence H given pinyin sequence P into a language model $P(w_i|w_{i-1})$ and a typing model $P(p_i|w_i)$. The typing model that was estimated on real user input data was for typo correction. However, real user input data can be very noisy and not very convenient to obtain. As we will propose a joint model in this paper, such an individual typing model is not necessarily built in our approach.

(Zheng et al., 2011a) developed an IME system with typo correction called CHIME using noisy channel error model and language-specific features. However their model depended on a very strong assumption that input pinyin sequence should have been segmented into pinyin words by the user. This assumption does not really hold in modern "sentence-based" IMEs. We release this assumption since our model solves segmentation, typo correction and PTC conversion jointly.

Besides the common HMM approach for PTC conversion, there are also various methods such as: support vector machine (Jiang et al., 2007), maximum entropy (ME) model (Wang et al., 2006), conditional random field (CRF) (Li et al., 2009) and statistical machine translation (SMT) (Yang et al., 2012a; Wang et al., 2013c; Zhang and Zhao, 2013), etc.

Spell checking or typo checking was first proposed for English (Peterson, 1980). (Mays et al., 1991) addressed that spell checking should be done within a context, i.e., a sentence or a long phrase with a certain meaning, instead of only in one word. A recent spell correction work is (Li et al., 2006), where a distributional similarity was introduced for spell correction of web queries.

Early attempts for Chinese spelling checking could date back to (Chang, 1994) where character tables for similar shape, pronunciation, meaning, and input-method-code characters were proposed. More recently, the 7th SIGHAN Workshop on Chinese Language Processing (Yu et al., 2013) held a shared task on Chinese spell checking. Various approaches were made for the task including language model (LM) based methods (Chen et al., 2013), ME model (Han and Chang, 2013), CRF (Wang et al., 2013d; Wang et al., 2013a), SMT (Chiu et al., 2013; Liu et al., 2013), and graph model (Jia et al., 2013), etc.

3 Pinyin Input Method Model

3.1 From English Letter to Chinese Sentence

It is a rather long journey from the first English letter typed on the keyboard to finally a completed Chinese sentence generated by IME. We will first take an overview of the entire process.

The average length of pinyin syllables is about 3 letters. There are about 410 pinyin syllables used in the current pinyin system. Each pinyin sylla-

ble has a bunch of corresponding Chinese characters which share the same pronunciation represented by the syllable. The number of those homophones ranges from 1 to over 300. Chinese characters then form words. But word in Chinese is a rather vague concept. Without word delimiters, linguists have argued on what a Chinese word really is for a long time and that is why there is always a primary word segmentation treatment in most Chinese language processing tasks (Zhao et al., 2006; Huang and Zhao, 2007; Zhao and Kit, 2008; Zhao et al., 2010; Zhao and Kit, 2011; Zhao et al., 2013). A Chinese word may contain from 1 to over 10 characters due to different word segmentation conventions. Figure 1 demonstrates the relationship of pinyin and word, from pinyin letters "*nihao*" to the word "你好 *(hello)*". Typically, an IME takes the pinyin input, segments it into syllables, looks up corresponding words in a dictionary and generates a sentence with the candidate words.

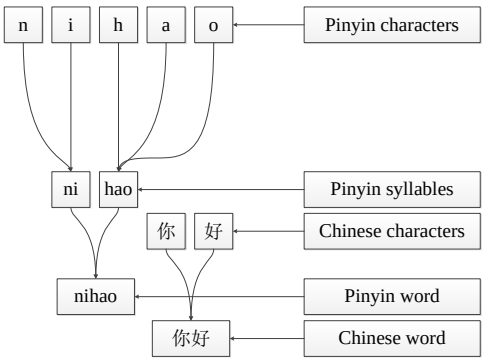

Figure 1: Relationship of pinyin and words

3.2 Pinyin Segmentation and Typo Correction

Non-Chinese users may feel confused or even surprised if they know that when typing pinyin through an IME, Chinese IME users will never enter delimiters such as "Space" key to segment either pinyin syllables or pinyin words, but just input the entire un-segmented pinyin sequence. For example, if one wants to input "你好世界 *(Hello world)*", he will just type "*nihaoshijie*" instead of segmented pinyin sequence "*ni hao shi jie*". Nevertheless, pinyin syllable segmentation is a much easier problem compared to Chinese word segmentation. Since pinyin syllables have a very limited vocabulary and follow a set of regularities strictly, it is convenient to perform pinyin syllable segmentation by using rules. But as the pinyin input is not segmented, it is nearly impossible to adopt previous spell checking methods for English to pinyin typo checking, although techniques for English spell checking have been well developed. A bit confusing but interesting, pinyin typo correction and segmentation come as two sides of one problem: when a pinyin sequence is mistyped, it is unlikely to be correctly segmented; when it is segmented in an awkward way, it is likely to be mistyped.

Inspired by (Yang et al., 2012b) and (Jia et al., 2013), we adopt the graph model for Chinese spell checking for pinyin segmentation and typo correction, which is based on the shortest path word segmentation algorithm (Casey and Lecolinet, 1996). The model has two major steps: segmentation and correction.

3.2.1 Pinyin Segmentation

The shortest path segmentation algorithm is based on the idea that a reasonable segmentation should minimize the number of segmented units. For a pinyin sequence $p_1 p_2 \dots p_L$, where p_i is a letter, first a directed acyclic graph (DAG) $G_S = (\mathbb{V}, \mathbb{E})$ is built for pinyin segmentation step. The vertex set $\mathbb{V}$ consists of the following parts:

- Virtual start vertex S_0 and end vertex S_E;
- Possible legal syllables fetched from dictionary $\mathbb{D}_p$ according to the input pinyin sequence:

$$\{S_{i,j} | S_{i,j} = p_i \dots p_j \in \mathbb{D}_p\};$$

- The letter itself as a fallback no matter if it is a legal pinyin syllable or not:

$$\{S_i | S_i = p_i\}.$$

The vertex weights w_S are all set to 0. The edges are from a syllable to all syllables next to it:

$$\mathbb{E} = \{E(S_{i,j} \to S_{j+1,k}) | S_{i,j}, S_{j+1,k} \in \mathbb{V}\}.$$

The edge weight the negative logarithm of conditional probability $P(S_{j+1,k}|S_{i,j})$ that a syllable $S_{i,j}$ is followed by $S_{j+1,k}$, which is give by a bigram language model of pinyin syllables:

$$W_{E(S_{i,j} \to S_{j+1,k})} = -\log P(S_{j+1,k}|S_{i,j})$$

The shortest path P^* on the graph is the path P with the least sum of weights:

$$P^* = \underset{(v,E) \in G \wedge (v,E) \in P}{\arg\min} \sum_v w_v + \sum_E W_E.$$

Computing the shortest path from S_0 to S_E on G_S yields the best segmentation. This is the single source shortest path (SSSP) problem on DAG which has an efficient algorithm by preprocessing the DAG with topology sort, then traversing vertices and edges in topological order. It has the time complexity of $O(|\mathbb{V}| + |\mathbb{E}|)$. For example, one intends to input "你好世界 *(Hello world)*" by typing "*nihaoshijie*", but mistyped as "*mihaoshijiw*". The graph for this input is shown in Figure 2. The shortest path, i.e., the best segmentation is "*mi hao shi ji w*". We will continue to use this example in the rest of this paper.

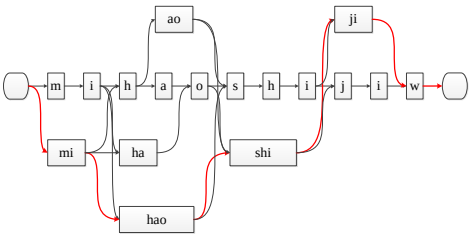

Figure 2: Graph model for pinyin segmentation

3.2.2 Pinyin Typo Correction

Next in the correction step, for the segmented pinyin sequence $S_1, S_2, \ldots, S_M$, a graph G_c is constructed to perform typo correction. The vertex set $\mathbb{V}$ consists of the following parts:

- Virtual start vertex S'_0 and end vertex S'_E with vertex weights of 0;
- All possible syllables similar to original syllable in G_s. If the adjacent syllables can be merged into a legal syllable, the merged syllable is also added into $\mathbb{V}$:

$$\{S'_{i,j} | S'_{i,j} = S'_i \ldots S'_j \in \mathbb{D}_p, \\ S'_k \sim S_k, k = i \le j\},$$

where the similarity $\sim$ is measured in Levenshtein distance (Levenshtein, 1966). Syllables with Levenshtein distance under a certain threshold are considered as similar:

$$\mathcal{L}(S_i, S_j) < T \leftrightarrow S_i \sim S_j.$$

The vertex weight is the Levenshtein distance multiply by a normalization parameter:

$$w_{S'_{i,j}} = \beta \sum_{k-i}^{j} \mathcal{L}(S'_k, S_k).$$

Similar to G_s, the edges are from one syllable to all syllables next to it and edge weights are the conditional probabilities between them. Computing the shortest path from S'_0 to S'_E on G_c yields the best typo correction result. In addition, the result has been segmented so far. Considering our running example, the graph G_c is shown in Figure 3, and the typo correction result is "*mi hao shi jie*".

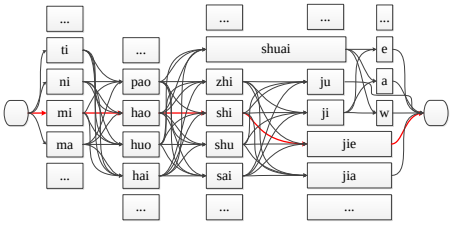

Figure 3: Graph model for pinyin typo correction

Merely using the above model, the typo correction result is not satisfying yet, no matter how much effort is paid. The major reason is that the basic semantic unit of Chinese language is actually word (tough vaguely defined) which is usually composed of several characters. Thus the conditional probability between characters does not make much sense. In addition, a pinyin syllable usually maps to dozens or even hundreds of corresponding homophonic characters, which makes the conditional probability between syllables much more noisy. However, using pinyin words instead of syllables is not a wise choice because pinyin word segmentation is not so easy a task as syllable segmentation. To make typo correction better, we consider to integrate it with PTC conversion using a joint model.

3.3 Hidden Markov Model for Pinyin-to-Chinese Conversion

PTC conversion has long been viewed as a decoding problem using HMM. We continue to follow this formalization. The best Chinese character sequence W^* for a given pinyin syllable sequence S is the one with the highest conditional probability $P(W|S)$ that

$$\begin{aligned} W^* &= \arg\max_W P(W|S) \\ &= \arg\max_W \frac{P(W)P(S|W)}{P(S)} \\ &= \arg\max_W P(W)P(S|W) \\ &= \arg\max_{w_1, w_w, \ldots, w_M} \prod_{w_i} P(w_i|w_{i-1}) \prod_{w_i} P(s_i|w_i) \end{aligned}$$

In the HMM for pinyin IME, observation states are pinyin syllables, hidden states are Chinese words, emission probability is $P(s_i|w_i)$, and transition probability is $P(w_i|w_{i-1})$. Note the transition probability is the conditional probability between words instead of characters. PTC conversion is to decode the Chinese word sequence from the pinyin sequence. The Viterbi algorithm (Viterbi, 1967) is used for the decoding.

The shortest path algorithm for typo correction and Viterbi algorithm for PTC conversion are very closely related. It has been strictly proven by (Forney, 1973) that the sequence decoding problem on HMM is formally identical to finding a shortest path on a certain graph, which can be constructed in the following manner.

Consider a first order HMM with all possible observations $\mathbb{O} = \{o_1, o_2, \ldots, o_M\}$, hidden states $\mathbb{S} = \{s_1, s_2, \ldots, s_N\}$, a special start state s_0, emission probabilities $(\mathcal{E}_{s_i,o_k}) = P(o_k|s_i)$, transition probabilities $(\mathcal{T}_{s_i,s_j}) = P(s_j|s_i)$, and start probabilities $(\mathcal{S}_{s_i}) = P(s_i|s_0)$. For an observation sequence of T time periods $Y = \{y_1, y_2, \ldots, y_T | y_t \in \mathbb{O}, t = 1, \ldots, T\}$, the decoding problem is to find the best corresponding hidden state sequence X^* with the highest probability, i.e.,

$$X^* = \arg\max_{x_1, x_t \in \mathbb{S}} \mathcal{S}_{x_1} \mathcal{E}_{x_1,y_1} \prod_{t=2}^{T} \mathcal{E}_{x_t,y_t} \mathcal{T}_{x_{t-1},x_t}. \quad (1)$$

Then we will construct a DAG $G = (\mathbb{V}, \mathbb{E})$ upon the HMM. The vertex set $\mathbb{V}$ includes:

- Virtual start vertex v_0 and end vertex v_E with vertex weight of 0;
- Normal vertices v_{x_t}, where $t = 1, \ldots, T$, and $\forall x_t \in \mathbb{S}$. The vertex weight is the negative logarithm of emission probability:

$$w_{v_{x_t}} = -\log \mathcal{E}_{x_t,y_t}.$$

The edge set $\mathbb{E}$ includes:

- Edges from the start vertex $E(v_0 \to v_{x_1})$ with edge weight

$$W_{E(v_0 \to v_{x_1})} = -\log \mathcal{S}_{x_1},$$

where $\forall x_1 \in \mathbb{S}$;

- Edges to the end vertex $E(v_{x_T} \to v_E)$ with vertex weights of 0;
- Edges between adjacent time periods $E(v_{x_{t-1}} \to v_{x_t})$ with edge weight

$$W_{E(v_{x_{t-1}} \to v_{x_t})} = -\log \mathcal{T}_{x_{t-1},x_t},$$

where $t = 2, \ldots, T$, and $\forall x_t, x_{t-1} \in \mathbb{S}$.

The shortest path P^* from v_0 to v_E is the one with the least sum of vertex and edge weights, i.e.,

$$\begin{aligned} P^* &= \arg\min_{v_{x_t} \in \mathbb{V}} \sum_{t=1}^{T} (w_{v_{x_t}} + W_{E(v_{x_{t-1}} \to v_{x_t})}) \\ &= \arg\min_{v_{x_1}, v_{x_t} \in \mathbb{V}} \{-\log \mathcal{S}_{x_1} - \log \mathcal{E}_{x_1,y_1} \\ &\quad + \sum_{t=2}^{T} (-\log \mathcal{E}_{x_t,y_t} - \log \mathcal{T}_{x_{t-1},x_t})\} \\ &= \arg\max_{v_{x_1}, v_{x_t} \in \mathbb{V}} \mathcal{S}_{x_1} \mathcal{E}_{x_1,y_1} \prod_{t=2}^{T} \mathcal{E}_{x_t,y_t} \mathcal{T}_{x_{t-1},x_t}. \quad (2) \end{aligned}$$

The optimization goal of P^* in Equation (2) is identical to that of X^* in Equation (1).

3.4 Joint Graph Model For Pinyin IME

Given HMM decoding problem is identical to SSSP problem on DAG, we propose a joint graph model for PTC conversion with typo correction. The joint graph model aims to find the global optimal for both PTC conversion and typo correction on the entire input pinyin sequence. The graph $G = (\mathbb{V}, \mathbb{E})$ is constructed based on graph G_c for typo correction in Section 3.2. The vertex set $\mathbb{V}$ consists of the following parts:

- Virtual start vertex V_0 and end vertex V_E with vertex weight of 0;
- Adjacent pinyin syllables in G_c are merged into pinyin words. Corresponding Chinese words are fetched from a PTC dictionary $\mathbb{D}_c$, which is a dictionary maps pinyin words to Chinese words, and added as vertices:

$$\{V_{i,j} | \forall V_{i,j} \in \mathbb{D}_c[S'_i \ldots S'_j], i \le j\};$$

The vertex weight consists of two parts: 1. the vertex weights of syllables in G_c, and 2. the emission probability:

$$\begin{aligned} w_{V_{i,j}} =& \beta \sum_{k=i}^{j} \mathcal{L}(S'_k, S_k) \\ & - \gamma \log P(S'_i \ldots S'_j | V_{i,j}); \end{aligned}$$

If the corresponding pinyin syllables in G_c have an edge between them, the vertices in G also have an edge:

$$\mathbb{E} = \{E(V_{i,j} \rightarrow V_{j+1,k}) | E(S_{i,j} \rightarrow S_{j+1,k}) \in \mathbb{G}_c\}.$$

The edge weights are the negative logarithm of the transition probabilities:

$$W_{E(V_{i,j} \rightarrow V_{j+1,k})} = -\log P(V_{j+1,k} | V_{i,j})$$

Although the model is formulated on first order HMM, i.e., the LM used for transition probability is a bigram one, it is easy to extend the model to take advantage of higher order n-gram LM, by tracking longer history while traversing the graph.

Computing the shortest path from V_0 to V_E on G yields the best pinyin-to-Chinese conversion with typo correction result. Considering our running example, the graph G is shown in Figure 4.

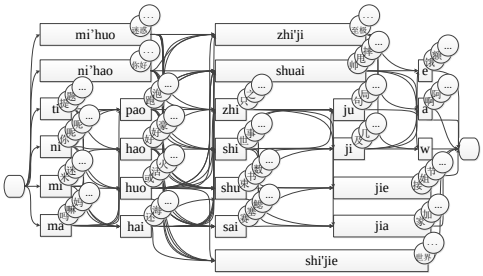

Figure 4: Joint graph model

The joint graph is rather huge and density. According to our empirical statistics, when setting threshold $T = 2$, for a sentence of M characters, the joint graph will have $|\mathbb{V}| = M \times 1,000$, and $|\mathbb{E}| = M \times 1,000,000$.

3.5 K-Shortest Paths

To reduce the scale of graph G, we filter graph G_c by searching its K-shortest paths first to get G'_c and construct G on top of G'_c. Figure 5 shows the 3-shortest paths filtered graph G'_c and Figure 6 shows the corresponding G for our running example. The scale of graph may be thus drastically reduced.

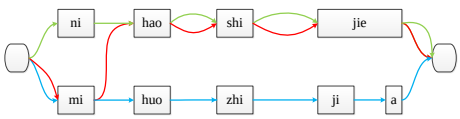

Figure 5: K-shortest paths in typo correction

An efficient heap data structure is required in K-shortest paths algorithm (Eppstein, 1998) for backtracking the best paths to current vertex while traversing. The heap is implemented as a priority queue of size K sorted according to path length that should support efficient push and pop operations. Fibonacci heap (Fredman and Tarjan, 1987) is adopted for the heap implementation since it has a push complexity of $O(1)$ which is better than the $O(K)$ for other heap structures.

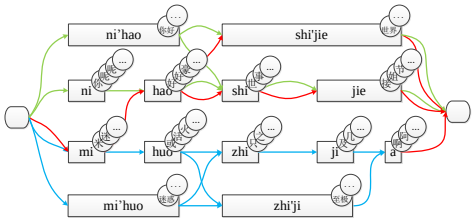

Figure 6: Filtered graph model

Another benefit provided by K-shortest paths is that it can be used for generating N-best candidates of PTC conversion, which may be helpful for further performance improvement.

4 Experiments

4.1 Corpora, Tools and Experiment Settings

The corpus for evaluation is the one provided in (Yang et al., 2012a), which is originally extracted from the *People's Daily* corpus and labeled with pinyin. The corpus has already been split into training **Train**, development **Dev** and test **Test** sets as shown in Table 1.

	Train	**Dev**	**Test**
#Sentence	1M	2K	100K
#character	43,679,593	83,765	4,123,184

Table 1: Data set size

SRILM (Stolcke, 2002) is adopted for language model training and KenLM (Heafield, 2011; Heafield et al., 2013) for language model query. The Chinese part of the corpus is segmented into words before LM training. Maximum matching word segmentation is used with a large word vocabulary $\mathcal{V}$ extracted from web data provided by (Wang et al., 2013b). The pinyin part is segmented according to the Chinese part. This vocabulary $\mathcal{V}$ also serves as the PTC dictionary. The original vocabulary is not labeled with pinyin, thus we use the PTC dictionary of *sunpinyin*[1] which is an open source Chinese pinyin IME, to label the

[1] http://code.google.com/p/sunpinyin/

vocabulary $\mathcal{V}$ with pinyin. The emission probabilities are estimated using the lexical translation module of MOSES (Koehn et al., 2007) as "translation probability" from pinyin to Chinese.

4.2 Evaluation Metrics

We will use conventional sequence labeling evaluation metrics such as sequence accuracy and character accuracy[2].

Chinese characters in a sentence may be separated by digits, punctuation and alphabets which are directly inputted without the IME. We follow the so-called term *Max Input Unit* (MIU), the longest consecutive Chinese character sequence proposed by (Jia and Zhao, 2013). We will mainly consider MIU accuracy (MIU-Acc) which is the ratio of the number of completely corrected generated MIUs over the number of all MIUs, and character accuracy (Ch-Acc), but the sentence accuracy (S-Acc) will also be reported in evaluation results.

We will also report the conversion error rate (ConvER) proposed by (Zheng et al., 2011a), which is the ratio of the number of mistyped pinyin word that is not converted to the right Chinese word over the total number of mistyped pinyin words[3].

4.3 Baseline System without Typo Correction

Firstly we build a baseline system without typo correction which is a pipeline of pinyin syllable segmentation and PTC conversion. The baseline system takes a pinyin input sequence, segments it into syllables, and then converts it to Chinese character sequence.

The pinyin syllable segmentation already has very high (over 98%) accuracy with a trigram LM using improved Kneser-Ney smoothing. According to our empirical observation, emission probabilities are mostly 1 since most Chinese words have unique pronunciation. So in this step we set $\gamma = 0$. We consider different LM smoothing methods including Kneser-Ney (KN), improved Kneser-Ney (IKN), and Witten-Bell (WB). All of the three smoothing methods for bigram and trigram LMs are examined both using back-off models and interpolated models. The number of N-best candidates for PTC conversion is set to 10. The results on **Dev** are shown in Figure 7 in which the "-i" suffix indicates using interpolated model. According to the results, we then choose the trigram LM using Kneser-Ney smoothing with interpolation.

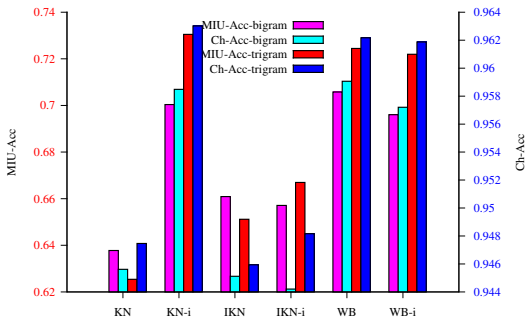

Figure 7: MIU-Acc and Ch-Acc with different LM smoothing

The choice of the number of N-best candidates for PTC conversion also has a strong impact on the results. Figure 8 shows the results on **Dev** with different Ns, of which the N axis is drawn in logarithmic scale. We can observe that MIU-Acc slightly decreases while N goes up, but Ch-Acc largely increases. We therefore choose $N = 10$ as trade-off.

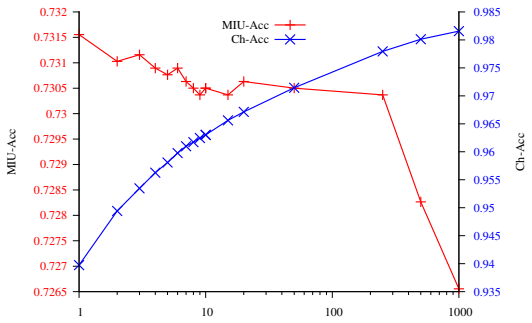

Figure 8: MIU-Acc and Ch-Acc with different Ns

The parameter γ determines emission probability. Results with different γ on **Dev** is shown in Figure 9, of which the γ axis is drawn in logarithmic scale. $\gamma = 0.03$ is chosen at last.

We compare our baseline system with several practical pinyin IMEs including *sunpinyin* and *Google Input Tools* (Online version)[4]. The results on **Dev** are shown in Table 2.

[2]We only work on the PTC conversion part of IME, thus we are unable to use existing evaluation systems (Jia and Zhao, 2013) for full Chinese IME functions.

[3]Other evaluation metrics are also proposed by (Zheng et al., 2011a) which is only suitable for their system since our system uses a joint model

[4]http://www.google.com/inputtools/try/

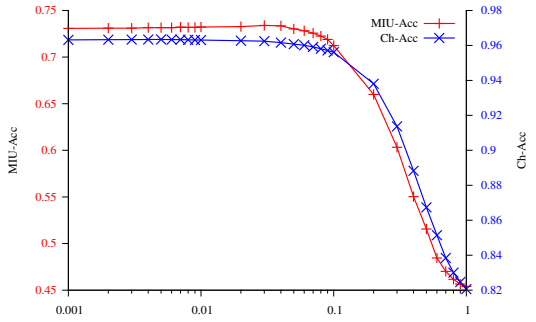

Figure 9: MIU-Acc and Ch-Acc with different γ

	MIU-Acc	Ch-Acc	S-Acc
Baseline	73.39	96.24	38.00
sunpinyin	52.37	87.51	13.95
Google	74.74	94.81	40.2
Yang-ME	-	93.3	30.2
Yang-MT	-	95.5	45.4

Table 2: Baseline system compared to other IMEs (%)

4.4 PTC Conversion with Typo Correction

Based upon the baseline system, we build the joint system of PTC conversion with typo correction.

