Preface: General Chair

I remember with great fondness the first ACL Conference I attended 20 years ago in Las Cruces, New Mexico. Some things have changed: papers presented there that I considered interesting or inconsequential have switched positions in my personal ranking as I learned more and more about our field; single sessions have long been replaced by parallel sessions to accommodate an ever increasing number of research contributions; the number of associated workshops and posters has mushroomed beyond anyone's dream. Almost without noticing, we transitioned from small conferences of a few hundred to conferences that bring together 1000 plus participants from all over the world. Our field has matured significantly attracting the attention of not only a handful of academics, but successful industries and Research Labs as well. Some things have stayed the same though: ACL continues to be the pre-eminent conference in our field and the best place to meet and make like-minded friends, discuss tantalizing tricks that you can learn about only in face-to-face communication settings, and celebrate the results we get.

ACL Conferences are never possible without the dedication and hard work of many people. Because ACL'2014 is no exception to this, I would like to thank each and every person who has volunteered their time to make the event possible.

Priscilla Rasmussen, the ACL Business Manager, and the ACL Executive Committee (Haifeng Wang, Gertjan van Noord, Graeme Hirst, Dragomir Radev, Renata Vieira, Jian Su, Min-Yen Kan, Stephen Clark, and Hal Daumé III) have been instrumental in setting ACL'2014 in motion and in guiding the ACL'2014 committee along the path from concept to execution. Without the collective memory and hands-on guidance of the committee, an ACL conference will never happen.

The ACL'2014 Committee did a fantastic job making this conference possible. The committee covered a lot of ground from logistics to paper selection, to co-located event selection and publishing. The masterminds of all these intertwining tasks were: Kristina Toutanova and Hua Wu (Program Committee Chairs); David Yarowsky (Local Arrangements Chair); Jill Burstein and Lluís Màrquez (Workshop Chairs); Alex Fraser and Yang Liu (Tutorial Chairs), Alexander Koller and Miyao Yusuke (Publication Chairs); Ekaterina Kochmar, Annie Louis, and Svitlana Volkova (Student Research Workshop Chairs); Bill Byrne and Jordan Boyd-Graber (Faculty Advisors for the Student Workshop Chairs); Kalina Bontcheva and Zhu Jingbo (Demonstration Chairs); and Jason Riesa (Publicity Chair). The Program Chairs were also instrumental in selecting our outstanding invited speakers: Corinna Cortez (Google) and Zoran Popovic (University of Washington).

I am also grateful to our sponsors for their generous contributions, without which the conference would become prohibitively expensive for the next generation of computational linguistic researchers: Baidu (Platinum Sponsor); Bloomberg, Google, Microsoft, Nuance, and Yahoo Labs (Gold Sponsors); Information Sciences Institute and Xerox Research Center Europe (Silver Sponsors); Brandeis University, Facebook, and Yandex (Bronze Sponsors); and IBM Research and the University of Washington (Supporters).

Finally, I would like to express my appreciation to the area chairs, workshop organizers, tutorial presenters, and reviewers. And to all the ACL'2014 attendees. This is *your* conference; make the most of it!

Welcome to ACL'2014!

The ACL'2014 General Chair
Daniel Marcu, Information Sciences Institute, USC

Preface: Program Committee Co-Chairs

Welcome to the 2014 Conference of the Association for Computational Linguistics! This year ACL received 572 long paper submissions and 551 short paper submissions. Of the long papers, 146 were accepted for presentation at ACL — 95 as oral, and 51 as poster presentations. 139 short papers were accepted — 51 as oral, and 88 as poster presentations.

The submissions were reviewed under different categories and using different review forms for empirical/data-driven, theoretical, applications/tools, resources/evaluation, and survey papers. For the short papers we additionally used a negative results category and were glad to see that the community is becoming more open to enabling the publication of useful negative results.

Based on feedback from prior years, this year we organized the posters in two large poster sessions to accommodate the growing number of high-quality submissions accepted in poster presentation format. We hope attendees and authors will benefit from this additional time to present and discuss ideas. Another innovation we are experimenting with this year is to optimize the conference schedule based on feedback from attendees on the talks they would like to see. We collected attendee responses using a scheduling survey developed with the help of David Yarowsky and Svitlana Volkova (thanks to the 338 volunteers who completed the survey!), and we optimized the conference schedule to assign popular sessions to large conference rooms, and to reduce the chance that two talks that an attendee is interested in are scheduled at the same time. Additionally, as in NAACL 2013, all talks will be recorded and made available for future viewing.

ACL 2014 will have two distinguished invited speakers. Corinna Cortes (Head of Google Research, NY) and Zoran Popović (Director of Center for Game Science, University of Washington).

There are many individuals to thank for their contributions to ACL 2014. We would like to thank the thirty three area chairs for their hard work on recruiting reviewers, leading the discussion process, and carefully ranking the submissions. We would like to thank Mark Dredze for developing and sharing a reviewer assignment tool, that was used at ACL this year. It was applied to ACL reviewing with the help of Jiang Guo and the area chairs who provided feedback at several stages of the process. We would also like to thank the seven hundred and seventy nine reviewers and seventy two secondary reviewers on whose efforts we depend to select high-quality and timely scientific work. This year we specifically acknowledged around 14% of the reviewers who went the extra mile and provided extremely helpful to the area chairs and authors reviews (their names are marked with a * in the organization section of the proceedings). The ACL coordinating committee members, including Dragomir Radev, Jian Su, Graeme Hirst, Hal Daumé III, Chris Callison-Burch, and Haifeng Wang were very helpful on various issues relating to the organization. We would like to thank the prior conference chairs Jason Eisner, Hal Daumé, Lucy Vanderwende, Jian Su, Rada Mihalcea, Marius Pasca, Pascale Fung, and Massimo Poesio for their advice. We are very grateful for the guidance and support of the general chair Daniel Marcu, to the ACL Business Manager Priscilla Rasmussen who knew practically everything, to the local chair David Yarowsky, the publication chairs Yusuke Miyao and Alexander Koller, and to Matt Post who stepped in to handle the conference handbook. We would also like to thank Jiang Guo who helped with reviewer assignment and numerous other tasks. Rich Gerber from Softconf was extremely responsive to all of our requests, and we are grateful for that.

We hope you will enjoy ACL 2014 in Baltimore!

ACL 2014 Program Co-Chairs
Kristina Toutanova, Microsoft Research
Hua Wu, Baidu

Organizing Committee

General Conference Chair

Daniel Marcu, ISI/USC

Program Committee Chairs

Kristina Toutanova, Microsoft Research
Hua Wu, Baidu

Local Arrangements Chair

David Yarowsky, Johns Hopkins University

Workshop Chairs

Jill Burstein, Educational Testing Service
Lluís Màrquez, Universitat Politècnica de Catalunya

Tutorial Chairs

Alex Fraser, University of Munich
Yang Liu, Tsinghua University

Publications Chairs

Alexander Koller, University of Potsdam
Yusuke Miyao, National Institute of Informatics Japan
We gratefully acknowledge the support of Ulla Behr, Anna Lukowiak, and Deyan Ginev.

Student Research Workshop Chairs

Ekaterina Kochmar, University of Cambridge
Annie Louis, University of Pennsylvania
Svitlana Volkova, Johns Hopkins University

Faculty Advisors for the Student Research Workshop

Bill Byrne, University of Cambridge
Jordan Boyd-Graber, University of Maryland

Demonstrations Chairs

Kalina Bontcheva, University of Sheffield
Jingbo Zhu, Northeastern University China

Publicity Chair

Jason Riesa, Google

Business Manager

Priscilla Rasmussen

Reviewing Coordinators

Mark Dredze, Johns Hopkins University
Jiang Guo, Harbin Institute of Technology

Conference Handbook Editor

Matt Post, Johns Hopkins University

Local Guide Editors

Juri Ganitkevitch, Johns Hopkins University
Ann Irvine, Johns Hopkins University

Student Volunteer Chair

Yuan Cao, Johns Hopkins University

Entertainment Chairs

Matt Gormley, Johns Hopkins University
Naomi Saphra, Johns Hopkins University

Graphic Design

Jeff Hayes, Jeff-Hayes.com
Meg Mitchell, Microsoft Research
Keisuke Sakaguchi, Johns Hopkins University

Local JHU/CLSP Administration

Laura Graham
Ruth Scally

Program Committee

Program Committee Chairs

Kristina Toutanova, Microsoft Research
Hua Wu, Baidu

Area Chairs

Klinton Bicknell, Northwestern University
Asli Celikyilmaz, Microsoft Research
Micha Elsner, Ohio State University
Michael Strube, HITS gGmbH
Jacob Eisenstein, Georgia Institute of Technology
Jun Zhao, Chinese Academy of Sciences
Barbara Di Eugenio, University of Illinois at Chicago
Ting Liu, Harbin Institute of Technology
Marius Pasca, Google Research
Mihai Surdeanu, University of Arizona
Nicoletta Calzolari, Institute of Computational Linguistics of the National Research Council
Nianwen Xue, Brandeis University
Eneko Agirre, University of the Basque Country
Kevin Duh, Nara Institute of Science and Technology
Jason Eisner, Johns Hopkins University
Colin Cherry, National Research Council, Canada
Niyu Ge, IBM Research
Liang Huang, City University of New York
Yanjun Ma, Baidu
Michel Galley, Microsoft Research
Brian Roark, Google Research
Mamoru Komachi, Tokyo Metropolitan University

Invited Talk: Learning Ensembles of Structured Prediction Rules

Corinna Cortes
Google Research, New York

Abstract

We present a series of algorithms with theoretical guarantees for learning accurate ensembles of several structured prediction rules for which no prior knowledge is assumed. This includes a number of randomized and deterministic algorithms devised by converting on-line learning algorithms to batch ones, and a boosting-style algorithm applicable in the context of structured prediction with a large number of labels. We also report the results of extensive experiments with these algorithms.

This is joint work with Vitaly Kuznetsov, NYU, and Mehryar Mohri, NYU/Google Research.

Biography

Corinna Cortes is the Head of Google Research, NY, where she is working on a broad range of theoretical and applied large-scale machine learning problems. Prior to Google, Corinna spent more than ten years at AT&T Labs - Research, formerly AT&T Bell Labs, where she held a distinguished research position. Corinna's research work is well-known in particular for her contributions to the theoretical foundations of support vector machines (SVMs), for which she jointly with Vladimir Vapnik received the 2008 Paris Kanellakis Theory and Practice Award, and her work on data-mining in very large data sets for which she was awarded the AT&T Science and Technology Medal in the year 2000. Corinna received her MS degree in Physics from University of Copenhagen and joined AT&T Bell Labs as a researcher in 1989. She received her Ph.D. in computer science from the University of Rochester in 1993. Corinna is also a competitive runner.

Invited Talk: Text Generation for Infinitely Adaptable Curricula

Zoran Popović
Center for Game Science, Computer Science & Engineering, University of Washington

Abstract

Recent studies show that to achieve mastery of a topic by 95% of the student population, some students need ten times more learning content than is available in current curricula. At issue is not just increased volume, but the need for a highly differentiated content specialized to promote optimal learning for each unique learner. To address this synthesis problem we have developed a generative platform capable of dynamically varying content based on the individual student needs. This approach recently achieved 93% mastery of a key algebra concept even for primary school students in three state-wide challenges. In this talk I will describe our work on extending the platform to enable students to solve all word problems in high-school within their preferred context (e.g. sci-fi, medieval, Harry Potter), as well as to automatically generate adaptive learning progressions for reading comprehension curricula in middle school.

Biography

Zoran Popović is a Director of Center for Game Science at University of Washington and founder of Engaged Learning. Trained as a computer scientist his research focus is on creating interactive engaging environments for learning and scientific discovery. His laboratory created Foldit, a biochemistry game that produced three Nature publications in just two years, an award-winning math learning games played by over five million learners worldwide. He is currently focusing on engaging methods that can rapidly develop experts in arbitrary domains with particular focus on revolutionizing K-12 math education. He has recently founded Engaged Learning to apply his work on generative adaptation to any curricula towards the goal of achieving school mastery by 95% of students. His contributions to the field of interactive computer graphics have been recognized by a number of awards including the NSF CAREER Award, Alfred P. Sloan Fellowship and ACM SIGGRAPH Significant New Researcher Award.

Table of Contents

Conference Program

Sunday, June 22, 2014

7:30–18:00 Registration

7:30–9:00 Breakfast

9:00–12:30 Morning Tutorial

Session T1: Gaussian Processes for Natural Language Processing

Session T2: Scalable Large-Margin Structured Learning: Theory and Algorithms

Session T3: Semantics for Large-Scale Multimedia: New Challenges for NLP

Session T4: Wikification and Beyond: The Challenges of Entity and Concept Grounding

12:30–14:00 Lunch break

14:00–17:30 Afternoon Tutorial

Session T5: New Directions in Vector Space Models of Meaning

Session T6: Structured Belief Propagation for NLP

Session T7: Semantics, Discourse and Statistical Machine Translation

Session T8: Syntactic Processing Using Global Discriminative Learning and Beam-Search Decoding

18:00–21:00 Welcome Reception

Monday, June 23, 2014

7:30–18:00 Registration

7:30–9:00 Breakfast

8:55–9:00 Opening session

9:00–9:40 President talk

9:40–10:10 Coffee break

Session 1A: Discourse, Dialogue, Coreference and Pragmatics

10:10–10:35 *Representation Learning for Text-level Discourse Parsing*
Yangfeng Ji and Jacob Eisenstein

10:35–11:00 *Text-level Discourse Dependency Parsing*
Sujian Li, Liang Wang, Ziqiang Cao and Wenjie Li

11:00–11:25 *Discovering Latent Structure in Task-Oriented Dialogues*
Ke Zhai and Jason D Williams

11:25–11:50 *Learning Structured Perceptrons for Coreference Resolution with Latent Antecedents and Non-local Features*
Anders Björkelund and Jonas Kuhn

Monday, June 23, 2014 (continued)

Session 1B: Semantics I

10:10–10:35 *Multilingual Models for Compositional Distributed Semantics*
Karl Moritz Hermann and Phil Blunsom

10:35–11:00 *Simple Negation Scope Resolution through Deep Parsing: A Semantic Solution to a Semantic Problem*
Woodley Packard, Emily M. Bender, Jonathon Read, Stephan Oepen and Rebecca Dridan

11:00–11:25 *Logical Inference on Dependency-based Compositional Semantics*
Ran Tian, Yusuke Miyao and Takuya Matsuzaki

11:25–11:50 *A practical and linguistically-motivated approach to compositional distributional semantics*
Denis Paperno, Nghia The Pham and Marco Baroni

Session 1C: Machine Translation I

10:10–10:35 *Lattice Desegmentation for Statistical Machine Translation*
Mohammad Salameh, Colin Cherry and Grzegorz Kondrak

10:35–11:00 *Bilingually-constrained Phrase Embeddings for Machine Translation*
Jiajun Zhang, Shujie Liu, Mu Li, Ming Zhou and Chengqing Zong

11:00–11:25 *Learning New Semi-Supervised Deep Auto-encoder Features for Statistical Machine Translation*
Shixiang Lu, Zhenbiao Chen and Bo Xu

11:25–11:50 *Learning Topic Representation for SMT with Neural Networks*
Lei Cui, Dongdong Zhang, Shujie Liu, Qiming Chen, Mu Li, Ming Zhou and Muyun Yang

Monday, June 23, 2014 (continued)

Session 1D: Syntax, Parsing and Tagging I

11:00–11:25 *Tagging The Web: Building A Robust Web Tagger with Neural Network*
Ji Ma, Yue Zhang and Jingbo Zhu

Session 1E: NLP for the Web and Social Media I

10:10–10:35 *Unsupervised Solution Post Identification from Discussion Forums*
Deepak P and Karthik Visweswariah

10:35–11:00 *Weakly Supervised User Profile Extraction from Twitter*
Jiwei Li, Alan Ritter and Eduard Hovy

11:00–11:25 *The effect of wording on message propagation: Topic- and author-controlled natural experiments on Twitter*
Chenhao Tan, Lillian Lee and Bo Pang

11:25–11:50 *Inferring User Political Preferences from Streaming Communications*
Svitlana Volkova, Glen Coppersmith and Benjamin Van Durme

11:50–13:20 Lunch break; Student Lunch

Session 2A: Syntax, Parsing and Tagging II

13:20–13:45 *Steps to Excellence: Simple Inference with Refined Scoring of Dependency Trees*
Yuan Zhang, Tao Lei, Regina Barzilay, Tommi Jaakkola and Amir Globerson

13:45–14:10 *Sparser, Better, Faster GPU Parsing*
David Hall, Taylor Berg-Kirkpatrick and Dan Klein

14:10–14:35 *Shift-Reduce CCG Parsing with a Dependency Model*
Wenduan Xu, Stephen Clark and Yue Zhang

14:35–15:00 *Less Grammar, More Features*
David Hall, Greg Durrett and Dan Klein

Monday, June 23, 2014 (continued)

Session 2B: Semantics II

13:20–13:45 *Don't count, predict! A systematic comparison of context-counting vs. context-predicting semantic vectors*
Marco Baroni, Georgiana Dinu and Germán Kruszewski

13:45–14:10 *Metaphor Detection with Cross-Lingual Model Transfer*
Yulia Tsvetkov, Leonid Boytsov, Anatole Gershman, Eric Nyberg and Chris Dyer

14:10–14:35 *Learning Word Sense Distributions, Detecting Unattested Senses and Identifying Novel Senses Using Topic Models*
Jey Han Lau, Paul Cook, Diana McCarthy, Spandana Gella and Timothy Baldwin

14:35–15:00 *Learning to Automatically Solve Algebra Word Problems*
Nate Kushman, Luke Zettlemoyer, Regina Barzilay and Yoav Artzi

Session 2C: Word Segmentation and POS Tagging

13:45–14:10 *Modelling function words improves unsupervised word segmentation*
Mark Johnson, Anne Christophe, Emmanuel Dupoux and Katherine Demuth

14:35–15:00 *Max-Margin Tensor Neural Network for Chinese Word Segmentation*
Wenzhe Pei, Tao Ge and Baobao Chang

Session 2D: SRW

Session 2E: Sentiment Analysis I

13:20–13:45 *An Empirical Study on the Effect of Negation Words on Sentiment*
Xiaodan Zhu, Hongyu Guo, Saif Mohammad and Svetlana Kiritchenko

13:45–14:10 *Extracting Opinion Targets and Opinion Words from Online Reviews with Graph Co-ranking*
Kang Liu, Liheng Xu and Jun Zhao

14:10–14:35 *Context-aware Learning for Sentence-level Sentiment Analysis with Posterior Regularization*
Bishan Yang and Claire Cardie

14:35–15:00 *Product Feature Mining: Semantic Clues versus Syntactic Constituents*
Liheng Xu, Kang Liu, Siwei Lai and Jun Zhao

Monday, June 23, 2014 (continued)

15:00–15:30 Coffee break

Session 3A: Topic Modeling

15:30–15:55 *Aspect Extraction with Automated Prior Knowledge Learning*
Zhiyuan Chen, Arjun Mukherjee and Bing Liu

15:55–16:20 *Anchors Regularized: Adding Robustness and Extensibility to Scalable Topic-Modeling Algorithms*
Thang Nguyen, Yuening Hu and Jordan Boyd-Graber

16:20–16:45 *A Bayesian Mixed Effects Model of Literary Character*
David Bamman, Ted Underwood and Noah A. Smith

Session 3B: Information Extraction I

15:30–15:55 *Collective Tweet Wikification based on Semi-supervised Graph Regularization*
Hongzhao Huang, Yunbo Cao, Xiaojiang Huang, Heng Ji and Chin-Yew Lin

15:55–16:20 *Zero-shot Entity Extraction from Web Pages*
Panupong Pasupat and Percy Liang

16:20–16:45 *Incremental Joint Extraction of Entity Mentions and Relations*
Qi Li and Heng Ji

Session 3C: Generation

15:30–15:55 *That's Not What I Meant! Using Parsers to Avoid Structural Ambiguities in Generated Text*
Manjuan Duan and Michael White

15:55–16:20 *Surface Realisation from Knowledge-Bases*
Bikash Gyawali and Claire Gardent

16:20–16:45 *Hybrid Simplification using Deep Semantics and Machine Translation*
Shashi Narayan and Claire Gardent

Monday, June 23, 2014 (continued)

Session 3D: Syntax, Parsing and Tagging III

15:55–16:20 *Grammatical Relations in Chinese: GB-Ground Extraction and Data-Driven Parsing*
Weiwei Sun, Yantao Du, Xin Kou, Shuoyang Ding and Xiaojun Wan

16:20–16:45 *Ambiguity-aware Ensemble Training for Semi-supervised Dependency Parsing*
Zhenghua Li, Min Zhang and Wenliang Chen

Session 3E: Language Resources and Evaluation I

15:30–15:55 *A Robust Approach to Aligning Heterogeneous Lexical Resources*
Mohammad Taher Pilehvar and Roberto Navigli

15:55–16:20 *Predicting the relevance of distributional semantic similarity with contextual information*
Philippe Muller, Cécile Fabre and Clémentine Adam

16:45–17:00 Break

17:00–18:00 Invited talk I: Corinna Cortes

17:00–18:00 *Learning Ensembles of Structured Prediction Rules*
Corinna Cortes, Vitaly Kuznetsov and Mehryar Mohri

Oral Sessions for Student Research Workshop Posters

18:50–21:30 Poster and Dinner Session I: TACL Papers, Long Papers, Short Papers, Student Research Workshop; Demonstrations

Interpretable Semantic Vectors from a Joint Model of Brain- and Text- Based Meaning
Alona Fyshe, Partha P. Talukdar, Brian Murphy and Tom M. Mitchell

Single-Agent vs. Multi-Agent Techniques for Concurrent Reinforcement Learning of Negotiation Dialogue Policies
Kallirroi Georgila, Claire Nelson and David Traum

A Linear-Time Bottom-Up Discourse Parser with Constraints and Post-Editing
Vanessa Wei Feng and Graeme Hirst

Negation Focus Identification with Contextual Discourse Information
Bowei Zou, Guodong Zhou and Qiaoming Zhu

New Word Detection for Sentiment Analysis
Minlie Huang, Borui Ye, Yichen Wang, Haiqiang Chen, Junjun Cheng and Xiaoyan Zhu

Ryo Nagata, Mikko Vilenius and Edward Whittaker

Tuesday, June 24, 2014

7:30–18:00 Registration

7:30–9:00 Breakfast

9:00–10:00 Invited talk II: Zoran Popović

9:00–10:00 *Text Generation for Infinitely Adaptable Curricula*
Zoran Popović

10:00–10:30 Coffee break

Session 4A: Machine Learning for NLP

10:30–10:55 *Kneser-Ney Smoothing on Expected Counts*
Hui Zhang and David Chiang

10:55–11:20 *Robust Entity Clustering via Phylogenetic Inference*
Nicholas Andrews, Jason Eisner and Mark Dredze

11:20–11:45 *Linguistic Structured Sparsity in Text Categorization*
Dani Yogatama and Noah A. Smith

11:45–12:10 *Perplexity on Reduced Corpora*
Hayato Kobayashi

Tuesday, June 24, 2014 (continued)

Session 4B: Information Extraction II

10:30–10:55 *Robust Domain Adaptation for Relation Extraction via Clustering Consistency*
Minh Luan Nguyen, Ivor W. Tsang, Kian Ming A. Chai and Hai Leong Chieu

10:55–11:20 *Encoding Relation Requirements for Relation Extraction via Joint Inference*
Liwei Chen, Yansong Feng, Songfang Huang, Yong Qin and Dongyan Zhao

11:20–11:45 *Medical Relation Extraction with Manifold Models*
Chang Wang and James Fan

11:45–12:10 *Distant Supervision for Relation Extraction with Matrix Completion*
Miao Fan, Deli Zhao, Qiang Zhou, Zhiyuan Liu, Thomas Fang Zheng and Edward Y. Chang

Session 4C: Machine Translation II

10:30–10:55 *Enhancing Grammatical Cohesion: Generating Transitional Expressions for SMT*
Mei Tu, Yu Zhou and Chengqing Zong

10:55–11:20 *Adaptive HTER Estimation for Document-Specific MT Post-Editing*
Fei Huang, Jian-Ming Xu, Abraham Ittycheriah and Salim Roukos

11:20–11:45 *Translation Assistance by Translation of L1 Fragments in an L2 Context*
Maarten van Gompel and Antal van den Bosch

11:45–12:10 *Response-based Learning for Grounded Machine Translation*
Stefan Riezler, Patrick Simianer and Carolin Haas

Tuesday, June 24, 2014 (continued)

Session 4D: Summarization

10:30–10:55 *Modelling Events through Memory-based, Open-IE Patterns for Abstractive Summarization*
Daniele Pighin, Marco Cornolti, Enrique Alfonseca and Katja Filippova

10:55–11:20 *Hierarchical Summarization: Scaling Up Multi-Document Summarization*
Janara Christensen, Stephen Soderland, Gagan Bansal and Mausam

11:20–11:45 *Query-Chain Focused Summarization*
Tal Baumel, Raphael Cohen and Michael Elhadad

11:45–12:10 *Exploiting Timelines to Enhance Multi-document Summarization*
Jun-Ping Ng, Yan Chen, Min-Yen Kan and Zhoujun Li

Session 4E: Language Resources and Evaluation II

10:55–11:20 *A chance-corrected measure of inter-annotator agreement for syntax*
Arne Skjærholt

11:20–11:45 *Two Is Bigger (and Better) Than One: the Wikipedia Bitaxonomy Project*
Tiziano Flati, Daniele Vannella, Tommaso Pasini and Roberto Navigli

12:10–13:30 Lunch break

Session 5A: Question Answering

13:30–13:55 *Information Extraction over Structured Data: Question Answering with Freebase*
Xuchen Yao and Benjamin Van Durme

13:55–14:20 *Knowledge-Based Question Answering as Machine Translation*
Junwei Bao, Nan Duan, Ming Zhou and Tiejun Zhao

14:20–14:45 *Discourse Complements Lexical Semantics for Non-factoid Answer Reranking*
Peter Jansen, Mihai Surdeanu and Peter Clark

Tuesday, June 24, 2014 (continued)

Session 5B: Information Extraction III

13:30–13:55 *Toward Future Scenario Generation: Extracting Event Causality Exploiting Semantic Relation, Context, and Association Features*
Chikara Hashimoto, Kentaro Torisawa, Julien Kloetzer, Motoki Sano, István Varga, Jong-Hoon Oh and Yutaka Kidawara

13:55–14:20 *Cross-narrative Temporal Ordering of Medical Events*
Preethi Raghavan, Eric Fosler-Lussier, Noémie Elhadad and Albert M. Lai

Language-Aware Truth Assessment of Fact Candidates
Ndapandula Nakashole and Tom M. Mitchell

Session 5C: Lexical Semantics and Ontology I

13:30–13:55 *That's sick dude!: Automatic identification of word sense change across different timescales*
Sunny Mitra, Ritwik Mitra, Martin Riedl, Chris Biemann, Animesh Mukherjee and Pawan Goyal

13:55–14:20 *A Step-wise Usage-based Method for Inducing Polysemy-aware Verb Classes*
Daisuke Kawahara, Daniel W. Peterson and Martha Palmer

14:20–14:45 *Structured Learning for Taxonomy Induction with Belief Propagation*
Mohit Bansal, David Burkett, Gerard de Melo and Dan Klein

Session 5D: Syntax, Parsing and Tagging IV

13:30–13:55 *A Provably Correct Learning Algorithm for Latent-Variable PCFGs*
Shay B. Cohen and Michael Collins

13:55–14:20 *Spectral Unsupervised Parsing with Additive Tree Metrics*
Ankur P. Parikh, Shay B. Cohen and Eric P. Xing

Tuesday, June 24, 2014 (continued)

Session 5E: Cognitive Modeling and Psycholinguistics

13:30–13:55 *Weak semantic context helps phonetic learning in a model of infant language acquisition*
Stella Frank, Naomi H. Feldman and Sharon Goldwater

13:55–14:20 *Bootstrapping into Filler-Gap: An Acquisition Story*
Marten van Schijndel and Micha Elsner

14:20–14:45 *Nonparametric Learning of Phonological Constraints in Optimality Theory*
Gabriel Doyle, Klinton Bicknell and Roger Levy

14:45–15:15 Coffee break

Abstract

We present a series of algorithms with theoretical guarantees for learning accurate ensembles of several structured prediction rules for which no prior knowledge is assumed. This includes a number of randomized and deterministic algorithms devised by converting on-line learning algorithms to batch ones, and a boosting-style algorithm applicable in the context of structured prediction with a large number of labels. We also report the results of extensive experiments with these algorithms.

1 Introduction

We study the problem of learning accurate ensembles of structured prediction experts. Ensemble methods are widely used in machine learning and have been shown to be often very effective (Breiman, 1996; Freund and Schapire, 1997; Smyth and Wolpert, 1999; MacKay, 1991; Freund et al., 2004). However, ensemble methods and their theory have been developed primarily for binary classification or regression tasks. Their techniques do not readily apply to structured prediction problems. While it is straightforward to combine scalar outputs for a classification or regression problem, it is less clear how to combine structured predictions such as phonemic pronunciation hypotheses, speech recognition lattices, parse trees, or alternative machine translations.

Consider for example the problem of devising an ensemble method for pronunciation, a critical component of modern speech recognition (Ghoshal et al., 2009). Often, several pronunciation models or experts are available for transcribing words into sequences of phonemes. These models may have been derived using other machine learning algorithms or they may be based on carefully hand-crafted rules. In general, none of these pronunciation experts is fully accurate and each expert may be making mistakes at different positions along the output sequence. One can hope that a model that *patches together* the pronunciation of different experts could achieve a superior performance.

Similar ensemble structured prediction problems arise in other tasks, including machine translation, part-of-speech tagging, optical character recognition and computer vision, with structures or substructures varying with each task. We seek to tackle all of these problems simultaneously and consider the general setting where the label or output associated to an input $\mathbf{x} \in \mathcal{X}$ is a structure $\mathbf{y} \in \mathcal{Y}$ that can be decomposed and represented by l substructures $y^1, \ldots, y^l$. For the pronunciation example just discussed, $\mathbf{x}$ is a specific word or word sequence and $\mathbf{y}$ its phonemic transcription. A natural choice for the substructures y^k is then the individual phonemes forming $\mathbf{y}$. Other possible choices include n-grams of consecutive phonemes or more general subsequences.

We will assume that the loss function considered admits an additive decomposition over the substructures, as is common in structured prediction. We also assume access to a set of structured prediction experts $h_1, \ldots, h_p$ that we treat as black boxes. Given an input $\mathbf{x} \in \mathcal{X}$, each expert predicts a structure $h_j(\mathbf{x}) = (h_j^1(\mathbf{x}), \ldots, h_j^l(\mathbf{x}))$. The hypotheses h_j may be the output of a structured prediction algorithm such as Conditional Random Fields (Lafferty et al., 2001), Averaged Perceptron (Collins, 2002), StructSVM (Tsochantaridis et al., 2005), Max Margin Markov Networks (Taskar et al., 2004) or the Regression Technique for Learning Transductions (Cortes et al., 2005), or some other algorithmic or human expert. Given a labeled training sample $(\mathbf{x}_1, \mathbf{y}_1), \ldots, (\mathbf{x}_m, \mathbf{y}_m)$, our objective is to use the predictions of these experts

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 1–12,
Baltimore, Maryland, USA, June 23-25 2014.

to form an accurate ensemble.

Variants of the ensemble problem just formulated have been studied in the past in the natural language processing and machine learning literature. One of the most recent, and possibly most relevant studies for sequence data is that of (Nguyen and Guo, 2007), which is based on the forward stepwise selection introduced by (Caruana et al., 2004). However, one disadvantage of this greedy approach is that it can be proven to fail to select an optimal ensemble of experts even in favorable cases where a specialized expert is available for each local prediction (Cortes et al., 2014a). Ensemble methods for structured prediction based on bagging, random forests and random subspaces have also been proposed in (Kocev et al., 2013). One of the limitations of this work is that it is applicable only to a very specific class of tree-based experts introduced in that paper. Similarly, a boosting approach was developed in (Wang et al., 2007) but it applies only to local experts. In the context of natural language processing, a variety of different re-ranking techniques have been proposed for somewhat related problems (Collins and Koo, 2005; Zeman and Žabokrtský, 2005; Sagae and Lavie, 2006; Zhang et al., 2009). But, re-ranking methods do not combine predictions at the level of substructures, thus the final prediction of the ensemble coincides with the prediction made by one of the experts, which can be shown to be suboptimal in many cases. Furthermore, these methods typically assume the use of probabilistic models, which is not a requirement in our learning scenario. Other ensembles of probabilistic models have also been considered in text and speech processing by forming a product of probabilistic models via the intersection of lattices (Mohri et al., 2008), or a straightforward combination of the posteriors from probabilistic grammars trained using EM with different starting points (Petrov, 2010), or some other rather intricate techniques in speech recognition (Fiscus, 1997). Finally, an algorithm of (MacKay, 1997) is another example of an ensemble method for structured prediction though it is not addressing directly the problem we are considering.

Most of the references just mentioned do not give a rigorous theoretical justification for the techniques proposed. We are not aware of any prior theoretical analysis for the ensemble structured prediction problem we consider. Here, we present two families of algorithms for learning ensembles of structured prediction rules that both perform well in practice and enjoy strong theoretical guarantees. In Section 3, we develop ensemble methods based on on-line algorithms. To do so, we extend existing on-line-to-batch conversions to our more general setting. In Section 4, we present a new boosting-style algorithm which is applicable even with a large set of classes as in the problem we consider, and for which we present margin-based learning guarantees. Section 5 reports the results of our extensive experiments.[1]

2 Learning scenario

As in standard supervised learning problems, we assume that the learner receives a training sample $S = ((\mathbf{x}_1, \mathbf{y}_1), \ldots, (\mathbf{x}_m, \mathbf{y}_m)) \in \mathcal{X} \times \mathcal{Y}$ of m labeled points drawn i.i.d. according to the some distribution $\mathcal{D}$ used both for training and testing. We also assume that the learner has access to a set of p predictors $h_1, \ldots, h_p$ mapping $\mathcal{X}$ to $\mathcal{Y}$ to devise an accurate ensemble prediction. Thus, for any input $\mathbf{x} \in \mathcal{X}$, he can use the prediction of the p experts $h_1(\mathbf{x}), \ldots, h_p(\mathbf{x})$. No other information is available to the learner about these p experts, in particular the way they have been trained or derived is not known to the learner. But, we will assume that the training sample S is distinct from what may have been used for training the algorithms that generated $h_1(\mathbf{x}), \ldots, h_p(\mathbf{x})$.

To simplify our analysis, we assume that the number of substructures $l \geq 1$ is fixed. This does not cause any loss of generality so long as the maximum number of substructures is bounded, which is the case in all the applications we consider. The quality of the predictions is measured by a loss function $L \colon \mathcal{Y} \times \mathcal{Y} \to \mathbb{R}_+$ that can be decomposed as a sum of loss functions $\ell_k \colon \mathcal{Y}_k \to \mathbb{R}_+$ over the substructure sets $\mathcal{Y}_k$, that is, for all $\mathbf{y} = (y^1, \ldots, y^l) \in \mathcal{Y}$ with $y^k \in \mathcal{Y}_k$ and $\mathbf{y}' = (y'^1, \ldots, y'^l) \in \mathcal{Y}$ with $y'^k \in \mathcal{Y}_k$,

$$L(\mathbf{y}, \mathbf{y}') = \sum_{k=1}^{l} \ell_k(y^k, y'^k). \tag{1}$$

We will assume in all that follows that the loss function L is bounded: $L(\mathbf{y}, \mathbf{y}') \leq M$ for all

[1] This paper is a modified version of (Cortes et al., 2014a) to which we refer the reader for the proofs of the theorems stated and a more detailed discussion of our algorithms.

$(\mathbf{y}, \mathbf{y}')$ for some $M > 0$. A prototypical example of such loss functions is the normalized Hamming loss L_{Ham}, which is the fraction of substructures for which two labels $\mathbf{y}$ and $\mathbf{y}'$ disagree, thus in that case $\ell_k(y^k, y'^k) = \frac{1}{l} I_{y^k \neq y'^k}$ and $M = 1$.

3 On-line learning approach

In this section, we present an on-line learning solution to the ensemble structured prediction problem just discussed. We first give a new formulation of the problem as that of on-line learning with expert advice, where the experts correspond to the paths of an acyclic automaton. The on-line algorithm generates at each iteration a distribution over the path-experts. A critical component of our approach consists of using these distributions to define a prediction algorithm with favorable generalization guarantees. This requires an extension of the existing on-line-to-batch conversion techniques to the more general case of combining distributions over path-experts, as opposed to combining single hypotheses.

3.1 Path experts

Each expert h_j induces a set of substructure hypotheses $h_j^1, \ldots, h_j^l$. As already discussed, one particular expert may be better at predicting the kth substructure while some other expert may be more accurate at predicting another substructure. Therefore, it is desirable to combine the substructure predictions of all experts to derive a more accurate prediction. This leads us to considering an acyclic finite automaton G such as that of Figure 1 which admits all possible sequences of substructure hypotheses, or, more generally, a finite automaton such as that of Figure 2 which only allows a subset of these sequences.

An automaton such as G compactly represents a set of *path experts*: each path from the initial vertex 0 to the final vertex l is labeled with a sequence of substructure hypotheses $h_{j_1}^1, \ldots, h_{j_l}^l$ and defines a hypothesis which associates to input $\mathbf{x}$ the output $h_{j_1}^1(\mathbf{x}) \cdots h_{j_l}^l(\mathbf{x})$. We will denote by H the set of all path experts. We also denote by h each path expert defined by $h_{j_1}^1, \ldots, h_{j_l}^l$, with $j_k \in \{1, \ldots, p\}$, and denote by h^k its kth substructure hypothesis $h_{j_k}^k$. Our ensemble structure prediction problem can then be formulated as that of selecting the best path expert (or collection of path experts) in G. Note that, in general, the path expert selected does not coincide with any of the original experts $h_1, \ldots, h_p$.

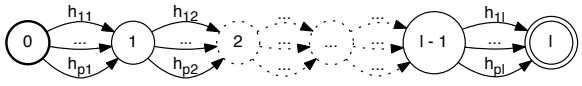

Figure 1: Finite automaton G of path experts.

3.2 On-line algorithm

Using an automaton G, the size of the pool of experts H we consider can be very large. For example, in the case of the automaton of Figure 1, the size of the pool of experts is p^l, and thus is exponentially large with respect to p. But, since learning guarantees in on-line learning admit only a logarithmic dependence on that size, they remain informative in this context. Nevertheless, the computational complexity of most on-line algorithms also directly depends on that size, which could make them impractical in this context. But, there exist several on-line solutions precisely designed to address this issue by exploiting the structure of the experts as in the case of our path experts. These include the algorithm of (Takimoto and Warmuth, 2003) denoted by WMWP, which is an extension of the (randomized) weighted-majority (WM) algorithm of (Littlestone and Warmuth, 1994) to more general bounded loss functions combined with the Weight Pushing (WP) algorithm of (Mohri, 1997); and the Follow the Perturbed Leader (FPL) algorithm of (Kalai and Vempala, 2005). The WMWP algorithm admits a more favorable regret guarantee than the FPL algorithm in our context and our discussion will focus on the use of WMWP for the design of our batch algorithm. However, we have also fully analyzed and implemented a batch algorithm based on FPL (Cortes et al., 2014a).

As in the standard WM algorithm (Littlestone and Warmuth, 1994), WMWP maintains at each round $t \in [1, T]$, a distribution p_t over the set of all experts, which in this context are the path experts $\mathsf{h} \in \mathsf{H}$. At each round $t \in [1, T]$, the algorithm receives an input sequence $\mathbf{x}_t$, incurs the loss $\mathbb{E}_{\mathsf{h} \sim \mathsf{p}_t}[L(\mathsf{h}(\mathbf{x}_t), \mathbf{y}_t)] = \sum_{\mathsf{h}} \mathsf{p}_t(\mathsf{h}) L(\mathsf{h}(\mathbf{x}_t), \mathbf{y}_t)$ and multiplicatively updates the distribution weight per expert:

$$\forall \mathsf{h} \in \mathsf{H}, \mathsf{p}_{t+1}(\mathsf{h}) = \frac{\mathsf{p}_t(\mathsf{h}) \beta^{L(\mathsf{h}(\mathbf{x}_t), \mathbf{y}_t)}}{\sum_{\mathsf{h}' \in \mathsf{H}} \mathsf{p}_t(\mathsf{h}') \beta^{L(\mathsf{h}'(\mathbf{x}_t), \mathbf{y}_t)}}, \quad (2)$$

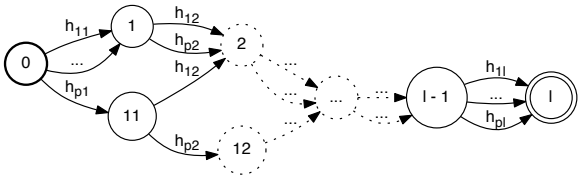

Figure 2: Alternative experts automaton.

where $\beta \in (0,1)$ is some fixed parameter. The number of paths is exponentially large in p and the cost of updating all paths is therefore prohibitive. However, since the loss function is additive in the substructures and the updates are multiplicative, it suffices to maintain instead a weight $w_t(e)$ per transition e, following the update

$$w_{t+1}(e) = \frac{w_t(e)\beta^{\ell_e(\mathbf{x}_t,\mathbf{y}_t)}}{\sum_{orig(e')=\mathrm{orig}(e)} w_t(e')\beta^{\ell_{e'}(\mathbf{x}_t,\mathbf{y}_t)}} \quad (3)$$

where $\ell_e(\mathbf{x}_t, \mathbf{y}_t)$ denotes the loss incurred by the substructure predictor labeling e for the input $\mathbf{x}_t$ and output $\mathbf{y}_t$, and $\mathrm{orig}(e')$ denotes the origin state of a transition e' (Takimoto and Warmuth, 2003). Thus, the cost of the update is then linear in the size of the automaton. To use the resulting weighted automaton for sampling, the weight pushing algorithm is used, whose complexity is also linear in the size of the automaton (Mohri, 1997).