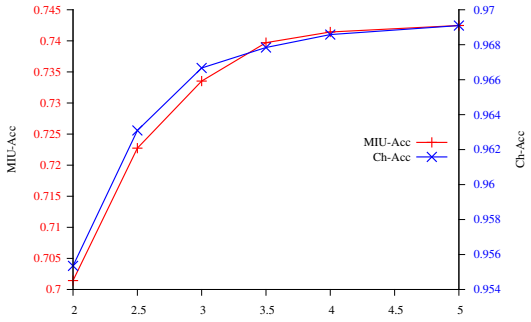
We simulate user typos by randomly generating errors automatically on the corpus. The typo rate is set according to previous Human-Computer Interaction (HCI) studies. Due to few works have been done on modeling Chinese text entry, we have to refer to those corresponding results on English (Wobbrock and Myers, 2006; MacKenzie and Soukoreff, 2002; Clarkson et al., 2005), which show that the average typo rate is about 2%. (Zheng et al., 2011a) performed an experiment that 2,000 sentences of 11,968 Chinese words were entered by 5 native speakers. The collected data consists of 775 mistyped pinyin words caused by one edit operation, and 85 caused by two edit operations. As we observe on **TRAIN** that the average pinyin word length is 5.24, then typo rate in the experiment of (Zheng et al., 2011a) can be roughly estimated as:

$$\frac{775 + 85 \times 2}{11968 \times 5.24} = 1.51\%,$$

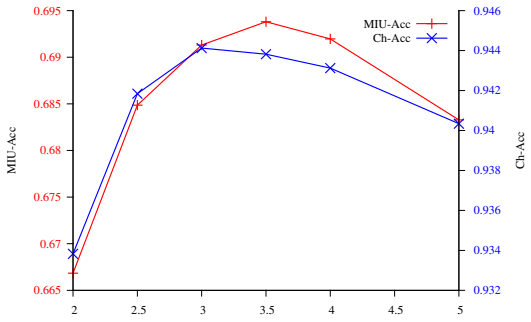
which is similar to the conclusion on English. Thus we generate corpora from **DEV** with typo rate of 0% (**0-P**), 2% (**2-P**), and 5% (**5-P**) to evaluate the system.

According to (Zheng et al., 2011a) most mistyped pinyin words are caused by one edit operation. Since pinyin syllable is much shorter than pinyin word, this ratio can be higher for pinyin syllables. From our statistics on **TRAIN**, with 2% randomly generated typos, $Pr(\mathcal{L}(S', S) < 2) = 99.86\%$. Thus we set the threshold T for $\mathcal{L}$ to 2.

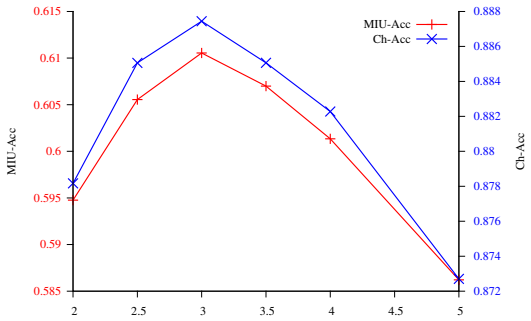
We first set K-shortest paths filter to $K = 10$ and tune β. Results with different β are shown in Figure 10. With $\beta = 3.5$, we select K. Results with different K are shown in Figure 11. We choose $K = 20$ since there is no significant improvement when $K > 20$.



(a) **0-P**



(b) **2-P**

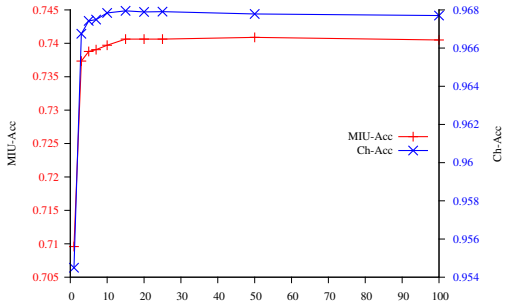


(c) **5-P**

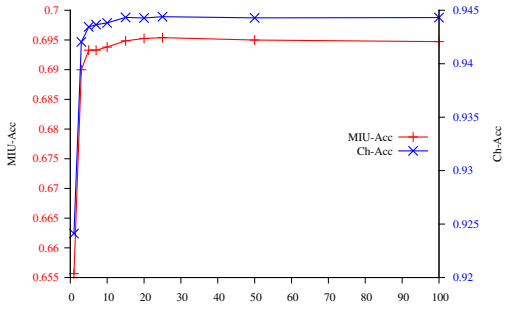
Figure 10: MIU-Acc and Ch-Acc with different β

The selection of K also directly guarantees the running time of the joint model. With $K = 20$, on a normal PC with Intel Pentium Dual-Core E6700 CPU, the PTC conversion rate is over 2000 characters-per-minute (*cpm*), which is much faster than the normal typing rate of 200 *cpm*.

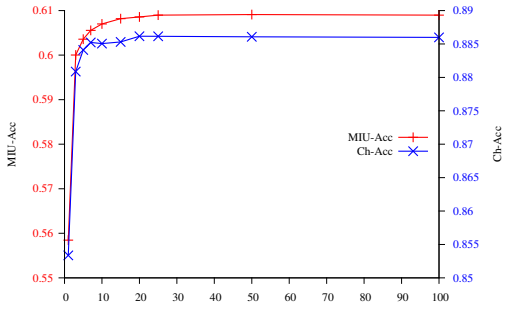
With all parameters optimized, results on **TEST**



(a) **0-P**



(b) **2-P**



(c) **5-P**

Figure 11: MIU-Acc and Ch-Acc with different K

using the proposed joint model are shown in Table 3 and Table 4. Our results are compared to the baseline system without typo correction and *Google Input Tool*. Since *sunpinyin* does not have typo correction module and performs much poorer than our baseline system, we do not include it in the comparison. Though no direct proofs can be found to indicate if Google Input Tool has an independent typo correction component, its outputs show that such a component is unlikely available.

Since *Google Input Tool* has to be accessed through a web interface and the network connection cannot be guaranteed. we only take a subset of 10K sentences of **TEST** to perform the experiments, and the results are shown in Table 3.

The scores reported in (Zheng et al., 2011a) are not listed in Table 4 since the data set is different. They reported a ConvER of 53.56%, which is given here for reference.

Additionally, to further inspect the robustness of our model, performance with typo rate ranges from 0% to 5% is shown in Figure 12. Although the performance decreases while typo rate goes up, it is still quite satisfying around typo rate of 2% which is assumed to be the real world situation.

	MIU-Acc	Ch-Acc	S-Acc	ConvER
Baseline **0-P**	79.90	97.47	48.87	-
Baseline **2-P**	50.47	90.53	11.12	99.95

5 Conclusion

In this paper, we have developed a joint graph model for pinyin-to-Chinese conversion with typo correction. This model finds a joint global optimal for typo correction and PTC conversion on the entire input pinyin sequence. The evaluation results show that our model outperforms both previous academic systems and existing commercial products. In addition, the joint model is efficient enough for practical use.

Abstract

Natural touch interfaces, common now in devices such as tablets and smartphones, make it cumbersome for users to select text. There is a need for a new text selection paradigm that goes beyond the high acuity selection-by-mouse that we have relied on for decades. In this paper, we introduce such a paradigm, called *Smart Selection*, which aims to recover a user's intended text selection from her touch input. We model the problem using an ensemble learning approach, which leverages multiple linguistic analysis techniques combined with information from a knowledge base and a Web graph. We collect a dataset of true intended user selections and simulated user touches via a large-scale crowdsourcing task, which we release to the academic community. We show that our model effectively addresses the smart selection task and significantly outperforms various baselines and standalone linguistic analysis techniques.

1 Introduction

The process of using a pointing device to select a span of text has a long history dating back to the invention of the mouse. It serves to access functions on text spans, such as copying/pasting, looking up a word in a dictionary, searching the Web, or accessing other accelerators. As consumers move from traditional PCs to mobile devices (e.g., tablets and smartphones), touch interaction is replacing the pointing devices of yore. Although more intuitive and arguably a more natural form of interaction, touch offers much less acuity (colloquially referred to as the *fat finger* problem). To select multi-word spans today, mobile devices require an intricate series of gestures that results in cumbersome user experiences[1]. Consequently, there is an opportunity to reinvent the way users select text in such devices.

Our task is, given a single user touch, to predict the span that the user likely intended to select. We call this task **smart selection**. We restrict our prediction task to cases where a user intends to perform research on a text span (dictionary/thesaurus lookup, translation, searching). We specifically consider operations on text spans that do not form a single unit (i.e., an entity, a concept, a topic, etc.) to be out of scope. For example, full sentences, paragraph and page fragments are out of scope.

Smart selection, as far as we know, is a new research problem. Yet there are many threads of research in the NLP community that identify multi-word sequences, which have coherent properties. For example, named-entity recognizers identify entities such as people/places/organizations, chunkers and parsers identify syntactic constituents such as noun phrases, key phrase detectors or term segmentors identify term boundaries. While each of these techniques retrieve meaningful linguistic units, our problem is a semantic one of recovering a user's *intent*, and as such none alone solves the entire smart selection problem.

In this paper, we model the problem of smart selection using an ensemble learning approach. We leverage various linguistic techniques, such as those discussed above, and augment them with other sources of information from a knowledge

[1] In order to select a multi-word span, a user would first have to touch on either word, then drag the left and right boundary handles to expand it to the adjacent words.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1524–1533,
Baltimore, Maryland, USA, June 23-25 2014.

base and a web graph. We evaluate our methods using a novel dataset constructed for our task. We construct our dataset of true user-intended selections by crowdsourcing the task of a user selecting spans of text in a researching task. We obtain 13,681 data points. For each intended selection, we construct test cases for each individual sub-word, simulating the user selecting via touch. The resulting testset consists of 33,912 $\langle$simulated selection, intended selection$\rangle$-pairs, which we further stratify into head, torso, and tail subsets. We release the full dataset and testset to the academic community for further research on this new NLP task. Finally, we empirically show that our ensemble model significantly improves upon various baseline systems.

In summary, the major contributions of our research are:

- We introduce a new natural language processing task, called *smart selection*, which aims to address an important problem in text selection for touch-enabled devices;
- We conduct a large crowd-sourced user study to collect a dataset of intended selections and simulated user selections, which we release to the academic community;
- We propose a machine-learned ensemble model for smart selection, which combines various linguistic annotation methods with information from a large knowledge base and web graph;
- We empirically show that our model can effectively address the smart selection task.

2 Related Work

Related work falls into three broad categories: linguistic unit detection, human computer interaction (HCI), and intent detection.

2.1 Linguistic Unit Detection

Smart selection is closely related to the detection of syntactic and semantic units: user selections are often entities, noun phrases, or concepts. A first approach to solving smart selection is to select an entity, noun phrase, or concept that subsumes the user selection. However, no single approach alone can cover the entire smart selection problem. For example, consider an approach that uses a state-of-the-art named-entity recognizer (NER) (Chinchor, 1998; Tjong Kim Sang and De Meulder, 2003; Finkel et al., 2005; Ratinov and Roth, 2009). We found in our dataset (see Section 3.2) that only a quarter of what users intend to select consists in fact of named entities. Although an NER approach can be very useful, it is certainly not sufficient. The remainder of the data can be partially addressed with noun phrase (NP) detectors (Abney, 1991; Ramshaw and Marcus, 1995; Muñoz et al., 1999; Kudo and Matsumoto, 2001) and lists of items in a knowledge base (KB), but again, each is not alone sufficient. NP detectors and KB-based methods are further very susceptible to the generation of false positives (i.e., text contains many nested noun phrases and knowledge base items include highly ambiguous terms).

In our work, we leverage all three techniques in order to benefit from their complementary coverage of user selections. We further create a novel unit detector, called the hyperlink intent model. Based on the assumption that Wikipedia anchor texts are similar in nature to what users would select in a researching task, it models the problem of recovering Wikipedia anchor texts from partial selections.

2.2 Human Computer Interaction

There is a substantial amount of research in the HCI community on how to facilitate interaction of a user with touch and speech enabled devices. To give but a few examples of trends in this field, Gunawardana et al. (2010) address the fat finger problem in the use of soft keyboards on mobile devices, Kumar et al. (2012) explore a novel speech interaction paradigm for text entry, and Sakamoto et al. (2013) introduce a technique that combines touch and voice input on a mobile device for improved navigation of user interface elements such as commands and controls. To the best of our knowledge, however, the problem of smart selection as we defined it has not been addressed.

2.3 Intent detection

There is a long line of research in the web literature on understanding user intent. The closest to smart selection is query recommendation (Baeza-Yates et al., 2005; Zhang and Nasraoui, 2006; Boldi et al., 2008), where the goal is to suggest queries that may be related to a user's intent. Query recommendation techniques are based either on clustering queries by their co-clicked URL patterns (Baeza-Yates et al., 2005) or on leveraging co-occurrences of sequential queries in web

search sessions (Zhang and Nasraoui, 2006; Boldi et al., 2008; Sadikov et al., 2010). The key difference from smart selection is that in our task the output is a selection that is relevant to the context of the document where the original selection appears (e.g., by adding terms neighboring the selection). In query recommendation, however, there is no notion of a document being read by the user and, instead, the recommendations are based exclusively on the aggregation of behavior of multiple users.

3 Problem Setting and Data

3.1 Smart Selection Definition

Let $\mathbf{D}$ be the set of all documents. We define a *selection* to be a character $\langle$offset, length$\rangle$-tuple in a document $d \in \mathbf{D}$. Let $\mathbf{S}$ be the set of all possible selections in $\mathbf{D}$ and let $\mathbf{S}_d$ be the set of all possible selections in d.

We define a scored smart selection, σ, in a document d, as a pair $\sigma = \langle x, y \rangle$ where $x \in \mathbf{S}_d$ is a selection and $y \in \mathbb{R}^+$ is a score for the selection.

We formally define the smart selection function ϕ as producing a ranked scored list of all possible selections from a document and user selection pair [2]:

$$\phi : \mathbf{D} \times \mathbf{S} \rightarrow (\sigma_1, ..., \sigma_{|\mathbf{S_d}|} \mid x_i \in \mathbf{S}_d, y_i \geq y_{i+1}) \quad (1)$$

Consider a user who selects s in a document d. Let τ be the target selection that best captures what the user intended to select. We define the smart selection task as recovering τ given the pair $\langle d, s \rangle$. Our problem then is to learn a function ϕ that best recovers the target selection from any user selection.

Note that even for a human, reconstructing an intended selection from a single word selection is not trivial. While there are some fairly clear cut cases such as expanding the selection "Obama" to `Barack Obama` in the sentence "*While in DC, Barack Obama met with...*", there are cases where the user intention depends on extrinsic factors such as the user's interests. For example, in a phrase "*University of California at Santa Cruz*" with a selection "California", some (albeit probably few) users may indeed be interested in the state of `California`, others in the `University of California` system of universities, and yet others specifically in the `University of California at Santa Cruz`. In the next section, we describe how we obtained a dataset of true intended user selections.

[2] The output consists of a ranked list of selections instead of a single selection to allow experiences such as proposing an n-best list to the user.

3.2 Data

In order to obtain a representative dataset for the smart selection task, we focus on a real-world application of users interacting with a touch-enabled e-reader device. In this application, a user is reading a book and chooses phrases for which she would like to get information from resources such as a dictionary, Wikipedia, or web search. Yet, because of the touch interface, she may only touch on a single word.

3.2.1 Crowdsourced Intended Selections

We obtain the intended selections through the following crowdsourcing exercise. We use the entire collection of textbooks in English from Wikibooks[3], a repository of publicly available textbooks. The corpus consists of 2,696 textbooks that span a large variety of categories such as Computing, Humanities, Science, etc. We first produce a uniform random sample of 100 books, and then sample one paragraph from each book. The resulting set of 100 paragraphs is then sent to the crowdsourcing system. Each paragraph is evaluated by 100 judges, using a pool of 152 judges. For each paragraph, we request the judges to select complete phrases for which they would like to "learn more in resources such as Wikipedia, search engines and dictionaries", i.e., our true user intended selections. As a result of this exercise, we obtain 13,681 judgments, corresponding to 4,067 unique intended selections. The distribution of number of unique judges who selected each unique intended selection, in a log-log scale, is shown in Figure 1. Notice that this is a Zipfian distribution since it follows a linear trend in the log-log scale.

Intuitively, the likelihood that a phrase is of interest to a user correlates with the number of judges who select that phrase. We thus use the number of judges who selected each phrase as a proxy for the likelihood that the phrase will be chosen by users.

The resulting dataset consists of 4,067 $\langle d, \tau \rangle$-pairs where d is a Wikibook document paragraph and τ is an intended selection, along with the number of judges who selected it. We further assigned

[3] Available at http://wikibooks.org.

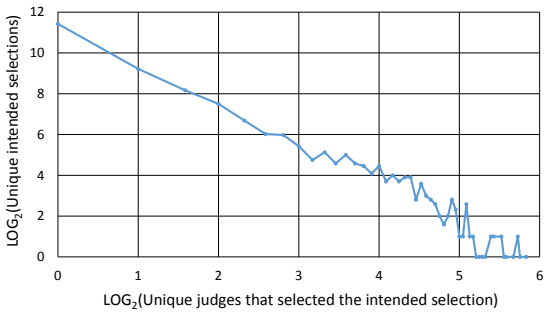

Figure 1: Zipfian distribution of unique intended selections vs. the number of judges who selected them, in log-log scale.

each pair to one of five randomly chosen folds, which are used for cross-validation experiments.

3.2.2 Testset Construction

We define a test case as a triple $\langle d, s, \tau \rangle$ where s is a simulated user selection. For each $\langle d, \tau \rangle$-pair in our dataset we construct n corresponding test cases by simulating the user selections $\{\langle d, \tau, s_1 \rangle, \ldots, \langle d, \tau, s_n \rangle\}$ where $s_1, \ldots, s_n$ correspond to the individual words in τ. In other words, each word in τ is considered as a candidate user selection.

We discard all target selections that only a single judge annotated since we observed that these mostly contained errors and noise, such as full sentences or nonsensical long sentence fragments.

Our first testset, labeled $\mathbf{T}_{\texttt{ALL}}$, is the resulting traffic-weighted multiset. That is, each test case $\langle d, s, \tau \rangle$ appears k times, where k is the number of judges who selected τ in d. $\mathbf{T}_{\texttt{ALL}}$ consists of 33,913 test cases.

We further utilize the distribution of judgments in the creation of three other testsets. Following the stratified sampling methodology commonly employed in the IR community, we construct testsets for the frequently, less frequently, and rarely annotated intended selections, which we call HEAD, TORSO, and TAIL, respectively. We obtain these testsets by first sorting each unique selection according to their frequency of occurrence, and then partitioning the set so that HEAD corresponds to the elements at the top of the list that account for 20% of the judgments; TAIL corresponds to the elements at the bottom also accounting for 20% of the judgments; and TORSO corresponds to the remaining elements. The resulting test sets, $\mathbf{T}_{\texttt{HEAD}}$, $\mathbf{T}_{\texttt{TORSO}}$, $\mathbf{T}_{\texttt{TAIL}}$ consist of 114, 2115, and 5798 test cases, respectively[4].

Test sets along with fold assignments and annotation guidelines are available at http://research.microsoft.com/en-us/downloads/eb42522c-068e-404c-b63f-cf632bd27344/.

3.3 Discussion

Our focus on single word selections is motivated by the touchscreen scenario presented in Section 1. Although our touch simulation assumes that each word in a target selection is equally likely to be selected by a user, in fact we expect this distribution to be non-uniform. For example, users may tend to select the first or last word more frequently than words in the middle of the target selection. Or perhaps users tend to select nouns and verbs more frequently than function words. We consider this out of scope for our paper, but view it as an important avenue of future investigation. Finally, for non-touchscreen environments, such as the desktop case, it would also be interesting to study the problem on multi-word user selections.

To get an idea of the kind of intended selections that comprise our dataset, we broke them down according to whether they referred to named entities or not. Perhaps surprisingly, the fraction of named entities in the dataset is quite low, 24.3%[5]. The rest of the intended selections mostly correspond to concepts and topics such as *embouchure formation*, *vocal fold relaxation*, *NHS voucher values*, *time-domain graphs*, etc.

4 Model

As argued in Section 1, existing techniques, such as NER taggers, chunkers, Knowledge Base lookup, etc., are geared towards *aspects* of the task (i.e., NEs, concepts, KB entries), but not the task as a whole. We can, however, combine the outputs of these systems with a learned "meta-model". The meta-model ranks the combined candidates according to a criterion that is derived from data that resembles real usage of smart selection as closely as possible. This technique is known

[4] We stress that $\mathbf{T}_{\texttt{ALL}}$ is a multi-set, reflecting the overall expected user traffic from our 100 judges per paragraph. $\mathbf{T}_{\texttt{HEAD}}$, $\mathbf{T}_{\texttt{TORSO}}$, $\mathbf{T}_{\texttt{TAIL}}$, in contrast, are not multi-sets since judgment frequency is already accounted for in the stratification process, as commonly done in the IR community.

[5] Becker et al. (2012) report a similar finding, showing that only 26% of questions, which a user might ask after reading a Wikipedia article, are focused on named entities.

in the machine learning community as *ensemble learning* (Dietterich, 1997).

Our ensemble approach, described in this section, serves as our main implementation of the smart selection function ϕ of Equation 1. Each of the ensemble members are themselves a separate implementation of ϕ and will be used as a point of comparison in our experiments. Below, we describe the ensemble members before turning to the ensemble learner.

4.1 Ensemble Members

4.1.1 Hyperlink Intent Model

The Hyperlink Intent Model (HIM), which leverages web graph information, is a machine-learned system based on the intuition that anchor texts in Wikipedia are good representations of what users might want to learn about. We build upon the fact that Wikipedia editors write anchor texts for entities, concepts, and things of potential interest for follow-up to other content. HIM learns to recover anchor texts from their single word subselections.

Specifically, HIM iteratively decides whether to expand the current selection (initially a single word) one word to the left or right via greedy binary decisions, until a stopping condition is met. At each step, two binary classifiers are consulted. The first one scores the left expansion decision and the second one scores the right expansion decision. In addition, we use the same two classifiers to evaluate the expansion decision "from the outside in", i.e., from the word next to the current selection (left and right, respectively) to the closest word in the current selection. If the probability for expansion of any model exceeds a predefined threshold, then the most probable expansion is chosen and we continue the iteration with the newly expanded selection as input. The algorithm is illustrated in Figure 2.

We automatically create our training set for HIM by first taking a random sample of 8K Wikipedia anchor texts. We treat each anchor text as an intended selection, and each word in the anchor text as a simulated user selection. For each word to the left (or the right) of the user selection that is part of the anchor text, we create a positive training example. Similarly, for each word to the left (or the right) that is outside of the anchor text, we create a negative training example. We include additional negative examples using random word selections from Wikipedia content. For this purpose we sample random words that are not part of an anchor text. Our final data consists of 2.6M data points, with a 1:20 ratio of positive to negative examples[6].

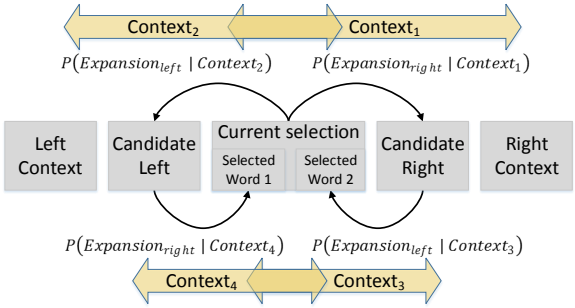

Figure 2: Hyperlink Intent Model (HIM) decoding flow for smart selection.

We use logistic regression as the classification algorithm for our binary classifiers. The features used by each model are computed over three strings: the current selection s (initially the single-word simulated user selection), the candidate expansion word w, and one word over from the right or left of s. The features fall into five feature families: (1) *character-level features*, including capitalization, all-cap formatting, character length, presence of opening/closing parentheses, presence and position of digits and non-alphabetic characters, and minimum and average character uni/bi/trigram frequencies (based on frequency tables computed offline from Wikipedia article content); (2) *stopword features*, which indicate the presence of a stop word (from a stop word list); (3) *tf.idf scores* precomputed from Wikipedia content statistics; (4) *knowledge base features*, which indicate whether a string matches an item or a substring of an item in the knowledge base described in Section 4.1.2 below; and (5) *lexical features*, which capture the actual string of the current selection and the candidate expansion word.

4.1.2 Unit Spotting

Our second qualitative class of ensemble members use notions of *unit* that are either based on linguistic constituency or knowledge base presence. The general process is that any unit that subsumes the user selection is treated as a smart selection candidate. Scoring of candidates is by normalized length, under the assumption that in general the most specific (longest) unit is more likely to be the intended selection.