3.3 On-line-to-batch conversion

The WMWP algorithm does not produce a sequence of path experts, rather, a sequence of distributions $\mathsf{p}_1, \ldots, \mathsf{p}_T$ over path experts. Thus, the on-line-to-batch conversion techniques described in (Littlestone, 1989; Cesa-Bianchi et al., 2004; Dekel and Singer, 2005) do not readily apply. Instead, we propose a generalization of the techniques of (Dekel and Singer, 2005). The conversion consists of two steps: extract a good collection of distributions $\mathcal{P} \subseteq \{\mathsf{p}_1, \ldots, \mathsf{p}_T\}$; next use $\mathcal{P}$ to define an accurate hypothesis for prediction. For a subset $\mathcal{P} \subseteq \{\mathsf{p}_1, \ldots, \mathsf{p}_T\}$, we define

$$\Gamma(\mathcal{P}) = \frac{1}{|\mathcal{P}|}\sum_{\mathsf{p}_t \in \mathcal{P}}\sum_{\mathsf{h}\in\mathsf{H}} \mathsf{p}_t(\mathsf{h})L(\mathsf{h}(\mathbf{x}_t),\mathbf{y}_t) + M\sqrt{\frac{\log\frac{1}{\delta}}{|\mathcal{P}|}}$$
$$= \frac{1}{|\mathcal{P}|}\sum_{\mathsf{p}_t \in \mathcal{P}}\sum_{e} w_t(e)\ell_e(\mathbf{x}_t),\mathbf{y}_t) + M\sqrt{\frac{\log\frac{1}{\delta}}{|\mathcal{P}|}},$$

where $\delta > 0$ is a fixed parameter. With this definition, we choose $\mathcal{P}_\delta$ as a minimizer of $\Gamma(\mathcal{P})$ over some collection $\mathcal{P}$ of subsets of $\{\mathsf{p}_1, \ldots, \mathsf{p}_T\}$: $\mathcal{P}_\delta \in \mathrm{argmin}_{\mathcal{P}\in\mathcal{P}}\Gamma(\mathcal{P})$. The choice of $\mathcal{P}$ is restricted by computational considerations. One natural option is to let $\mathcal{P}$ be the union of the suffix sets $\{\mathsf{p}_t, \ldots, \mathsf{p}_T\}$, $t = 1, \ldots, T$. We will assume in what follows that $\mathcal{P}$ includes the set $\{\mathsf{p}_1, \ldots, \mathsf{p}_T\}$.

Next, we define a randomized algorithm based on $\mathcal{P}_\delta$. Given an input $\mathbf{x}$, the algorithm consists of randomly selecting a path h according to

$$\mathsf{p}(\mathsf{h}) = \frac{1}{|\mathcal{P}_\delta|}\sum_{\mathsf{p}_t\in\mathcal{P}_\delta} \mathsf{p}_t(\mathsf{h}), \quad (4)$$

and returning the prediction $\mathsf{h}(\mathbf{x})$. Note that computing and storing p directly is not efficient. To sample from p, we first choose $\mathsf{p}_t \in \mathcal{P}_\delta$ uniformly at random and then sample a path h according to that p_t. Sampling a path according to p_t can be done efficiently using the weight pushing algorithm. Note that once an input $\mathbf{x}$ is received, the distribution p over the path experts h induces a probability distribution $\mathsf{p}_\mathbf{x}$ over the output space $\mathcal{Y}$. It is not hard to see that sampling a prediction $\mathbf{y}$ according to $\mathsf{p}_\mathbf{x}$ is statistically equivalent to first sampling h according to p and then predicting $\mathsf{h}(\mathbf{x})$. We will denote by $\mathcal{H}_{\mathrm{Rand}}$ the randomized hypothesis thereby generated.

An inherent drawback of randomized solutions such as the one just described is that for the same input $\mathbf{x}$ the user can receive different predictions over time. Randomized solutions are also typically more costly to store. A collection of distributions $\mathcal{P}$ can also be used to define a deterministic prediction rule based on the scoring function approach. The majority vote scoring function is defined by

$$\widetilde{\mathsf{h}}_{\mathrm{MVote}}(\mathbf{x},\mathbf{y}) = \prod_{k=1}^{l}\Big(\frac{1}{|\mathcal{P}_\delta|}\sum_{\mathsf{p}_t\in\mathcal{P}_\delta}\sum_{j=1}^{p} w_{t,kj}\mathbf{1}_{h_j^k(\mathbf{x})=y^k}\Big). \quad (5)$$

The majority vote algorithm denoted by $\mathcal{H}_{\mathrm{MVote}}$ is then defined for all $\mathbf{x} \in \mathcal{X}$, by $\mathcal{H}_{\mathrm{MVote}}(\mathbf{x}) = \mathrm{argmax}_{\mathbf{y}\in\mathcal{Y}}\widetilde{\mathsf{h}}_{\mathrm{MVote}}(\mathbf{x},\mathbf{y})$. For an expert automaton accepting all path experts such as that of Figure 1, the maximizer of $\widetilde{\mathsf{h}}_{\mathrm{MVote}}$ can be found very efficiently by choosing $\mathbf{y}$ such that y^k has the maximum weight in position k.

In the next section, we present learning guarantees for $\mathcal{H}_{\mathrm{Rand}}$ and $\mathcal{H}_{\mathrm{MVote}}$. For a more extensive dis-

cussion of alternative prediction rules, see (Cortes et al., 2014a).

3.4 Batch learning guarantees

We first present learning bounds for the randomized prediction rule $\mathcal{H}_{\text{Rand}}$. Next, we upper bound the generalization error of $\mathcal{H}_{\text{MVote}}$ in terms of that of $\mathcal{H}_{\text{Rand}}$.

Theorem 1. *For any $\delta > 0$, with probability at least $1-\delta$ over the choice of the sample $((\mathbf{x}_1, \mathbf{y}_1), \ldots, (\mathbf{x}_T, \mathbf{y}_T))$ drawn i.i.d. according to $\mathcal{D}$, the following inequalities hold:*

$$\mathbb{E}[L(\mathcal{H}_{\text{Rand}}(\mathbf{x}), \mathbf{y})] \leq \inf_{\mathsf{h} \in \mathsf{H}} \mathbb{E}[L(\mathsf{h}(\mathbf{x}), \mathbf{y})] + 2M\sqrt{\frac{l \log p}{T}} + 2M\sqrt{\frac{\log \frac{2}{\delta}}{T}}.$$

For the normalized Hamming loss L_{Ham}, the bound of Theorem 1 holds with $M = 1$.

We now upper bound the generalization error of the majority-vote algorithm $\mathcal{H}_{\text{MVote}}$ in terms of that of the randomized algorithm $\mathcal{H}_{\text{Rand}}$, which, combined with Theorem 1, immediately yields generalization bounds for the majority-vote algorithm $\mathcal{H}_{\text{MVote}}$.

Proposition 2. *The following inequality relates the generalization error of the majority-vote algorithm to that of the randomized one:*

$$\mathbb{E}[L_{\text{Ham}}(\mathcal{H}_{\text{MVote}}(\mathbf{x}), \mathbf{y})] \leq 2\,\mathbb{E}[L_{\text{Ham}}(\mathcal{H}_{\text{Rand}}(\mathbf{x}), \mathbf{y})],$$

where the expectations are taken over $(\mathbf{x}, \mathbf{y}) \sim \mathcal{D}$ and $\mathsf{h} \sim \mathsf{p}$.

Proposition 2 suggests that the price to pay for derandomization is a factor of 2. More refined and more favorable guarantees can be proven for the majority-vote algorithm (Cortes et al., 2014a).

4 Boosting-style algorithm

In this section, we devise a boosting-style algorithm for our ensemble structured prediction problem. The variants of AdaBoost for multi-class classification such as AdaBoost.MH or AdaBoost.MR (Freund and Schapire, 1997; Schapire and Singer, 1999; Schapire and Singer, 2000) cannot be readily applied in this context. First, the number of classes to consider here is quite large, as in all structured prediction problems, since it is exponential in the number of substructures l. For example, in the case of the pronunciation problem where the number of phonemes for English is in the order of 50, the number of classes is 50^l. But, the objective function for AdaBoost.MH or AdaBoost.MR as well as the main steps of the algorithms include a sum over all possible labels, whose computational cost in this context would be prohibitive. Second, the loss function we consider is the normalized Hamming loss over the substructures predictions, which does not match the multi-class losses for the variants of AdaBoost.[2] Finally, the natural base hypotheses for this problem admit a structure that can be exploited to devise a more efficient solution, which of course was not part of the original considerations for the design of these variants of AdaBoost.

4.1 Hypothesis sets

The predictor $\mathcal{H}_{\text{Boost}}$ returned by our boosting algorithm is based on a scoring function $\widetilde{\mathsf{h}}\colon \mathcal{X} \times \mathcal{Y} \to \mathbb{R}$, which, as for standard ensemble algorithms such as AdaBoost, is a convex combination of base scoring functions $\widetilde{\mathsf{h}}_t$: $\widetilde{\mathsf{h}} = \sum_{t=1}^{T} \alpha_t \widetilde{\mathsf{h}}_t$, with $\alpha_t \geq 0$. The base scoring functions used in our algorithm have the form

$$\forall (\mathbf{x}, \mathbf{y}) \in \mathcal{X} \times \mathcal{Y}, \quad \widetilde{\mathsf{h}}_t(\mathbf{x}, \mathbf{y}) = \sum_{k=1}^{l} \widetilde{\mathsf{h}}_t^k(\mathbf{x}, \mathbf{y}).$$

In particular, these can be derived from the path experts in H by letting $\mathsf{h}_t^k(\mathbf{x}, \mathbf{y}) = \mathbf{1}_{\mathsf{h}_t^k(\mathbf{x}) = y^k}$. Thus, the score assigned to $\mathbf{y}$ by the base scoring function $\widetilde{\mathsf{h}}_t$ is the number of positions at which $\mathbf{y}$ matches the prediction of path expert h_t given input $\mathbf{x}$. $\mathcal{H}_{\text{Boost}}$ is defined as follows in terms of $\widetilde{\mathsf{h}}$ or h_ts:

$$\forall \mathbf{x} \in \mathcal{X}, \mathcal{H}_{\text{Boost}}(\mathbf{x}) = \operatorname*{argmax}_{\mathbf{y} \in \mathcal{Y}} \widetilde{\mathsf{h}}(\mathbf{x}, \mathbf{y})$$

We remark that the analysis and algorithm presented in this section are also applicable with a scoring function that is the product of the scores

[2] (Schapire and Singer, 1999) also present an algorithm using the Hamming loss for multi-class classification, but that is a Hamming loss over the set of classes and differs from the loss function relevant to our problem. Additionally, the main steps of that algorithm are also based on a sum over all classes.

at each substructure k as opposed to a sum, that is,

$$\widetilde{\mathsf{h}}(\mathbf{x}, \mathbf{y}) = \prod_{k=1}^{l} \left(\sum_{t=1}^{T} \alpha_t \widetilde{\mathsf{h}}_t^k(\mathbf{x}, \mathbf{y}) \right).$$

This can be used for example in the case where the experts are derived from probabilistic models.

4.2 ESPBoost algorithm

To simplify our exposition, the algorithm that we now present uses base learners of the form $\mathsf{h}_t^k(\mathbf{x}, \mathbf{y}) = \mathbf{1}_{\mathsf{h}_t^k(\mathbf{x}) = y^k}$. The general case can be handled in the same fashion with the only difference being the definition of the direction and step of the optimization procedure described below. For any $i \in [1, m]$ and $k \in [1, l]$, we define the *margin of* $\widetilde{\mathsf{h}}^k$ *for point* $(\mathbf{x}_i, \mathbf{y}_i)$ by $\rho(\widetilde{\mathsf{h}}^k, \mathbf{x}_i, \mathbf{y}_i) = \widetilde{\mathsf{h}}^k(\mathbf{x}_i, y_i^k) - \max_{y^k \neq y_i^k} \widetilde{\mathsf{h}}^k(\mathbf{x}_i, y^k)$. We first derive an upper bound on the empirical normalized Hamming loss of a hypothesis $\mathcal{H}_{\text{Boost}}$, with $\widetilde{\mathsf{h}} = \sum_{t=1}^{T} \alpha_t \widetilde{\mathsf{h}}_t$.

Lemma 3. *The following upper bound holds for the empirical normalized Hamming loss of the hypothesis* $\mathcal{H}_{\text{Boost}}$*:*

$$\mathop{\mathbb{E}}_{(\mathbf{x},\mathbf{y})\sim S}[L_{\text{Ham}}(\mathcal{H}_{\text{Boost}}(\mathbf{x}), \mathbf{y})] \leq \frac{1}{ml} \sum_{i=1}^{m} \sum_{k=1}^{l} \exp\Big(- \sum_{t=1}^{T} \alpha_t \rho(\widetilde{\mathsf{h}}_t^k, \mathbf{x}_i, \mathbf{y}_i) \Big).$$

The proof of this lemma as well as that of several other theorems related to this algorithm can be found in (Cortes et al., 2014a).

In view of this upper bound, we consider the objective function $F\colon \mathbb{R}^N \to \mathbb{R}$ defined for all $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_N) \in \mathbb{R}^N$ by

$$F(\boldsymbol{\alpha}) = \frac{1}{ml} \sum_{i=1}^{m} \sum_{k=1}^{l} \exp\Big(- \sum_{j=1}^{N} \alpha_j \rho(\widetilde{\mathsf{h}}_j^k, \mathbf{x}_i, \mathbf{y}_i) \Big),$$

where $\mathsf{h}_1, \ldots, \mathsf{h}_N$ denote the set of all path experts in H. F is a convex and differentiable function of $\boldsymbol{\alpha}$. Our algorithm, ESPBoost (Ensemble Structured Prediction Boosting), is defined by the application of coordinate descent to the objective F. Algorithm 1 shows the pseudocode of the ESPBoost.

Algorithm 1 ESPBoost Algorithm

Inputs: $S = ((\mathbf{x}_1, \mathbf{y}_1), \ldots, (\mathbf{x}_m, \mathbf{y}_m))$; set of experts $\{h_1, \ldots, h_p\}$
for $i = 1$ **to** m **and** $k = 1$ **to** l **do**
  $\mathcal{D}_1(i, k) \leftarrow \frac{1}{ml}$
end for
for $t = 1$ **to** T **do**
  $\mathsf{h}_t \leftarrow \operatorname{argmin}_{\mathsf{h} \in \mathsf{H}} \mathbb{E}_{(i,k)\sim \mathcal{D}_t}[\mathbf{1}_{\mathsf{h}^k(\mathbf{x}_i) \neq y_i^k}]$
  $\epsilon_t \leftarrow \mathbb{E}_{(i,k)\sim \mathcal{D}_t}[\mathbf{1}_{\mathsf{h}_t^k(\mathbf{x}_i) \neq y_i^k}]$
  $\alpha_t \leftarrow \frac{1}{2} \log \frac{1-\epsilon_t}{\epsilon_t}$
  $Z_t \leftarrow 2\sqrt{\epsilon_t(1-\epsilon_t)}$
  for $i = 1$ **to** m **and** $k = 1$ **to** l **do**
    $\mathcal{D}_{t+1}(i, k) \leftarrow \frac{\exp(-\alpha_t \rho(\widetilde{\mathsf{h}}_t^k, \mathbf{x}_i, \mathbf{y}_i)) \mathcal{D}_t(i,k)}{Z_t}$
  end for
end for
Return $\widetilde{\mathsf{h}} = \sum_{t=1}^{T} \alpha_t \widetilde{\mathsf{h}}_t$

Let $\boldsymbol{\alpha}_{t-1} \in \mathbb{R}^N$ denote the vector obtained after $t-1$ iterations and $\mathbf{e}_t$ the tth unit vector in $\mathbb{R}^N$. We denote by $\mathcal{D}_t$ the distribution over $[1, m] \times [1, l]$ defined by

$$\mathcal{D}_t(i, k) = \frac{\frac{1}{ml} \exp\Big(- \sum_{u=1}^{t-1} \alpha_u \rho(\widetilde{\mathsf{h}}_u^k, \mathbf{x}_i, \mathbf{y}_i) \Big)}{A_{t-1}}$$

where A_{t-1} is a normalization factor, $A_{t-1} = \frac{1}{ml} \sum_{i=1}^{m} \sum_{k=1}^{l} \exp\big(- \sum_{u=1}^{t-1} \alpha_u \rho(\widetilde{\mathsf{h}}_u^k, \mathbf{x}_i, \mathbf{y}_i) \big)$. The direction $\mathbf{e}_t$ selected at the tth round is the one minimizing the directional derivative, that is

$$\begin{aligned} &\frac{dF(\boldsymbol{\alpha}_{t-1} + \eta \mathbf{e}_t)}{d\eta}\bigg|_{\eta=0} \\ &= - \sum_{i=1}^{m} \sum_{k=1}^{l} \rho(\widetilde{\mathsf{h}}_t^k, \mathbf{x}_i, \mathbf{y}_i) \mathcal{D}_t(i, k) A_{t-1} \\ &= \Big[2 \sum_{i,k:\mathsf{h}_t^k(\mathbf{x}_i) \neq y_i^k} \mathcal{D}_t(i, k) - 1 \Big] A_{t-1} \\ &= (2\epsilon_t - 1) A_{t-1}, \end{aligned}$$

where ϵ_t is the average error of h_t given by

$$\begin{aligned} \epsilon_t &= \sum_{i=1}^{m} \sum_{k=1}^{l} \mathcal{D}_t(i, k) \mathbf{1}_{\mathsf{h}_t^k(\mathbf{x}_i) \neq y_i^k} \\ &= \mathop{\mathbb{E}}_{(i,k)\sim \mathcal{D}_t} [\mathbf{1}_{\mathsf{h}_t^k(\mathbf{x}_i) \neq y_i^k}]. \end{aligned}$$

The remaining steps of our algorithm can be determined as in the case of AdaBoost. In particular, given the direction $\mathbf{e}_t$, the best step α_t is obtained by solving the equation $\frac{dF(\boldsymbol{\alpha}_{t-1} + \alpha_t \mathbf{e}_t)}{d\alpha_t} =$

0, which admits the closed-form solution $\alpha_t = \frac{1}{2}\log\frac{1-\epsilon_t}{\epsilon_t}$. The distribution $\mathcal{D}_{t+1}$ can be expressed in terms of $\mathcal{D}_t$ with the normalization factor $Z_t = 2\sqrt{\epsilon_t(1-\epsilon_t)}$.

Our *weak learning assumption* in this context is that there exists $\gamma > 0$ such that at each round, ϵ_t verifies $\epsilon_t < \frac{1}{2} - \gamma$. Note that, at each round, the path expert h_t with the smallest error ϵ_t can be determined easily and efficiently by first finding for each substructure k, the h_t^k that is the best with respect to the distribution weights $\mathcal{D}_t(i,k)$.

Observe that, while the steps of our algorithm are syntactically close to those of AdaBoost and its multi-class variants, our algorithm is distinct and does not require sums over the exponential number of all possible labelings of the substructures and is quite efficient.

4.3 Learning guarantees

We have derived both a margin-based generalization bound in support of the ESPBoost algorithm and a bound on the empirical margin loss.

For any $\rho > 0$, define the empirical margin loss of $\mathcal{H}_{\text{Boost}}$ by the following:

$$\widehat{R}_\rho\left(\frac{\widetilde{\mathsf{h}}}{\|\boldsymbol{\alpha}\|_1}\right) = \frac{1}{ml}\sum_{i=1}^{m}\sum_{k=1}^{l}\mathbf{1}_{\rho(\widetilde{\mathsf{h}}^k,\mathbf{x}_i,\mathbf{y}_i)\leq\rho\|\boldsymbol{\alpha}\|_1},$$

where $\widetilde{\mathsf{h}}$ is the corresponding scoring function. The following theorem can be proven using the multi-class classification bounds of (Koltchinskii and Panchenko, 2002; Mohri et al., 2012) as can be shown in (Cortes et al., 2014a).

Theorem 4. *Let $\mathcal{F}$ denote the set of functions $\mathcal{H}_{\text{Boost}}$ with $\widetilde{\mathsf{h}} = \sum_{t=1}^{T}\alpha_t\mathsf{h}_t$ for some $\alpha_1,\ldots,\alpha_t \geq 0$ and $\mathsf{h}_t \in \mathsf{H}$ for all $t \in [1,T]$. Fix $\rho > 0$. Then, for any $\delta > 0$, with probability at least $1-\delta$, the following holds for all $\mathcal{H}_{\text{Boost}} \in \mathcal{F}$:*

$$\mathop{\mathbb{E}}_{(\mathbf{x},\mathbf{y})\sim\mathcal{D}}[L_{\text{Ham}}(\mathcal{H}_{\text{Boost}}(\mathbf{x}),\mathbf{y})] \leq \widehat{R}_\rho\left(\frac{\widetilde{\mathsf{h}}}{\|\boldsymbol{\alpha}\|_1}\right) + \frac{2}{\rho l}\sum_{k=1}^{l}|\mathcal{Y}_k|^2\mathfrak{R}_m(H^k) + \sqrt{\frac{\log\frac{l}{\delta}}{2m}},$$

where $\mathfrak{R}_m(H^k)$ denotes the Rademacher complexity of the class of functions

$$H^k = \{\mathbf{x}\mapsto\widetilde{\mathsf{h}}_t^k : j\in[1,p], y\in\mathcal{Y}_k\}.$$

Table 1: Average Normalized Hamming Loss, ADS1 and ADS2. $\beta_{ADS1} = 0.95$, $\beta_{ADS2} = 0.95$, $T_{SLE} = 100$, $\delta = 0.05$.

	ADS1, $m = 200$	ADS2, $m = 200$
$\mathcal{H}_{\text{MVote}}$	**0.0197 ± 0.00002**	**0.2172 ± 0.00983**
$\mathcal{H}_{\text{FPL}}$	0.0228 ± 0.00947	0.2517 ± 0.05322
$\mathcal{H}_{\text{CV}}$	**0.0197 ± 0.00002**	0.2385 ± 0.00002
$\mathcal{H}_{\text{FPL-CV}}$	0.0741 ± 0.04087	0.4001 ± 0.00028
$\mathcal{H}_{\text{ESPBoost}}$	**0.0197 ± 0.00002**	**0.2267 ± 0.00834**
$\mathcal{H}_{\text{SLE}}$	0.5641 ± 0.00044	0.2500 ± 0.05003
$\mathcal{H}_{\text{Rand}}$	0.1112 ± 0.00540	0.4000 ± 0.00018
Best h_j	0.5635 ± 0.00004	0.4000

This theorem provides a margin-based guarantee for convex ensembles such as those returned by ESPBoost. The following theorem further provides an upper bound on the empirical margin loss for ESPBoost.

Theorem 5. *Let $\widetilde{\mathsf{h}}$ denote the scoring function returned by ESPBoost after $T \geq 1$ rounds. Then, for any $\rho > 0$, the following inequality holds:*

$$\widehat{R}_\rho\left(\frac{\widetilde{\mathsf{h}}}{\|\boldsymbol{\alpha}\|_1}\right) \leq 2^T\prod_{t=1}^{T}\sqrt{\epsilon_t^{1-\rho}(1-\epsilon_t)^{1+\rho}}.$$

As in the case of AdaBoost (Schapire et al., 1997), it can be shown that for $\rho < \gamma$, $\epsilon_t^{1-\rho}(1-\epsilon_t)^{1+\rho} \leq (1-2\gamma)^{1-\rho}(1+2\gamma)^{1+\rho} < 1$ and the right-hand side of this bound decreases exponentially with T.

5 Experiments

We used a number of artificial and real-world data sets for our experiments. For each data set, we performed 10-fold cross-validation with disjoint training sets.[3] We report the average error for each task. In addition to the $\mathcal{H}_{\text{MVote}}$, $\mathcal{H}_{\text{Rand}}$ and $\mathcal{H}_{\text{ESPBoost}}$ hypotheses, we experimented with two algorithms discussed in more detail in (Cortes et al., 2014a): a cross-validation on-line-to-batch conversion of the WMWP algorithm, $\mathcal{H}_{\text{CV}}$, a majority-vote on-line-to-batch conversion with FPL, $\mathcal{H}_{\text{FPL}}$, and a cross-validation on-line-to-batch conversion with FPL, $\mathcal{H}_{\text{FPL-CV}}$. Finally, we compare with the $\mathcal{H}_{\text{SLE}}$ algorithm of (Nguyen and Guo, 2007).

5.1 Artificial data sets

Our artificial data set, ADS1 and ADS2 simulate the scenarios described in Section 1. In ADS1 the

[3] For the OCR data set, these subsets are predefined.

kth expert has a high accuracy on the kth position, in ADS2 an expert has low accuracy in a fixed set of positions.

For the first artificial data set, ADS1, we used local experts $h_1, \ldots, h_p$ with $p = 5$. To generate the data we chose an arbitrary Markov chain over the English alphabet and sampled $40{,}000$ random sequences each consisting of 10 symbols. Each of the five experts was designed to have a certain probability of making a mistake at each position in the sequence. Expert h_j correctly predicted positions $2j-1$ and $2j$ with probability 0.97 and other positions with probability 0.5. We forced experts to make similar mistakes by making them select an adjacent alphabet symbol in case of an error. For example, when a mistake was made on a symbol b, the expert prediction was forced to be either a or c. The second artificial data set, ADS2, modeled the case of rather poor experts. ADS2 was generated in the same way as ADS1, but the expert predictions were different. This time each expert made mistakes at four out of the ten distinct random positions in each sequence.

Table 1 reports the results of our experiments. For all experiments with the algorithms $\mathcal{H}_{\text{Rand}}$, $\mathcal{H}_{\text{MVote}}$, and $\mathcal{H}_{\text{CV}}$, we ran the WMWP algorithm for $T = m$ rounds with the β values listed in the caption of Table 1, generating distributions $\mathcal{P} \subseteq \{\mathsf{p}_1, \ldots, \mathsf{p}_T\}$. For $\mathcal{P}$ we used the collection of all suffix sets $\{\mathsf{p}_t, \ldots, \mathsf{p}_T\}$ and $\delta = 0.05$. For the algorithms based on FPL, we used $\epsilon = 0.5/pl$. The same parameter choices were used for the subsequent experiments.

As can be seen from Table 1, in both cases, $\mathcal{H}_{\text{MVote}}$, our majority-vote algorithm based on our on-line-to-batch conversion using the WMWP algorithm (together with most of the other on-line based algorithms), yields a significant improvement over the best expert. It also outperforms $\mathcal{H}_{\text{SLE}}$, which in the case of ADS1 even fails to outperform the best h_j. After 100 iterations on ADS1, the ensemble learned by $\mathcal{H}_{\text{SLE}}$ consists of a single expert, which is why it leads to such a poor performance.

It is also worth pointing out that $\mathcal{H}_{\text{FPL-CV}}$ and $\mathcal{H}_{\text{Rand}}$ fail to outperform the best model on ADS2 set. This is in total agreement with our theoretical analysis since, in this case, any path expert has exactly the same performance and the error of the best path expert is an asymptotic upper bound on the errors of these algorithms. The superior performance of the majority-vote-based algorithms suggests that these algorithms may have an advantage over other prediction rules beyond what is suggested by our learning bounds.

Table 2: Average Normalized Hamming Loss for ADS3. $\beta_{ADS1} = 0.95$, $\beta_{ADS2} = 0.95$, $T_{SLE} = 100$, $\delta = 0.05$.

$\mathcal{H}_{\text{MVote}}$	$\mathbf{0.1788 \pm 0.00004}$
$\mathcal{H}_{\text{FPL}}$	0.2189 ± 0.04097
$\mathcal{H}_{\text{CV}}$	$\mathbf{0.1788 \pm 0.00004}$
$\mathcal{H}_{\text{FPL-CV}}$	0.3148 ± 0.00387
$\mathcal{H}_{\text{ESPBoost}}$	0.1831 ± 0.00240
$\mathcal{H}_{\text{SLE}}$	0.1954 ± 0.00185
$\mathcal{H}_{\text{Rand}}$	0.3196 ± 0.00018
Best h_j	0.2957 ± 0.00005

Table 3: Average Normalized Hamming Loss, PDS1 and PDS2. $\beta_{PDS1} = 0.85$, $\beta_{PDS2} = 0.97$, $T_{SLE} = 100$, $\delta = 0.05$.

	PDS1, $m = 130$	PDS2, $m = 400$
$\mathcal{H}_{\text{MVote}}$	$\mathbf{0.2225 \pm 0.00301}$	$\mathbf{0.2323 \pm 0.00069}$
$\mathcal{H}_{\text{FPL}}$	0.2657 ± 0.07947	0.2337 ± 0.00229
$\mathcal{H}_{\text{CV}}$	$\mathbf{0.2316 \pm 0.00189}$	$\mathbf{0.2364 \pm 0.00080}$
$\mathcal{H}_{\text{FPL-CV}}$	0.4451 ± 0.02743	0.4090 ± 0.01388
$\mathcal{H}_{\text{ESPBoost}}$	0.3625 ± 0.01054	0.3499 ± 0.00509
$\mathcal{H}_{\text{SLE}}$	0.3130 ± 0.05137	0.3308 ± 0.03182
$\mathcal{H}_{\text{Rand}}$	0.4713 ± 0.00360	0.4607 ± 0.00131
Best h_j	0.3449 ± 0.00368	0.3413 ± 0.00067

We also synthesized a third data set, ADS3. Here, we simulated the case where each expert specialized in predicting some subset of the labels. In particular, we generated $40{,}000$ random sequences over the English alphabet in the same way as for ADS1 and ADS2. To generate expert predictions, we partitioned the alphabet into 5 disjoint subsets A_j. Expert j always correctly predicted the label in A_j and the probability of correctly predicting the label not in A_j was set to 0.7. To train the ensemble algorithms, we used a training set of size $m = 200$.

The results are presented in Table 2. $\mathcal{H}_{\text{MVote}}$, $\mathcal{H}_{\text{CV}}$ and $\mathcal{H}_{\text{ESPBoost}}$ achieve the best performance on this data set with a considerable improvement in accuracy over the best expert h_j. We also observe as for the ADS2 experiment that $\mathcal{H}_{\text{Rand}}$ and $\mathcal{H}_{\text{FPL-CV}}$ fail to outperform the best model and approach the accuracy of the best path expert only asymptotically.

Table 4: Average edit distance, PDS1 and PDS2. $\beta_{PDS1} = 0.85$, $\beta_{PDS2} = 0.97$, $T_{SLE} = 100$, $\delta = 0.05$.

	PDS1, $m = 130$	PDS2, $m = 400$
$\mathcal{H}_{\text{MVote}}$	**0.8395 ± 0.01076**	**0.9626 ± 0.00341**
$\mathcal{H}_{\text{FPL}}$	1.0158 ± 0.34379	0.9744 ± 0.01277
$\mathcal{H}_{\text{CV}}$	**0.8668 ± 0.00553**	**0.9840 ± 0.00364**
$\mathcal{H}_{\text{FPL-CV}}$	1.8044 ± 0.09315	1.8625 ± 0.06016
$\mathcal{H}_{\text{ESPBoost}}$	1.3977 ± 0.06017	1.4092 ± 0.04352
$\mathcal{H}_{\text{SLE}}$	1.1762 ± 0.12530	1.2477 ± 0.12267
$\mathcal{H}_{\text{Rand}}$	1.8962 ± 0.01064	2.0838 ± 0.00518
Best h_j	1.2163 ± 0.00619	1.2883 ± 0.00219

5.2 Pronunciation data sets

We had access to two proprietary pronunciation data sets, PDS1 and PDS2. In both sets, each example is an English word, typically a proper name. For each word, 20 possible phonemic sequences are available, ranked by some pronunciation model. Since the true pronunciation was not available, we set the top sequence to be the target label and used the remaining as the predictions made by the experts. The only difference between PDS1 and PDS2 is their size: 1,313 words for PDS1 and 6,354 for PDS2.

In both cases, on-line based algorithms, specifically $\mathcal{H}_{\text{MVote}}$, significantly outperform the best model as well as $\mathcal{H}_{\text{SLE}}$, see Table 3. The poor performance of $\mathcal{H}_{\text{ESPBoost}}$ is due to the fact that the weak learning assumption is violated after 5-8 iterations and hence the algorithm terminates.

It can be argued that for this task the edit-distance is a more suitable measure of performance than the average Hamming loss. Thus, we also report the results of our experiments in terms of the edit-distance in Table 4. Remarkably, our on-line based algorithms achieve a comparable improvement over the performance of the best model in the case of edit-distance as well.

5.3 OCR data set

Rob Kassel's OCR data set is available for download from http://ai.stanford.edu/~btaskar/ocr/. It contains 6,877 word instances with a total of 52,152 characters. Each character is represented by $16 \times 8 = 128$ binary pixels. The task is to predict a word given its sequence of pixel vectors. To generate experts, we used several software packages: CRFsuite (Okazaki, 2007) and SVM^{struct}, SVM^{multiclass} (Joachims, 2008), and the Stanford Classifier (Rafferty et al., 2014). We trained these algorithms on each of the predefined folds of the data set and generated predictions on the test fold using the resulting models.

Table 5: Average Normalized Hamming Loss, TR1 and TR2. $\beta_{TR1} = 0.95$, $\beta_{TR2} = 0.98$, $T_{SLE} = 100$, $\delta = 0.05$.

	TR1, $m = 800$	TR2, $m = 1000$
$\mathcal{H}_{\text{MVote}}$	**0.0850 ± 0.00096**	**0.0746 ± 0.00014**
$\mathcal{H}_{\text{FPL}}$	**0.0859 ± 0.00110**	**0.0769 ± 0.00218**
$\mathcal{H}_{\text{CV}}$	**0.0843 ± 0.00006**	**0.0741 ± 0.00011**
$\mathcal{H}_{\text{FPL-CV}}$	0.1093 ± 0.00129	0.1550 ± 0.00182
$\mathcal{H}_{\text{ESPBoost}}$	0.1041 ± 0.00056	0.1414 ± 0.00233
$\mathcal{H}_{\text{SLE}}$	**0.0778 ± 0.00934**	**0.0814 ± 0.02558**
$\mathcal{H}_{\text{Rand}}$	0.1128 ± 0.00048	0.1652 ± 0.00077
Best h_j	0.1032 ± 0.00007	0.1415 ± 0.00005

Our results (see (Cortes et al., 2014a)) show that ensemble methods lead only to a small improvement in performance over the best h_j. This is because here the best model h_j dominates all other experts and ensemble methods cannot benefit from patching together different outputs.

5.4 Penn Treebank data set

The part-of-speech task, POS, consists of labeling each word of a sentence with its correct part-of-speech tag. The Penn Treebank 2 data set is available through LDC license at http://www.cis.upenn.edu/~treebank/ and contains 251,854 sentences with a total of 6,080,493 tokens and 45 different parts-of-speech.

For the first experiment, TR1, we used 4 disjoint training sets to produce 4 SVM^{multiclass} models and 4 maximum entropy models using the Stanford Classifier. We also used the union of these training sets to devise one CRFsuite model. For the second experiment, TR2, we trained 5 SVM^{struct} models. The same features were used for both experiments. For the SVM algorithms, we generated 267,214 bag-of-word binary features. The Stanford Classifier and CRFsuite packages use internal routines to generate features.

The results of the experiments are summarized in Table 5. For TR1, our on-line ensemble methods improve over the best model. Note that $\mathcal{H}_{\text{SLE}}$ has the best average loss over 10 runs for this experiment. This comes at a price of much higher standard deviation which does not allow us to conclude that the difference in performance between our methods and $\mathcal{H}_{\text{SLE}}$ is statistically significant.

Table 6: Average Normalized Hamming Loss, SDS. $l \geq 4$, $\beta = 0.97$, $\delta = 0.05$, $T_{SLE} = 100$.

	$p = 5, m = 1500$	$p = 10, m = 1200$
$\mathcal{H}_{\text{MVote}}$	**0.2465 ± 0.00248**	**0.2606 ± 0.00320**
$\mathcal{H}_{\text{FPL}}$	0.2500 ± 0.00248	**0.2622 ± 0.00316**
$\mathcal{H}_{\text{CV}}$	0.2504 ± 0.00576	**0.2755 ± 0.00212**
$\mathcal{H}_{\text{FPL-CV}}$	0.2726 ± 0.00839	0.3219 ± 0.01176
$\mathcal{H}_{\text{ESPBoost}}$	0.2572 ± 0.00062	0.2864 ± 0.00103
$\mathcal{H}_{\text{SLE}}$	0.2572 ± 0.00061	0.2864 ± 0.00102
$\mathcal{H}_{\text{Rand}}$	0.2877 ± 0.00480	0.3430 ± 0.00468
Best h_j	0.2573 ± 0.00060	0.2865 ± 0.00101

Table 7: Average Normalized Hamming Loss, SDS. $l \geq 4$, $\beta = 0.97$,$\delta = 0.05$, $T_{SLE} = 100$.

	$p = 20, m = 900$	$p = 50, m = 700$
$\mathcal{H}_{\text{MVote}}$	**0.2773 ± 0.00139**	**0.3217 ± 0.00375**
$\mathcal{H}_{\text{FPL}}$	**0.2797 ± 0.00154**	**0.3189 ± 0.00344**
$\mathcal{H}_{\text{CV}}$	0.2986 ± 0.00075	0.3401 ± 0.00054
$\mathcal{H}_{\text{FPL-CV}}$	0.3816 ± 0.01457	0.4451 ± 0.01360
$\mathcal{H}_{\text{ESPBoost}}$	0.3115 ± 0.00089	0.3426 ± 0.00071
$\mathcal{H}_{\text{SLE}}$	0.3114 ± 0.00087	0.3425 ± 0.00076
$\mathcal{H}_{\text{Rand}}$	0.3977 ± 0.00302	0.4608 ± 0.00303
Best h_j	0.3116 ± 0.00087	0.3427 ± 0.00077

In fact, on two runs, $\mathcal{H}_{\text{SLE}}$ chooses an ensemble consisting of a single expert and fails to outperform the best model.

5.5 Speech recognition data set

For our last set of experiments, we used another proprietary speech recognition data set, SDS. Each example in this data set is represented by a sequence of length $l \in [2, 15]$. Therefore, for training we padded the true labels and the expert predictions to normalize the sequence lengths. For each of the 22,298 examples, there are between 2 and 251 expert predictions available. Since the ensemble methods we presented assume that the predictions of all p experts are available for each example in the training and test sets, we needed to restrict ourselves to the subsets of the data where at least some fixed number of expert predictions were available. In particular, we considered $p = 5, 10, 20$ and 50. For each value of p we used only the top p experts in our ensembles.

Our initial experiments showed that, as in the case of OCR data set, ensemble methods offer only a modest increase in performance over the best h_j. This is again largely due to the dominant performance of the best expert h_j. However, it was observed that the accuracy of the best model is a decreasing function of l, suggesting that ensemble algorithm may be used to improve performance for longer sequences. Subsequent experiments show that this is indeed the case: when training and testing with $l \geq 4$, ensemble algorithms outperform the best model. Table 6 and Table 7 summarize these results for $p = 5, 10, 20, 50$.

Our results suggest that the following simple scheme can be used: for short sequences use the best expert model and for longer sequences, use the ensemble model. A more elaborate variant of this algorithm can be derived based on the observation that the improvement in accuracy of the ensemble model over the best expert increases with the number of experts available.

6 Conclusion

We presented a broad analysis of the problem of ensemble structured prediction, including a series of algorithms with learning guarantees and extensive experiments. Our results show that our algorithms, most notably $\mathcal{H}_{\text{MVote}}$, can result in significant benefits in several tasks, which can be of a critical practical importance. We also reported very favorable results for $\mathcal{H}_{\text{MVote}}$ when used with the edit-distance, which is the standard loss used in many applications. A natural extension of this work consists of devising new algorithms and providing learning guarantees specific to other loss functions such as the edit-distance. While we aimed for an exhaustive study, including multiple on-learning algorithms, different conversions to batch and derandomizations, we are aware that the problem we studied is very rich and admits many more facets and scenarios that we plan to investigate in the future. Finally, the boosting-style algorithm we presented can be enhanced using recent theoretical and algorithmic results on *deep boosting* (Cortes et al., 2014b).

Acknowledgments

We warmly thank our colleagues Francoise Beaufays and Fuchun Peng for kindly extracting and making available to us the pronunciation data sets, Cyril Allauzen for providing us with the speech recognition data, and Richard Sproat and Brian Roark for help with other data sets. This work was partly funded by the NSF award IIS-1117591 and the NSERC PGS D3 award.

Representation Learning for Text-level Discourse Parsing

Abstract

Text-level discourse parsing is notoriously difficult, as distinctions between discourse relations require subtle semantic judgments that are not easily captured using standard features. In this paper, we present a representation learning approach, in which we transform surface features into a latent space that facilitates RST discourse parsing. By combining the machinery of large-margin transition-based structured prediction with representation learning, our method jointly learns to parse discourse while at the same time learning a discourse-driven projection of surface features. The resulting shift-reduce discourse parser obtains substantial improvements over the previous state-of-the-art in predicting relations and nuclearity on the RST Treebank.

1 Introduction

Discourse structure describes the high-level organization of text or speech. It is central to a number of high-impact applications, such as text summarization (Louis et al., 2010), sentiment analysis (Voll and Taboada, 2007; Somasundaran et al., 2009), question answering (Ferrucci et al., 2010), and automatic evaluation of student writing (Miltsakaki and Kukich, 2004; Burstein et al., 2013). Hierarchical discourse representations such as Rhetorical Structure Theory (RST) are particularly useful because of the computational applicability of tree-shaped discourse structures (Taboada and Mann, 2006), as shown in Figure 1.

Unfortunately, the performance of discourse parsing is still relatively weak: the state-of-the-art F-measure for text-level relation detection in the RST Treebank is only slightly above 55% (Joty et al., 2013). While recent work has introduced increasingly powerful features (Feng and Hirst, 2012) and inference techniques (Joty et al., 2013), discourse relations remain hard to detect, due in part to a long tail of "alternative lexicalizations" that can be used to realize each relation (Prasad et al., 2010). Surface and syntactic features are not capable of capturing what are fundamentally semantic distinctions, particularly in the face of relatively small annotated training sets.