[6]Note that this training set is generated automatically and is, by design, of a different nature than the manually labeled data we use to train and test the ensemble model.

Our first unit spotter, labeled NER is geared towards recognizing named entities. We use a commercial and proprietary state-of-the-art NER system, trained using the perceptron algorithm (Collins, 2002) over more than a million hand-annotated labels.

Our second approach uses purely syntactic information and treats noun phrases as units. We label this model as NP. For this purpose we parse the sentence containing the user selection with a syntactic parser following (Ratnaparkhi, 1999). We then treat every noun phrase that subsumes the user selection as a candidate smart selection.

Finally, our third unit spotter, labeled KB, is based on the assumption that concepts and other entries in a knowledge base are, by nature, things that can be of interest to people. For our knowledge base lookup, we use a proprietary graph consisting of knowledge from Wikipedia, Freebase, and paid feeds from various providers from domains such as entertainment, local, and finance.

4.1.3 Heuristics

Our third family of ensemble members implements simple heuristics, which tend to be high precision especially in the HEAD of our data.

The first heuristic, representing the current touch-enabled selection paradigm seen in many of today's tablets and smartphones, is labeled CUR. It simply assumes that the intended selection is always the user-selected word.

The second is a capitalization-based heuristic (CAP), which simply expands every selected capitalized word selection to the longest uninterrupted sequence of capitalized words.

4.2 Ensemble Learning

In this section, we describe how we train our meta-learner, labeled ENS, which takes as input the candidate lists produced by the ensemble members from Section 4.1, and scores each candidate, producing a final scored ranked list.

We use logistic regression as a classification algorithm to address this task. Our 22 features in ENS consist of three main classes: (1) features related to the individual ensemble members; (2) features related to the user selection; and (3) features related to the candidate smart selection. For (1), the features consist of whether a particular ensemble member generated the candidate smart selection and its score for that candidate. If the candidate smart selection is not in the candidate list of an ensemble member, its score is set to zero. For both (2) and (3), features account for length and capitalization properties of the user selection and the candidate smart selection (e.g., token length, ratio of capitalized tokens, ratio of capitalized characters, whether or not the first and last tokens are capitalized.)

Although training data for the HIM model was automatically generated from Wikipedia, for ENS we desire training data that reflects the true expected user experience. For this, we use five-fold cross-validation over our data collection described in Section 3.2. That is, to decode a fold with our meta-learner, we train ENS with the other four folds. Note that every candidate selection for a $\langle$document, user selection$\rangle$-pair, $\langle d, s\rangle$, for the same d and s, are assigned to a single fold, hence the training process does not see any user selection from the test set.

5 Experimental Results

5.1 Experimental Setup

Recall our testsets $\mathbf{T}_{\texttt{ALL}}$, $\mathbf{T}_{\texttt{HEAD}}$, $\mathbf{T}_{\texttt{TORSO}}$, and $\mathbf{T}_{\texttt{TAIL}}$ from Section 3.2.2, where a test case is defined as a triple $\langle d, s, \tau\rangle$, and where d is a document, s is a user selection, and τ is the intended user selection. In this section, we describe our evaluation metric and summarize the system configurations that we evaluate.

5.1.1 Metric

In our evaluation, we apply the smart selection function $\phi(d, s)$ (see Eq. 1) to each test case and measure how well it recovers τ.

Let $\mathbf{A}$ be the set of $\langle d, \tau\rangle$-pairs from our dataset described in Section 3.2.1 that corresponds to a testset $\mathbf{T}$. Let $\mathbf{T}_{\langle d,\tau\rangle}$ be the set of all test cases in $\mathbf{T}$ with a fixed d and τ. We define the macro precision of a smart selection function, P_ϕ, as follows:

$$P_\phi = \frac{1}{\mid \mathbf{A} \mid} \sum_{\langle d,\tau\rangle \in \mathbf{A}} P_\phi(d, \tau) \qquad (2)$$

$$P_\phi(d, \tau) = \frac{1}{\mid \mathbf{T}_{\langle d,\tau\rangle} \mid} \sum_{\langle d,s,\tau\rangle \in \mathbf{T}_{\langle d,\tau\rangle}} P_\phi(d, s, \tau)$$

$$P_\phi(d, s, \tau) = \frac{1}{\mid \phi(d, s) \mid} \sum_{\sigma \in \phi(d,s)} I(\sigma, \tau)$$

$$I(\sigma, \tau) = \begin{cases} 1 & \text{if } \sigma = \langle x, y\rangle \wedge x = \tau \\ 0 & \text{otherwise} \end{cases}$$

HIM	48.1	48.8	48.8	48.8	48.8
ENS	$56.8^{\dagger}$	$76.0^{\ddagger}$	$82.6^{\ddagger}$	$85.2^{\ddagger}$	$86.6^{\ddagger}$

Table 1: Smart selection performance, as a function of CP, on $\mathbf{T}_{\texttt{ALL}}$. ‡ and † indicate statistical significance with $p = 0.01$ and 0.05, respectively. An oracle ensemble would achieve an upper bound CP of 87.3%.

We report cumulative macro precision at rank (**CP@k**) in our experiments since our testsets contain a single true user-intended selection for each test case[7]. However, this is an overly conservative metric since in many cases an alternative smart selection might equally please the user. For example, if our testset contains a user intended selection τ = `The University of Southern California`, then given the simulated selection "California", both τ and `University of Southern California` would most likely equally satisfy the user intent (whereas the latter would be considered incorrect in our evaluation). In fact, the ideal testset would further evaluate the *distance* or *relevance* of the smart selection to the intended user selection. We would then find perhaps that `Southern California` is a more reasonable smart selection than `of Southern California`. However, precisely defining such a *relevance* function and designing the guidelines for a user study is non-trivial and left for future work.

5.1.2 Systems

In our experiments, we evaluate the following systems, each described in detail in Section 4: Passthrough (CUR), Capitalization (CAP), Named-Entity Recognizer (NER), Noun Phrase (NP), Knowledge Base (KB), Hyperlink Intent Model (HIM), Ensemble (ENS).

5.2 Results

Table 1 reports the smart selection performance on the full traffic weighted testset $\mathbf{T}_{\texttt{ALL}}$, as a function of CP@$k$. Our ensemble approach recovers the true user-intended selection in 56.8% of the cases. In its top-2 and top-3 ranked smart selections, the true user-intended selection is retrieved 76.0% and 82.6% of the time, respectively. In position 1, ENS significantly outperforms all other systems with 95% confidence. Moreover, we notice that the divergence between ENS and the other systems greatly increases for $K \geq 2$, where the significance is now at the 99% level.

The CUR system models the selection paradigm of today's consumer touch-enabled devices (i.e., it assumes that the intented selection is always the touched word). Without changing the user interface, we report a 45% improvement in predicting what the user intended to select over this baseline. If we changed the user interface to allow two or three options to be displayed to the user, then we would improve by 93% and 110%, respectively.

For CUR and NER, we report results only at $K = 1$ since these systems only ever return a single smart selection. Note also that when no named entity is found by NER, or no noun phrase is found by NP or no knowledge base entry is found by KB, the corresponding systems return the original user selection as their smart selection.

CAP does not vary much across K: when the intended selection is a capitalized multi-word, the longest string tends to be the intended selection. The same holds for KB.

Whereas Table 1 reports the aggregate expected traffic performance, we further explore the performance against the stratified $\mathbf{T}_{\texttt{HEAD}}$, $\mathbf{T}_{\texttt{TORSO}}$, and $\mathbf{T}_{\texttt{TAIL}}$ testsets. The results are summarized in Table 2. As outlined in Section 3.2, the HEAD selections tend to be disproportionately entities and capitalized terms when compared to the TORSO and TAIL. Hence CAP, NER and KB perform much better on the HEAD. In fact, on the HEAD, CAP performs statistically as well as the ENS model. This means that at position 1, for systems that need to focus only on the HEAD, a very simple solution is adequate. For TORSO and TAIL, however, ENS performs better. At positions 2 and 3, across all strata, the ENS model significantly outperforms all other systems (with 99% confidence).

Next, we studied the relative contribution of each ensemble member to the ENS model. Figure 3 illustrates the results of the ablation study. The ensemble member that results in the biggest performance drop when removed is HIM. Perhaps

[7]Because there is only a single true intended selection for each test case, Recall@k = CP@k.

Table 2: Smart selection performance, as a function of CP, on the $\mathbf{T}_{\texttt{HEAD}}$, $\mathbf{T}_{\texttt{TORSO}}$, and $\mathbf{T}_{\texttt{TAIL}}$ testsets. ‡ and † indicate statistical significance with $p = 0.01$ and 0.05, respectively. An oracle ensemble would achieve an upper bound CP of 98.5%, 86.8% and 64.8% for $\mathbf{T}_{\texttt{HEAD}}$, $\mathbf{T}_{\texttt{TORSO}}$, and $\mathbf{T}_{\texttt{TAIL}}$, respectively.

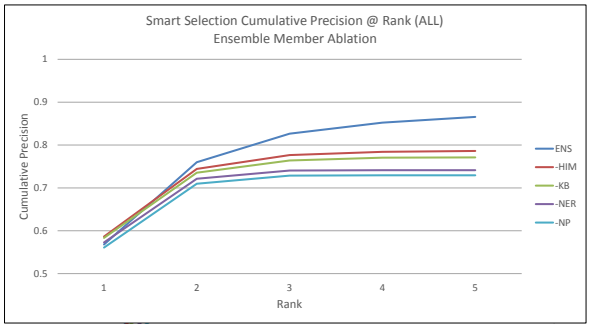

Figure 3: Ablation of ensemble model members over $\mathbf{T}_{\texttt{ALL}}$. Each consecutive model removes one member specified in the series name.

surprisingly, a first ablation of either the CAP or KB model, two of the better individual performing models from Table 1, leads to an ablated-ENS performance that is nearly identical to the full ENS model. One possible reason is that both tend to generate similar candidates (i.e., many entities in our KB are capitalized). Although the HIM model as a standalone system does not outperform simple linguistic unit selection models, it appears to be the most important contributor to the overall ensemble.

5.3 Error Analysis: Oracle Ensemble

We begin by assessing an upper bound for our ensemble, i.e., an *oracle ensemble*, by assuming that if a correct candidate is generated by any ensemble member, the oracle ensemble model places it in first position. For $\mathbf{T}_{\texttt{ALL}}$ the oracle performance is 87.3%. In other words, our choice of ensemble members was able to recover a correct smart selection as a candidate in 87.3% of the user study cases. For $\mathbf{T}_{\texttt{HEAD}}$, $\mathbf{T}_{\texttt{TORSO}}$, and $\mathbf{T}_{\texttt{TAIL}}$, the oracle performance is 98.5%, 86.8%, and 64.8%, respectively.

Although our ENS model's CP@3 is within 2-6 points of the oracle, there is room to significantly improve our CP@1, see Table 1 and Table 2. We analyze this opportunity by inspecting a random sample of 200 test cases where ENS produced an incorrect smart selection in position 1. The breakdown of these cases is: 1 case from $\mathbf{T}_{\texttt{HEAD}}$; 50 cases from $\mathbf{T}_{\texttt{TORSO}}$; 149 cases from $\mathbf{T}_{\texttt{TAIL}}$, i.e., most errors occur in the TAIL.

For 146 of these cases (73%), not a single ensemble member produced the correct target selection τ as a candidate. We analyze these cases in detail in Section 5.4. Of the remaining cases, 25, 10, 9, 4, 4, and 2 were correct in positions 2, 3, 4, 5, 6, 7, respectively. Table 3 lists some examples.

In 18 cases (33%), the result in position 1 is very reasonable given the context and user selection (see lines 1-4 in Table 3 for examples). Often the target selection was also found in second position. These cases highlight the need for a more relaxed, relevance-based user study, as pointed out at the end of Section 5.1.1.

We attributed 7 (13%) of the cases to data problems: some cases had a punctuation as a sole character user selection, some had a mishandled escaped quotation character, and some had a UTF-8 encoding error.

The remaining 29 (54%) were truly model errors. Some examples are shown in lines 5-8 in Table 3. We found three categories of errors here. First, our model has learned a strong prior on preferring the original user selection (see example line 5). From a user experience point of view, when the model is unsure of itself, it is in fact better not to alter her selection. Second, we also learned a strong capitalization prior, i.e., to trust the CAP member (see example line 6). Finally, we noticed that we have difficulty handling user selections consisting of a stopword (we noted determiners, prepositions, and the word "and"). Adding a few simple features to ENS based on a stopwords list or a list of closed-class words should address this problem.

	Text Snippet	User Selection	ENS 1st Result
1	"The **Russian conquest of the South Caucasus in the 19th century** split the speech community across two states..."	Caucasus	South Caucasus
2	"...are generally something that **transportation** agencies would like to minimize..."	transportation	transportation agencies
3	"The **vocal organ of birds**, the syrinx, is located at the base of the blackbird's trachea."	vocal	vocal organ
4	"An example of this may be an idealised **waveform** like a square wave..."	waveform	idealised waveform
5	"Tickets may be purchased from either the **ticket counter** or from automatic machines..."	counter	counter
6	"PBXT features include the following: **MVCC** Support: MVCC stands for Multi-version Concurrency Control."	MVCC	MVCC Support
7	"Centers for song production pathways include the High vocal center; **robust nucleus of archistriatum** (RA); and the tracheosyringeal part of the hypoglossal nucleus..."	robust	robust nucleus
8	"...and get an **11gR2 RAC cluster database** running inside virtual machines..."	cluster	RAC cluster

Table 3: Position 1 errors when applying ENS to our test cases. The text snippet is a substring of a paragraph presented to our judges with the target selection (τ) indicated in bold.

5.4 Error Analysis: Ensemble Members

Over all test cases, the distribution of cases without a correct candidate generated by an ensemble member in the HEAD, TORSO, TAIL is 0.3%, 34.6%, and 65.1%, respectively. We manually inspected a random sample of 100 such test cases.

The majority of them, 83%, were large sentence fragments, which we consider out of scope according to our prediction task definition outlined in Section 1. The average token length of the target selection τ for these was 15.3. In comparison, we estimate the average token length of the task-admissable cases to be 2.7 tokens. Although most of these long fragment selections seem to be noise, a few cases are statements that a user would reasonably want to know more about, such as: (i) "Talks of a merger between the NHL and the WHA were growing" or (ii) "NaN + NaN * 1.0i".

In 10% of the cases, we face a punctuation-handling issue, and in each case our ensemble was able to generate a correct candidate when fixing the punctuation. For example, for the book title $\tau =$ What is life?, our ensemble found the candidate What is life, dropping the question mark. For $\tau =$ Near Earth Asteroid. our ensemble found Near Earth Asteroid, dropping the period. Similar problems occurred with parentheses and quotation marks.

In two cases, our ensemble members dropped a leading "the" token, e.g., for $\tau =$ the Hume Highway, we found Hume Highway.

Finally, 2 cases were UTF-8 encoding mistakes, leaving five "true error" cases.

6 Conclusion and Future Work

We introduced a new paradigm, *smart selection*, to address the cumbersome text selection capabilities of today's touch-enabled mobile devices. We report 45% improvement in predicting what the user intended to select over current touch-enabled consumer platforms, such as iOS, Android and Windows. We release to the community a dataset of $33,912$ crowdsourced true intended user selections and corresponding simulated user touches.

There are many avenues for future work, including understanding the distribution of user touches on their intended selection, other interesting scenarios (e.g., going beyond the e-reader towards document editors and web browsers may show different distributions in what users select), leveraging other sources of signal such as a user's profile, her interests and her local session context, and exploring user interfaces that leverage n-best smart selection prediction lists, for example by providing selection options to the user after her touch.

With the release of our $33,912$-crowdsourced dataset and our model analyses, it is our hope that the research community can help accelerate the progress towards reinventing the way text selection occurs today, the initial steps for which we have taken in this paper.

Modeling Prompt Adherence in Student Essays

Abstract

Recently, researchers have begun exploring methods of scoring student essays with respect to particular dimensions of quality such as coherence, technical errors, and prompt adherence. The work on modeling prompt adherence, however, has been focused mainly on whether individual sentences adhere to the prompt. We present a new annotated corpus of essay-level prompt adherence scores and propose a feature-rich approach to scoring essays along the prompt adherence dimension. Our approach significantly outperforms a knowledge-lean baseline prompt adherence scoring system yielding improvements of up to 16.6%.

1 Introduction

Automated essay scoring, the task of employing computer technology to evaluate and score written text, is one of the most important educational applications of natural language processing (NLP) (see Shermis and Burstein (2003) and Shermis et al. (2010) for an overview of the state of the art in this task). A major weakness of many existing scoring engines such as the Intelligent Essay Assessor^{TM}(Landauer et al., 2003) is that they adopt a holistic scoring scheme, which summarizes the quality of an essay with a single score and thus provides very limited feedback to the writer. In particular, it is not clear which dimension of an essay (e.g., style, coherence, relevance) a score should be attributed to. Recent work addresses this problem by scoring a particular dimension of essay quality such as coherence (Miltsakaki and Kukich, 2004), technical errors, organization (Persing et al., 2010), and thesis clarity (Persing and Ng, 2013). Essay grading software that provides feedback along multiple dimensions of essay quality such as E-*rater*/Criterion (Attali and Burstein, 2006) has also begun to emerge.

Our goal in this paper is to develop a computational model for scoring an essay along an under-investigated dimension — *prompt adherence*. Prompt adherence refers to how related an essay's content is to the prompt for which it was written. An essay with a high prompt adherence score consistently remains on the topic introduced by the prompt and is free of irrelevant digressions.

To our knowledge, little work has been done on scoring the prompt adherence of student essays since Higgins et al. (2004). Nevertheless, there are major differences between Higgins et al.'s work and our work with respect to both the way the task is formulated and the approach. Regarding task formulation, while Higgins et al. focus on classifying each *sentence* as having either *good* or *bad* adherence to the prompt, we focus on assigning a prompt adherence score to the entire *essay*, allowing the score to range from one to four points at half-point increments. As far as the approach is concerned, Higgins et al. adopt a *knowledge-lean* approach to the task, where almost all of the features they employ are computed based on a word-based semantic similarity measure known as *Random Indexing* (Kanerva et al., 2000). On the other hand, we employ a large variety of features, including lexical and knowledge-based features that encode how well the concepts in an essay match those in the prompt, LDA-based features that provide semantic generalizations of lexical features, and "error type" features that encode different types of errors the writer made that are related to prompt adherence.

In sum, our contributions in this paper are twofold. First, we develop a scoring model for the prompt adherence dimension on student essays using a feature-rich approach. Second, in order to stimulate further research on this task, we make our data set consisting of prompt adherence an-

notations of 830 essays publicly available. Since progress in prompt adherence modeling is hindered in part by the lack of a publicly annotated corpus, we believe that our data set will be a valuable resource to the NLP community.

2 Corpus Information

We use as our corpus the 4.5 million word International Corpus of Learner English (ICLE) (Granger et al., 2009), which consists of more than 6000 essays written by university undergraduates from 16 countries and 16 native languages who are learners of English as a Foreign Language. 91% of the ICLE texts are argumentative. We select a subset consisting of 830 argumentative essays from the ICLE to annotate for training and testing of our essay prompt adherence scoring system. Table 1 shows three of the 13 topics selected for annotation. Fifteen native languages are represented in the set of annotated essays.

3 Corpus Annotation

We ask human annotators to score each of the 830 argumentative essays along the prompt adherence dimension. Our annotators were selected from over 30 applicants who were familiarized with the scoring rubric and given sample essays to score. The six who were most consistent with the expected scores were given additional essays to annotate. Annotators evaluated how well each essay adheres to its prompt using a numerical score from one to four at half-point increments (see Table 2 for a description of each score). This contrasts with previous work on prompt adherence essay scoring, where the corpus is annotated with a binary decision (i.e., *good* or *bad*) (e.g., Higgins et al. (2004; 2006), Louis and Higgins (2010)). Hence, our annotation scheme not only provides a finer-grained distinction of prompt adherence (which can be important in practice), but also makes the prediction task more challenging.

Score	Description of Prompt Adherence
4	essay fully addresses the prompt and **consistently stays on topic**
3	essay mostly addresses the prompt or **occasionally wanders off topic**
2	essay does not fully address the prompt or **consistently wanders off topic**
1	essay does not address the prompt at all or is **completely off topic**

Table 2: Descriptions of the meaning of scores.

To ensure consistency in annotation, we randomly select 707 essays to have graded by multiple annotators. Analysis reveals that the Pearson's correlation coefficient computed over these doubly annotated essays is 0.243. Though annotators exactly agree on the prompt adherence score of an essay only 38% of the time, the scores they apply fall within 0.5 points in 66% of essays and within 1.0 point in 89% of essays. For the sake of our experiments, whenever annotators disagree on an essay's prompt adherence score, we assign the essay the average of all annotations rounded to the nearest half point. Table 3 shows the number of essays that receive each of the seven scores for prompt adherence.

score	1.0	1.5	2.0	2.5	3.0	3.5	4.0
essays	0	0	8	44	105	230	443

Table 3: Distribution of prompt adherence scores.

4 Score Prediction

In this section, we describe in detail our system for predicting essays' prompt adherence scores.

4.1 Model Training and Application

We cast the problem of predicting an essay's prompt adherence score as 13 regression problems, one for each prompt. Each essay is represented as an instance whose label is the essay's true score (one of the values shown in Table 3) with up to seven types of features including baseline (Section 4.2) and six other feature types proposed by us (Section 4.3). Our regressors may assign an essay any score in the range of $1.0-4.0$.

Using regression captures the fact that some pairs of scores are more similar than others (e.g., an essay with a prompt adherence score of 3.5 is more similar to an essay with a score of 4.0 than it is to one with a score of 1.0). A classification sys-

tem, by contrast, may sometimes believe that the scores 1.0 and 4.0 are most likely for a particular essay, even though these scores are at opposite ends of the score range.

Using a different regressor for each prompt captures the fact that it may be easier for an essay to adhere to some prompts than to others, and common problems students have writing essays for one prompt may not apply to essays written in response to another prompt. For example, in essays written in response to the prompt "Marx once said that religion was the opium of the masses. If he was alive at the end of the 20th century, he would replace religion with television," students sometimes write essays about all the evils of television, forgetting that their essay is only supposed to be about whether it is "the opium of the masses". Students are less likely to make an analogous mistake when writing for the prompt "Crime does not pay."

After creating training instances for prompt p_i, we train a linear regressor, r_i, with regularization parameter c_i for scoring test essays written in response to p_i using the linear SVM regressor implemented in the LIBSVM software package (Chang and Lin, 2001). All SVM-specific learning parameters are set to their default values except c_i, which we tune to maximize performance on held-out validation data.

After training the classifiers, we use them to classify the test set essays. The test instances are created in the same way as the training instances.

4.2 Baseline Features

Our baseline system for score prediction employs various features based on Random Indexing.

1. Random Indexing Random Indexing (RI) is "an efficient, scalable and incremental alternative" (Sahlgren, 2005) to Latent Semantic Indexing (Deerwester et al., 1990; Landauer and Dutnais, 1997) which allows us to automatically generate a semantic similarity measure between any two words. We train our RI model on over 30 million words of the English Gigaword corpus (Parker et al., 2009) using the S-Space package (Jurgens and Stevens, 2010). We expect that features based on RI will be useful for prompt adherence scoring because they may help us find text related to the prompt even if some of its concepts have have been rephrased (e.g., an essay may talk about "jail" rather than "prison", which is mentioned in one of the prompts), and because they have already proven useful for the related task of determining which sentences in an essay are related to the prompt (Higgins et al., 2004).

For each essay, we therefore attempt to adapt the RI features used by Higgins et al. (2004) to our problem of prompt adherence scoring. We do this by generating one feature encoding the entire essay's similarity to the prompt, another encoding the essay's highest individual sentence's similarity to the prompt, a third encoding the highest entire essay similarity to one of the prompt sentences, another encoding the highest individual sentence similarity to an individual prompt sentence, and finally one encoding the entire essay's similarity to a manually rewritten version of the prompt that excludes extraneous material (such as "In his novel Animal Farm, George Orwell wrote," which is introductory material from the third prompt in Table 1). Our RI feature set necessarily excludes those features from Higgins et al. that are not easily translatable to our problem since we are concerned with an entire essay's adherence to its prompt rather than with each of its sentences' relatedness to the prompt. Since RI does not provide a straightforward way to measure similarity between groups of words such as sentences or essays, we use Higgins and Burstein's (2007) method to generate these features.

4.3 Novel Features

Next, we introduce six types of novel features.

2. N-grams As our first novel feature, we use the 10,000 most important lemmatized unigram, bigram, and trigram features that occur in the essay. N-grams can be useful for prompt adherence scoring because they can capture useful words and phrases related to a prompt. For example, words and phrases like "university degree", "student", and "real world" are relevant to the first prompt in Table 1, so it is more likely that an essay adheres to the prompt if they appear in the essay.

We determine the "most important" n-gram features using information gain computed over the training data (Yang and Pedersen, 1997). Since the essays vary greatly in length, we normalize each essay's set of n-gram features to unit length.