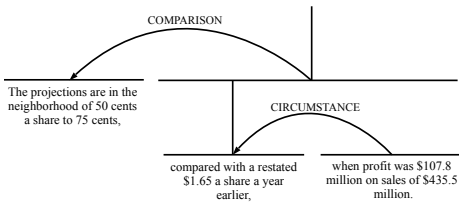

Figure 1: An example of RST discourse structure.

In this paper, we present a representation learning approach to discourse parsing. The core idea of our work is to learn a transformation from a bag-of-words surface representation into a latent space in which discourse relations are easily identifiable. The latent representation for each discourse unit can be viewed as a discriminatively-trained vector-space representation of its meaning. Alternatively, our approach can be seen as a non-linear learning algorithm for incremental structure prediction, which overcomes feature sparsity through effective parameter tying. We consider several alternative methods for transforming the original features, corresponding to different ideas of the meaning and role of the latent representation.

Our method is implemented as a shift-reduce discourse parser (Marcu, 1999; Sagae, 2009). Learning is performed as large-margin transition-based structure prediction (Taskar et al., 2003), while at the same time jointly learning to project the surface representation into latent space. The

Baltimore, Maryland, USA, June 23-25 2014.

resulting system strongly outperforms the prior state-of-the-art at labeled F-measure, obtaining raw improvements of roughly 6% on relation labels and 2.5% on nuclearity. In addition, we show that the latent representation coheres well with the characterization of discourse connectives in the Penn Discourse Treebank (Prasad et al., 2008).

2 Model

The core idea of this paper is to project lexical features into a latent space that facilitates discourse parsing. In this way, we can capture the meaning of each discourse unit, without suffering from the very high dimensionality of a lexical representation. While such feature learning approaches have proven to increase robustness for parsing, POS tagging, and NER (Miller et al., 2004; Koo et al., 2008; Turian et al., 2010), they would seem to have an especially promising role for discourse, where training data is relatively sparse and ambiguity is considerable. Prasad et al. (2010) show that there is a long tail of alternative lexicalizations for discourse relations in the Penn Discourse Treebank, posing obvious challenges for approaches based on directly matching lexical features observed in the training data.

Based on this observation, our goal is to learn a function that transforms lexical features into a much lower-dimensional latent representation, while simultaneously learning to predict discourse structure based on this latent representation. In this paper, we consider a simple transformation function, linear projection. Thus, we name the approach DPLP: Discourse Parsing from Linear Projection. We apply transition-based (incremental) structured prediction to obtain a discourse parse, training a predictor to make the correct incremental moves to match the annotations of training data in the RST Treebank. This supervision signal is then used to learn both the weights and the projection matrix in a large-margin framework.

2.1 Shift-reduce discourse parsing

We construct RST Trees using shift-reduce parsing, as first proposed by Marcu (1999). At each point in the parsing process, we maintain a stack and a queue; initially the stack is empty and the first elementary discourse unit (EDU) in the document is at the front of the queue.[1] The parser can then choose either to *shift* the front of the queue onto the top of the stack, or to *reduce* the top two elements on the stack in a discourse relation. The reduction operation must choose both the type of relation and which element will be the nucleus. So, overall there are multiple reduce operations with specific relation types and nucleus positions. Shift-reduce parsing can be learned as a classification task, where the classifier uses features of the elements in the stack and queue to decide what move to take. Previous work has employed decision trees (Marcu, 1999) and the averaged perceptron (Collins and Roark, 2004; Sagae, 2009) for this purpose. Instead, we employ a large-margin classifier, because we can compute derivatives of the margin-based objective function with respect to both the classifier weights as well as the projection matrix.

Notation	Explanation
$\mathcal{V}$	Vocabulary for surface features
V	Size of $\mathcal{V}$
K	Dimension of latent space
$\mathbf{w}_m$	Classification weights for class m
C	Total number of classes, which correspond to possible shift-reduce operations
$\mathbf{A}$	Parameter of the representation function (also the projection matrix in the linear representation function)
$\mathbf{v}_i$	Word count vector of discourse unit i
$\mathbf{v}$	Vertical concatenation of word count vectors for the three discourse units currently being considered by the parser
λ	Regularization for classification weights
τ	Regularization for projection matrix
ξ_i	Slack variable for sample i
$\eta_{i,m}$	Dual variable for sample i and class m
α_t	Learning rate at iteration t

Table 1: Summary of mathematical notation

2.2 Discourse parsing with projected features

More formally, we denote the surface feature vocabulary $\mathcal{V}$, and represent each EDU as the numeric vector $\mathbf{v} \in \mathbb{N}^V$, where $V = \#|\mathcal{V}|$ and the n-th element of $\mathbf{v}$ is the count of the n-th surface feature in this EDU (see Table 1 for a summary of notation). During shift-reduce parsing, we consider features of three EDUs:[2] the top two elements on

[1] We do not address segmentation of text into elementary discourse units in this paper. Standard classification-based approaches can achieve a segmentation F-measure of 94% (Hernault et al., 2010); a more complex reranking model does slightly better, at 95% F-Measure with automatically-generated parse trees, and 96.6% with gold annotated trees (Xuan Bach et al., 2012). Human agreement reaches 98% F-Measure.

[2] After applying a reduce operation, the stack will include a span that contains multiple EDUs. We follow the *strong*

the stack ($\mathbf{v}_1$ and $\mathbf{v}_2$), and the front of the queue ($\mathbf{v}_3$). The vertical concatenation of these vectors is denoted $\mathbf{v} = [\mathbf{v}_1; \mathbf{v}_2; \mathbf{v}_3]$. In general, we can formulate the decision function for the multi-class shift-reduce classifier as

$$\hat{m} = \underset{m \in \{1,\ldots,C\}}{\arg\max}\ \mathbf{w}_m^\top \mathbf{f}(\mathbf{v}; \mathbf{A}) \quad (1)$$

where $\mathbf{w}_m$ is the weight for the m-th class and $\mathbf{f}(\mathbf{v}; \mathbf{A})$ is the *representation function* parametrized by $\mathbf{A}$. The score for class m (in our case, the value of taking the m-th shift-reduce operation) is computed by the inner product $\mathbf{w}_m^\top \mathbf{f}(\mathbf{v}; \mathbf{A})$. The specific shift-reduce operation is chosen by maximizing the decision value in Equation 1.

The representation function $\mathbf{f}(\mathbf{v}; \mathbf{A})$ can be defined in any form; for example, it could be a non-linear function defined by a neural network model parametrized by $\mathbf{A}$. We focus on the linear projection,

$$\mathbf{f}(\mathbf{v}; \mathbf{A}) = \mathbf{A}\mathbf{v}, \quad (2)$$

where $\mathbf{A} \in \mathbb{R}^{K \times 3V}$ is projects the surface representation $\mathbf{v}$ of three EDUs into a latent space of size $K \ll V$.

Note that by setting $\tilde{\mathbf{w}}_m^\top = \mathbf{w}_m^\top \mathbf{A}$, the decision scoring function can be rewritten as $\tilde{\mathbf{w}}_m^\top \mathbf{v}$, which is linear in the original surface features. Therefore, the expressiveness of DPLP is identical to a linear separator in the original feature space. However, the learning problem is considerably different. If there are C total classes (possible shift-reduce operations), then a linear classifier must learn $3VC$ parameters, while DPLP must learn $(3V + C)K$ parameters, which will be smaller under the assumption that $K < C \ll V$. This can be seen as a form of *parameter tying* on the linear weights $\tilde{\mathbf{w}}_m$, which allows statistical strength to be shared across training instances. We will consider special cases of $\mathbf{A}$ that reduce the parameter space still further.

2.3 Special forms of the projection matrix

We consider three different constructions for the projection matrix $\mathbf{A}$.

- *General form*: In the general case, we place no special constraint on the form of $\mathbf{A}$.

$$\mathbf{f}(\mathbf{v}; \mathbf{A}) = \mathbf{A} \begin{bmatrix} \mathbf{v}_1 \\ \mathbf{v}_2 \\ \mathbf{v}_3 \end{bmatrix} \quad (3)$$

  This form is shown in Figure 2(a).

- *Concatenation form*: In the concatenation form, we choose a block structure for $\mathbf{A}$, in which a single projection matrix $\mathbf{B}$ is applied to each EDU:

$$\mathbf{f}(\mathbf{v}; \mathbf{A}) = \begin{bmatrix} \mathbf{B} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{B} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{B} \end{bmatrix} \begin{bmatrix} \mathbf{v}_1 \\ \mathbf{v}_2 \\ \mathbf{v}_3 \end{bmatrix} \quad (4)$$

  In this form, we transform the representation of each EDU separately, but do not attempt to represent interrelationships between the EDUs in the latent space. The number of parameters in $\mathbf{A}$ is $\frac{1}{3}KV$. Then, the total number of parameters, including the decision weights $\{\mathbf{w}_m\}$, in this form is $(\frac{V}{3} + C)K$.

- *Difference form*. In the difference form, we explicitly represent the *differences* between adjacent EDUs, by constructing $\mathbf{A}$ as a block difference matrix,

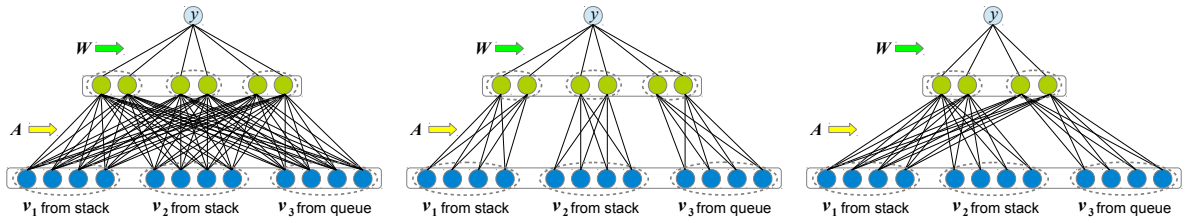
$$\mathbf{f}(\mathbf{v}; \mathbf{A}) = \begin{bmatrix} \mathbf{C} & -\mathbf{C} & \mathbf{0} \\ \mathbf{C} & \mathbf{0} & -\mathbf{C} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{v}_1 \\ \mathbf{v}_2 \\ \mathbf{v}_3 \end{bmatrix}, \quad (5)$$

  The result of this projection is that the latent representation has the form $[\mathbf{C}(\mathbf{v}_1 - \mathbf{v}_2); \mathbf{C}(\mathbf{v}_1 - \mathbf{v}_3)]$, representing the difference between the top two EDUs on the stack, and between the top EDU on the stack and the first EDU in the queue. This is intended to capture semantic similarity, so that reductions between related EDUs will be preferred. Similarly, the total number of parameters to estimate in this form is $(V + 2C)\frac{K}{3}$.

3 Large-Margin Learning Framework

We apply a large margin structure prediction approach to train the model. There are two parameters that need to be learned: the classification weights $\{\mathbf{w}_m\}$, and the projection matrix $\mathbf{A}$. As we will see, it is possible to learn $\{\mathbf{w}_m\}$ using standard support vector machine (SVM) training (holding $\mathbf{A}$ fixed), and then make a simple gradient-based update to $\mathbf{A}$ (holding $\{\mathbf{w}_m\}$ fixed). By interleaving these two operations, we arrive at a saddle point of the objective function.

compositionality criterion of Marcu (1996) and consider only the nuclear EDU of the span. Later work may explore the composition of features between the nucleus and satellite.



(a) General form (b) Concatenation form (c) Difference form

Figure 2: Decision problem with different representation functions

Specifically, we formulate the following constrained optimization problem,

$$\begin{aligned} \min_{\{\mathbf{w}_{1:C},\xi_{1:l},\mathbf{A}\}} & \frac{\lambda}{2}\sum_{m=1}^{C}\|\mathbf{w}_m\|_2^2+\sum_{i=1}^{l}\xi_i+\frac{\tau}{2}\|\mathbf{A}\|_F^2 \\ \text{s.t. } & (\mathbf{w}_{y_i}-\mathbf{w}_m)^\top\mathbf{f}(\mathbf{v}_i;\mathbf{A})\geq 1-\delta_{y_i=m}-\xi_i, \\ & \forall\, i,m \end{aligned} \tag{6}$$

where $m \in \{1,\ldots,C\}$ is the index of the shift-reduce decision taken by the classifier (e.g., SHIFT, REDUCE-CONTRAST-RIGHT, etc), $i \in \{1,\cdots,l\}$ is the index of the training sample, and $\mathbf{w}_m$ is the vector of classification weights for class m. The slack variables ξ_i permit the margin constraint to be violated in exchange for a penalty, and the delta function $\delta_{y_i=m}$ is unity if $y_i = m$, and zero otherwise.

As is standard in the multi-class linear SVM (Crammer and Singer, 2001), we can solve the problem defined in Equation 6 via Lagrangian optimization:

$$\begin{aligned} &\mathcal{L}(\{\mathbf{w}_{1:C},\xi_{1:l},\mathbf{A},\eta_{1:l,1:C}\}) = \\ &\quad\frac{\lambda}{2}\sum_{m=1}^{C}\|\mathbf{w}_m\|_2^2+\sum_{i=1}^{l}\xi_i+\frac{\tau}{2}\|\mathbf{A}\|_F^2 \\ &\quad+\sum_{i,m}\eta_{i,m}\Big\{(\mathbf{w}_m^\top-\mathbf{w}_{y_i}^\top)\mathbf{f}(\mathbf{v}_i;\mathbf{A})+1-\delta_{y_i=m}-\xi_i\Big\} \\ &\quad\text{s.t. } \eta_{i,m}\geq 0\ \forall i,m \end{aligned} \tag{7}$$

Then, to optimize $\mathcal{L}$, we need to find a saddle point, which would be the minimum for the variables $\{\mathbf{w}_{1:C},\xi_{1:l}\}$ and the projection matrix $\mathbf{A}$, and the maximum for the dual variables $\{\eta_{1:l,1:C}\}$.

If $\mathbf{A}$ is fixed, then the optimization problem is equivalent to a standard multi-class SVM, in the transformed feature space $\mathbf{f}(\mathbf{v}_i;\mathbf{A})$. We can obtain the weights $\{\mathbf{w}_{1:C}\}$ and dual variables $\{\eta_{1:l,1:C}\}$ from a standard dual-form SVM solver. We then update $\mathbf{A}$, recompute $\{\mathbf{w}_{1:C}\}$ and $\{\eta_{1:l,1:C}\}$, and iterate until convergence. This iterative procedure is similar to the latent variable structural SVM (Yu and Joachims, 2009), although the specific details of our learning algorithm are different.

3.1 Learning Projection Matrix A

We update $\mathbf{A}$ while holding fixed the weights and dual variables. The derivative of $\mathcal{L}$ with respect to $\mathbf{A}$ is

$$\begin{aligned} \frac{\partial\mathcal{L}}{\partial\mathbf{A}} &= \tau\mathbf{A}+\sum_{i,m}\eta_{i,m}(\mathbf{w}_m^\top-\mathbf{w}_{y_i}^\top)\frac{\partial\mathbf{f}(\mathbf{v}_i;\mathbf{A})}{\partial\mathbf{A}} \\ &= \tau\mathbf{A}+\sum_{i,m}\eta_{i,m}(\mathbf{w}_m-\mathbf{w}_{y_i})\mathbf{v}_i{}^\top \end{aligned} \tag{8}$$

Setting $\frac{\partial\mathcal{L}}{\partial\mathbf{A}}=0$, we have the closed-form solution,

$$\begin{aligned} \mathbf{A} &= \frac{1}{\tau}\sum_{i,m}\eta_{i,m}(\mathbf{w}_m-\mathbf{w}_{y_i})\mathbf{v}_i{}^\top \\ &= \frac{1}{\tau}\sum_{i,j}(\mathbf{w}_{y_i}-\sum_m\eta_{i,m}\mathbf{w}_m)\mathbf{v}_i{}^\top, \end{aligned} \tag{9}$$

because the dual variables for each instance must sum to one, $\sum_m\eta_{i,m}=1$.

Note that for a given i, the matrix $(\mathbf{w}_{y_i}-\sum_m\eta_{i,m}\mathbf{w}_m)\mathbf{v}_i{}^\top$ is of (at most) rank-1. Therefore, the solution of $\mathbf{A}$ can be viewed as the linear combination of a sequence of rank-1 matrices, where each rank-1 matrix is defined by distributional representation $\mathbf{v}_i$ and the weight difference between the weight of true label $\mathbf{w}_{y_i}$ and the "expected" weight $\sum_m\eta_{i,m}\mathbf{w}_m$.

One property of the dual variables is that $\mathbf{f}(\mathbf{v}_i;\mathbf{A})$ is a support vector only if the dual variable $\eta_{i,y_i}<1$. Since the dual variables for each instance are guaranteed to sum to one, we have $\mathbf{w}_{y_i}-\sum_m\eta_{i,m}\mathbf{w}_m=0$ if $\eta_{i,y_i}=1$. In other words, the contribution from non support vectors to the projection matrix $\mathbf{A}$ is 0. Then, we can further simplify the updating equation as

$$\mathbf{A}=\frac{1}{\tau}\sum_{\mathbf{v}_i\in\mathrm{SV}}(\mathbf{w}_{y_i}-\sum_m\eta_{i,m}\mathbf{w}_m)\mathbf{v}_i{}^\top \tag{10}$$

This is computationally advantageous since many instances are not support vectors, and it shows that the discriminatively-trained projection matrix only incorporates information from each instance to the extent that the correct classification receives low confidence.

Algorithm 1 Mini-batch learning algorithm

while $t = 1, \ldots, T$ **do**
  Randomly choose a subset of training samples $\mathcal{D}_t$ from $\mathcal{D}$
  Train SVM with $\mathbf{A}_{t-1}$ to obtain $\{\mathbf{w}_m^{(t)}\}$ and $\{\eta_{i,m}^{(t)}\}$
  Update $\mathbf{A}_t$ using Equation 11 with $\alpha_t = \frac{1}{t}$
  if $\frac{\|\mathbf{A}_t - \mathbf{A}_{t-1}\|_F}{\|\mathbf{A}_2 - \mathbf{A}_1\|_F} < \varepsilon$ **then**
    Return
  end if
end while
Re-train SVM with $\mathcal{D}$ and the final $\mathbf{A}$
Output: Projection matrix $\mathbf{A}$, SVM classifier with weights $\mathbf{w}$

3.2 Gradient-based Learning for A

Solving the quadratic programming defined by the dual form of the SVM is time-consuming, especially on a large-scale dataset. But if we focus on learning the projection matrix $\mathbf{A}$, we can speed up learning by sampling only a small proportion of the training data to compute an approximate optimum for $\{\mathbf{w}_{1:C}, \eta_{1:l,1:C}\}$, before each update of $\mathbf{A}$. This idea is similar to the mini-batch learning, which has been used in large-scale SVM problem (Nelakanti et al., 2013) and deep learning models (Le et al., 2011).

Specifically, in iteration t, the algorithm randomly chooses a subset of training samples $\mathcal{D}_t$ to train the model. We cannot make a closed-form update to $\mathbf{A}$ based on this small sample, but we can take an approximate gradient step,

$$\mathbf{A}_t = (1 - \alpha_t \tau)\mathbf{A}_{t-1} + \alpha_t \Big\{ \sum_{\mathbf{v}_i \in \mathrm{SV}(\mathcal{D}_t)} \Big(\mathbf{w}_{y_i}^{(t)} - \sum_m \eta_{i,m}^{(t)} \mathbf{w}_m^{(t)} \Big) {\mathbf{v}_i}^\top \Big\}, \quad (11)$$

where α_t is a learning rate. In iteration t, we choose $\alpha_t = \frac{1}{t}$. After convergence, we obtain the weights $\mathbf{w}$ by applying the SVM over the entire dataset, using the final $\mathbf{A}$. The algorithm is summarized in Algorithm 1 and more details about implementation will be clarified in Section 4. While minibatch learning requires more iterations, the SVM training is much faster in each batch, and the overall algorithm is several times faster than using the entire training set for each update.

4 Implementation

The learning algorithm is applied in a shift-reduce parser, where the training data consists of the (unique) list of shift and reduce operations required to produce the gold RST parses. On test data, we choose parsing operations in an online fashion — at each step, the parsing algorithm changes the status of the stack and the queue according the selected transition, then creates the next sample with the updated status.

4.1 Parameters and Initialization

There are three free parameters in our approach: the latent dimension K, and regularization parameters λ and τ. We consider the values $K \in \{30, 60, 90, 150\}$, $\lambda \in \{1, 10, 50, 100\}$ and $\tau \in \{1.0, 0.1, 0.01, 0.001\}$, and search over this space using a development set of thirty document randomly selected from within the RST Treebank training data. We initialize each element of $\mathbf{A}_0$ to a uniform random value in the range $[0, 1]$. For mini-batch learning, we fixed the batch size to be 500 training samples (shift-reduce operations) in each iteration.

4.2 Additional features

As described thus far, our model considers only the projected representation of each EDU in its parsing decisions. But prior work has shown that other, structural features can provide useful information (Joty et al., 2013). We therefore augment our classifier with a set of simple feature templates. These templates are applied to individual EDUs, as well as pairs of EDUs: (1) the two EDUs on top of the stack, and (2) the EDU on top of the stack and the EDU in front of the queue. The features are shown in Table 2. In computing these features, all tokens are downcased, and numerical features are not binned. The dependency structure and POS tags are obtained from MALTParser (Nivre et al., 2007).