3. Thesis Clarity Keywords Our next set of features consists of the keyword features we introduced in our previous work on essay thesis clarity scoring (Persing and Ng, 2013). Below we give an overview of these keyword features and motivate

why they are potentially useful for prompt adherence scoring.

The keyword features were formed by first examining the 13 essay prompts, splitting each into its component pieces. As an example of what is meant by a "component piece", consider the first prompt in Table 1. The components of this prompt would be "Most university degrees are theoretical", "Most university degrees do not prepare students for the real world", and "Most university degrees are of very little value."

Then the most important (primary) and second most important (secondary) words were selected from each prompt component, where a word was considered "important" if it would be a good word for a student to use when stating her thesis about the prompt. So since the lemmatized version of the third component of the second prompt in Table 1 is "it should rehabilitate they", "rehabilitate" was selected as a primary keyword and "society" as a secondary keyword.

Features are then computed based on these keywords. For instance, one thesis clarity keyword feature is computed as follows. The RI similarity measure is first taken between the essay and each group of the prompt's primary keywords. The feature then gets assigned the lowest of these values. If this feature has a low value, that suggests that the student ignored the prompt component from which the value came when writing the essay.

To compute another of the thesis clarity keyword features, the numbers of combined primary and secondary keywords the essay contains from each component of its prompt are counted. These numbers are then divided by the total count of primary and secondary features in their respective components. The greatest of the fractions generated in this way is encoded as a feature because if it has a low value, that indicates the essay's thesis may not be very relevant to the prompt.[1]

4. Prompt Adherence Keywords The thesis clarity keyword features described above were intended for the task of determining how clear an essay's thesis is, but since our goal is instead to determine how well an essay adheres to its prompt, it makes sense to adapt keyword features to our task rather than to adopt keyword features exactly as they have been used before. For this reason, we construct a new list of keywords for each prompt component, though since prompt adherence is more concerned with what the student says about the topics than it is with whether or not what she says about them is stated clearly, our keyword lists look a little different than the ones discussed above. For an example, we earlier alluded to the problem of students merely discussing all the evils of television for the prompt "Marx once said that religion was the opium of the masses. If he was alive at the end of the 20th century, he would replace religion with television." Since the question suggests that students discuss whether television is analogous to religion in this way, our set of prompt adherence keywords for this prompt contains the word "religion" while the previously discussed keyword sets do not. This is because a thesis like "Television is bad" can be stated very clearly without making any reference to religion at all, and so an essay with a thesis like this can potentially have a very high thesis clarity score. It should not, however, have a very high prompt adherence score, as the prompt asked the student to discuss whether television is like religion in a particular way, so religion should be at least briefly addressed for an essay to be awarded a high prompt adherence score.

Additionally, our prompt adherence keyword sets do not adopt the notions of primary and secondary groups of keywords for each prompt component, instead collecting all the keywords for a component into one set because "secondary" keywords tend to be things that are important when we are concerned with what a student is saying about the topic rather than just how clearly she said it.

We form two types of features from prompt adherence keywords. While both types of features measure how much each prompt component was discussed in an essay, they differ in how they encode the information. To obtain feature values of the first type, we take the RI similarities between the whole essay and each set of prompt adherence keywords from the prompt's components. This results in one to three features, as some prompts have one component while others have up to three.

We obtain feature values of the second type as follows. For each component, we count the number of prompt adherence keywords the essay contains. We divide this number by the number of prompt adherence keywords we identified from

[1] Space limitations preclude a complete listing of the thesis clarity keyword features. See our website at `http://www.hlt.utdallas.edu/~persingq/ICLE/` for the complete list.

the component. This results in one to three features since a prompt has one to three components.

5. LDA Topics A problem with the features we have introduced up to this point is that they have trouble identifying topics that are not mentioned in the prompt, but are nevertheless related to the prompt. These topics should not diminish the essay's prompt adherence score because they are at least related to prompt concepts. For example, consider the prompt "All armies should consist entirely of professional soldiers: there is no value in a system of military service." An essay containing words like "peace", "patriotism", or "training" are probably not digressions from the prompt, and therefore should not be penalized for discussing these topics. But the various measures of keyword similarities described above will at best not notice that anything related to the prompt is being discussed, and at worst, this might have effects like lowering some of the RI similarity scores, thereby probably lowering the prompt adherence score the regressor assigns to the essay. While n-gram features do not have exactly the same problem, they would still only notice that these example words are related to the prompt if multiple essays use the same words to discuss these concepts. For this reason, we introduce Latent Dirichlet Allocation (LDA) (Blei et al., 2003) features.

In order to construct our LDA features, we first collect all essays written in response to each prompt into its own set. Note that this feature type exploits unlabeled data: it includes all essays in the ICLE responding to our prompts, not just those in our smaller annotated 830 essay dataset. We then use the MALLET (McCallum, 2002) implementation of LDA to build a topic model of 1,000 topics around each of these sets of essays. This results in what we can think of as a soft clustering of words into 1,000 sets for each prompt, where each set of words represents one of the topics LDA identified being discussed in the essays for that prompt. So for example, the five most important words in the most frequently discussed topic for the military prompt we mentioned above are "man", "military", "service", "pay", and "war".

We also use the MALLET-generated topic model to tell us how much of each essay is spent discussing each of the 1,000 topics. The model might tell us, for example, that a particular essay written on the military prompt spends 35% of the time discussing the "man", "military", "service", "pay", and "war" topic and 65% of the time discussing a topic whose most important words are "fully", "count", "ordinary", "czech", and "day". Since the latter topic is discussed so much in the essay and does not appear to have much to do with the military prompt, this essay should probably get a bad prompt adherence score. We construct 1,000 features from this topic model, one for each topic. Each feature's value is obtained by using the topic model to tell us how much of the essay was spent discussing the feature's corresponding topic. From these features, our regressor should be able to learn which topics are important to a good prompt adherent essay.

6. Manually Annotated LDA Topics A weakness of the LDA topics feature type is that it may result in a regressor that has trouble distinguishing between an infrequent topic that is adherent to the prompt and one that just represents an irrelevant digression. This is because an infrequent topic may not appear in the training set often enough for the regressor to make this judgment. We introduce the manually annotated LDA topics feature type to address this problem.

In order to construct manually annotated LDA topic features, we first build 13 topic models, one for each prompt, just as described in the section on LDA topic features. Rather than requesting models of 1,000 topics, however, we request models of only 100 topics[2]. We then go through all 13 lists of 100 topics as represented by their top ten words, manually annotating each topic with a number from 0 to 5 representing how likely it is that the topic is adherent to the prompt. A topic labeled 5 is very likely to be related to the prompt, where a topic labeled 0 appears totally unrelated.

Using these annotations alongside the topic distribution for each essay that the topic models provide us, we construct ten features. The first five features encode the sum of the contributions to an essay of topics annotated with a number ≥ 1, the sum of the contributions to an essay of topics annotated with a number ≥ 2, and so on up to 5.

The next five features are similar to the last, with one feature taking on the sum of the contributions to an essay of topics annotated with the number 0, another feature taking on the sum of the

[2]We use 100 topics for each prompt in the manually annotated version of LDA features rather than the 1,000 topics we use in the regular version of LDA features because 1,300 topics are not too costly to annotate, but manually annotating 13,000 topics would take too much time.

contributions to an essay of topics annotated with the number 1, and so on up to 4. We do not include a feature for topics annotated with the number 5 because it would always have the same value as the feature for topics ≥ 5.

Features like these should give the regressor a better idea how much of an essay is composed of prompt-related arguments and discussion and how much of it is irrelevant to the prompt, even if some of the topics occurring in it are too infrequent to judge just from training data.

7. Predicted Thesis Clarity Errors In our previous work on essay thesis clarity scoring (Persing and Ng, 2013), we identified five classes of errors that detract from the clarity of an essay's thesis:
Confusing Phrasing. The thesis is phrased oddly, making it hard to understand the writer's point.
Incomplete Prompt Response. The thesis leaves some part of a multi-part prompt unaddressed.
Relevance to Prompt. The apparent thesis's weak relation to the prompt causes confusion.
Missing Details. The thesis leaves out an important detail needed to understand the writer's point.
Writer Position. The thesis describes a position on the topic without making it clear that this is the position the writer supports.

We hypothesize that these errors, though originally intended for thesis clarity scoring, could be useful for prompt adherence scoring as well. For instance, an essay that has a Relevance to Prompt error or an Incomplete Prompt Response error should intuitively receive a low prompt adherence score. For this reason, we introduce features based on these errors to our feature set for prompt adherence scoring[3].

While each of the essays in our data set was previously annotated with these thesis clarity errors, in a realistic setting a prompt adherence scoring system will not have access to these manual error labels. As a result, we first need to predict which of these errors is present in each essay. To do this, we train five maximum entropy classifiers for each prompt, one for each of the five thesis clarity errors, using MALLET's (McCallum, 2002) implementation of maximum entropy classification. Instances are presented to classifier for prompt p for error e in the following way. If a training essay is written in response to p, it will be used to generate a training instance whose label is 1 if e was annotated for it or 0 otherwise. Since error prediction and prompt adherence scoring are related problems, the features we associate with this instance are features $1-6$ which we have described earlier in this section. The classifier is then used to generate probabilities telling us how likely it is that each test essay has error e.

Then, when training our regressor for prompt adherence scoring, we add the following features to our instances. We add a binary feature indicating the presence or absence of each error. Or in the case of test essays, the feature takes on a real value from 0 to 1 indicating how likely the classifier thought it was that the essay had each of the errors. This results in five additional features, one for each error.

5 Evaluation

In this section, we evaluate our system for prompt adherence scoring. All the results we report are obtained via five-fold cross-validation experiments. In each experiment, we use $\frac{3}{5}$ of our labeled essays for model training, another $\frac{1}{5}$ for parameter tuning, and the final $\frac{1}{5}$ for testing.

5.1 Experimental Setup

5.1.1 Scoring Metrics

We employ four evaluation metrics. As we will see below, $S1$, $S2$, and $S3$ are *error* metrics, so lower scores imply better performance. In contrast, PC is a *correlation* metric, so higher correlation implies better performance.

The simplest metric, $S1$, measures the frequency at which a system predicts the wrong score out of the seven possible scores. Hence, a system that predicts the right score only 25% of the time would receive an $S1$ score of 0.75.

The $S2$ metric measures the average distance between a system's score and the actual score. This metric reflects the idea that a system that predicts scores close to the annotator-assigned scores should be preferred over a system whose predictions are further off, even if both systems estimate the correct score at the same frequency.

The $S3$ metric measures the average square of the distance between a system's score predictions and the annotator-assigned scores. The intuition behind this system is that not only should we prefer a system whose predictions are close to the annotator scores, but we should also prefer

[3]See our website at `http://www.hlt.utdallas.edu/~persingq/ICLE/` for the complete list of error annotations.

one whose predictions are not too frequently very far away from the annotator scores. These three scores are given by:

$$\frac{1}{N}\sum_{A_j \neq E'_j} 1, \quad \frac{1}{N}\sum_{i=1}^{N} |A_j - E_j|, \quad \frac{1}{N}\sum_{i=1}^{N} (A_j - E_j)^2$$

where A_j, E_j, and E'_j are the annotator assigned, system predicted, and rounded system predicted scores[4] respectively for essay j, and N is the number of essays.

The last metric, PC, computes Pearson's correlation coefficient between a system's predicted scores and the annotator-assigned scores. PC ranges from -1 to 1. A positive (negative) PC implies that the two sets of predictions are positively (negatively) correlated.

5.1.2 Parameter Tuning

As mentioned earlier, for each prompt p_i, we train a linear regressor r_i using LIBSVM with regularization parameter c_i. To optimize our system's performance on the three error measures described previously, we use held-out validation data to independently tune each of the c_i values[5]. Note that each of the c_i values can be tuned independently because a c_i value that is optimal for predicting scores for p_i essays with respect to any of the error performance measures is necessarily also the optimal c_i when measuring that error on essays from all prompts. However, this is not case with Pearson's correlation coefficient, as the PC value for essays from all 13 prompts cannot be simplified as a weighted sum of the PC values obtained on each individual prompt. In order to obtain an optimal result as measured by PC, we jointly tune the c_i parameters to optimize the PC value achieved by our system on the same held-out validation data. However, an exact solution to this optimization problem is computationally expensive, as there are too many (7^{13}) possible combinations of c values to exhaustively search. Consequently, we find a local maximum by employing the simulated annealing algorithm (Kirkpatrick et al., 1983), altering one c_i value at a time to optimize PC while holding the remaining parameters fixed.

[4]Since our regressor assigns each essay a real value rather than an actual valid score, it would be difficult to obtain a reasonable $S1$ score without rounding the system estimated score to one of the possible values. For that reason, we round the estimated score to the nearest of the seven scores the human annotators were permitted to assign (1.0, 1.5, 2.0, 2.5, 3.0, 3.5, 4.0) only when calculating $S1$. For other scoring metrics, we only round the predictions to 1.0 or 4.0 if they fall outside the 1.0−4.0 range.

[5]For parameter tuning, we employ the following values. c_i may be assigned any of the values 10^0 10^1, 10^2, 10^3, 10^4, 10^5, or 10^6.

System	$S1$	$S2$	$S3$	PC
Baseline	.517	.368	.234	.233
Our System	.488	.348	.197	.360

Table 4: Five-fold cross-validation results for prompt adherence scoring.

5.2 Results and Discussion

Five-fold cross-validation results on prompt adherence score prediction are shown in Table 4. On the first line, this table shows that our baseline system, which recall uses only various RI features, predicts the wrong score 51.7% of the time. Its predictions are off by an average of .368 points, and the average squared distance between its predicted score and the actual score is .234. In addition, its predicted scores and the actual scores have a Pearson correlation coefficient of 0.233.

The results from our system, which uses all seven feature types described in Section 4, are shown in row 2 of the table. Our system obtains $S1$, $S2$, $S3$, and PC scores of .488, .348, .197, and .360 respectively, yielding a significant improvement over the baseline with respect to $S2$, $S3$, and PC with $p < 0.05$, $p < 0.01$, and $p < 0.06$ respectively[6]. While our system yields improvements by all four measures, its improvement over the baseline $S1$ score is not significant. These results mean that the greatest improvements our system makes are that it ensures that our score predictions are not too often very far away from an essay's actual score, as making such predictions would tend to drive up $S3$, yielding a relative error reduction in $S3$ of 15.8%, and it also ensures a better correlation between predicted and actual scores, thus yielding the 16.6% improvement in PC.[7] It also gives more modest improvements in how frequently exactly the right score is predicted ($S1$) and is better at predicting scores closer to the actual scores ($S2$).

5.3 Feature Ablation

To gain insight into how much impact each of the feature types has on our system, we perform fea-

[6]All significance tests are paired t-tests.

[7]These numbers are calculated $\frac{B-O}{B-P}$ where B is the baseline system's score, O is our system's score, and P is a perfect score. Perfect scores for error measures and PC are 0 and 1 respectively.

ture ablation experiments in which we remove the feature types from our system one-by-one.

Results of the ablation experiments when performed using the four scoring metrics are shown in Table 5. The top line of each subtable shows what our system's score would be if we removed just one of the feature types from our system. So to see how our system performs by the $S1$ metric if we remove only predicted thesis clarity error features, we would look at the first row of results of Table 5(a) under the column headed by the number 7 since predicted thesis clarity errors are the seventh feature type introduced in Section 4. The number here tells us that our system's $S1$ score without this feature type is .502. Since Table 4 shows that when our system includes this feature type (along with all the other feature types), it obtains an $S1$ score of .488, this feature type's removal costs our system .014 $S1$ points, and thus its inclusion has a beneficial effect on the $S1$ score.

From row 1 of Table 5(a), we can see that removing feature 4 yields a system with the best $S1$ score in the presence of the other feature types in this row. For this reason, we permanently remove feature 4 from the system before we generate the results on line 2. Thus, we can see what happens when we remove both feature 4 and feature 5 by looking at the second entry in row 2. And since removing feature 6 harms performance least in the presence of row 2's other feature types, we permanently remove both 4 and 6 from our feature set when we generate the third row of results. We iteratively remove the feature type that yields a system with the best performance in this way until we get to the last line, where only one feature type is used to generate each result.

Since the feature type whose removal yields the best system is always the rightmost entry in a line, the order of column headings indicates the relative importance of the feature types, with the leftmost feature types being most important to performance and the rightmost feature types being least important in the presence of the other feature types. This being the case, it is interesting to note that while the relative importance of different feature types does not remain exactly the same if we measure performance in different ways, we can see that some feature types tend to be more important than others in a majority of the four scoring metrics. Features 2 (n-grams), 3 (thesis clarity keywords), and 6 (manually annotated LDA topics) tend to be the most important feature types, as they tend to be the last feature types removed in the ablation subtables. Features 1 (RI) and 5 (LDA topics) are of middling importance, with neither ever being removed first or last, and each tending to have a moderate effect on performance. Finally, while features 4 (prompt adherence keywords) and 7 (predicted thesis clarity errors) may by themselves provide useful information to our system, in the presence of the other feature types they tend to be the least important to performance as they are often the first feature types removed.

While there is a tendency for some feature types to always be important (or unimportant) regardless of which scoring metric is used to measure per-

Table 6: Regressor scores for our system.

formance, the relative importance of different feature types does not always remain consistent if we measure performance in different ways. For example, while we identified feature 3 (thesis clarity keywords) as one of the most important feature types generally due to its tendency to have a large beneficial impact on performance, when we are measuring performance using $S3$, it is the least useful feature type. Furthermore, its removal increases the $S3$ score by a small amount, meaning that its inclusion actually makes our system perform worse with respect to $S3$. Though feature 3 is an extreme example, all feature types fluctuate in importance, as we see when we compare their orders of removal among the four ablation subtables. Hence, it is important to know how performance is measured when building a system for scoring prompt adherence.

Feature 3 is not the only feature type whose removal sometimes has a beneficial impact on performance. As we can see in Table 5(b), the removal of features 4, 5, and 7 improves our system's $S2$ score by .001 points. The same effect occurs in Table 5(c) when we remove features 4, 7, and 3. These examples illustrate that under some scoring metrics, the inclusion of some feature types is actively harmful to performance. Fortunately, this effect does not occur in any other cases than the two listed above, as most feature types usually have a beneficial or at least neutral impact on our system's performance.

For those feature types whose effect on performance is neutral in the first lines of ablation results (feature 4 in $S1$, features 3, 5, and 7 in $S2$, and features 1, 4, 5, and 7 in $S3$), it is important to note that their neutrality does not mean that they are unimportant. It merely means that they do not improve performance in the presence of other feature types. We can see this is the case by noting that they are not all the least important feature types in their respective subtables as indicated by column order. For example, by the time feature 1 gets permanently removed in Table 5(c), its removal harms performance by .002 $S3$ points.

5.4 Analysis of Predicted Scores

To more closely examine the behavior of our system, in Table 6 we chart the distributions of scores it predicts for essays having each gold standard score. As an example of how to read this table, consider the number 3.06 appearing in row 2.0 in the .25 column of the $S3$ region. This means that 25% of the time, when our system with parameters tuned for optimizing $S3$ is presented with a test essay having a gold standard score of 2.0, it predicts that the essay has a score less than or equal to 3.06.

From this table, we see that our system has a strong bias toward predicting more frequent scores as there are no numbers less than 3.0 in the table, and about 93.7% of all essays have gold standard scores of 3.0 or above. Nevertheless, our system does not rely entirely on bias, as evidenced by the fact that each column in the table has a tendency for its scores to ascend as the gold standard score increases, implying that our system has some success at predicting lower scores for essays with lower gold standard prompt adherence scores.

Another interesting point to note about this table is that the difference in error weighting between the $S2$ and $S3$ scoring metrics appears to be having its desired effect, as every entry in the $S3$ subtable is less than its corresponding entry in the $S2$ subtable due to the greater penalty the $S3$ metric imposes for predictions that are very far away from the gold standard scores.

6 Conclusion

We proposed a feature-rich approach to the under-investigated problem of predicting essay-level prompt adherence scores on student essays. In an evaluation on 830 argumentative essays selected from the ICLE corpus, our system significantly outperformed a Random Indexing based baseline by several evaluation metrics. To stimulate further research on this task, we make all our annotations, including our prompt adherence scores, the LDA topic annotations, and the error annotations publicly available.

Abstract

We introduce *ConnotationWordNet*, a connotation lexicon over the network of *words* in conjunction with *senses*. We formulate the lexicon induction problem as collective inference over pairwise-Markov Random Fields, and present a loopy belief propagation algorithm for inference. The key aspect of our method is that it is the *first unified* approach that assigns the polarity of *both* word- and sense-level connotations, exploiting the innate bipartite graph structure encoded in WordNet. We present comprehensive evaluation to demonstrate the quality and utility of the resulting lexicon in comparison to existing connotation and sentiment lexicons.

1 Introduction

We introduce *ConnotationWordNet*, a connotation lexicon over the network of *words* in conjunction with *senses*, as defined in WordNet. A connotation lexicon, as introduced first by Feng et al. (2011), aims to encompass subtle shades of sentiment a word may conjure, even for seemingly objective words such as *"sculpture"*, *"Ph.D."*, *"rosettes"*. Understanding the rich and complex layers of connotation remains to be a challenging task. As a starting point, we study a more feasible task of learning the *polarity* of connotation.

For non-polysemous words, which constitute a significant portion of English vocabulary, learning the *general* connotation at the *word-level* (rather than at the *sense-level*) would be a natural operational choice. However, for polysemous words, which correspond to most frequently used words, it would be an overly crude assumption that the same connotative polarity should be assigned for all senses of a given word. For example, consider *"abound"*, for which lexicographers of WordNet prescribe two different senses:

- (v) **abound**: (be abundant of plentiful; exist in large quantities)
- (v) **abound, burst, bristle**: (be in a state of movement or action) *"The room abounded with screaming children"*; *"The garden bristled with toddlers"*

For the first sense, which is the most commonly used sense for *"abound"*, the general overtone of the connotation would seem positive. That is, although one can use this sense in both positive and negative contexts, this sense of *"abound"* seems to collocate more often with items that are good to be abundant (e.g., *"resources"*), than unfortunate items being abundant (e.g., *"complaints"*).

However, as for the second sense, for which *"burst"* and *"bristle"* can be used interchangeably with respect to this particular sense,[1] the general overtone is slightly more negative with a touch of unpleasantness, or at least not as positive as that of the first sense. Especially if we look up the WordNet entry for *"bristle"*, there are noticeably more negatively connotative words involved in its gloss and examples.

This word sense issue has been a universal challenge for a range of Natural Language Processing applications, including sentiment analysis. Recent studies have shown that it is fruitful to tease out subjectivity and objectivity corresponding to different senses of the same word, in order to improve computational approaches to sentiment analysis (e.g. Pestian et al. (2012), Mihalcea et al. (2012) Balahur et al. (2014)). Encouraged by these recent successes, in this study, we investigate if we can attain similar gains if we model the connotative polarity of senses separately.

There is one potential practical issue we would like to point out in building a sense-level lexical resource, however. End-users of such a lexicon may not wish to deal with Word Sense Disam-

[1] Hence a *sense* in WordNet is defined by *synset (= synonym set)*, which is the set of words sharing the same sense.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1544–1554,
Baltimore, Maryland, USA, June 23-25 2014.

biguation (WSD), which is known to be often too noisy to be incorporated into the pipeline with respect to other NLP tasks. As a result, researchers often would need to aggregate labels across different senses to derive the word-level label. Although such aggregation is not entirely unreasonable, it does not seem to be the most optimal and principled way of integrating available resources.

Therefore, in this work, we present the first unified approach that learns *both* sense- and word-level connotations simultaneously. This way, end-users will have access to more accurate sense-level connotation labels if needed, while also having access to more general word-level connotation labels. We formulate the lexicon induction problem as collective inference over pairwise-Markov Random Fields (pairwise-MRF) and derive a loopy belief propagation algorithm for inference.

The key aspect of our approach is that we exploit the innate bipartite graph structure between words and senses encoded in WordNet. Although our approach seems conceptually natural, previous approaches, to our best knowledge, have not directly exploited these relations between words and senses for the purpose of deriving lexical knowledge over words and senses collectively. In addition, previous studies (for both sentiment and connotation lexicons) aimed to produce only either of the two aspects of the polarity: word-level or sense-level, while we address both.

Another contribution of our work is the introduction of loopy belief propagation (loopy-BP) as a lexicon induction algorithm. Loopy-BP in our study achieves statistically significantly better performance over the constraint optimization approaches previously explored. In addition, it runs much faster and it is considerably easier to implement. Last but not least, by using probabilistic representation of pairwise-MRF in conjunction with Loopy-BP as inference, the resulting solution has the natural interpretation as the intensity of connotation. This contrasts to approaches that seek discrete solutions such as Integer Linear Programming(Papadimitriou and Steiglitz, 1998).

ConnotationWordNet, the final outcome of our study, is a new lexical resource that has connotation labels over both words and senses following the structure of WordNet. The lexicon is publicly available at: `http://www.cs.sunysb.edu/~junkang/connotation_wordnet`.)

In what follows, we will first describe the network of words and senses (Section 2), then introduce the representation of the network structure as pairwise Markov Random Fields, and a loopy belief propagation algorithm as collective inference (Section 3). We then present comprehensive evaluation (Section 4 & 5 & 6), followed by related work (Section 7) and conclusion (Section 8).

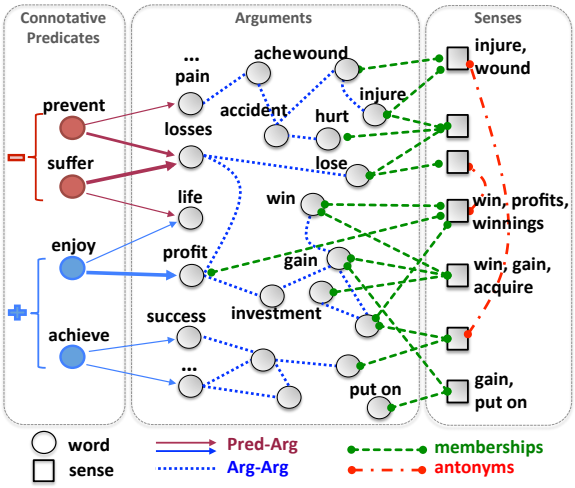

Figure 1: $G^{\text{WORD+SENSE}}$ with words and senses.

2 Network of Words and Senses

The connotation graph, called $G^{\text{WORD+SENSE}}$, is a heterogeneous graph with multiple types of nodes and edges. As shown in Figure 1, it contains two types of nodes; (i) lemmas (i.e., words, 115K) and (ii) synsets (63K), and four types of edges; (t_1) predicate-argument (179K), (t_2) argument-argument (144K), (t_3) argument-synset (126K), and (t_4) synset-synset (3.4K) edges.

The predicate-argument edges, first introduced by Feng et al. (2011), depict the selectional preference of connotative predicates (i.e., the polarity of a predicate indicates the polarity of its arguments) and encode their co-occurrence relations based on the Google Web 1T corpus. The argument-argument edges are based on the distributional similarities among the arguments. The argument-synset edges capture the synonymy between argument nodes through the corresponding synsets. Finally, the synset-synset edges depict the antonym relations between synset pairs.

In general, our graph construction is similar to that of Feng et al. (2013), but there are a few important differences. Most notably, we model both words and synsets explicitly, and exploit the membership relations between words and senses. We expect that edges between words and senses will encourage *senses that belong to the same word* to

receive the same connotation label. Conversely, we expect that these edges will also encourage *words that belong to the same sense* (i.e., synset definition) to receive the same connotation label.

Another benefit of our approach is that for various WordNet relations (e.g., antonym relations), which are defined over synsets (not over words), we can add edges directly between corresponding synsets, rather than projecting (i.e., approximating) those relations over words. Note that the latter, which has been employed by several previous studies (e.g., Kamps et al. (2004), Takamura et al. (2005), Andreevskaia and Bergler (2006), Su and Markert (2009), Lu et al. (2011), Kaji and Kitsuregawa (2007), Feng et al. (2013)), could be a source of noise, as one needs to assume that the semantic relation between a pair of synsets transfers over the pair of words corresponding to that pair of synsets. For polysemous words, this assumption may be overly strong.

3 Pairwise Markov Random Fields and Loopy Belief Propagation

We formulate the task of learning sense- and word-level connotation lexicon as a graph-based classification task (Sen et al., 2008). More formally, we denote the connotation graph $\text{G}^{\text{WORD+SENSE}}$ by $G = (V, E)$, in which a total of n word and synset nodes $V = \{v_1, \ldots, v_n\}$ are connected with typed edges $e(v_i, v_j, t) \in E$, where edge types $t \in \{pred\text{-}arg, arg\text{-}arg, syn\text{-}arg, syn\text{-}syn\}$ depict the four edge types as described in Section 2. A neighborhood function $\mathcal{N}$, where $\mathcal{N}_v = \{u|\ e(u, v) \in E\} \subseteq V$, describes the underlying network structure.

In our collective classification formulation, each node in V is represented as a random variable that takes a value from an appropriate class label domain; in our case, $\mathcal{L} = \{+, -\}$ for positive and negative connotation. In this classification task, we denote by $\mathcal{Y}$ the nodes the labels of which need to be assigned, and let y_i refer to Y_i's label.

3.1 Pairwise Markov Random Fields

We next define our objective function. We propose to use an objective formulation that utilizes pairwise Markov Random Fields (MRFs) (Kindermann and Snell, 1980), which we adapt to our problem setting. MRFs are a class of probabilistic graphical models that are suited for solving inference problems in networked data. An MRF consists of an undirected graph where each node can be in any of a finite number of states (i.e., class labels). The state of a node is assumed to be dependent on each of its neighbors and independent of other nodes in the graph.[2] In pairwise MRFs, the joint probability of the graph can be written as a product of pairwise factors, parameterized over the edges. These factors are referred to as clique potentials in general MRFs, which are essentially functions that collectively determine the graph's joint probability.

Specifically, let $G = (V, E)$ denote a network of random variables, where V consists of the unobserved variables $\mathcal{Y}$ that need to be assigned values from label set $\mathcal{L}$. Let Ψ denote a set of clique potentials that consists of two types of factors:

- For each $Y_i \in \mathcal{Y}$, $\psi_i \in \Psi$ is a *prior* mapping $\psi_i : \mathcal{L} \rightarrow \mathbb{R}_{\geq 0}$, where $\mathbb{R}_{\geq 0}$ denotes non-negative real numbers.
- For each $e(Y_i, Y_j, t) \in E$, $\psi_{ij}^t \in \Psi$ is a *compatibility* mapping $\psi_{ij}^t : \mathcal{L} \times \mathcal{L} \rightarrow \mathbb{R}_{\geq 0}$.

Objective formulation Given an assignment $\mathbf{y}$ to all the unobserved variables $\mathcal{Y}$ and $\mathbf{x}$ to observed ones $\mathcal{X}$ (variables with known labels, if any), our objective function is associated with the following joint probability distribution

$$P(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \prod_{Y_i \in \mathcal{Y}} \psi_i(y_i) \prod_{e(Y_i, Y_j, t) \in E} \psi_{ij}^t(y_i, y_j) \quad (1)$$

where $Z(\mathbf{x})$ is the normalization function. Our goal is then to infer the maximum likelihood assignment of states (i.e., labels) to unobserved variables (i.e., nodes) that will maximize Equation (1).

Problem Definition Having introduced our graph-based classification task and objective formulation, we define our problem more formally.

Given
- a connotation graph $G = (V, E)$ of words and synsets connected with *typed* edges,
- *prior* knowledge (i.e., probabilities) of (some or all) nodes belonging to each class,
- *compatibility* of two nodes with a given pair of labels being connected to each other;

Classify the nodes $Y_i \in \mathcal{Y}$, into one of two classes; $\mathcal{L} = \{+, -\}$, such that the class assignments y_i maximize our objective in Equation (1).

We can further *rank* the network objects by the probability of their connotation polarity.

[2] This assumption yields a *pairwise* Markov Random Field (MRF); a special case of general MRFs (Yedidia et al., 2003).

3.2 Loopy Belief Propagation

Finding the best assignments to unobserved variables in our objective function is the inference problem. The brute force approach through enumeration of all possible assignments is exponential and thus intractable. In general, exact inference is known to be NP-hard and there is no known algorithm which can be theoretically shown to solve the inference problem for general MRFs. Therefore in this work, we employ a computationally tractable (in fact linearly scalable with network size) approximate inference algorithm called Loopy Belief Propagation (LBP) (Yedidia et al., 2003), which we extend to handle typed graphs like our connotation graph.

Our inference algorithm is based on iterative message passing and the core of it can be concisely expressed as the following two equations:

$$m_{i\to j}(y_j) = \alpha \sum_{y_i \in \mathcal{L}} \left(\psi_{ij}^t(y_i, y_j)\ \psi_i(y_i) \prod_{Y_k \in \mathcal{N}_i \cap \mathcal{Y} \setminus Y_j} m_{k\to i}(y_i) \right), \quad \forall y_j \in \mathcal{L} \tag{2}$$

$$b_i(y_i) = \beta\ \psi_i(y_i) \prod_{Y_j \in \mathcal{N}_i \cap \mathcal{Y}} m_{j\to i}(y_i), \forall y_i \in \mathcal{L} \tag{3}$$

A message $m_{i\to j}$ is sent from node i to node j and captures the belief of i about j, which is the probability distribution over the labels of j; i.e. what i "thinks" j's label is, given the current label of i and the *type* of the edge that connects i and j. Beliefs refer to marginal probability distributions of nodes over labels; for example $b_i(y_i)$ denotes the *belief* of node i having label y_i. α and β are the normalization constants, which respectively ensure that each message and each set of marginal probabilities sum to 1. At every iteration, each node computes its belief based on messages received from its neighbors, and uses the compatibility mapping to transform its belief into messages for its neighbors. The key idea is that after enough iterations of message passes between the nodes, the "conversations" are likely to come to a consensus, which determines the marginal probabilities of all the unknown variables.

The pseudo-code of our method is given in Algorithm 1. It first initializes all messages to 1 and *prior*s to unbiased (i.e., equal) probabilities for all nodes except the seed nodes for which the sentiment is known (lines 3-9). It then proceeds by making each $Y_i \in \mathcal{Y}$ communicate messages

Algorithm 1: CONNOTATION INFERENCE

1 **Input:** Connotation graph G=(V, E), prior potentials ψ_s for seed words $s \in S$, and compatibility potentials ψ_{ij}^t
2 **Output:** Connotation label probabilities for each node $i \in V \setminus P$
3 **foreach** $e(Y_i, Y_j, t) \in E$ **do** // *initialize msg.s*
4 **foreach** $y_j \in \mathcal{L}$ **do**
5 $m_{i\to j}(y_j) \leftarrow 1$
6 **foreach** $i \in V$ **do** // *initialize priors*
7 **foreach** $y_j \in \mathcal{L}$ **do**
8 **if** $i \in S$ **then** $\phi_i(y_j) \leftarrow \psi_i(y_j)$ **else** $\phi_i(y_j) \leftarrow 1/|\mathcal{L}|$
9 **repeat** // *iterative message passing*
10 **foreach** $e(Y_i, Y_j, t) \in E$, $Y_j \in \mathcal{Y}^{V\setminus S}$ **do**
11 **foreach** $y_j \in \mathcal{L}$ **do**
12 Use Equation (2)
13 **until** all messages stop changing
14 **foreach** $Y_i \in \mathcal{Y}^{V\setminus S}$ **do** // *compute final beliefs*
15 **foreach** $y_i \in \mathcal{L}$ **do**
16 Use Equation (3)

with their neighbors in an iterative fashion until the messages stabilize (lines 10-14), i.e. convergence is reached.[3] At convergence, we calculate the marginal probabilities, that is of assigning Y_i with label y_i, by computing the final beliefs $b_i(y_i)$ (lines 15-17). We use these maximum likelihood probabilities for label assignment; for each node i, we assign the label $\mathcal{L}_i \leftarrow \max_{y_i} b_i(y_i)$.

To completely define our algorithm, we need to instantiate the potentials Ψ, in particular the priors and the compatibilities, which we discuss next.

Priors The *prior* beliefs ψ_i of nodes can be suitably initialized if there is any prior knowledge for their connotation sentiment (e.g., `enjoy` is positive, `suffer` is negative). As such, our method is flexible to integrate available side information. In case there is no prior knowledge available, each node is initialized equally likely to have any of the possible labels, i.e., $\frac{1}{|\mathcal{L}|}$ as in Algorithm 1 (line 9).

Compatibilities The *compatibility* potentials can be thought of as matrices, with entries

[3] Although convergence is not theoretically guaranteed, in practice LBP converges to beliefs within a small threshold of change (e.g., 10^{-6}) fairly quickly with accurate results (Pandit et al., 2007; McGlohon et al., 2009; Akoglu et al., 2013).

$\psi_{ij}^t(y_i, y_j)$ that give the likelihood of a node having label y_i, given that it has a neighbor with label y_j to which it is connected through a type t edge. A key difference of our method from earlier models is that we use clique potentials that differ for edge types, since the connotation graph is heterogeneous. This is exactly because the compatibility of class labels of two adjacent nodes depends on the type of the edge connecting them: e.g., $+ \xrightarrow{syn\text{-}arg} +$ is highly compatible, whereas $+ \xrightarrow{syn\text{-}syn} +$ is unlikely; as $syn\text{-}arg$ edges capture synonymy; i.e., words-sense memberships, while $syn\text{-}syn$ edges depict antonym relations.

A sample instantiation of the compatibilities is shown in Table 1. Notice that the potentials for $pred\text{-}arg$, $arg\text{-}arg$, and $syn\text{-}arg$ capture homophily, i.e., nodes with the same label are likely to connect to each other through these types of edges.[4] On the other hand, $syn\text{-}syn$ edges connect nodes that are antonyms of each other, and thus the compatibilities capture the reverse relationship among their labels.

Table 1: Instantiation of compatibility potentials. Entry $\psi_{ij}^t(y_i, y_j)$ is the compatibility of a node with label y_i having a neighbor labeled y_j, given the edge between i and j is type t, for small ϵ.

t: t_1	**A**	
P	+	−
+	1-ϵ	ϵ
−	ϵ	1-ϵ

(t_1) $pred\text{-}arg$

t: t_2	**A**	
A	+	−
+	1-2ϵ	2ϵ
−	2ϵ	1-2ϵ

(t_2) $arg\text{-}arg$

t: t_3	**A**	
S	+	−
+	1-ϵ	ϵ
−	ϵ	1-ϵ

(t_3) $syn\text{-}arg$
(synonym relations)

t: t_4	**S**	
S	+	−
+	ϵ	1-ϵ
−	1-ϵ	ϵ

(t_4) $syn\text{-}syn$
(antonym relations)

Complexity analysis Most demanding component of Algorithm 1 is the iterative message passing over the edges (lines 10-14), with time complexity $O(ml^2r)$, where $m = |E|$ is the number of edges in the connotation graph, $l = |\mathcal{L}|$, the classes, and r, the iterations until convergence. Often, l is quite small (in our case, $l = 2$) and $r \ll m$. Thus running time grows linearly with the number of edges and is scalable to large datasets.

[4] $arg\text{-}arg$ edges are based on co-occurrence (see Section 2), which does not carry as strong indication of the same connotation as e.g., synonymy. Thus, we enforce less homophily for nodes connected through edges of $arg\text{-}arg$ type.

4 Evaluation I: Agreement with Sentiment Lexicons

ConnotationWordNet is expected to be the superset of a sentiment lexicon, as it is highly likely for any word with positive/negative sentiment to carry connotation of the same polarity. Thus, we use two conventional sentiment lexicons, General Inquirer (GENINQ) (Stone et al., 1966) and MPQA (Wilson et al., 2005b), as surrogates to measure the performance of our inference algorithm.

4.1 Variants of Graph Construction

The construction of the connotation graph, denoted by $G^{WORD+SENSE}$, which includes words and synsets, has been described in Section 2. In addition to this graph, we tried several other graph constructions, the first three of which have previously been used in (Feng et al., 2013). We briefly describe these graphs below, and compare performance on all the graphs in the proceeding.

G^{WORD} W/ PRED-ARG: This is a (bipartite) subgraph of $G^{WORD+SENSE}$, which only includes the connotative predicates and their arguments. As such, it contains only type t_1 edges. The edges between the predicates and the arguments can be weighted by their Point-wise Mutual Information (PMI)[5] based on the Google Web 1T corpus.

G^{WORD} W/ OVERLAY: The second graph is also a proper subgraph of $G^{WORD+SENSE}$, which includes the predicates and all the argument words. Predicate words are connected to their arguments as before. In addition, argument pairs (a_1, a_2) are connected if they occurred together in the "a_1 and a_2" or "a_2 and a_1" coordination (Hatzivassiloglou and McKeown, 1997; Pickering and Branigan, 1998). This graph contains both type t_1 and t_2 edges. The edges can also be weighted based on the distributional similarities of the word pairs.

G^{WORD}: The third graph is a super-graph of G^{WORD} W/ OVERLAY, with additional edges, where argument pairs in synonym and antonym relation are connected to each other. Note that unlike the connotation graph $G^{WORD+SENSE}$, it does *not* contain any synset nodes. Rather, the words that are synonyms or antonyms of each other are directly linked in the graph. As such, this graph contains all edge types t_1 through t_4.

[5] PMI scores are widely used in previous studies to measure association between words (e.g., (Church and Hanks, 1990), (Turney, 2001), (Newman et al., 2009)).

G$^{\text{WORD+SENSE}}$ W/ SYNSIM: This is a super-graph of our original G$^{\text{WORD+SENSE}}$ graph; that is, it has all the predicate, arguments, and synset nodes, as well as the four types of edges between them. In addition, we add edges of a fifth type t_5 between the synset nodes to capture their similarity. To define similarity, we use the glossary definitions of the synsets and derive three different scores. Each score utilizes the `count`(s_1, s_2) of overlapping nouns, verbs, and adjectives/adverbs among the glosses of the two synsets s_1 and s_2.

G$^{\text{WORD+SENSE}}$ W/ SYNSIM1: We discard edges with `count` less than 3. The weighted version has the `counts` normalized between 0 and 1.

G$^{\text{WORD+SENSE}}$ W/ SYNSIM2: We normalize the `counts` by the length of the gloss (the avg of two lengths), that is, p = `count / avg(len_gloss(`s_1`), len_gloss(`s_2`))` and discard edges with $p < 0.5$. The weighted version contains p values as edge weights.

G$^{\text{WORD+SENSE}}$ W/ SYNSIM3: To further sparsify the graph we discard edges with $p < 0.6$. To weigh the edges, we use the cosine similarity between the gloss vectors of the synsets based on the TF-IDF values of the words the glosses contain.

Note that the connotation inference algorithm, as given in Algorithm 1, remains exactly the same for all the graphs described above. The only difference is the set of parameters used; while G$^{\text{WORD}}$ W/ PRED-ARG and G$^{\text{WORD}}$ W/ OVERLAY contain one and two edge types, respectively and only use compatibilities (t_1) and (t_2), G$^{\text{WORD}}$ uses all four as given in Table 1. The G$^{\text{WORD+SENSE}}$ W/ SYNSIM graphs use an additional compatibility matrix for the synset similarity edges of type t_5, which is the same as the one used for t_1, i.e., similar synsets are likely to have the same connotation label. This flexibility is one of the key advantages of our algorithm as new types of nodes and edges can be added to the graph seamlessly.

4.2 Sentiment-Lexicon based Performance

In this section, we first compare the performance of our connotation graph G$^{\text{WORD+SENSE}}$ to graphs that do not include synset nodes but only words. Then we analyze the performance when the additional synset similarity edges are added. First, we briefly describe our performance measures.

The sentiment lexicons we use as gold standard are small, compared to the size (i.e., number of words) our graphs contain. Thus, we first find the `overlap` between each graph and a sentiment lexicon. Note that the `overlap` size may be smaller than the `lexicon size`, as some sentiment words may be missing from our graphs. Then, we calculate the number of `correct` label assignments. As such, precision is defined as (`correct` / `overlap`), and recall as (`correct` / `lexicon size`). Finally, F1-score is their harmonic mean and reflects the overall accuracy.

	GENINQ			MPQA
	P	**R**	**F**	**F**
Variations of G$^{\text{WORD}}$				
W/ PRED-ARG	88.0	67.6	76.5	57.3
W/ PRED-ARG-W	84.9	68.9	76.1	57.8
W/ OVERLAY	87.8	70.4	78.1	58.4
W/ OVERLAY-W	82.2	67.7	74.2	54.2
G$^{\text{WORD}}$	88.5	83.1	85.7	69.7
G$^{\text{WORD}}$-W	75.5	71.5	73.4	53.2
Variations of G$^{\text{WORD+SENSE}}$				
G$^{\text{WORD+SENSE}}$	**88.8**	**84.1**	**86.4**	**70.0**
G$^{\text{WORD+SENSE}}$-W	76.8	73.0	74.9	54.6
W/ SYNSIM1	87.2	83.3	85.2	67.9
W/ SYNSIM2	83.9	80.8	82.3	65.1
W/ SYNSIM3	86.5	83.2	84.8	67.8
W/ SYNSIM1-W	88.0	**84.3**	86.1	69.2
W/ SYNSIM2-W	86.4	83.7	85.0	68.5
W/ SYNSIM3-W	86.7	83.4	85.0	68.2

Table 2: Connotation inference performance on various graphs. '-W' indicates weighted versions (see §4.1). **P**: precision, **R**: recall, **F**: F1-score (%).

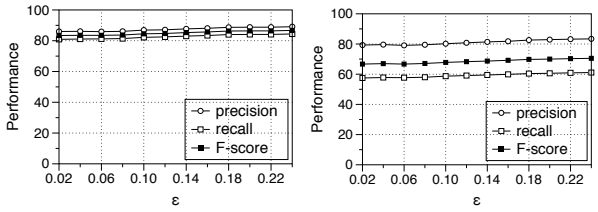
As shown in Table 2 (top), we first observe that including the synonym and antonym relations in the graph, as with G$^{\text{WORD}}$ and G$^{\text{WORD+SENSE}}$, improve the performance significantly, almost by an order of magnitude, over graphs G$^{\text{WORD}}$ W/ PRED-ARG and G$^{\text{WORD}}$ W/ OVERLAY that do not contain those relation types. Furthermore, we notice that the performances on the G$^{\text{WORD+SENSE}}$ graph are better than those on the word-only graphs. This shows that including the synset nodes explicitly in the graph structure is beneficial. What is more, it gives us a means to obtain connotation labels for the synsets themselves, which we use in the evaluations in the next sections. Finally, we note that using the unweighted versions of the graphs provide relatively more robust performance, potentially due to noise in the relative edge weights.

Next we analyze the performance when the new edges between synsets are introduced, as given in Table 2 (bottom). We observe that connecting the synset nodes by their gloss-similarity (at least in the ways we tried) does not yield better performance than on our original G$^{\text{WORD+SENSE}}$ graph. Different from earlier, the weighted versions of the similarity based graphs provide better perfor-

mance than their unweighted counterparts. This suggests that glossary similarity would be a more robust means to correlate nodes; we leave it as future work to explore this direction for predicate-argument and argument-argument relations.

4.3 Parameter Sensitivity

Our belief propagation based connotation sentiment inference algorithm has one user-specified parameter ϵ (see Table 1). To study the sensitivity of its performance to the choice of ϵ, we reran our experiments for $\epsilon = \{0.02, 0.04, \ldots, 0.24\}$[6] and report the accuracy results on our $G^{\text{WORD+SENSE}}$ in Figure 2 for the two lexicons. The results indicate that the performances remain quite stable across a wide range of the parameter choice.



(a) GENINQ EVAL (b) MPQA EVAL

Figure 2: Performance is stable across various ϵ.

5 Evaluation II: Human Evaluation on ConnotationWordNet

In this section, we present the result of human evaluation we executed using Amazon Mechanical Turk (AMT). We collect two separate sets of labels: a set of labels at the word-level, and another set at the sense-level. We first describe the labeling process of sense-level connotation: We selected 350 polysemous words and one of their senses, and each Turker was asked to rate the connotative polarity of a given word (or of a given sense), from -5 to 5, 0 being the neutral.[7] For each word, we asked 5 Turkers to rate and we took the average of the 5 ratings as the connotative intensity score of the word. We labeled a word as *negative* if its intensity score is less than 0 and *positive* otherwise. For word-level labels we apply similar procedure as above.

[6]Note that for $\epsilon > 0.25$, compatibilities of ψ^{t_2} in Table 1 are reversed, hence the maximum of 0.24.

[7]Because senses in WordNet can be tricky to understand, care should be taken in designing the task so that the Turkers will focus only on the corresponding sense of a word. Therefore, we provided the part of speech tag, the WordNet gloss of the selected sense, and a few examples as given in WordNet. As an incentive, each Turker was rewarded $0.07 per hit which consists of 10 words to label.

Lexicon	Word-level	Sense-level
SentiWordNet	27.22	14.29
OpinionFinder	31.95	-
Feng2013	62.72	-
$G^{\text{WORD+SENSE}}(95\%)$	84.91	83.43
$G^{\text{WORD+SENSE}}(99\%)$	84.91	83.71
E-$G^{\text{WORD+SENSE}}(95\%)$	**86.98**	**86.29**
E-$G^{\text{WORD+SENSE}}(99\%)$	86.69	85.71

Table 3: Word-/Sense-level evaluation results

5.1 Word-Level Evaluation

We first evaluate the word-level assignment of connotation, as shown in Table 3. The agreement between the new lexicon and human judges varies between 84% and 86.98%. Sentiment lexicons such as SentiWordNet (Baccianella et al. (2010)) and OpinionFinder (Wilson et al. (2005a)) show low agreement rate with human, which is somewhat as expected: human judges in this study are labeling for subtle connotation, not for more explicit sentiment. OpinionFinder's low agreement rate was mainly due to the low hit rate of the words (successful look-up rate, 33.43%). Feng2013 is the lexicon presented in (Feng et al., 2013) and it showed a relatively higher 72.13% hit rate.