5 Experiments

We evaluate DPLP on the RST Discourse Treebank (Carlson et al., 2001), comparing against state-of-the-art results. We also investigate the information encoded by the projection matrix.

5.1 Experimental Setup

Dataset The RST Discourse Treebank (RST-DT) consists of 385 documents, with 347 for train-

Feature	Examples
Words at beginning and end of the EDU	⟨BEGIN-WORD-STACK1 = *but*⟩ ⟨BEGIN-WORD-STACK1-QUEUE1 = *but, the*⟩
POS tag at beginning and end of the EDU	⟨BEGIN-TAG-STACK1 = CC⟩ ⟨BEGIN-TAG-STACK1-QUEUE1 = CC, DT⟩
Head word set from each EDU. The set includes words whose parent in the depenency graph is ROOT or is not within the EDU (Sagae, 2009).	⟨HEAD-WORDS-STACK2 = *working*⟩
Length of EDU in tokens	⟨LEN-STACK1-STACK2 = ⟨7, 8⟩⟩
Distance between EDUs	⟨DIST-STACK1-QUEUE1 = 2⟩
Distance from the EDU to the beginning of the document	⟨DIST-FROM-START-QUEUE1 = 3⟩
Distance from the EDU to the end of the document	⟨DIST-FROM-END-STACK1 = 1⟩
Whether two EDUs are in the same sentence	⟨SAME-SENT-STACK1-QUEUE1 = True⟩

Table 2: Additional features for RST parsing

ing and 38 for testing in the standard split. As we focus on relational discourse parsing, we follow prior work (Feng and Hirst, 2012; Joty et al., 2013), and use gold EDU segmentations. The strongest automated RST segmentation methods currently attain 95% accuracy (Xuan Bach et al., 2012).

Preprocessing In the RST-DT, most nodes have exactly two children, one nucleus and one satellite. For non-binary relations, we use right-branching to binarize the tree structure. For multi-nuclear relations, we choose the left EDU as "head" EDU. The vocabulary $\mathcal{V}$ includes all unigrams after down-casing. No other preprocessing is performed. In total, there are 16250 unique unigrams in $\mathcal{V}$.

Fixed projection matrix baselines Instead of learning from data, a simple way to obtain a projection matrix is to use matrix factorization. Recent work has demonstrated the effectiveness of non-negative matrix factorization (NMF) for measuring distributional similarity (Dinu and Lapata, 2010; Van de Cruys and Apidianaki, 2011). We can construct $\mathbf{B}_{nmf}$ in the *concatenation form* of the projection matrix by applying NMF to the EDU-feature matrix, $\mathbf{M} \approx \mathbf{WH}$. As a result, $\mathbf{W}$ describes each EDU with a K-dimensional vector, and $\mathbf{H}$ describes each word with a K-dimensional vector. We can then construct $\mathbf{B}_{nmf}$ by taking the pseudo-inverse of $\mathbf{H}$, which then projects from word-count vectors into the latent space.

Another way to construct $\mathbf{B}$ is to use neural word embeddings (Collobert and Weston, 2008). In this case, we can view the product $\mathbf{Bv}$ as a composition of the word embeddings, using the simple *additive* composition model proposed by Mitchell and Lapata (2010). We used the word embeddings from Collobert and Weston (2008) with dimension $\{25, 50, 100\}$. Grid search over heldout training data was used to select the optimum latent dimension for both the NMF and word embedding baselines. Note that the size K of the resulting projection matrix is three times the size of the embedding (or NMF representation) due to the concatenate construction.

We also consider the special case where $\mathbf{A} = \mathbf{I}$.

Competitive systems We compare our approach with HILDA (Hernault et al., 2010) and TSP (Joty et al., 2013). Joty et al. (2013) proposed two different approaches to combine sentence-level parsing models: *sliding windows* (TSP SW) and *1 sentence-1 subtree* (TSP 1-1). In the comparison, we report the results of both approaches. All results are based on the same gold standard EDU segmentation. We cannot compare with the results of Feng and Hirst (2012), because they do not evaluate on the overall discourse *structure*, but rather treat each relation as an individual classification problem.

Metrics To evaluate the parsing performance, we use the three standard ways to measure the performance: unlabeled (i.e., hierarchical spans) and labeled (i.e., nuclearity and relation) F-score, as defined by Black et al. (1991). The application of this approach to RST parsing is described by Marcu (2000b).[3] To compare with previous works on RST-DT, we use the 18 coarse-grained relations defined in (Carlson et al., 2001).

[3]We implemented the evaluation metrics by ourselves. Together with the DPLP system, all codes are published on `https://github.com/jiyfeng/DPLP`

Method	Matrix Form	+Features	K	Span	Nuclearity	Relation
Prior work						
1. HILDA (Hernault *et al.*, 2010)				**83.0**	68.4	54.8
2. TSP 1-1 (Joty *et al.*, 2013)				82.47	68.43	55.73
3. TSP SW (Joty *et al.*, 2013)				82.74	68.40	55.71
Our work						
4. Basic features	$\mathbf{A} = \mathbf{0}$	Yes		79.43	67.98	52.96
5. Word embeddings	Concatenation	No	75	75.28	67.14	53.79
6. NMF	Concatenation	No	150	78.57	67.66	54.80
7. Bag-of-words	$\mathbf{A} = \mathbf{I}$	Yes		79.85	69.01	60.21
8. DPLP	Concatenation	No	60	80.91	69.39	58.96
9. DPLP	Difference	No	60	80.47	68.61	58.27
10. DPLP	Concatenation	Yes	60	82.08	**71.13**	**61.63**
11. DPLP	General	Yes	30	81.60	**70.95**	**61.75**
Human annotation				88.70	77.72	65.75

Table 3: Parsing results of different models on the RST-DT test set. The results of TSP and HILDA are reprinted from prior work (Joty et al., 2013; Hernault et al., 2010).

5.2 Experimental Results

Table 3 presents RST parsing results for DPLP and some alternative systems. All versions of DPLP outperform the prior state-of-the-art on nuclearity and relation detection. This includes relatively simple systems whose features are simply a projection of the word count vectors for each EDU (lines 7 and 8). The addition of the features from Table 2 improves performance further, leading to absolute F-score improvement of around 2.5% in nuclearity and 6% in relation prediction (lines 9 and 10).

On span detection, DPLP performs slightly worse than the prior state-of-the-art. These systems employ richer syntactic and contextual features, which might be especially helpful for span identification. As shown by line 4 of the results table, the basic features from Table 2 provide most of the predictive power for spans; however, these features are inadequate at the more semantically-oriented tasks of nuclearity and relation prediction, which benefit substantially from the projected features. Since correctly identifying spans is a precondition for nuclearity and relation prediction, we might obtain still better results by combining features from HILDA and TSP with the representation learning approach described here.

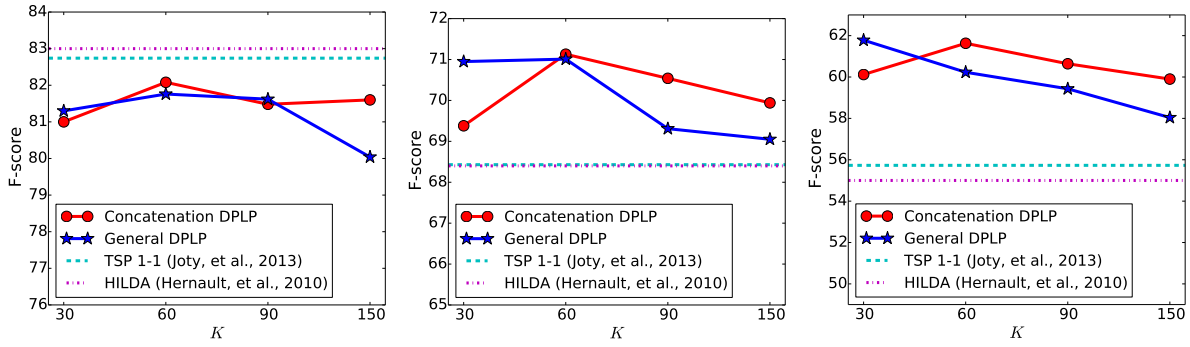
Lines 5 and 6 show that discriminative learning of the projection matrix is crucial, as fixed projections obtained from NMF or neural word embeddings perform substantially worse. Line 7 shows that the original bag-of-words representation together with basic features could give us some benefit on discourse parsing, but still not as good as results from DPLP. From lines 8 and 9, we see that the concatenation construction is superior to the difference construction, but the comparison between lines 10 and 11 is inconclusive on the merits of the general form of $\mathbf{A}$. This suggests that using the projection matrix to model interrelationships between EDUs does not substantially improve performance, and the simpler concatenation construction may be preferred.

Figure 3 shows how performance changes for different latent dimensions K. At each value of K, we employ grid search over a development set to identify the optimal regularizers λ and τ. For the concatenation construction, performance is not overly sensitive to K. For the general form of $\mathbf{A}$, performance decreases with large K. Recall from Section 2.3 that this construction has nine times as many parameters as the concatenation form; with large values of K, it is likely to overfit.

5.3 Analysis of Projection Matrix

Why does projection of the surface features improve discourse parsing? To answer this question, we examine what information the projection matrix is learning to encoded. We take the projection matrix from the concatenation construction and $K = 60$ as an example for case study. Recalling the definition in equation 4, the projection matrix $\mathbf{A}$ will be composed of three identical submatrices $\mathbf{B} \in \mathbb{R}^{20 \times V}$. The columns of the $\mathbf{B}$ matrix can be viewed as 20-dimensional descriptors of the words in the vocabulary.

For the purpose of visualization, we further reduce the dimension of latent representation from $K = 20$ to 2 dimensions using t-SNE (van der Maaten and Hinton, 2008). One further simpli-



(a) Span (b) Nuclearity (c) Relation

Figure 3: The performance of our parser over different latent dimension K. Results for DPLP include the additional features from Table 3

fication for visualization is we consider only the top 1000 frequent unigrams in the RST-DT training set. For comparison, we also apply t-SNE to the projection matrix $\mathbf{B}_{nmf}$ recovered from non-negative matrix factorization.

Figure 4 highlights words that are related to discourse analysis. Among the top 1000 words, we highlight the words from 5 major discourse connective categories provided in Appendix B of the PDTB annotation manual (Prasad et al., 2008): CONJUNCTION, CONTRAST, PRECEDENCE, RESULT, and SUCCESSION. In addition, we also highlighted two verb categories from the top 1000 words: modal verbs and reporting verbs, with their inflections (Krestel et al., 2008).

From the figure, it is clear DPLP has learned a projection matrix that successfully groups several major discourse-related word classes: particularly modal and reporting verbs; it has also grouped succession and precedence connectives with some success. In contrast, while NMF does obtain compact clusters of words, these clusters appear to be completely unrelated to discourse function of the words that they include. This demonstrates the value of using discriminative training to obtain the transformed representation of the discourse units.

6 Related Work

Early work on document-level discourse parsing applied hand-crafted rules and heuristics to build trees in the framework of Rhetorical Structure Theory (Sumita et al., 1992; Corston-Oliver, 1998; Marcu, 2000a). An early data-driven approach was offered by Schilder (2002), who used distributional techniques to rate the topicality of each discourse unit, and then chose among underspecified discourse structures by placing more topical sentences near the root. Learning-based approaches were first applied to identify within-sentence discourse relations (Soricut and Marcu, 2003), and only later to cross-sentence relations at the document level (Baldridge and Lascarides, 2005). Of particular relevance to our inference technique are incremental discourse parsing approaches, such as shift-reduce (Sagae, 2009) and A* (Muller et al., 2012). Prior learning-based work has largely focused on lexical, syntactic, and structural features, but the close relationship between discourse structure and semantics (Forbes-Riley et al., 2006) suggests that shallow feature sets may struggle to capture the long tail of alternative lexicalizations that can be used to realize discourse relations (Prasad et al., 2010; Marcu and Echihabi, 2002). Only Subba and Di Eugenio (2009) incorporate rich compositional semantics into discourse parsing, but due to the ambiguity of their semantic parser, they must manually select the correct semantic parse from a forest of possiblities.

Recent work has succeeded in pushing the state-of-the-art in RST parsing by innovating on several fronts. Feng and Hirst (2012) explore rich linguistic linguistic features, including lexical semantics and discourse production rules suggested by Lin et al. (2009) in the context of the Penn Discourse Treebank (Prasad et al., 2008). Muller et al. (2012) show that A* decoding can outperform both greedy and graph-based decoding algorithms. Joty et al. (2013) achieve the best prior results on RST relation detection by (i) jointly performing relation detection and classification, (ii) performing bottom-up rather than greedy decoding, and (iii) distinguishing between intra-sentence and inter-sentence relations. Our approach is largely orthogonal to this prior work: we focus on trans-

(b) Latent representation of words from non-negative matrix factorization with $K = 20$.

Figure 4: t-SNE Visualization on latent representations of words.

forming the lexical representation of discourse units into a latent space to facilitate learning. As shown in Figure 4(a), this projection succeeds at grouping words with similar discourse functions. We might expect to obtain further improvements by augmenting this representation learning approach with rich syntactic features (particularly for span identification), more accurate decoding, and special treatment of intra-sentence relations; this is a direction for future research.

Discriminative learning of latent features for discourse processing can be viewed as a form of *representation learning* (Bengio et al., 2013). Also called Deep Learning, such approaches have recently been applied in a number of NLP tasks (Collobert et al., 2011; Socher et al., 2012). Of particular relevance are applications to the detection of semantic or discourse relations, such as paraphrase, by comparing sentences in an induced latent space (Socher et al., 2011; Guo and Diab, 2012; Ji and Eisenstein, 2013). In this work, we show how discourse structure annotations can function as a supervision signal to discriminatively learn a transformation from lexical features to a latent space that is well-suited for discourse parsing. Unlike much of the prior work on representation learning, we induce a simple linear transformation. Extension of our approach by incorporating a non-linear activation function is a natural topic for future research.

7 Conclusion

We have presented a framework to perform discourse parsing while jointly learning to project to a low-dimensional representation of the discourse units. Using the vector-space representation of EDUs, our shift-reduce parsing system substantially outperforms existing systems on nuclearity detection and discourse relation identification. By adding some additional surface features, we obtain further improvements. The low dimensional representation also captures basic intuitions about discourse connectives and verbs, as shown in Figure 4(a).

Deep learning approaches typically apply a non-linear transformation such as the sigmoid function (Bengio et al., 2013). We have conducted a few unsuccessful experiments with the "hard tanh" function proposed by Collobert and Weston (2008), but a more complete exploration of non-linear transformations must wait for future work. Another direction would be more sophisticated composition of the surface features within each elementary discourse unit, such as the hierarchical convolutional neural network (Kalchbrenner and Blunsom, 2013) or the recursive tensor network (Socher et al., 2013). It seems likely that a better accounting for syntax could improve the latent representations that our method induces.

Acknowledgments

We thank the reviewers for their helpful feedback, particularly for the connection to multitask learning. We also want to thank Kenji Sagae and Vanessa Wei Feng for the helpful discussion via email communication. This research was supported by Google Faculty Research Awards to the second author.

Abstract

Previous researches on Text-level discourse parsing mainly made use of constituency structure to parse the whole document into one discourse tree. In this paper, we present the limitations of constituency based discourse parsing and first propose to use dependency structure to directly represent the relations between elementary discourse units (EDUs). The state-of-the-art dependency parsing techniques, the Eisner algorithm and maximum spanning tree (MST) algorithm, are adopted to parse an optimal discourse dependency tree based on the arc-factored model and the large-margin learning techniques. Experiments show that our discourse dependency parsers achieve a competitive performance on text-level discourse parsing.

1 Introduction

It is widely agreed that no units of the text can be understood in isolation, but in relation to their context. Researches in discourse parsing aim to acquire such relations in text, which is fundamental to many natural language processing applications such as question answering, automatic summarization and so on.

One important issue behind discourse parsing is the representation of discourse structure. Rhetorical Structure Theory (RST) (Mann and Thompson, 1988), one of the most influential discourse theories, posits a hierarchical generative tree representation, as illustrated in Figure 1. The leaves of a tree correspond to contiguous text spans called Elementary Discourse Units (EDUs)[1]. The adjacent EDUs are combined into the larger text spans by rhetorical relations (e.g., Contrast and Elaboration) and the larger text spans continue to be combined until the whole text constitutes a parse tree. The text spans linked by rhetorical relations are annotated as either *nucleus* or *satellite* depending on how salient they are for interpretation. It is attractive and challenging to parse the whole text into one tree.

Since such a hierarchical discourse tree is analogous to a constituency based syntactic tree except that the constituents in the discourse trees are text spans, previous researches have explored different constituency based syntactic parsing techniques (eg. CKY and chart parsing) and various features (eg. length, position et al.) for discourse parsing (Soricut and Marcu, 2003; Joty et al., 2012; Reitter, 2003; LeThanh et al., 2004; Baldridge and Lascarides, 2005; Subba and Di Eugenio, 2009; Sagae, 2009; Hernault et al., 2010b; Feng and Hirst, 2012). However, the existing approaches suffer from at least one of the following three problems. First, it is difficult to design a set of production rules as in syntactic parsing, since there are no determinate generative rules for the interior text spans. Second, the different levels of discourse units (e.g. EDUs or larger text spans) occurring in the generative process are better represented with different features, and thus a uniform framework for discourse analysis is hard to develop. Third, to reduce the time complexity of the state-of-the-art constituency based parsing techniques, the approximate parsing approaches are prone to trap in local maximum.

In this paper, we propose to adopt the *dependency structure* in discourse representation to overcome the limitations mentioned above. Here is the basic idea: the discourse structure consists of EDUs which are linked by the binary, asymmetrical relations called *dependency relations*. A dependency relation holds between a subordinate EDU called the *dependent*, and another EDU on

[1] EDU segmentation is a relatively trivial step in discourse parsing. Since our work focus here is not EDU segmentation but discourse parsing. We assume EDUs are already known.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 25–35,
Baltimore, Maryland, USA, June 23-25 2014.

which it depends called the *head*, as illustrated in Figure 2. Each EDU has one head. So, the dependency structure can be seen as a set of *head-dependent* links, which are labeled by functional relations. Now, we can analyze the relations between EDUs directly, without worrying about any interior text spans. Since dependency trees contain much fewer nodes and on average they are simpler than constituency based trees, the current dependency parsers can have a relatively low computational complexity. Moreover, concerning linearization, it is well known that dependency structures can deal with non-projective relations, while constituency-based models need the addition of complex mechanisms like transformations, movements and so on. In our work, we adopt the graph based dependency parsing techniques learned from large sets of annotated dependency trees. The Eisner (1996) algorithm and maximum spanning tree (MST) algorithm are used respectively to parse the optimal projective and non-projective dependency trees with the large-margin learning technique (Crammer and Singer, 2003). To the best of our knowledge, we are the first to apply the dependency structure and introduce the dependency parsing techniques into discourse analysis.

The rest of this paper is organized as follows. Section 2 formally defines discourse dependency structure and introduces how to build a discourse dependency treebank from the existing RST corpus. Section 3 presents the discourse parsing approach based on the Eisner and MST algorithms. Section 4 elaborates on the large-margin learning technique as well as the features we use. Section 5 discusses the experimental results. Section 6 introduces the related work and Section 7 concludes the paper.

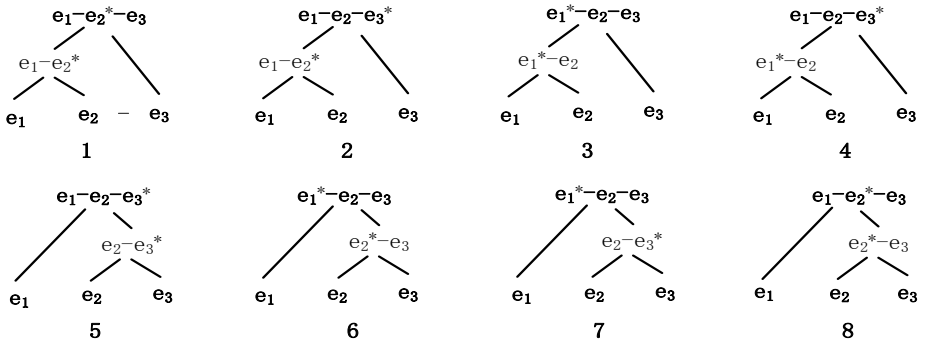

Figure 1: Headed Constituency based Discourse Tree Structure (e_1,e_2 and e_3 denote three EDUs, and * denotes the NUCLEUS constituent)

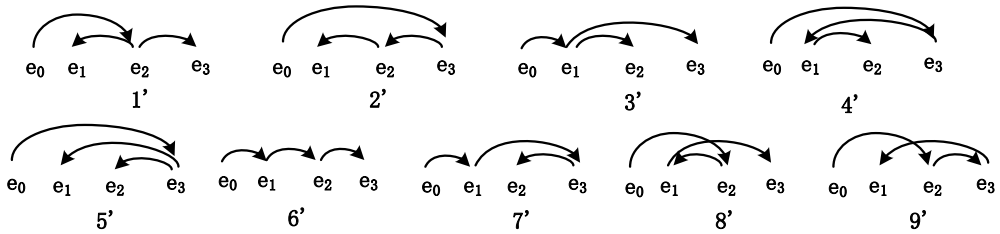

Figure 2: Discourse Dependency Tree Structures (e_1,e_2 and e_3 denote three EDUS, and the directed arcs denote one dependency relations. The artificial e_0 is also displayed here.)