Note that belief propagation was run until 95% and 99% of the nodes were converged in their beliefs. In addition, the seed words with known connotation labels originally consist of 20 positive and 20 negative predicates. We also extended the seed set with the sentiment lexicon words and denote these runs with E- for 'Extended'.

5.2 Sense-Level Evaluation

We also examined the agreement rates on the sense-level. Since OpinionFinder and Feng2013 do not provide the polarity scores at the sense-level, we excluded them from this evaluation. Because sense-level polarity assignment is a harder (more subtle) task, the performance of all lexicons decreased to some degree in comparison to that of word-level evaluations.

5.3 Pair-wise Intensity Ranking

A notable goodness of our induction algorithm is that the outcome of the algorithm can be interpreted as an *intensity* of the corresponding connotation. But are these values meaningful? We answer this question in this section. We formulate a pair-wise ranking task as a binary decision task as follows: given a pair of words, we ask which one is more positive (or more negative) than the other. Since we collect human labels based on *scales*, we

Lexicon	Correct	Undecided
SentiWordNet	33.77	23.34
$G^{\text{WORD+SENSE}}$(95%)	74.83	0.58
$G^{\text{WORD+SENSE}}$(99%)	73.01	0.58
E-$G^{\text{WORD+SENSE}}$(95%)	73.84	1.16
E-$G^{\text{WORD+SENSE}}$(99%)	74.01	1.16

Table 4: Results of pair-wise intensity evaluation, for intensity difference threshold = 2.0

already have this information at hand. Because different human judges have different notion of scales however, subtle differences are more likely to be noisy. Therefore, we experiment with varying degrees of differences in their scales, as shown in Figure 3. Threshold values (ranging from 0.5 to 3.0) indicate the minimum differences in scales for any pair of words, for the pair to be included in the test set. As expected, we observe that the performance improves as we increase the threshold (as pairs get better separated). Within range [0.5, 1.5] (249 pairs examined), the accuracies are as high as 68.27%, which shows that even the subtle differences of the connotative intensities are relatively well reflected in the new lexicons.

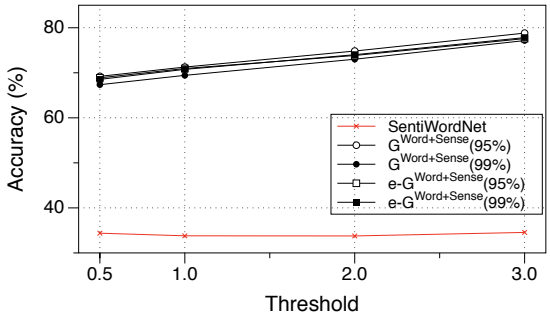


Figure 3: Trend of accuracy for pair-wise intensity evaluation over threshold

The results for pair-wise intensity evaluation (threshold=2.0, 1,208 pairs) are given in Table 4. Despite that intensity is generally a harder property to measure (than the coarser binary categorization of polarities), our connotation lexicons perform surprisingly well, reaching up to 74.83% accuracy. Further study on the incorrect cases reveals that SentiWordNet has many pair of words with the same polarity score (23.34%). Such cases seems to be due to the limited score patterns of SentiWordNet. The ratio of such cases are accounted as *Undecided* in Table 4.

6 Evaluation III: Sentiment Analysis using ConnotationWordNet

Finally, to show the utility of the resulting lexicon in the context of a concrete sentiment analysis task, we perform lexicon-based sentiment analysis. We experiment with SemEval dataset (Strapparava and Mihalcea, 2007) that includes the human labeled dataset for predicting whether a news headline is a *good news* or a *bad news*, which we expect to have a correlation with the use of *connotative* words that we focus on in this paper. The good/bad news are annotated with scores (ranging from -100 to 87). We construct several data sets by applying different thresholds on scores. For example, with the threshold set to 60, we discard the instances whose scores lie between -60 and 60. For comparison, we also test the connotation lexicon from (Feng et al., 2013) and the combined sentiment lexicon GENINQ+MPQA.

Note that there is a difference in how humans judge the orientation and the degree of connotation for a given word out of context, and how the use of such words in context can be perceived as *good/bad* news. In particular, we conjecture that humans may have a bias toward the use of positive words, which in turn requires calibration from the readers' minds (Pennebaker and Stone, 2003). That is, we might need to tone down the level of positiveness in order to correctly measure the actual intended positiveness of the message.

With this in mind, we tune the appropriate calibration from a small training data, by using 1 fold from N fold cross validation, and using the remaining $N-1$ folds as testing. We simply learn the mixture coefficient λ to scale the contribution of positive and negative connotation values. We tune this parameter λ[8] for other lexicons we compare against as well. Note that due to this parameter learning, we are able to report better performance for the connotation lexicon of (Feng et al., 2013) than what the authors have reported in their paper (labeled with *) in Table 5.

Table 5 shows the results for N=15, where the new lexicon consistently outperforms other competitive lexicons. In addition, Figure 4 shows that the performance does not change much based on the size of training data used for parameter tuning (N=$\{5, 10, 15, 20\}$).

7 Related Work

Several previous approaches explored the use of graph propagation for sentiment lexicon induction (Velikovich et al., 2010) and connotation lexicon

[8]What is reported is based on $\lambda \in \{20, 40, 60, 80\}$. More detailed parameter search does not change the results much.

Lexicon	SemEval Threshold			
	20	40	60	80
Instance Size	955	649	341	86
Feng2013	71.5	77.1	81.6	90.5
GENINQ+MPQA	72.8	77.2	80.4	86.7
$G^{\text{WORD+SENSE}}(95\%)$	74.5	**79.4**	86.5	**91.9**
$G^{\text{WORD+SENSE}}(99\%)$	**74.6**	**79.4**	**86.8**	**91.9**
E-$G^{\text{WORD+SENSE}}(95\%)$	72.5	76.8	82.3	87.2
E-$G^{\text{WORD+SENSE}}(99\%)$	72.6	76.9	82.5	87.2
Feng2013*	70.8	74.6	80.8	93.5
GENINQ+MPQA*	64.5	69.0	74.0	80.5

Table 5: SemEval evaluation results, for N=15

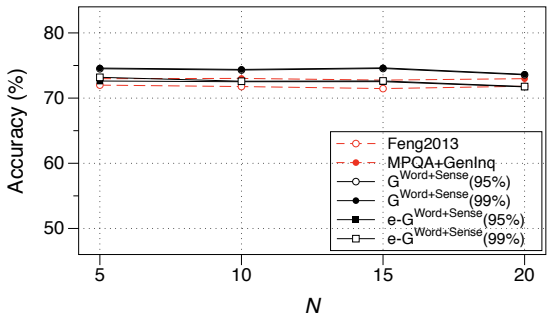

Figure 4: Trend of SemEval performance over N, the number of CV folds

induction (Feng et al., 2013). Our work introduces the use of loopy belief propagation over pairwise-MRF as an alternative solution to these tasks. At a high-level, both approaches share the general idea of propagating confidence or belief over the graph connectivity. The key difference, however, is that in our MRF representation, we can explicitly model various types of word-word, sense-sense and word-sense relations as edge potentials. In particular, we can naturally encode relations that encourage the same assignment (e.g., synonym) as well as the opposite assignment (e.g., antonym) of the polarity labels. Note that integration of the latter is not straightforward in the graph propagation framework.

There have been a number of previous studies that aim to construct a word-level sentiment lexicon (Wiebe et al., 2005; Qiu et al., 2009) and a sense-level sentiment lexicon (Esuli and Sebastiani, 2006). But none of these approaches considered to induce the polarity labels at both the word-level and sense-level. Although we focus on learning connotative polarity of words and senses in this paper, the same approach would be applicable to constructing a sentiment lexicon as well.

There have been recent studies that address word sense disambiguation issues for sentiment analysis. SentiWordNet (Esuli and Sebastiani, 2006) was the very first lexicon developed for sense-level labels of sentiment polarity. In recent years, Akkaya et al. (2009) report a successful empirical result where WSD helps improving sentiment analysis, while Wiebe and Mihalcea (2006) study the distinction between objectivity and subjectivity in each different sense of a word, and their empirical effects in the context of sentiment analysis. Our work shares the high-level spirit of accessing the sense-level polarity, while also deriving the word-level polarity.

In recent years, there has been a growing research interest in investigating more fine-grained aspects of lexical sentiment beyond positive and negative sentiment. For example, Mohammad and Turney (2010) study the affects words can *evoke* in people's minds, while Bollen et al. (2011) study various moods, e.g., "tension", "depression", beyond simple dichotomy of positive and negative sentiment. Our work, and some recent work by Feng et al. (2011) and Feng et al. (2013) share this spirit by targeting more subtle, nuanced sentiment even from those words that would be considered as objective in early studies of sentiment analysis.

8 Conclusion

We have introduced a novel formulation of lexicon induction operating over both words and senses, by exploiting the innate structure between the words and senses as encoded in WordNet. In addition, we introduce the use of loopy belief propagation over *pairwise*-Markov Random Fields as an effective lexicon induction algorithm. A notable strength of our approach is its expressiveness: various types of prior knowledge and lexical relations can be encoded as node potentials and edge potentials. In addition, it leads to a lexicon of better quality while also offering faster run-time and easiness of implementation. The resulting lexicon, called *ConnotationWordNet*, is the first lexicon that has polarity labels over both words and senses. *ConnotationWordNet* is publicly available for research and practical use.

Abstract

We present a method that learns word embedding for Twitter sentiment classification in this paper. Most existing algorithms for learning continuous word representations typically only model the syntactic context of words but ignore the sentiment of text. This is problematic for sentiment analysis as they usually map words with similar syntactic context but opposite sentiment polarity, such as *good* and *bad*, to neighboring word vectors. We address this issue by learning sentiment-specific word embedding (**SSWE**), which encodes sentiment information in the continuous representation of words. Specifically, we develop three neural networks to effectively incorporate the supervision from sentiment polarity of text (e.g. sentences or tweets) in their loss functions. To obtain large scale training corpora, we learn the sentiment-specific word embedding from massive distant-supervised tweets collected by positive and negative emoticons. Experiments on applying SSWE to a benchmark Twitter sentiment classification dataset in SemEval 2013 show that (1) the SSWE feature performs comparably with hand-crafted features in the top-performed system; (2) the performance is further improved by concatenating SSWE with existing feature set.

1 Introduction

Twitter sentiment classification has attracted increasing research interest in recent years (Jiang et al., 2011; Hu et al., 2013). The objective is to classify the sentiment polarity of a tweet as positive, negative or neutral. The majority of existing approaches follow Pang et al. (2002) and employ machine learning algorithms to build classifiers from tweets with manually annotated sentiment polarity. Under this direction, most studies focus on designing effective features to obtain better classification performance. For example, Mohammad et al. (2013) build the top-performed system in the Twitter sentiment classification track of SemEval 2013 (Nakov et al., 2013), using diverse sentiment lexicons and a variety of hand-crafted features.

Feature engineering is important but labor-intensive. It is therefore desirable to discover explanatory factors from the data and make the learning algorithms less dependent on extensive feature engineering (Bengio, 2013). For the task of sentiment classification, an effective feature learning method is to compose the representation of a sentence (or document) from the representations of the words or phrases it contains (Socher et al., 2013b; Yessenalina and Cardie, 2011). Accordingly, it is a crucial step to learn the word representation (or word embedding), which is a dense, low-dimensional and real-valued vector for a word. Although existing word embedding learning algorithms (Collobert et al., 2011; Mikolov et al., 2013) are intuitive choices, they are not effective enough if directly used for sentiment classification. The most serious problem is that traditional methods typically model the syntactic context of words but ignore the sentiment information of text. As a result, words with opposite polarity, such as *good* and *bad*, are mapped into close vectors. It is meaningful for some tasks such as pos-tagging (Zheng et al., 2013) as the two words have similar usages and grammatical roles, but it becomes a disaster for sentiment analysis as they have the opposite sentiment polarity.

In this paper, we propose learning sentiment-specific word embedding (**SSWE**) for sentiment analysis. We encode the sentiment information in-

* This work was done when the first and third authors were visiting Microsoft Research Asia.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1555–1565,
Baltimore, Maryland, USA, June 23-25 2014.

to the continuous representation of words, so that it is able to separate *good* and *bad* to opposite ends of the spectrum. To this end, we extend the existing word embedding learning algorithm (Collobert et al., 2011) and develop three neural networks to effectively incorporate the supervision from sentiment polarity of text (e.g. sentences or tweets) in their loss functions. We learn the sentiment-specific word embedding from tweets, leveraging massive tweets with emoticons as distant-supervised corpora without any manual annotations. These automatically collected tweets contain noises so they cannot be directly used as gold training data to build sentiment classifiers, but they are effective enough to provide weakly supervised signals for training the sentiment-specific word embedding.

We apply SSWE as features in a supervised learning framework for Twitter sentiment classification, and evaluate it on the benchmark dataset in SemEval 2013. In the task of predicting positive/negative polarity of tweets, our method yields 84.89% in macro-F1 by only using SSWE as feature, which is comparable to the top-performed system based on hand-crafted features (84.70%). After concatenating the SSWE feature with existing feature set, we push the state-of-the-art to 86.58% in macro-F1. The quality of SSWE is also directly evaluated by measuring the word similarity in the embedding space for sentiment lexicons. In the accuracy of polarity consistency between each sentiment word and its top N closest words, SSWE outperforms existing word embedding learning algorithms.

The major contributions of the work presented in this paper are as follows.

- We develop three neural networks to learn sentiment-specific word embedding (SSWE) from massive distant-supervised tweets without any manual annotations;
- To our knowledge, this is the first work that exploits word embedding for Twitter sentiment classification. We report the results that the SSWE feature performs comparably with hand-crafted features in the top-performed system in SemEval 2013;
- We release the sentiment-specific word embedding learned from 10 million tweets, which can be adopted off-the-shell in other sentiment analysis tasks.

2 Related Work

In this section, we present a brief review of the related work from two perspectives, Twitter sentiment classification and learning continuous representations for sentiment classification.

2.1 Twitter Sentiment Classification

Twitter sentiment classification, which identifies the sentiment polarity of short, informal tweets, has attracted increasing research interest (Jiang et al., 2011; Hu et al., 2013) in recent years. Generally, the methods employed in Twitter sentiment classification follow traditional sentiment classification approaches. The lexicon-based approaches (Turney, 2002; Ding et al., 2008; Taboada et al., 2011; Thelwall et al., 2012) mostly use a dictionary of sentiment words with their associated sentiment polarity, and incorporate negation and intensification to compute the sentiment polarity for each sentence (or document).

The learning based methods for Twitter sentiment classification follow Pang et al. (2002)'s work, which treat sentiment classification of texts as a special case of text categorization issue. Many studies on Twitter sentiment classification (Pak and Paroubek, 2010; Davidov et al., 2010; Barbosa and Feng, 2010; Kouloumpis et al., 2011; Zhao et al., 2012) leverage massive noisy-labeled tweets selected by positive and negative emoticons as training set and build sentiment classifiers directly, which is called *distant supervision* (Go et al., 2009). Instead of directly using the distant-supervised data as training set, Liu et al. (2012) adopt the tweets with emoticons to smooth the language model and Hu et al. (2013) incorporate the emotional signals into an unsupervised learning framework for Twitter sentiment classification.

Many existing learning based methods on Twitter sentiment classification focus on feature engineering. The reason is that the performance of sentiment classifier being heavily dependent on the choice of feature representation of tweets. The most representative system is introduced by Mohammad et al. (2013), which is the state-of-the-art system (the top-performed system in SemEval 2013 Twitter Sentiment Classification Track) by implementing a number of hand-crafted features. Unlike the previous studies, we focus on learning discriminative features automatically from massive distant-supervised tweets.

2.2 Learning Continuous Representations for Sentiment Classification

Pang et al. (2002) pioneer this field by using bag-of-word representation, representing each word as a one-hot vector. It has the same length as the size of the vocabulary, and only one dimension is 1, with all others being 0. Under this assumption, many feature learning algorithms are proposed to obtain better classification performance (Pang and Lee, 2008; Liu, 2012; Feldman, 2013). However, the one-hot word representation cannot sufficiently capture the complex linguistic characteristics of words.

With the revival of interest in deep learning (Bengio et al., 2013), incorporating the continuous representation of a word as features has been proving effective in a variety of NLP tasks, such as parsing (Socher et al., 2013a), language modeling (Bengio et al., 2003; Mnih and Hinton, 2009) and NER (Turian et al., 2010). In the field of sentiment analysis, Bespalov et al. (2011; 2012) initialize the word embedding by Latent Semantic Analysis and further represent each document as the linear weighted of ngram vectors for sentiment classification. Yessenalina and Cardie (2011) model each word as a matrix and combine words using iterated matrix multiplication. Glorot et al. (2011) explore Stacked Denoising Autoencoders for domain adaptation in sentiment classification. Socher et al. propose Recursive Neural Network (RNN) (2011b), matrix-vector RNN (2012) and Recursive Neural Tensor Network (RNTN) (2013b) to learn the compositionality of phrases of any length based on the representation of each pair of children recursively. Hermann et al. (2013) present Combinatory Categorial Autoencoders to learn the compositionality of sentence, which marries the Combinatory Categorial Grammar with Recursive Autoencoder.

The representation of words heavily relies on the applications or tasks in which it is used (Labutov and Lipson, 2013). This paper focuses on learning sentiment-specific word embedding, which is tailored for sentiment analysis. Unlike Maas et al. (2011) that follow the probabilistic document model (Blei et al., 2003) and give an sentiment predictor function to each word, we develop neural networks and map each ngram to the sentiment polarity of sentence. Unlike Socher et al. (2011c) that utilize manually labeled texts to learn the meaning of phrase (or sentence) through compositionality, we focus on learning the meaning of word, namely word embedding, from massive distant-supervised tweets. Unlike Labutov and Lipson (2013) that produce task-specific embedding from an existing word embedding, we learn sentiment-specific word embedding from scratch.

3 Sentiment-Specific Word Embedding for Twitter Sentiment Classification

In this section, we present the details of learning sentiment-specific word embedding (**SSWE**) for Twitter sentiment classification. We propose incorporating the sentiment information of sentences to learn continuous representations for words and phrases. We extend the existing word embedding learning algorithm (Collobert et al., 2011) and develop three neural networks to learn SSWE. In the following sections, we introduce the traditional method before presenting the details of SSWE learning algorithms. We then describe the use of SSWE in a supervised learning framework for Twitter sentiment classification.

3.1 C&W Model

Collobert et al. (2011) introduce C&W model to learn word embedding based on the syntactic contexts of words. Given an ngram *"cat chills on a mat"*, C&W replaces the center word with a random word w^r and derives a **corrupted** ngram *"cat chills w^r a mat"*. The training objective is that the original ngram is expected to obtain a higher language model score than the corrupted ngram by a margin of 1. The ranking objective function can be optimized by a hinge loss,

$$loss_{cw}(t, t^r) = max(0, 1 - f^{cw}(t) + f^{cw}(t^r)) \quad (1)$$

where t is the original ngram, t^r is the corrupted ngram, $f^{cw}(\cdot)$ is a one-dimensional scalar representing the language model score of the input ngram. Figure 1(a) illustrates the neural architecture of C&W, which consists of four layers, namely $lookup \rightarrow linear \rightarrow hTanh \rightarrow linear$ (from bottom to top). The original and corrupted ngrams are treated as inputs of the feed-forward neural network, respectively. The output f^{cw} is the language model score of the input, which is calculated as given in Equation 2, where L is the lookup table of word embedding, w_1, w_2, b_1, b_2 are the parameters of linear layers.

$$f^{cw}(t) = w_2(a) + b_2 \quad (2)$$

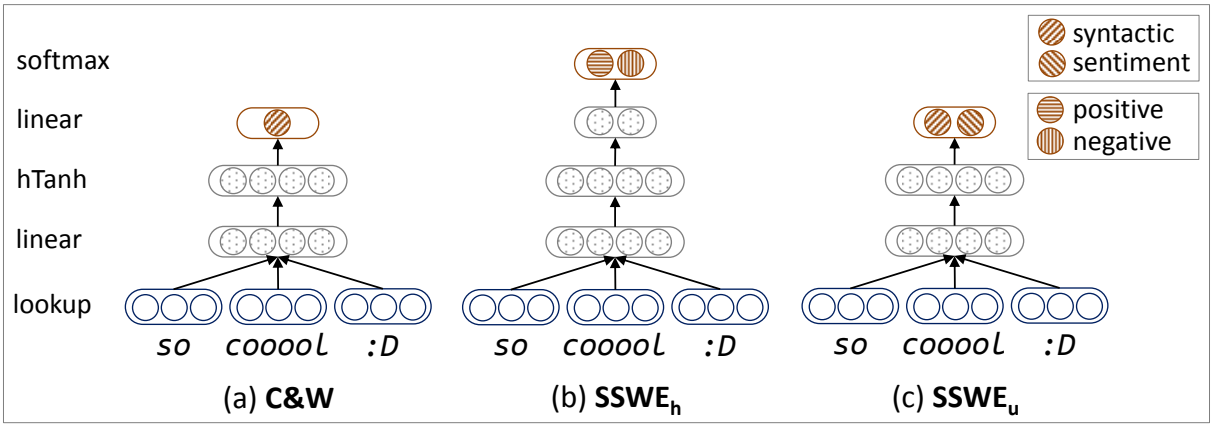

Figure 1: The traditional C&W model and our neural networks (SSWE$_h$ and SSWE$_u$) for learning sentiment-specific word embedding.

$$a = hTanh(w_1 L_t + b_1) \quad (3)$$

$$hTanh(x) = \begin{cases} -1 & \text{if } x < -1 \\ x & \text{if } -1 \leq x \leq 1 \\ 1 & \text{if } x > 1 \end{cases} \quad (4)$$

3.2 Sentiment-Specific Word Embedding

Following the traditional C&W model (Collobert et al., 2011), we incorporate the sentiment information into the neural network to learn sentiment-specific word embedding. We develop three neural networks with different strategies to integrate the sentiment information of tweets.

Basic Model 1 (SSWE$_h$). As an unsupervised approach, C&W model does not explicitly capture the sentiment information of texts. An intuitive solution to integrate the sentiment information is predicting the sentiment distribution of text based on input ngram. We do not utilize the entire sentence as input because the length of different sentences might be variant. We therefore slide the window of ngram across a sentence, and then predict the sentiment polarity based on each ngram with a shared neural network. In the neural network, the distributed representation of higher layer are interpreted as features describing the input. Thus, we utilize the continuous vector of top layer to predict the sentiment distribution of text.

Assuming there are K labels, we modify the dimension of top layer in C&W model as K and add a $softmax$ layer upon the top layer. The neural network (**SSWE$_h$**) is given in Figure 1(b). $Softmax$ layer is suitable for this scenario because its outputs are interpreted as conditional probabilities. Unlike C&W, SSWE$_h$ does not generate any corrupted ngram. Let $\boldsymbol{f}^g(t)$, where K denotes the number of sentiment polarity labels, be the gold K-dimensional multinomial distribution of input t and $\sum_k \boldsymbol{f}^g_k(t) = 1$. For positive/negative classification, the distribution is of the form [1,0] for positive and [0,1] for negative. The cross-entropy error of the $softmax$ layer is :

$$loss_h(t) = -\sum_{k=\{0,1\}} \boldsymbol{f}^g_k(t) \cdot log(\boldsymbol{f}^h_k(t)) \quad (5)$$

where $\boldsymbol{f}^g(t)$ is the gold sentiment distribution and $\boldsymbol{f}^h(t)$ is the predicted sentiment distribution.

Basic Model 2 (SSWE$_r$). SSWE$_h$ is trained by predicting the positive ngram as [1,0] and the negative ngram as [0,1]. However, the constraint of SSWE$_h$ is too strict. The distribution of [0.7,0.3] can also be interpreted as a positive label because the positive score is larger than the negative score. Similarly, the distribution of [0.2,0.8] indicates negative polarity. Based on the above observation, the hard constraints in SSWE$_h$ should be relaxed. If the sentiment polarity of a tweet is positive, the predicted positive score is expected to be larger than the predicted negative score, and the exact reverse if the tweet has negative polarity.

We model the relaxed constraint with a ranking objective function and borrow the bottom four layers from SSWE$_h$, namely $lookup \rightarrow linear \rightarrow hTanh \rightarrow linear$ in Figure 1(b), to build the relaxed neural network (**SSWE$_r$**). Compared with SSWE$_h$, the $softmax$ layer is removed because SSWE$_r$ does not require probabilistic interpretation. The hinge loss of SSWE$_r$ is modeled as de-

scribed below.

$$loss_r(t) = max(0, 1 - \delta_s(t)\boldsymbol{f}_0^r(t) + \delta_s(t)\boldsymbol{f}_1^r(t)\ ) \quad (6)$$

where $\boldsymbol{f}_0^r$ is the predicted positive score, $\boldsymbol{f}_1^r$ is the predicted negative score, $\delta_s(t)$ is an indicator function reflecting the sentiment polarity of a sentence,

$$\delta_s(t) = \begin{cases} 1 & \text{if } \boldsymbol{f}^g(t) = [1, 0] \\ -1 & \text{if } \boldsymbol{f}^g(t) = [0, 1] \end{cases} \quad (7)$$

Similar with SSWE$_h$, SSWE$_r$ also does not generate the corrupted ngram.

Unified Model (SSWE$_u$). The C&W model learns word embedding by modeling syntactic contexts of words but ignoring sentiment information. By contrast, SSWE$_h$ and SSWE$_r$ learn sentiment-specific word embedding by integrating the sentiment polarity of sentences but leaving out the syntactic contexts of words. We develop a unified model (**SSWE$_u$**) in this part, which captures the sentiment information of sentences as well as the syntactic contexts of words. SSWE$_u$ is illustrated in Figure 1(c).

Given an original (or corrupted) ngram and the sentiment polarity of a sentence as the input, SSWE$_u$ predicts a two-dimensional vector for each input ngram. The two scalars ($\boldsymbol{f}_0^u$, $\boldsymbol{f}_1^u$) stand for language model score and sentiment score of the input ngram, respectively. The training objectives of SSWE$_u$ are that (1) the original ngram should obtain a higher language model score $\boldsymbol{f}_0^u(t)$ than the corrupted ngram $\boldsymbol{f}_0^u(t^r)$, and (2) the sentiment score of original ngram $\boldsymbol{f}_1^u(t)$ should be more consistent with the gold polarity annotation of sentence than corrupted ngram $\boldsymbol{f}_1^u(t^r)$. The loss function of SSWE$_u$ is the linear combination of two hinge losses,

$$loss_u(t, t^r) = \alpha \cdot loss_{cw}(t, t^r) + (1 - \alpha) \cdot loss_{us}(t, t^r) \quad (8)$$

where $loss_{cw}(t, t^r)$ is the syntactic loss as given in Equation 1, $loss_{us}(t, t^r)$ is the sentiment loss as described in Equation 9. The hyper-parameter α weighs the two parts.

$$loss_{us}(t, t^r) = max(0, 1 - \delta_s(t)\boldsymbol{f}_1^u(t) + \delta_s(t)\boldsymbol{f}_1^u(t^r)\ ) \quad (9)$$

Model Training. We train sentiment-specific word embedding from massive distant-supervised tweets collected with positive and negative emoticons[1]. We crawl tweets from April 1st, 2013 to April 30th, 2013 with TwitterAPI. We tokenize each tweet with TwitterNLP (Gimpel et al., 2011), remove the *@user* and *URLs* of each tweet, and filter the tweets that are too short (< 7 words). Finally, we collect 10M tweets, selected by 5M tweets with positive emoticons and 5M tweets with negative emoticons.

We train SSWE$_h$, SSWE$_r$ and SSWE$_u$ by taking the derivative of the loss through back-propagation with respect to the whole set of parameters (Collobert et al., 2011), and use AdaGrad (Duchi et al., 2011) to update the parameters. We empirically set the window size as 3, the embedding length as 50, the length of hidden layer as 20 and the learning rate of AdaGrad as 0.1 for all baseline and our models. We learn embedding for unigrams, bigrams and trigrams separately with same neural network and same parameter setting. The contexts of unigram (bigram/trigram) are the surrounding unigrams (bigrams/trigrams), respectively.

3.3 Twitter Sentiment Classification

We apply sentiment-specific word embedding for Twitter sentiment classification under a supervised learning framework as in previous work (Pang et al., 2002). Instead of hand-crafting features, we incorporate the continuous representation of words and phrases as the feature of a tweet. The sentiment classifier is built from tweets with manually annotated sentiment polarity.

We explore min, $average$ and max convolutional layers (Collobert et al., 2011; Socher et al., 2011a), which have been used as simple and effective methods for compositionality learning in vector-based semantics (Mitchell and Lapata, 2010), to obtain the tweet representation. The result is the concatenation of vectors derived from different convolutional layers.

$$z(tw) = [z_{max}(tw), z_{min}(tw), z_{average}(tw)]$$

where $z(tw)$ is the representation of tweet tw and $z_x(tw)$ is the results of the convolutional layer $x \in \{min, max, average\}$. Each convolutional layer

[1] We use the emoticons selected by Hu et al. (2013). The positive emoticons are :) :) :-) :D =), and the negative emoticons are :(: (:-(.

z_x employs the embedding of unigrams, bigrams and trigrams separately and conducts the matrix-vector operation of x on the sequence represented by columns in each lookup table. The output of z_x is the concatenation of results obtained from different lookup tables.

$$z_x(tw) = [w_x\langle L_{uni}\rangle^{tw}, w_x\langle L_{bi}\rangle^{tw}, w_x\langle L_{tri}\rangle^{tw}]$$

where w_x is the convolutional function of z_x, $\langle L\rangle^{tw}$ is the concatenated column vectors of the words in the tweet. L_{uni}, L_{bi} and L_{tri} are the lookup tables of the unigram, bigram and trigram embedding, respectively.

4 Experiment

We conduct experiments to evaluate SSWE by incorporating it into a supervised learning framework for Twitter sentiment classification. We also directly evaluate the effectiveness of the SSWE by measuring the word similarity in the embedding space for sentiment lexicons.

4.1 Twitter Sentiment Classification

Experiment Setup and Datasets. We conduct experiments on the latest Twitter sentiment classification benchmark dataset in SemEval 2013 (Nakov et al., 2013). The training and development sets were completely in full to task participants. However, we were unable to download all the training and development sets because some tweets were deleted or not available due to modified authorization status. The test set is directly provided to the participants. The distribution of our dataset is given in Table 1. We train sentiment classifier with LibLinear (Fan et al., 2008) on the training set, tune parameter $-c$ on the dev set and evaluate on the test set. Evaluation metric is the Macro-F1 of positive and negative categories [2].

	Positive	Negative	Neutral	Total
Train	2,642	994	3,436	7,072
Dev	408	219	493	1,120
Test	1,570	601	1,639	3,810

Table 1: Statistics of the SemEval 2013 Twitter sentiment classification dataset.

Baseline Methods. We compare our method with the following sentiment classification algorithms:

(1) *DistSuper*: We use the 10 million tweets selected by positive and negative emoticons as training data, and build sentiment classifier with LibLinear and ngram features (Go et al., 2009).

(2) *SVM*: The ngram features and Support Vector Machine are widely used baseline methods to build sentiment classifiers (Pang et al., 2002). LibLinear is used to train the SVM classifier.

(3) *NBSVM*: NBSVM (Wang and Manning, 2012) is a state-of-the-art performer on many sentiment classification datasets, which trades-off between Naive Bayes and NB-enhanced SVM.

(4) *RAE*: Recursive Autoencoder (Socher et al., 2011c) has been proven effective in many sentiment analysis tasks by learning compositionality automatically. We run RAE with randomly initialized word embedding.

(5) *NRC*: NRC builds the top-performed system in SemEval 2013 Twitter sentiment classification track which incorporates diverse sentiment lexicons and many manually designed features. We re-implement this system because the codes are not publicly available [3]. *NRC-ngram* refers to the feature set of *NRC* leaving out ngram features.

Except for $DistSuper$, other baseline methods are conducted in a supervised manner. We do not compare with RNTN (Socher et al., 2013b) because we cannot efficiently train the RNTN model. The reason lies in that the tweets in our dataset do not have accurately parsed results or fine grained sentiment labels for phrases. Another reason is that the RNTN model trained on movie reviews cannot be directly applied on tweets due to the differences between domains (Blitzer et al., 2007).

Results and Analysis. Table 2 shows the macro-F1 of the baseline systems as well as the SSWE-based methods on positive/negative sentiment classification of tweets. Distant supervision is relatively weak because the noisy-labeled tweets are treated as the gold standard, which affects the performance of classifier. The results of bag-of-ngram (uni/bi/tri-gram) features are not satisfied because the one-hot word representation cannot capture the latent connections between words. NBSVM and RAE perform comparably and have

[2]We investigate 2-class Twitter sentiment classification (positive/negative) instead of 3-class Twitter sentiment classification (positive/negative/neutral) in SemEval2013.

[3]For 3-class sentiment classification in SemEval 2013, our re-implementation of NRC achieved 68.3%, 0.7% lower than NRC (69%) due to less training data.

Method	Macro-F1
DistSuper + unigram	61.74
DistSuper + uni/bi/tri-gram	63.84
SVM + unigram	74.50
SVM + uni/bi/tri-gram	75.06
NBSVM	75.28
RAE	75.12
NRC (**Top System** in SemEval)	**84.73**
NRC - ngram	84.17
$SSWE_u$	**84.98**
$SSWE_u$+NRC	**86.58**
$SSWE_u$+NRC-ngram	**86.48**

Table 2: Macro-F1 on positive/negative classification of tweets.

a big gap in comparison with the NRC and SSWE-based methods. The reason is that RAE and NBSVM learn the representation of tweets from the small-scale manually annotated training set, which cannot well capture the comprehensive linguistic phenomenons of words.

NRC implements a variety of features and reaches 84.73% in macro-F1, verifying the importance of a better feature representation for Twitter sentiment classification. We achieve 84.98% by using only $SSWE_u$ as features without borrowing any sentiment lexicons or hand-crafted rules. The results indicate that $SSWE_u$ automatically learns discriminative features from massive tweets and performs comparable with the state-of-the-art manually designed features. After concatenating $SSWE_u$ with the feature set of *NRC*, the performance is further improved to 86.58%. We also compare $SSWE_u$ with the ngram feature by integrating SSWE into *NRC-ngram*. The concatenated features *$SSWE_u$+NRC-ngram* (86.48%) outperform the original feature set of NRC (84.73%).

As a reference, we apply $SSWE_u$ on subjective classification of tweets, and obtain 72.17% in macro-F1 by using only $SSWE_u$ as feature. After combining $SSWE_u$ with the feature set of *NRC*, we improve NRC from 74.86% to 75.39% for subjective classification.

Comparision between Different Word Embedding. We compare sentiment-specific word embedding ($SSWE_h$, $SSWE_r$, $SSWE_u$) with baseline embedding learning algorithms by only using word embedding as features for Twitter sentiment classification. We use the embedding of unigrams, bigrams and trigrams in the experiment. The embeddings of C&W (Collobert et al., 2011), word2vec[4], WVSA (Maas et al., 2011) and our models are trained with the same dataset and same parameter setting. We compare with C&W and word2vec as they have been proved effective in many NLP tasks. The trade-off parameter of ReEmb (Labutov and Lipson, 2013) is tuned on the development set of SemEval 2013.

Table 3 shows the performance on the positive/negative classification of tweets[5]. ReEmb(C&W) and ReEmb(w2v) stand for the use of embeddings learned from 10 million distant-supervised tweets with C&W and word2vec, respectively. Each row of Table 3 represents a word embedding learning algorithm. Each column stands for a type of embedding used to compose features of tweets. The column *uni+bi* denotes the use of unigram and bigram embedding, and the column *uni+bi+tri* indicates the use of unigram, bigram and trigram embedding.

Embedding	unigram	uni+bi	uni+bi+tri
C&W	74.89	75.24	75.89
Word2vec	73.21	75.07	76.31
ReEmb(C&W)	75.87	–	–
ReEmb(w2v)	75.21	–	–
WVSA	77.04	–	–
$SSWE_h$	81.33	83.16	83.37
$SSWE_r$	80.45	81.52	82.60
$SSWE_u$	**83.70**	**84.70**	**84.98**

Table 3: Macro-F1 on positive/negative classification of tweets with different word embeddings.

From the first column of Table 3, we can see that the performance of C&W and word2vec are obviously lower than sentiment-specific word embeddings by only using unigram embedding as features. The reason is that C&W and word2vec do not explicitly exploit the sentiment information of the text, resulting in that the words with opposite polarity such as *good* and *bad* are mapped to close word vectors. When such word embeddings are fed as features to a Twitter sentiment classifier, the discriminative ability of sentiment words are weakened thus the classification performance is affected. Sentiment-specific word em-

[4]Available at https://code.google.com/p/word2vec/. We utilize the Skip-gram model because it performs better than CBOW in our experiments.

[5]MVSA and ReEmb are not suitable for learning bigram and trigram embedding because their sentiment predictor functions only utilize the unigram embedding.

beddings (SSWE$_h$, SSWE$_r$, SSWE$_u$) effectively distinguish words with opposite sentiment polarity and perform best in three settings. SSWE outperforms MVSA by exploiting more contextual information in the sentiment predictor function. SSWE outperforms ReEmb by leveraging more sentiment information from massive distant-supervised tweets. Among three sentiment-specific word embeddings, SSWE$_u$ captures more context information and yields best performance. SSWE$_h$ and SSWE$_r$ obtain comparative results.

From each row of Table 3, we can see that the bigram and trigram embeddings consistently improve the performance of Twitter sentiment classification. The underlying reason is that a phrase, which cannot be accurately represented by unigram embedding, is directly encoded into the n-gram embedding as an idiomatic unit. A typical case in sentiment analysis is that the composed phrase and multiword expression may have a different sentiment polarity than the individual words it contains, such as *not [bad]* and *[great] deal of* (the word in the bracket has different sentiment polarity with the ngram). A very recent study by Mikolov et al. (2013) also verified the effectiveness of phrase embedding for analogically reasoning phrases.

Effect of α in SSWE$_u$ We tune the hyper-parameter α of SSWE$_u$ on the development set by using unigram embedding as features. As given in Equation 8, α is the weighting score of syntactic loss of SSWE$_u$ and trades-off the syntactic and sentiment losses. SSWE$_u$ is trained from 10 million distant-supervised tweets.

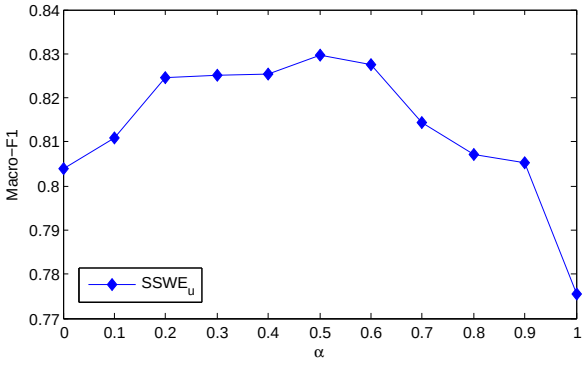

Figure 2: Macro-F1 of SSWE$_u$ on the development set of SemEval 2013 with different α.

Figure 2 shows the macro-F1 of SSWE$_u$ on positive/negative classification of tweets with different α on our development set. We can see that SSWE$_u$ performs better when α is in the range of [0.5, 0.6], which balances the syntactic context and sentiment information. The model with α=1 stands for C&W model, which only encodes the syntactic contexts of words. The sharp decline at α=1 reflects the importance of sentiment information in learning word embedding for Twitter sentiment classification.

Effect of Distant-supervised Data in SSWE$_u$ We investigate how the size of the distant-supervised data affects the performance of SSWE$_u$ feature for Twitter sentiment classification. We vary the number of distant-supervised tweets from 1 million to 12 million, increased by 1 million. We set the α of SSWE$_u$ as 0.5, according to the experiments shown in Figure 2. Results of positive/negative classification of tweets on our development set are given in Figure 3.

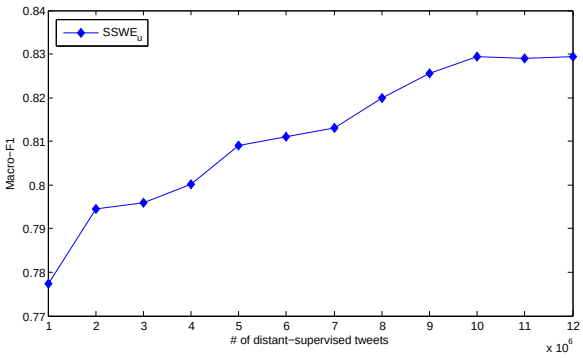

Figure 3: Macro-F1 of SSWE$_u$ with different size of distant-supervised data on our development set.

We can see that when more distant-supervised tweets are added, the accuracy of SSWE$_u$ consistently improves. The underlying reason is that when more tweets are incorporated, the word embedding is better estimated as the vocabulary size is larger and the context and sentiment information are richer. When we have 10 million distant-supervised tweets, the SSWE$_u$ feature increases the macro-F1 of positive/negative classification of tweets to 82.94% on our development set. When we have more than 10 million tweets, the performance remains stable as the contexts of words have been mostly covered.

4.2 Word Similarity of Sentiment Lexicons

The quality of SSWE has been implicitly evaluated when applied in Twitter sentiment classification in the previous subsection. We explicitly evaluate it in this section through word similarity in the em-

bedding space for sentiment lexicons. The evaluation metric is the accuracy of polarity consistency between each sentiment word and its top N closest words in the sentiment lexicon,

$$Accuracy = \frac{\sum_{i=1}^{\#Lex} \sum_{j=1}^{N} \beta(w_i, c_{ij})}{\#Lex \times N} \quad (10)$$

where $\#Lex$ is the number of words in the sentiment lexicon, w_i is the *i-th* word in the lexicon, c_{ij} is the *j-th* closest word to w_i in the lexicon with cosine similarity, $\beta(w_i, c_{ij})$ is an indicator function that is equal to 1 if w_i and c_{ij} have the same sentiment polarity and 0 for the opposite case. The higher accuracy refers to a better polarity consistency of words in the sentiment lexicon. We set N as 100 in our experiment.

Experiment Setup and Datasets We utilize the widely-used sentiment lexicons, namely *MPQA* (Wilson et al., 2005) and *HL* (Hu and Liu, 2004), to evaluate the quality of word embedding. For each lexicon, we remove the words that do not appear in the lookup table of word embedding. We only use unigram embedding in this section because these sentiment lexicons do not contain phrases. The distribution of the lexicons used in this paper is listed in Table 4.

Lexicon	Positive	Negative	Total
HL	1,331	2,647	3,978
MPQA	1,932	2,817	4,749
Joint	1,051	2,024	3,075

Table 4: Statistics of the sentiment lexicons. *Joint* stands for the words that occur in both *HL* and *MPQA* with the same sentiment polarity.

Results. Table 5 shows our results compared to other word embedding learning algorithms. The accuracy of *random* result is 50% as positive and negative words are randomly occurred in the nearest neighbors of each word. Sentiment-specific word embeddings (SSWE$_h$, SSWE$_r$, SSWE$_u$) outperform existing neural models (C&W, word2vec) by large margins. SSWE$_u$ performs best in three lexicons. SSWE$_h$ and SSWE$_r$ have comparable performances. Experimental results further demonstrate that sentiment-specific word embeddings are able to capture the sentiment information of texts and distinguish words with opposite sentiment polarity, which are not well solved in traditional neural models like C&W and word2vec. SSWE outperforms MVSA and ReEmb by exploiting more context information of words and sentiment information of sentences, respectively.

Embedding	HL	MPQA	Joint
Random	50.00	50.00	50.00
C&W	63.10	58.13	62.58
Word2vec	66.22	60.72	65.59
ReEmb(C&W)	64.81	59.76	64.09
ReEmb(w2v)	67.16	61.81	66.39
WVSA	68.14	64.07	67.12
SSWE$_h$	74.17	68.36	74.03
SSWE$_r$	73.65	68.02	73.14
SSWE$_u$	**77.30**	**71.74**	**77.33**

Table 5: Accuracy of the polarity consistency of words in different sentiment lexicons.

5 Conclusion

In this paper, we propose learning continuous word representations as features for Twitter sentiment classification under a supervised learning framework. We show that the word embedding learned by traditional neural networks are not effective enough for Twitter sentiment classification. These methods typically only model the context information of words so that they cannot distinguish words with similar context but opposite sentiment polarity (e.g. *good* and *bad*). We learn sentiment-specific word embedding (SSWE) by integrating the sentiment information into the loss functions of three neural networks. We train SSWE with massive distant-supervised tweets selected by positive and negative emoticons. The effectiveness of SSWE has been implicitly evaluated by using it as features in sentiment classification on the benchmark dataset in SemEval 2013, and explicitly verified by measuring word similarity in the embedding space for sentiment lexicons. Our unified model combining syntactic context of words and sentiment information of sentences yields the best performance in both experiments.

Towards a General Rule for Identifying Deceptive Opinion Spam

Abstract

Consumers' purchase decisions are increasingly influenced by user-generated online reviews. Accordingly, there has been growing concern about the potential for posting deceptive opinion spam—fictitious reviews that have been deliberately written to sound authentic, to deceive the reader. In this paper, we explore generalized approaches for identifying online deceptive opinion spam based on a new gold standard dataset, which is comprised of data from three different domains (i.e. Hotel, Restaurant, Doctor), each of which contains three types of reviews, i.e. *customer generated truthful reviews*, *Turker generated deceptive reviews* and *employee (domain-expert) generated deceptive reviews*. Our approach tries to capture the general difference of language usage between deceptive and truthful reviews, which we hope will help customers when making purchase decisions and review portal operators, such as TripAdvisor or Yelp, investigate possible fraudulent activity on their sites.[1]

1 Introduction

Consumers increasingly rely on user-generated online reviews when making purchase decision (Cone, 2011; Ipsos, 2012). Unfortunately, the ease of posting content to the Web, potentially anonymously, creates opportunities and incentives for unscrupulous businesses to post *deceptive opinion spam*—fictitious reviews that are deliberately written to sound authentic, in order to deceive the reader.[2] Accordingly, there appears to be widespread and growing concern among both businesses and the public about this potential abuse (Meyer, 2009; Miller, 2009; Streitfeld, 2012; Topping, 2010; Ott, 2013).

Existing approaches for spam detection are usually focused on developing supervised learning-based algorithms to help users identify deceptive opinion spam, which are highly dependent upon high-quality gold-standard labeled data (Jindal and Liu, 2008; Jindal et al., 2010; Lim et al., 2010; Wang et al., 2011; Wu et al., 2010). Studies in the literature rely on a couple of approaches for obtaining labeled data, which usually fall into two categories. The first relies on the judgements of human annotators (Jindal et al., 2010; Mukherjee et al., 2012). However, recent studies show that deceptive opinion spam is not easily identified by human readers (Ott et al., 2011). An alternative approach, as introduced by Ott et al. (2011), crowdsourced deceptive reviews using Amazon Mechanical Turk.[3] A couple of follow-up works have been introduced based on Ott et al.'s dataset, including estimating prevalence of deception in online reviews (Ott et al., 2012), identification of negative deceptive opinion spam (Ott et al., 2013), and identifying manipulated offerings (Li et al., 2013b).

Despite the advantages of soliciting deceptive gold-standard material from Turkers (it is easy, large-scale, and affordable), it is unclear whether Turkers are representative of the general population that generate fake reviews, or in other words, Ott et al.'s data set may correspond to only one type of online deceptive opinion spam — fake reviews generated by people who have never been to offerings or experienced the entities. Specifically, according to their findings (Ott et al., 2011;

[1]Dataset available by request from the first author.

[2]Manipulating online reviews may also have legal consequences. For example, the Federal Trade Commission (FTC) has updated their guidelines on the use of endorsements and testimonials in advertising to suggest that posting deceptive reviews may be unlawful in the United States (FTC, 2009).

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1566–1576,
Baltimore, Maryland, USA, June 23-25 2014.

Li et al., 2013a), truthful hotel reviews encode more spatial details, characterized by terms such as "bathroom" and "location", while deceptive reviews talk about general concepts such as why or with whom they went to the hotel. However, a hotel can instead solicit fake reviews from their employees or customers who possess substantial domain knowledge to write fake reviews and encode more spatial details in their lies. Indeed, cases have been reported where hotel owners bribe guests in return for good reviews on TripAdvisor[4], or companies ordered employees to pretend they were satisfied customers and write glowing reviews of its face-lift procedure on Web sites.[5] The domain knowledge possessed by domain experts enables them to craft reviews that are much more difficult for classifiers to detect, compared to the crowdsourced fake reviews.

Additionally, existing supervised algorithms in the literature are usually narrowed to one specific domain and heavily rely on domain-specific vocabulary. For example, classifiers assign high weights to domain-specific terms such as "hotel", "rooms", or even the name of the hotels such as "Hilton" when trained on reviews on hotels. It is unclear whether these classifiers will perform well at detecting deception in other domains, e.g., Restaurant or Doctor reviews. Even in a single domain, e.g., Hotel, classifiers trained from reviews of one city (e.g., Chicago) may not be effective if directly applied to reviews from other cities (e.g., New York City) (Li et al., 2013b). In the examples in Table 1, we trained a linear SVM classifier on Ott's Chicago-hotel dataset on *unigram* features and tested it on a couple of different domains (the details of data acquisition are illustrated in Section 3). Good performance is obtained on Chicago-hotel reviews (Ott et al., 2011), but not as good on New York City ones. The performance is reasonable in Restaurant reviews due to the many shared properties among restaurants and hotels, but suffers in Doctor settings.

In this paper, we try to obtain a deeper understanding of the general nature of deceptive opinion spam. One contribution of the work presented here is the creation of the cross-domain (i.e., Hotel, Restaurant and Doctor) gold-standard dataset.