2 Discourse Dependency Structure and Tree Bank

2.1 Discourse Dependency Structure

Similar to the syntactic dependency structure defined by McDonald (2005a, 2005b), we insert an artificial EDU e_0 in the beginning for each document and label the dependency relation linking from e_0 as **ROOT**. This treatment will simplify both formal definitions and computational implementations. Normally, we assume that each EDU should have one and only one head except for e_0. A labeled directed arc is used to represent the dependency relation from one head to its dependent. Then, discourse dependency structure can be formalized as the labeled directed graph, where nodes correspond to EDUs and labeled arcs correspond to labeled dependency relations.

We assume that the text[2] T is composed of n+1 EDUs including the artificial e_0. That is $T=e_0\ e_1\ e_2\ \dots\ e_n$. Let $R=\{r_1,r_2,\ \dots\ ,r_m\}$ denote a finite set of functional relations that hold between two EDUs. Then a discourse dependency graph can be denoted by $G=<V, A>$ where V denotes a set of nodes and A denotes a set of labeled directed arcs, such that for the text $T=e_0\ e_1\ e_2\ \dots\ e_n$ and the label set R the following holds:

(1) $V = \{ e_0, e_1, e_2, \dots e_n \}$

(2) $A \subseteq V \times R \times V$, where $<e_i, r, e_j> \in A$ represents an arc from the head e_i to the dependent e_j labeled with the relation r.

(3) If $<e_i, r, e_j> \in A$ then $<e_k, r', e_j> \notin A$ for all $k \neq i$

(4) If $<e_i, r, e_j> \in A$ then $<e_i, r', e_j> \notin A$ for all $r' \neq r$

The third condition assures that each EDU has one and only one head and the fourth tells that only one kind of dependency relation holds between two EDUs. According to the definition, we illustrate all the 9 possible unlabeled dependency trees for a text containing three EDUs in Figure 2. The dependency trees 1' to 7' are projective while 8' and 9' are non-projective with crossing arcs.

2.2 Our Discourse Dependency Treebank

To automatically conduct discourse dependency parsing, constructing a discourse dependency treebank is fundamental. It is costly to manually construct such a treebank from scratch. Fortunately, RST Discourse Treebank (RST-DT) (Carlson et al., 2001) is an available resource to help with.

A RST tree constitutes a hierarchical structure for one document through rhetorical relations. A total of 110 fine-grained relations (e.g. Elaboration-part-whole and List) were used for tagging RST-DT. They can be categorized into 18 classes (e.g. Elaboration and Joint). All these relations can be hypotactic ("mononuclear") or paratactic ("multi-nuclear"). A hypotactic relation holds between a *nucleus* span and an adjacent *satellite* span, while a paratactic relation connects two or more equally important adjacent *nucleus* spans. For convenience of computation, we convert the n-ary (n>2) RST trees[3] to binary trees through adding a new node for the latter n-1 nodes and assume each relation is connected to only one *nucleus*[4]. This departure from the original theory is not such a major step as it may appear, since any nucleus is known to contribute to the essential meaning. Now, each RST tree can be seen as a headed constituency based binary tree where the nuclei are heads and the children of each node are linearly ordered. Given three EDUs[5], Figure 1 shows the possible 8 headed constituency based trees where the superscript * denotes the heads (nuclei). We use dependency trees to simulate the headed constituency based trees.

Contrasting Figure 1 with Figure 2, we use dependency tree 1' to simulate binary trees 1 and 8, and dependency tress 2'- 7' to simulate binary trees 2-7 correspondingly. The rhetorical relations in RST trees are kept as the functional relations which link the two EDUs in dependency trees. With this kind of conversion, we can get our discourse dependency treebank. It is worth noting that the non-projective trees like 8' and 9' do not exist in our dependency treebank, though they are eligible according to the definition of discourse dependency graph.

3 Discourse Dependency Parsing

3.1 System Overview

As stated above, $T=e_0\ e_1\ \dots e_n$ represents an input text (document) where e_i denotes the i^{th} EDU of T. We use V to denote all the EDU nodes and $V\times R\times V_{-0}$ ($V_{-0}=V-\{e_0\}$) denote all the possible discourse dependency arcs. The goal of discourse dependency parsing is to parse an optimal spanning tree from $V\times R\times V_{-0}$. Here we follow the arc factored method and define the score of a dependency tree as the sum of the scores of all the arcs in the tree. Thus, the optimal dependency tree for T is a spanning tree with the highest score and obtained through the function $DT(T,\boldsymbol{w})$:

$$DT(T,\boldsymbol{w}) = argmax_{G_T \subseteq V\times R\times V_{-0}}\ score(T, G_T)$$
$$= argmax_{G_T \subseteq V\times R\times V_{-0}} \sum_{<e_i,r,e_j>\in G_T} \lambda(e_i, r, e_j)$$
$$= argmax_{G_T \subseteq V\times R\times V_{-0}} \sum_{<e_i,r,e_j>\in G_T} \boldsymbol{w}\cdot\mathbf{f}(e_i, r, e_j)$$

where G_T means a possible spanning tree with $score(T, G_T)$ and $\lambda(e_i, r, e_j)$ denotes the score of the arc $<e_i, r, e_j>$ which is calculated according to its feature representation $\mathbf{f}(e_i,r,e_j)$ and a weight vector $\boldsymbol{w}$.

Next, two basic problems need to be solved: how to find the dependency tree with the highest

[2] The two terms "text" and "document" are used interchangeably and represent the same meaning.

[3] According to our statistics, there are totally 381 n-ary relations in RST-DT.

[4] We set the first nucleus as the only nucleus.

[5] We can easily get all possible headed binary trees for one more complex text containing more than three EDUs, by extending the 8 possible situations for three EDUs.

score for T given all the arc scores (i.e. a parsing problem), and how to learn and compute the scores of arcs according to a set of arc features (i.e. a learning problem).

The following of this section addresses the first problem. Given the text T, we first reduce the multi-digraph composed of all possible arcs to the digraph. The digraph keeps only one arc $<e_i, r, e_j>$ between two nodes which satisfies $\lambda(e_i, r, e_j) = max_{r'}\lambda(e_i, r', e_j)$. Thus, we can proceed with a reduction from labeled parsing to unlabeled parsing. Next, two algorithms, i.e. the Eisner algorithm and MST algorithm, are presented to parse the projective and non-projective unlabeled dependency trees respectively.

3.2 Eisner Algorithm

It is well known that projective dependency parsing can be handled with the Eisner algorithm (1996) which is based on the bottom-up dynamic programming techniques with the time complexity of $O(n^3)$. The basic idea of the Eisner algorithm is to parse the left and right dependents of an EDU independently and combine them at a later stage. This reduces the overhead of indexing heads. Only two binary variables, i.e. c and d, are required to specify whether the heads occur leftmost or rightmost and whether an item is complete.

Eisner(T, λ)
Input: Text $T=e_0\, e_1 \ldots\, e_n$; Arc scores $\lambda(e_i,e_j)$
1 Instantiate E[i, i, d, c]=0.0 for all i, d, c
2 For m := 1 to n
3 For i := 1 to n
4 $j = i + m$
5 if $j > n$ then break;
6 # Create subgraphs with c=0 by adding arcs
7 E[i, j, 0, 0]=$\max_{i\le q<j}$ (E[i,q,1,1]+E[q+1,j,0,1]+$\lambda(e_j,e_i)$)
8 E[i, j, 1, 0]=$\max_{i\le q<j}$ (E[i,q,1,1]+E[q+1,j,0,1]+$\lambda(e_i,e_j)$)
9 # Add corresponding left/right subgraphs
10 E[i, j, 0, 1]=$\max_{i\le q<j}$ (E[i,q,0,1]+E[q,j,0,0]
11 E[i, j, 1, 1]=$\max_{i\le q<j}$ (E[i,q,1,0]+E[q,j,1,1])

Figure 3: Eisner Algorithm

Figure 3 shows the pseudo-code of the Eisner algorithm. A dynamic programming table E[i,j,d,c] is used to represent the highest scored subtree spanning e_i to e_j. d indicates whether e_i is the head (d=1) or e_j is head (d=0). c indicates whether the subtree will not take any more dependents (c=1) or it needs to be completed (c=0). The algorithm begins by initializing all length-one subtrees to a score of 0.0. In the inner loop, the first two steps (Lines 7 and 8) are to construct the new dependency arcs by taking the maximum over all the internal indices ($i \le q \le j$) in the span, and calculating the value of merging the two subtrees and adding one new arc. The last two steps (Lines 10 and 11) attempt to achieve an optimal left/right subtree in the span by adding the corresponding left/right subtree to the arcs that have been added previously. This algorithm considers all the possible subtrees. We can then get the optimal dependency tree with the score $E[0,n,1,1]$.

3.3 Maximum Spanning Tree Algorithm

As the bottom-up Eisner Algorithm must maintain the nested structural constraint, it cannot parse the non-projective dependency trees like 8' and 9' in Figure 2. However, the non-projective dependency does exist in real discourse. For example, the earlier text mainly talks about the topic A with mentioning the topic B, while the latter text gives a supplementary explanation for the topic B. This example can constitute a non-projective tree and its pictorial diagram is exhibited in Figure 4. Following the work of McDonald (2005b), we formalize discourse dependency parsing as searching for a maximum spanning tree (MST) in a directed graph.

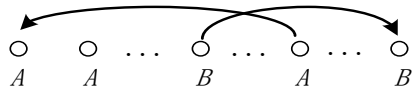

Figure 4: Pictorial Diagram of Non-projective Trees

Chu and Liu (1965) and Edmonds (1967) independently proposed the virtually identical algorithm named the Chu-Liu/Edmonds algorithm, for finding MSTs on directed graphs (McDonald et al. 2005b). Figure 5 shows the details of the Chu-Liu/Edmonds algorithm for discourse parsing. Each node in the graph greedily selects the incoming arc with the highest score. If one tree results, the algorithm ends. Otherwise, there must exist a cycle. The algorithm contracts the identified cycle into a single node and recalculates the scores of the arcs which go in and out of the cycle. Next, the algorithm recursively call itself on the contracted graph. Finally, those arcs which go in or out of one cycle will recover themselves to connect with the original nodes in V. Like McDonald et al. (2005b), we adopt an efficient implementation of the Chu-Liu/Edmonds algorithm that is proposed by Tarjan (1997) with $O(n^2)$ time complexity.

Chu-Liu-Edmonds(G, λ)
Input: Text $T=e_0\, e_1 \ldots\, e_n$; Arc scores $\lambda(e_i,e_j)$
A' = {<e_i, e_j>| e_i = argmax $\lambda(e_i,e_j)$; $1\le j\le|V|$}
G' = (V, A')
If G' has no cycles, then return G'
Find an arc set A_C that is a cycle in G'
<G_C, ep> = contract(G, A_C, λ)
G = (V, A)=Chu-Liu-Edmonds(G_C, λ)
For the arc <e_i,e_C> where ep(e_i,e_C)=e_j:
    A=$A\cup A_C\cup${<e_i,e_j>}-{<e_i,e_C>, <a(e_j),e_j>}
For the arc <e_C, e_i> where ep(e_C ,e_i)=e_j:
    A=$A\cup${<e_j,e_i>}-{<e_C,e_i>}
V = V
Return G
Contract(G=(V,A), A_C, λ)
Let G_C be the subgraph of G excluding nodes in C
Add a node e_C to G_C denoting the cycle C
For $e_j \in V$-C : $\exists e_i \in C$ <e_i,e_j>$\in A$
    Add arc <e_C,e_j> to G_C with
        ep(e_C,e_j)=argmax$_{e_i\in C}\lambda(e_i,e_j)$
    $\lambda(e_C,e_j)$ = λ(ep(e_C,e_j),e_j)
For $e_i \in V$-C: $\exists e_j \in$C (e_i,e_j)$\in$A
    Add arc <e_i,e_C> to G_C with
        ep(e_i,e_C)= =argmax$_{e_i\in C}$ [$\lambda(e_i,e_j)$-$\lambda(a(e_i),e_j)$]
    $\lambda(e_i,e_C)$ =$\lambda(e_i,e_j)$-$\lambda(a(e_i),e_j)$+score(C)
Return <G_C, ep>

Figure 5: Chu-Liu/Edmonds MST Algorithm

4 Learning

In Section 3, we assume that the arc scores are available. In fact, the score of each arc is calculated as a linear combination of feature weights. Thus, we need to determine the features for arc representation first. With referring to McDonald et al. (2005a; 2005b), we use the Margin Infused Relaxed Algorithm (MIRA) to learn the feature weights based on a training set of documents annotated with dependency structures $\{(T_i, \boldsymbol{y}_i)\}_{i=1}^{N}$ where $\boldsymbol{y}_i$ denotes the correct dependency tree for the text T_i.

4.1 Features

Following (Feng and Hirst, 2012; Lin et al., 2009; Hernault et al., 2010b), we explore the following 6 feature types combined with relations to represent each labeled arc <e_i, r, e_j> .

(1) WORD: The first one word, the last one word, and the first bigrams in each EDU, the pair of the two first words and the pair of the two last words in the two EDUs are extracted as features.

(2) POS: The first one and two POS tags in each EDU, and the pair of the two first POS tags in the two EDUs are extracted as features.

(3) Position: These features concern whether the two EDUs are included in the same sentence, and the positions where the two EDUs are located in one sentence, one paragraph, or one document.

(4) Length: The length of each EDU.

(5) Syntactic: POS tags of the dominating nodes as defined in Soricut and Marcu (2003) are extracted as features. We use the syntactic trees from the Penn Treebank to find the dominating nodes,.

(6) Semantic similarity: We compute the semantic relatedness between the two EDUs based on WordNet. The word pairs are extracted from (e_i, e_j) and their similarity is calculated. Then, we can get a weighted complete bipartite graph where words are deemed as nodes and similarity as weights. From this bipartite graph, we get the maximum weighted matching and use the averaged weight of the matches as the similarity between e_i and e_j. In particular, we use path_similarity, wup_similarity, res_similarity, jcn_similarity and lin_similarity provided by the nltk.wordnet.similarity (Bird et. al., 2009) package for calculating word similarity.

As for relations, we experiment two sets of relation labels from RST-DT. One is composed of 19 coarse-grained relations and the other 111 fine-grained relations[6].

4.2 MIRA based Learning

Margin Infused Relaxed Algorithm (MIRA) is an online algorithm for multiclass classification and is extended by Taskar et al. (2003) to cope with structured classification.

MIRA Input: a training set $\{(T_i, \boldsymbol{y}_i)\}_{i=1}^{N}$
$\boldsymbol{w}^0$ = 0; $\boldsymbol{v}$ = 0; j = 0
For *iter* := 1 to K
    For i := 1 to N
        update $\boldsymbol{w}$ according to $(T_i, \boldsymbol{y}_i)$:
        $\min \|\boldsymbol{w}^{j+1} - \boldsymbol{w}^{j}\|$
        s.t. $s(T_i, \boldsymbol{y}_i) - s(T_i, \boldsymbol{y}_i') \ge L(\boldsymbol{y}_i, \boldsymbol{y}_i')$
        where $\boldsymbol{y}_i' = DT(T_i, \boldsymbol{w}^j)$
        $\boldsymbol{v} = \boldsymbol{v} + \boldsymbol{w}^j$;
        $j = j+1$
$\boldsymbol{w} = \boldsymbol{v}/(K*N)$

Figure 6: MIRA based Learning

Figure 6 gives the pseudo-code of the MIRA algorithm (McDonld et al., 2005b). This algorithm is designed to update the parameters $\boldsymbol{w}$ using a single training instance $(T_i, \boldsymbol{y}_i)$ in each iteration. On each update, MIRA attempts to keep the norm of the change to the weight vector

[6] 19 relations include the original 18 relation in RST-DT plus one artificial **ROOT** relation. The 111 relations also include the ROOT relation.

as small as possible, which is subject to constructing the correct dependency tree under consideration with a margin at least as large as the loss of the incorrect dependency trees. We define the loss of a discourse dependency tree y_i' (denoted by $L(y_i, y_i')$) as the number of the EDUs that have incorrect heads. Since there are exponentially many possible incorrect dependency trees and thus exponentially many margin constraints, here we relax the optimization and stay with a single best dependency tree $y_i' = DT(T_i, w^j)$ which is parsed under the weight vector w^j. In this algorithm, the successive updated values of w are accumulated and averaged to avoid overfitting.

5 Experiments

5.1 Preparation

We test our methods experimentally using the discourse dependency treebank which is built as in Section 2. The training part of the corpus is composed of 342 documents and contains 18,765 EDUs, while the test part consists of 38 documents and 2,346 EDUs. The number of EDUs in each document ranges between 2 and 304. Two sets of relations are adopted. One is composed of 19 relations and Table 1 shows the number of each relation in the training and test corpus. The other is composed of 111 relations. Due to space limitation, Table 2 only lists the 10 highest-distributed relations with regard to their frequency in the training corpus.

The following experiments are conducted: (1) to measure the parsing performance with different relation sets and different feature types; (2) to compare our parsing methods with the state-of-the-art discourse parsing methods.

Table 2: 10 Highest Distributed Fine-grained Relations

5.2 Feature Influence on Two Relation Sets

So far, researches on discourse parsing avoid adopting too fine-grained relations and the relation sets containing around 20 labels are widely used. In our experiments, we observe that adopting a fine-grained relation set can even be helpful to building the discourse trees. Here, we conduct experiments on two relation sets that contain 19 and 111 labels respectively. At the same time, different feature types are tested their effects on discourse parsing.

Method	Features	Unlabeled Acc.	Labeled Acc.
Eisner	1+2	0.3602	0.2651
	1+2+3	0.7310	0.4855
	1+2+3+4	0.7370	0.4868
	1+2+3+4+5	**0.7447**	**0.4957**

	1+2+3	0.7366	0.4054
	1+2+3+4	0.7468	0.4071
	1+2+3+4+5	**0.7494**	**0.4288**
	1+2+3+4+5+6	**0.7460**	**0.4309**

Table 4: Performance Using Fine-grained Relations.

Based on the MIRA leaning algorithm, the Eisner algorithm and MST algorithm are used to parse the test documents respectively. Referring to the evaluation of syntactic dependency parsing,

we use *unlabeled accuracy* to calculate the ratio of EDUs that correctly identify their heads, *labeled accuracy* the ratio of EDUs that have both correct heads and correct relations. Table 3 and Table 4 show the performance on two relation sets. The numbers (1-6) represent the corresponding feature types described in Section 4.1.

From Table 3 and Table 4, we can see that the addition of more feature types, except the 6th feature type (semantic similarity), can promote the performance of relation labeling, whether using the coarse-grained 19 relations and the fine-grained 111 relations. As expected, the first and second types of features (WORD and POS) are the ones which play an important role in building and labeling the discourse dependency trees. These two types of features attain similar performance on two relation sets. The Eisner algorithm can achieve unlabeled accuracy around 0.36 and labeled accuracy around 0.26, while MST algorithm achieves unlabeled accuracy around 0.20 and labeled accuracy around 0.14.

The third feature type (Position) is also very helpful to discourse parsing. With the addition of this feature type, both unlabeled accuracy and labeled accuracy exhibit a marked increase. Especially, when applying MST algorithm on discourse parsing, unlabeled accuracy rises from around 0.20 to around 0.73. This result is consistent with Hernault's work (2010b) whose experiments have exhibited the usefulness of those position-related features. The other two types of features which are related to length and syntactic parsing, only promote the performance slightly.

As we employed the MIRA learning algorithm, it is possible to identify which specific features are useful, by looking at the weights learned to each feature using the training data. Table 5 selects 10 features with the highest weights in absolute value for the parser which uses the coarse-grained relations, while Table 6 selects the top 10 features for the parser using the fine-grained relations. Each row denotes one feature: the left part before the symbol "&" is from one of the 6 feature types and the right part denotes a specific relation. From Table 5 and Table 6, we can see that some features are reasonable. For example, The sixth feature in Table 5 represents that the dependency relation is preferred to be labeled *Explanation* with the fact that "because" is the first word of the dependent EDU. From these two tables, we also observe that most of the heavily weighted features are usually related to those highly distributed relations. When using the coarse-grained relations, the popular relations (eg. Elaboration, Attribution and Joint) are always preferred to be labeled. When using the fine-grained relations, the large relations including List and Elaboration-object-attribute-e are given the precedence of labeling. This phenomenon is mainly caused by the sparseness of the training corpus and the imbalance of relations. To solve this problem, the augment of training corpus is necessary.