	Accuracy	Precision	Recall	F1
NYC-Hotel	0.799	0.794	0.758	0.766
Chicago-Restaurant	0.785	0.813	0.742	0.778
Doctor	0.550	0.537	0.725	0.617

Table 1: SVM performance on datasets for a classifier trained on Chicago hotel review based on Unigram feature.

In contrast to existing work (Ott et al., 2011; Li et al., 2013b), our new gold standard includes three types of reviews: *domain expert deceptive opinion spam* (*Employee*), *crowdsourced deceptive opinion spam* (*Turker*), and *truthful Customer reviews* (*Customer*). In addition, some of domains contain both positive (**P**) and negative (**N**) reviews.[6]

To explore the general rule of deceptive opinion spam, we extended SAGE Model (Eisenstein et al., 2011), a bayesian generative approach that can capture the multiple generative facets (i.e., deceptive vs truthful, positive vs negative, experienced vs non-experienced, hotel vs restaurant vs doctor) in the text collection. We find that more general features, such as LIWC and POS, are more robust when modeled using SAGE, compared with just bag-of-words.

We additionally make theoretical contributions that may shed light on a longstanding debate in the literature about deception. For example, in contrast to existing findings that highlight the lack of spatial detail in deceptive reviews (Ott et al., 2011; Li et al., 2013b), we find that a lack of spatial detail may not be a universal cue to deception, since it does not apply to fake reviews written by domain experts. Instead, our finding suggest that other linguistic features may offer more robust cues to deceptive opinion spam, such as overly highlighted sentiment in the review or the overuse of first-person singular pronouns.

The rest of this paper is organized as follows. In Section 2, we briefly go over related work. We describe the creation of our data set in Section 3 and present our model in Section 4. Experimental results are shown in Section 5. We present analysis of general cues to deception in Section 6 and conclude this paper in Section 7.

[4]http://www.dailymail.co.uk/travel/article-2013391/Tripadvisor-Hotel-owners-bribe-guests-return-good-reviews.html

[5]http://www.nytimes.com/2009/07/15/technology/internet/15lift.html?_r=0

[6]For example, a hotel manager could hire people to write positive reviews to increase the reputation of his own hotel or post negative ones to degrade his competitors. Identifying positive/negative opinion spam is explored in (Ott et al., 2011; Ott et al., 2013)

2 Related Work

Spam has been historically studied in the contexts of Web text (Gyöngyi et al., 2004; Ntoulas et al., 2006) or email (Drucker et al., 1999). Recently there has been increasing concern about deceptive opinion spam (Jindal and Liu, 2008; Ott et al., 2011; Wu et al., 2010; Mukherjee et al., 2013b; Wang et al., 2012).

Jindal and Liu (2008) first studied the deceptive opinion problem and trained models using features based on the review text, reviewer, and product to identify duplicate opinions, i.e., opinions that appear more than once in the corpus with similar contexts. Wu et al. (2010) propose an alternative strategy to detect deceptive opinion spam in the absence of a gold standard. Yoo and Gretzel (2009) gathered 40 truthful and 42 deceptive hotel reviews and manually compare the linguistic differences between them. Ott et al. created a gold-standard collection by employing Turkers to write fake reviews, and follow-up research was based on their data (Ott et al., 2012; Ott et al., 2013; Li et al., 2013b; Feng and Hirst, 2013). For example, Song et al. (2012) looked into syntactic features from Context Free Grammar parse trees to improve the classifier performance. A step further, Feng and Hirst (2013) make use of degree of *compatibility* between the personal experiment and a collection of reference reviews about the same product rather than simple textual features.

In addition to exploring text or linguistic features in deception, some existing work looks into customers' behavior to identify deception (Mukherjee et al., 2013a). For example, Mukherjee et al. (2011; 2012) delved into group behavior to identify group of reviewers who work collaboratively to write fake reviews. Qian and Liu (2013) identified multiple user IDs that are generated by the same author, as these authors are more likely to generate deceptive reviews.

In the psychological literature, researchers have looked into possible linguistic cues to deception (Newman et al., 2003), such as *decreased spatial detail*, which is consistent with theories of reality monitoring (Johnson and Raye, 1981), increased negative emotion terms (Newman et al., 2003), or the writing style difference between informative (truthful) and imaginative (deceptive) writings in (Rayson et al., 2001). The former typically consists of more nouns, adjectives, prepositions, determiners, and coordinating conjunctions, while the latter consists of more verbs, adverbs, pronouns, and pre-determiners.

SAGE (Sparse Additive Generative Model): SAGE is an generative bayesian approach introduced by Eisenstein et al. (2011), which can be viewed as an combination of topic models (Blei et al., 2003) and generalized additive models (Hastie and Tibshirani, 1990). Unlike other derivatives of topic models, SAGE drops the Dirichlet-multinomial assumption and adopts a Laplacian prior, triggering sparsity in topic-word distribution. The reason why SAGE is tailored for our task is that SAGE constructs multi-faceted latent variable models by simply adding together the component vectors rather than incorporating multiple switching latent variables in multiple facets.

3 Dataset Construction

In this section, we report our efforts to gather gold-standard opinion spam datasets. Our datasets contain the following domains, namely Hotel, Restaurant, and Doctor.

3.1 *Turker* set, using Mechanical Turk

Crowdsourcing services such as AMT greatly facilitate large-scale data annotation and collection efforts. Anyone with basic programming skills can create Human Intelligence Tasks (HITs) and access a marketplace of anonymous online workers (Turkers) willing to complete the tasks. We borrowed some rules used by Ott et al. to create their dataset, such as restricting task to Turkers located in the United States, and who maintain an approval rating of at least 90%.

Hotel-Turker : We directly borrowed datasets from Ott[7] and Li.[8]

Restaurant-Turker : We gathered 20 positive (P) deceptive reviews for each of 10 of the most popular restaurants in Chicago, for a total of 200 positive deceptive restaurant reviews.

Doctor-Turker : We gathered a total number of 200 positive reviews from Turkers.

3.2 *Employee* set, by domain experts

We seek deceptive opinion spam written by people with expert-level domain knowledge. It is not appropriate to use crowdsourcing to obtain this data,

[7] http://myleott.com/op_spam/

[8] http://www.cs.cmu.edu/~jiweil/html/four_city.html

	Turker	*Expert*	*Customer*
Hotel (P/N)	400/400	140/140	400/400
Restaurant (P/N)	200/0	120/0	200/200
Doctor (P/N)	200/0	32/0	200/0

Table 2: Statistics for our dataset.

so instead we solicit reviews written by employees in each domain.

Hotel-Employee: We asked two hotel employees from each of seven hotels (14 employees total) each to write 10 deceptive positive-sentiment reviews of their own hotel, and 10 deceptive negative-sentiment reviews of their biggest local competitor's hotel. In total, we obtained 280 deceptive reviews of 14 hotels, including a balanced mix of positive- and negative-sentiment reviews.

Restaurant-Employee: We asked employees from selected restaurants (a waiter/waitress or cook) to each write positive-sentiment reviews of their restaurant.

Doctor-Employee: We asked real doctors to write positive fake reviews about themselves. In total we obtained 32 reviews from 15 doctors.

3.3 *Customer* set from Actual Customers

Hotel-Customer: We borrowed from Ott et al.'s dataset.

Restaurant/Doctor-Customer: We solicited data by matching a set of truthful reviews as Ott et al. did in collecting truthful hotel reviews.

3.4 Summary for Data Creation

Statistics for our data set is presented in Table 2. Due to the difficulty in obtaining gold-standard data in the literature, there is no doubt that our data set is not perfect. Some parts are missing, some are unbalanced, participants in the survey may not be representative of the general population. However, as far as we know, this is the most comprehensive dataset for deceptive opinion spam so far, and may to some extent shed insights on the nature of online deception.

4 Feature-based Additive Model

In this section, we briefly describe our model. Since mathematics are not the main theme of this paper, we omit the exact details for inference, which can be found in (Eisenstein et al., 2011).

Before describing the model in detail, we note the following advantages of the SAGE model, and our reasons for using it in this paper:

1. the "additive" nature of SAGE allows a better understanding of which features contribute most to each type of deceptive review and how much each such feature contributes to the final decision jointly. If we instead use SVM, for example, we would have to train classifiers one by one (due to the distinct features from different sources) to draw conclusions regarding the differences between Turker vs Expert vs truthful reviews, positive expert vs negative expert reviews, or reviews from different domains. This would not only become intractable, but would make the conclusions less clear.

2. For cross-domain classification task, standard machine learning approaches may suffer due to domain-specific properties (See Section 5.2).

4.1 Model

In SAGE, each term w is drawn from a distribution proportional to $\exp(m^{(w)} + \eta_{y_d}^{(T)(w)} + \eta_{z_n}^{(A)(w)} + \eta_{y_d,z_n}^{(I)(w)})$, where $m^{(w)}$ is the observed background term frequency, η_{y_d}, η_{z_n} and η_{y_d,z_n} denote the log frequency deviation representing topic z_n, facet y_d, and the second-order interaction part respectively. Superscripts T, A and I respectively denote the index of the topic, facet, and second-order interaction. In our task, we adapt the SAGE model as follows:

$$\begin{aligned} Y = \{&y_{Sentiment} \in \{\text{positive, negative}\}, \\ &y_{Domain} \in \{\text{hotel, restaurant, doctor}\}, \\ &y_{Source} \in \{\text{employee, turker, customer}\}\} \end{aligned}$$

We model three η's, one for each type of y. Let i, j, k denote the index of the different types of y, so that each term w is drawn as follows:

$$\begin{aligned} P(w|i,j,k) \propto \exp(&m^{(w)} + \eta_{y_{Sentiment}}^{(i)(w)} \\ &+\eta_{y_{Domain}}^{(j)(w)} + \eta_{y_{Scource}}^{(k)(w)} + \textit{higher order}) \end{aligned}$$

where the *higher order* parts denote the interactions between different facets.

In our approach each document-level feature f is drawn from the following distribution:

$$\begin{aligned} P(f|i,j,k) \propto \exp(&m^{(f)} + \eta_{y_{Sentiment}}^{(i)(f)} + \eta_{y_{Domain}}^{(j)(f)} \\ &+ \eta_{y_{Scource}}^{(k)(f)} + higher\ order) \end{aligned} \quad (1)$$

where $m^{(f)}$ can be interpreted as the background value of feature f. For each review d, the probability that it is drawn from facets with index i, j, k is as follows:

$$P(d|i,j,k) = \prod_{f \in d} P(f|i,j,k) \prod_{w \in d} P(w|i,j,k) \quad (2)$$

In the training process, parameters $\eta_y^{(w)}$ and $\eta_y^{(f)}$ are to be learned by maximizing the posterior distribution following the original SAGE training procedure. For prediction, we estimate y_{Source} for each document given all or part of $\eta_y^{(w)}$ and $\eta_y^{(f)}$ as follows:

$$y_{Source} = \underset{y'_{Source}}{\operatorname{argmax}} P(d|y'_{Source}, y_{Sentiment}, y_{Domain}),$$

where we assume $y_{Sentiment}$ and y_{Domain} are given for each document d. Note that we assume conditional independence between features and words given y, similar to other topic models (Blei et al., 2003). Notably, our revised SAGE model degenerates into a model similar to Generalized Additive Model (Hastie and Tibshirani, 1990) when word features are not considered.

5 Experiments

In this section, we report our experimental results. We first restrict experiments to the within-domain task and see what features most characterize the deceptive reviews, and how. We later extend it to cross domains to explore a more general classifier of deceptive opinion spam.

5.1 Intra-Domain Classification

We explore the effect of both domain experts and crowdsourcing workers on intra-domain deception. Specifically, we reframe it as a **intra-domain multi-class classification task**, where given the labeled training data from one domain, we learn a classifier to classify reviews according to their source, i.e., *Employee*, *Turker* and *Customer*. Since the machine learning classifier is trained and tested within the same domain, $\eta_{y_{Domain}}^{(j)(w)}$ and $\eta_{y_{Domain}}^{(i)(f)}$ are not considered here.

We use a *One-Versus-Rest* (OvR) scheme, in which we train m classifiers using SAGE, such that each classifier f_i, for $i \in [1, m]$, is trained to distinguish between class i on the one hand, and all classes except i on the other. To make an m-way decision, we then choose the class c with the most confident prediction. OvR approaches have been shown to produce state-of-art performance compared to other multi-class approaches such as *Multinomial Naive Bayes* or *One-Versus-One* classification scheme. We train the OvR classifier on three sets of features, *LIWC*, *Unigram*, and *POS*.[9]

Multi-class classification results are given at Table 3. We report both OvR performance and the performance of three One-versus-One binary classifiers, trained to distinguish between each pair of classes. In particular, the three-class classifier is around 69% accurate at distinguishing between *Employee*, *Customer*, and *Turker* for each of the domains using Unigram, significantly higher than random guess. We also observe that each of the three *One-versus-One* binary classifications performs significantly better than chance, suggesting that *Employee*, *Customer*, and *Turker* are in fact three different classes. In particular, the two-class classifier is around 0.76 accurate in distinguishing between *Turker* and *Employee* reviews, despite both kinds of reviews being deceptive opinion spam.

Best performance is achieved on Unigram features, constantly outperforming LIWC and POS features in both three-class and two-class settings in the hotel domain. Similar results are observed for restaurant and doctor domains and details are excluded for brevity. This suggests that a universal set of keyword-based deception cues (e.g., LIWC) is not the best approach for Intra-Domain Classification. Similar results were also reported in previous work (Ott et al., 2012; Ott, 2013).

5.2 Cross-domain Classification

In this subsection, we frame our problem as a *domain adaptation task* (Pan and Yang, 2010). Again, we explore 3 feature sets: *LIWC*, *Unigram* and *POS*. We train a classifier on hotel reviews, and evaluate the performance on other domains. For simplicity, we focus on **truthful** (*Customer*) versus **deceptive** (*Turker*) binary classification rather than a multi-class classification.

We report results from SAGE and SVM[10] in Table 4. We first observe that classifiers trained on hotel reviews apply well in the restaurant domain, which is reasonable due to the many shared prop-

[9] Part-of-speech tags were assigned based on Stanford Parser `http://nlp.stanford.edu/software/lex-parser.shtml`

[10] We use SVMlight (Joachims, 1999) to train our linear SVM classifiers

Table 4: Classifier performance in cross-domain adaptation.

erties among restaurants and hotels. Among three types of features, Unigram still performs best. POS and LIWC features are also robust across domains.

In the doctor domain, we observe that models trained on Unigram features from the hotels domain do not generalize well to doctor reviews, and the performance is a little bit better than random guess with only 0.55 accuracy. For SVM, models trained on POS and LIWC features achieve even lower accuracy than Unigram. POS and LIWC features obtain around 0.5 precision and 1.0 recall, indicating that all doctor reviews are classified as deceptive by the classifier. One plausible explanation could be doctor reviews generally encode some type of positive-weighted (deceptive) features more than hotel reviews and these types of features dominate the decision making procedures, leading all reviews to be classified as deceptive.

Tables 5 and 6 give the top weighted LIWC and POS features. We observe that many features are indeed shared among doctor and hotel domains. Notably, POS features are more robust than LIWC as more shared features are observed. As domain specific properties will be considered in the interaction part (η^{LIWC}_{domain} and η^{POS}_{domain}) of the additive model, SAGE achieve much better results than SVM, and is around 0.65 accurate in the cross-domain task.

LIWC (hotel)		LIWC (doctor)

cause	dash	future	money

Table 5: Top weighted LIWC features for Turker vs Customer in Doctor and Hotel reviews. Blue denotes shared positive (deceptive) features and red denotes negative (truthful) features.

6 General Linguistic Cues of Deceptive Opinion Spam

In this section, we examine a number of general POS and LIWC features that may shed light on a general rule for identifying deceptive opinion

Figure 1: Visualization of the η for POS features: Horizontal axes correspond to the values η and are NORMALIZED from the log-frequency function.

JJS	VBZ	PRP	VBN

Table 6: Top weighted POS features for Turker vs Customer in Doctor and Hotel reviews. Blue denotes shared positive (deceptive) features and red denotes negative (truthful) features.

spam. Our modified SAGE model provides us with a tailored tool for this analysis. Specifically, each feature f is associated with a background value m^f. For each facet A, η_A^f, presents the facet-specific preference value for feature f. Note that sentiments are separated into positive and negative dimensions, which is necessary because hotel employee authors wrote positive-sentiment reviews when reviewing their own hotels, and negative-sentiment reviews when reviewing their competitors' hotels.

6.1 POS features

Early findings in the literature (Rayson et al., 2001; Buller and Burgoon, 1996; Biber et al., 1999) found that informative (truthful) writings typically consist of more nouns, adjectives, prepositions, determiners, and coordinating conjunctions, while imaginative (deceptive) writing consist of more verbs, adverbs, pronouns, and pre-determiners (with a few exceptions). Our findings with POS features are largely in agreement with these findings when distinguishing between Turker and Customer reviews, but are violated in the Employee set.

We present the eight types of POS features in Figure 1, namely, N (Noun), JJ (Adjective), IN (Preposition or subordinating conjunction) and DT (Determiner), V (Verb), RB (Adverb), PRP (Pronouns, both personal and possessive) and PDT (Pre-Determiner).

From Figures 1(a)(b)(e)(f), we observe that with the exception of PDT, the word frequency of which is too small to draw a conclusion, *Turker* and *Customer* reviews exhibit linguistic patterns in agreement with previous findings in the literature, where truthful reviews (*Customer*) tend to include more N, JJ, IN and DT, while deceptive writings tend to encode more V, RB and PRP.

However, in the case of the *Employee-Positive* dataset, which is equally deceptive, most of these rules are violated. Notably, reviews from the *Employee-Positive* set did not encode fewer N, JJ and DT terms, as expected (see Figures 1(a)(c)). Instead, they encode even more N, JJ and DT vocabularies than truthful reviews from the *Customer* reviews. Also, fewer V and RB are found in *Employee-Positive* reviews compared with *Customer* reviews (see Figures 1(e)(g)).

One explanation for these observations is that informative (truthful) writing tends to be more introductory and descriptive, encoding more concrete details, when compared with imaginary writings. As domain experts possess considerable knowledge of their own offerings, they highlight

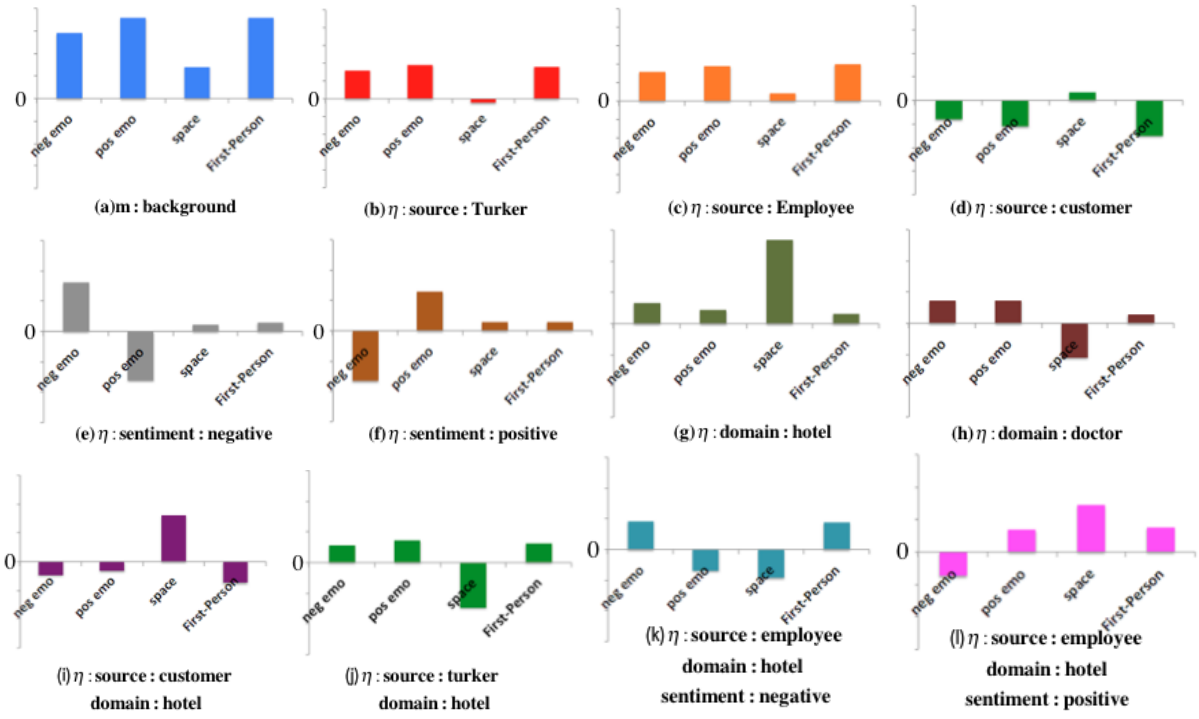

Figure 2: Visualization of the η for LIWC features: Horizontal axes correspond to the values η and are normalized from the log-frequency function.

the details and their lies may be even more informative and descriptive than those generated by real customers! This explains why *Employee-Positive* contains more N, IN and DT. Meanwhile, as domain experts are engaged more in talking about the details, they inevitably overlook other information, possibly leading to fewer V and RB.

For *Employee-Positive* reviews, shown in Figures 1(d)(h), it turns out that domain experts do not compensate for their lack of prior experience when writing negative reviews for competitors' offerings, as we will see again with LIWC features in the next subsection.

6.2 LIWC features

We explore 3 LIWC categories (from left to right in subfigures of Figure 2): sentiment (*neg emo* and *pos emo*), spatial detail (*space*), and first-person singular pronouns (*first-person*).

Space: Note that spatial details are more specific in the *Hotel* and *Restaurant* domains, which is reflected in the high positive value of $\eta_{domain}^{Hotel,space}$ (see Figure 2(g)) and negative value of $\eta_{domain}^{Doctor,space}$ (see Figure 2(h)). It illustrates how domain-specific details can be predictive of deceptive text. Similarly predictive LIWC features are *home* for the *Hotel* domain, *ingest* for the *Restaurant* domain, and *health* and *body* for the *Doctor* domain.

In Figure 2(i)(j)(k)(l), we can easily see that both actual customers and domain experts encode more spatial details in their reviews (positive value of η), which is in agreement with our expectation. This further demonstrates that a lack of spatial details would not be a general cue for deception. Moreover, it appears that general domain expertise does not compensate for the lack of prior experience when writing deceptive negative reviews for competitors' hotels, as demonstrated by the lack of spatial details in the negative-sentiment reviews by employees shown in Figure 2(k).

Sentiment: According to our findings, the presence of sentiment is a general cue to deceptive opinion spam, as observed when comparing Figure 2(b) to Figure 2(c) and (d). Participants, both Employees and Turkers, tend to exaggerate sentiment, and include more sentiment-related vocabularies in their lies. In other words, positive deceptive reviews were generally more positive and negative deceptive reviews were more negative in sentiment when compared with the truthful reviews generated by actual customers. A similar pattern can also be observed when comparing Figure 2(i) to Figure 2(j).

First-Person Singular Pronouns: The literature also associates deception with decreased usage of first-person singular pronouns, an effect attributed to psychological distancing, whereby deceivers talk less about themselves due either to a lack of personal experience, or to detach themselves from the lie (Newman et al., 2003; Zhou et al., 2004; Buller et al., 1996; Knapp and Comaden, 1979). However, according to our findings, we find the opposite to hold. Increased first person singular is an apparent indicator of deception, when comparing Figure 2(b) to 2(c) and 2(e). We suspect that this relates to an effect observed in previous studies of deception, where liars inadvertently undermine their lies by overemphasizing aspects of their deception that they believe reflect credibility (Bond and DePaulo, 2006; DePaulo et al., 2003). One interpretation for this phenomenon would be that deceivers try to overemphasize their physical presence because they believe that this increases their credibility.

7 Conclusion and Discussion

In this work, we have developed a multi-domain large-scale dataset containing gold-standard deceptive opinion spam. It includes reviews of Hotels, Restaurants and Doctors, generated through crowdsourcing and domain experts. We study this data using SAGE, which enables us to make observations about the respects in which truthful and deceptive text differs. Our model includes several domain-independent features that shed light on these differences, which further allows us to formulate some general rules for recognizing deceptive opinion spam.

We also acknowledge several important caveats to this work. By soliciting fake reviews from participants, including crowd workers and domain experts, we have found that is possible to detect fake reviews with above-chance accuracy, and have used our models to explore several psychological theories of deception. However, it is still very difficult to estimate the practical impact of such methods, as it is very challenging to obtain gold-standard data in the real world. Moreover, by soliciting deceptive opinion spam in an artificial environment, we are endorsing the deception, which may influence the cues that we observe (Feeley and others, 1998; Frank and Ekman, 1997; Newman et al., 2003; Ott, 2013). Finally, it may be possible to train people to tell more convincing lies. Many of the characteristics regarding fake review generation might be overcome by well-trained fake review writers, which would results in opinion spam that is harder for detect. Future work may wish to consider some of these additional challenges.