	Feature description	**Weight**
1	Last two words in dependent EDU are "appeals court" & Joint	0.475
2	First word in dependent EDU is "racked" & Elaboration	0.445
3	First two words in head EDU are "I 'd" & Attribution	0.324
4	Last word in dependent EDU is "in" & Elaboration	-0.323
5	The res_similarity between two EDUs is 0 & Elaboration	0.322
6	First word in dependent EDU is "because" & Explanation	0.306
7	First POS in head EDU is "DT" & Joint	-0.299
8	First two words in dependent EDU are "that required" & Elaboration	0.287
9	First two words in dependent EDU are "that the" & Elaboration	0.277
10	First word in dependent EDU is "because" & Cause	0.265

Table 5: Top 10 Feature Weights for Coarse-grained Relation Labeling (Eisner Algorithm)

	Features	**Weight**
1	Last two words in dependent EDU are "appeals court" & List	0.576
2	First two words in head EDU are "I 'd" & Attribution	0.385
3	First two words in dependent EDU is "that the" & Elaboration-object-attribute-e	0.348
4	First POS in head EDU is "DT" & List	-0.323
5	Last word in dependent EDU is "in" & List	-0.286
6	First word in dependent EDU is "racked" & Elaboration-object-attribute-e	0.445
7	First two word pairs are <"In an","But even"> & List	-0.252
8	Dependent EDU has a dominating node tagged "CD"& Elaboration-object-attribute-e	-0.244
9	First two words in dependent EDU are "patents disputes" & Purpose	0.231
10	First word in dependent EDU is "to" & Purpose	0.230

Table 6: Top 10 Feature Weights for Coarse-grained Relation Labeling (Eisner Algorithm)

Unlike previous discourse parsing approaches, our methods combine tree building and relation labeling into a uniform framework naturally. This means that relations play a role in building the dependency tree structure. From Table 3 and Table 4, we can see that fine-grained relations are more helpful to building unlabeled discourse

trees more than the coarse-grained relations. The best result of unlabeled accuracy using 111 relations is 0.7506, better than the best performance (0.7447) using 19 relations. We can also see that the labeled accuracy using the fine-grained relations can achieve 0.4309, only 0.06 lower than the best labeled accuracy (0.4915) using the coarse-grained relations.

In addition, comparing the MST algorithm with the Eisner algorithm, Table 3 and Table 4 show that their performances are not significantly different from each other. But we think that MST algorithm has more potential in discourse dependency parsing, because our converted discourse dependency treebank contains only projective trees and somewhat suppresses the MST algorithm to exhibit its advantage of parsing non-projective trees. In fact, we observe that some non-projective dependencies produced by the MST algorithm are even reasonable than what they are in the dependency treebank. Thus, it is important to build a manually labeled discourse dependency treebank, which will be our future work.

5.3 Comparison with Other Systems

The state-of-the-art discourse parsing methods normally produce the constituency based discourse trees. To comprehensively evaluate the performance of a labeled constituency tree, the blank tree structure ('S'), the tree structure with nuclearity indication ('N'), and the tree structure with rhetorical relation indication but no nuclearity indication ('R') are evaluated respectively using the *F* measure (Marcu 2000).

To compare our discourse parsers with others, we adopt MIRA and Eisner algorithm to conduct discourse parsing with all the 6 types of features and then convert the produced projective dependency trees to constituency based trees through their correspondence as stated in Section 2. Our parsers using two relation sets are named *Our-coarse* and *Our-fine* respectively. The inputted EDUs of our parsers are from the standard segmentation of RST-DT. Other text-level discourse parsing methods include: (1) *Percep-coarse*: we replace MIRA with the averaged perceptron learning algorithm and the other settings are the same with *Our-coarse*; (2) *HILDA-manual* and *HILDA-seg* are from Hernault (2010b)'s work, and their inputted EDUs are from RST-DT and their own EDU segmenter respectively; (3) *LeThanh* indicates the results given by LeThanh el al. (2004), which built a multi-level rule based parser and used 14 relations evaluated on 21 documents from RST-DT; (4) *Marcu* denotes the results given by Marcu(2000)'s decision-tree based parser which used 15 relations evaluated on unspecified documents.

Table 7 shows the performance comparison for all the parsers mentioned above. *Human* denotes the manual agreement between two human annotators. From this table, we can see that both our parsers perform better than all the other parsers as a whole, though our parsers are not developed directly for constituency based trees. Our parsers do not exhibit obvious advantage than *HILDA-manual* on labeling the blank tree structure, because our parsers and *HILDA-manual* all perform over 94% of *Human* and this performance level somewhat reaches a bottleneck to promote more. However, our parsers outperform the other parsers on both nuclearity and relation labeling. *Our-coarse* achieves 94.2% and 91.8% of the human *F*-scores, on labeling nuclearity and relation respectively, while *Our-fine* achieves 95.2% and 87.6%. We can also see that the averaged perceptron learning algorithm, though simple, can achieve a comparable performance, better than *HILDA-manual*. The parsers *HILDA-seg*, *LeThanh* and *Marcu* use their own automatic EDU segmenters and exhibit a relatively low performance. This means that EDU segmentation is important to a practical discourse parser and worth further investigation.

	S	N	R
Our-coarse	**82.9**	**73.0**	**60.6**
Our-fine	**83.4**	**73.8**	**57.8**
Percep-coarse	82.3	72.6	59.4
HILDA-manual	83.0	68.4	55.3
HILDA-seg	72.3	59.1	47.8
LeThanh	53.7	47.1	39.9
Marcu	44.8	30.9	18.8
Human	**88.1**	**77.5**	**66.0**

Table 7: Full Parser Evaluation

	MAFS	WAFS	Acc
Our-coarse	**0.454**	**0.643**	**66.84**
Percep-coarse	0.438	0.633	65.37
Feng	0.440	0.607	65.30
HILDA-manual	0.428	0.604	64.18
Baseline	-	-	35.82

Table 8: Relation Labeling Performance

To further compare the performance of relation labeling, we follow Hernault el al. (2010a) and use Macro-averaged F-score (MAFS) to evaluate each relation. Due to space limitation, we do not list the *F* scores for each relation. Macro-averaged F-score is not influenced by the number of instances that are contained in each

relation. Weight-averaged F-score (WAFS) weights the performance of each relation by the number of its existing instances. Table 8 compares our parser *Our-coarse* with other parsers *HILDA-manual*, *Feng* (Feng and Hirst, 2012) and *Baseline*. *Feng* (Feng and Hirst, 2012) can be seen as a strengthened version of HILDA which adopts more features and conducts feature selection. *Baseline* always picks the most frequent relation (i.e. Elaboration). From the results, we find that *Our-coarse* consistently provides superior performance for most relations over other parsers, and therefore results in higher MAFS and WAFS.

6 Related Work

So far, the existing discourse parsing techniques are mainly based on two well-known treebanks. One is the Penn Discourse TreeBank (PDTB) (Prasad et al., 2007) and the other is RST-DT.

PDTB adopts the predicate-arguments representation by taking an implicit/explicit connective as a predication of two adjacent sentences (arguments). Then the discourse relation between each pair of sentences is annotated independently to characterize its predication. A majority of researches regard discourse parsing as a classification task and mainly focus on exploiting various linguistic features and classifiers when using PDTB (Wellner et al., 2006; Pitler et al., 2009; Wang et al., 2010). However, the predicate-arguments annotation scheme itself has such a limitation that one can only obtain the local discourse relations without knowing the rich context.

In contrast, RST and its treebank enable people to derive a complete representation of the whole discourse. Researches have begun to investigate how to construct a RST tree for the given text. Since the RST tree is similar to the constituency based syntactic tree except that the constituent nodes are different, the syntactic parsing techniques have been borrowed for discourse parsing (Soricut and Marcu, 2003; Baldridge and Lascarides, 2005; Sagae, 2009; Hernault et al., 2010b; Feng and Hirst, 2012). Soricut and Marcu (2003) use a standard bottom-up chart parsing algorithm to determine the discourse structure of sentences. Baldridge and Lascarides (2005) model the process of discourse parsing with the probabilistic head driven parsing techniques. Sagae (2009) apply a transition based constituent parsing approach to construct a RST tree for a document. Hernault et al. (2010b) develop a greedy bottom-up tree building strategy for discourse parsing. The two adjacent text spans with the closest relations are combined in each iteration. As the extension of Hernault's work, Feng and Hirst (2012) further explore various features aiming to achieve better performance. However, as analyzed in Section 1, there exist three limitations with the constituency based discourse representation and parsing. We innovatively adopt the dependency structure, which can be benefited from the existing RST-DT, to represent the discourse. To the best of our knowledge, this work is the first to apply dependency structure and dependency parsing techniques in discourse analysis.

7 Conclusions

In this paper, we present the benefits and feasibility of applying dependency structure in text-level discourse parsing. Through the correspondence between constituency-based trees and dependency trees, we build a discourse dependency treebank by converting the existing RST-DT. Based on dependency structure, we are able to directly analyze the relations between the EDUs without worrying about the additional interior text spans, and apply the existing state-of-the-art dependency parsing techniques which have a relatively low time complexity. In our work, we use the graph based dependency parsing techniques learned from the annotated dependency trees. The Eisner algorithm and the MST algorithm are applied to parse the optimal projective and non-projective dependency trees respectively based on the arc-factored model. To calculate the score for each arc, six types of features are explored to represent the arcs and the feature weights are learned based on the MIRA learning technique. Experimental results exhibit the effectiveness of the proposed approaches. In the future, we will focus on non-projective discourse dependency parsing and explore more effective features.

Abstract

A key challenge for computational conversation models is to discover latent structure in task-oriented dialogue, since it provides a basis for analysing, evaluating, and building conversational systems. We propose three new unsupervised models to discover latent structures in task-oriented dialogues. Our methods synthesize hidden Markov models (for underlying state) and topic models (to connect words to states). We apply them to two real, non-trivial datasets: human-computer spoken dialogues in bus query service, and human-human text-based chats from a live technical support service. We show that our models extract meaningful state representations and dialogue structures consistent with human annotations. Quantitatively, we show our models achieve superior performance on held-out log likelihood evaluation and an ordering task.

1 Introduction

Modeling human conversation is a fundamental scientific pursuit. In addition to yielding basic insights into human communication, computational models of conversation underpin a host of real-world applications, including interactive dialogue systems (Young, 2006), dialogue summarization (Murray et al., 2005; Daumé III and Marcu, 2006; Liu et al., 2010), and even medical applications such as diagnosis of psychological conditions (DeVault et al., 2013).

Computational models of conversation can be broadly divided into two genres: *modeling* and *control*. *Control* is concerned with choosing actions in interactive settings—for example to maximize task completion—using reinforcement learning (Levin et al., 2000), supervised learning (Hurtado et al., 2010), hand-crafted rules (Larsson and Traum, 2000), or mixtures of these (Henderson and Lemon, 2008). By contrast, *modeling*—the genre of this paper—is concerned with inferring a phenomena in an existing corpus, such as dialogue acts in two-party conversations (Stolcke et al., 2000) or topic shifts in multi-party dialogues (Galley et al., 2003; Purver et al., 2006; Hsueh et al., 2006; Banerjee and Rudnicky, 2006).

Many past works rely on supervised learning or human annotations, which usually requires manual labels and annotation guidelines (Jurafsky et al., 1997). It constrains scaling the size of training examples, and application domains. By contrast, unsupervised methods operate only on the observable signal (e.g. words) and are estimated without labels or their attendant limitations (Crook et al., 2009). They are particularly relevant because conversation is a *temporal process* where models are trained to infer a latent *state* which evolves as the dialogue progresses (Bangalore et al., 2006; Traum and Larsson, 2003).

Our basic approach is to assume that each utterance in the conversation is in a latent *state*, which has a causal effect on the words the conversants produce. Inferring this model yields basic insights into the structure of conversation and also has broad practical benefits, for example, speech recognition (Williams and Balakrishnan, 2009), natural language generation (Rieser and Lemon, 2010), and new features for dialogue policy optimization (Singh et al., 2002; Young, 2006).

There has been limited past work on unsupervised methods for conversation modeling. Chotimongkol (2008) studies task-oriented conversation and proposed a model based on a *hidden Markov model* (HMM). Ritter et al. (2010) extends it by introducing additional word sources, and applies to *non-task-oriented* conversations—social interactions on Twitter, where the subjects

[*]Work done at Microsoft Research.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 36–46,
Baltimore, Maryland, USA, June 23-25 2014.

discussed are very diffuse. The additional word sources capture the subjects, leaving the state-specific models to express common dialogue flows such as question/answer pairs.

In this paper, we retain the underlying HMM, but assume words are emitted using *topic models* (TM), exemplified by *latent Dirichlet allocation* (Blei et al., 2003, LDA). LDA assumes each word in an utterance is drawn from one of a set of latent topics, where each topic is a multinomial distribution over the vocabulary. The key idea is that the set of topics is *shared* across all states, and each state corresponds to a mixture of topics. We propose three model variants that link topics and states in different ways.

Sharing topics across states is an attractive property in task-oriented dialogue, where a single concept can be discussed at many points in a dialogue, yet different topics often appear in predictable sequences. Compared to past works, the *decoupling* of states and topics gives our models more expressive power and the potential to be more data efficient. Empirically, we find that our models outperform past approaches on two real-world corpora of task-oriented dialogues.

This paper is organized as follows: Section 2 introduces two task-oriented domains and corpora; Section 3 details three new unsupervised generative models which combine HMMs and LDA and efficient inference schemes; Section 4 evaluates our models qualitatively and quantitatively, and finally conclude in Section 5.

2 Data

To test the generality of our models, we study two very different datasets: a set of human-computer spoken dialogues in quering bus timetable (*BusTime*), and a set of human-human text-based dialogues in the technical support domain (*TechSupport*). In *BusTime*, the conversational structure is known because the computer followed a deterministic program (Williams, 2012), making it possible to directly compare an inferred model to ground truth on this corpus.[1] In *TechSupport*, there is no known flowchart,[2] making this a realistic application of unsupervised methods.

[1] Available for download at `http://research.microsoft.com/en-us/events/dstc/`

[2] Technical support human agents use many types of documentation—mainly checklists and guidelines, but in general, there are no flowcharts.

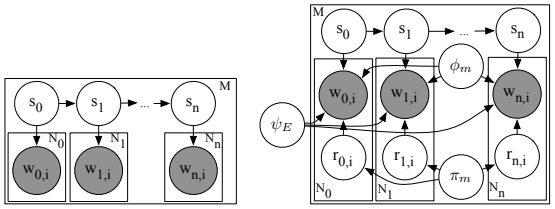
BusTime This corpus consists of logs of telephone calls between a spoken dialogue system and real bus users in Pittsburgh, USA (Black et al., 2010). For the user side, the words logged are the words recognized by the automatic speech recognizer. The vocabulary of the recognizer was constrained to the bus timetable task, so only words known to the recognizer in advance are output. Even so, the word error rate is approximately 30-40%, due to the challenging audio conditions of usage—with traffic noise and extraneous speech. The system asked users sequentially for a bus route, origin and destination, and optionally date and time. The system confirmed low-confidence speech recognition results. Due to the speech recognition channel, system and user turns always alternate. An example dialogue is given below:

System: Say a route like ⟨bus-route⟩, or say I'm not sure.
User: ⟨bus-route⟩.
System: I thought you said ⟨bus-route⟩, is that right?
User: Yes.
System: Say where're you leaving from, like ⟨location⟩.
User: ⟨location⟩.
System: Okay, ⟨location⟩, where are you going to?
...

We discard dialogues with fewer than 20 utterances. We also map all named entities (e.g., "downtown" and "28X") to their semantic types (resp. ⟨location⟩ and ⟨bus-route⟩) to reduce vocabulary size. The corpus we use consists of approximately 850 dialogue sessions or 30,000 utterances. It contains 370,000 tokens (words or semantic types) with vocabulary size 250.

TechSupport This corpus consists of logs of real web-based human-human text "chat" conversations between clients and technical support agents at a large corporation. Usually, clients and agents first exchange names and contact information; after that, dialogues are quite free-form, as agents ask questions and suggest fixes. Most dialogues ultimately end when the client's issue has been resolved; some clients are provided with a reference number for future follow-up. An example dialogue is given below:

Agent: Welcome to the answer desk! My name is ⟨agent-name⟩. How can I help you today?
Agent: May I have your name, email and phone no.?
Client: Hi, ⟨agent-name⟩. I recently installed new software but I kept getting error, can you help me?
Agent: Sorry to hear that. Let me help you with that.
Agent: May I have your name, email and phone no.?
Client: The error code is ⟨error-code⟩.
Client: It appears every time when I launch it.
Client: Sure. My name is ⟨client-name⟩.
Client: My email and phone are ⟨email⟩, ⟨phone⟩.
Agent: Thanks, ⟨client-name⟩, please give me a minute.



(a) *LM-HMM* (b) *LM-HMMS*

Figure 1: Plate diagrams of baseline models, from existing work (Chotimongkol, 2008; Ritter et al., 2010). Variable definitions are given in the text.

...

This data is less structured than *BusTime*; clients' issues span software, hardware, networking, and other topics. In addition, clients use common internet short-hand (e.g., "thx", "gtg", "ppl", "hv", etc), with mis-spellings (e.g., "ofice", "offfice", "erorr", etc). In addition, chats from the web interface are segmented into turns when a user hits "Enter" on a keyboard. Therefore, clients' input and agents' responses do **not** necessarily alternate consecutively, e.g., an agent's response may take multiple turns as in the above example. Also, it is unreasonable to group consecutive chats from the same party to form a "alternating" structure like *BusTime* dataset due to the asynchronism of different states. For instance, the second block of client inputs clearly comes from two different states which should *not* be merged together.

We discard dialogues with fewer than 30 utterances. We map named entities to their semantic types, apply stemming, and remove stop words.[3] The corpus we use contains approximately $2,000$ dialogue sessions or $80,000$ conversation utterances. It consists of $770,000$ tokens, with a a vocabulary size of $6,600$.

3 Latent Structure in Dialogues

In this work, our goal is to infer latent structure presented in task-oriented conversation. We assume that the structure can be encoded in a probabilistic state transition diagram, where the dialogue is in one state at each utterance, and states have a causal effect on the words observed. We assume the boundaries between utterances are given, which is trivial in many corpora.

The simplest formulation we consider is an HMM where each state contains a unigram *language model* (LM), proposed by Chotimongkol (2008) for task-oriented dialogue and originally developed for discourse analysis by Barzilay and Lee (2004). We call it *LM-HMM* as in Figure 1(a). For a corpus of M dialogues, the m-th dialogue contains n utterances, each of which contains N_n words (we omit index m from terms because it will be clear from context). At n-th utterance, we assume the dialogue is in some latent state s_n. Words in n-th utterance $w_{n,1}, \ldots, w_{n,N_n}$ are generated (independently) according to the *LM*. When an utterance is complete, the next state is drawn according to *HMM*, i.e., $P(s'|s)$.

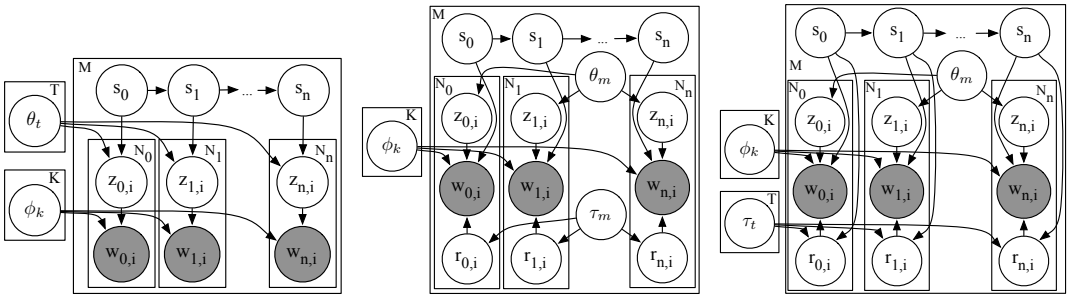
While *LM-HMM* captures the basic intuition of conversation structure, it assumes words are conditioned only on state. Ritter et al. (2010) extends *LM-HMM* to allow words to be emitted from two *additional* sources: the topic of current dialogue $\boldsymbol{\phi}$, or a background *LM* $\boldsymbol{\psi}$ shared across all dialogues. A multinomial $\boldsymbol{\pi}$ indicates the expected fraction of words from these three sources. For every word in an utterance, first draw a source indicator r from $\boldsymbol{\pi}$, and then generate the word from the corresponding source. We call it *LM-HMMS* (Figure 1(b)). Ritter et al. (2010) finds these alternate sources are important in non-task-oriented domains, where events are diffuse and fleeting. For example, Twitter exchanges often focus on a particular event (labeled X), and follow patterns like "saw X last night?", "X was amazing". Here X appears throughout the dialogue but does not help to distinguish conversational states in social media. We also explore similar variants.

In this paper, these two models form our baselines. For all models, we use *Markov chain Monte Carlo* (MCMC) inference (Neal, 2000) to find latent variables that best fit observed data. We also assume symmetric Dirichlet priors on all multinomial distributions and apply collapsed Gibbs sampling. In the rest of this section, we present our models and their inference algorithms in turn.

3.1 TM-HMM

Our approach is to modify the emission probabilities of states to be *distributions over topics* rather than distributions over words. In other words, instead of generating words via a *LM*, we generate words from a *topic model* (TM), where each state maps to a mixture of topics. The key benefit of this additional layer of abstraction is to enable states to express higher-level concepts through pooling of topics across states. For example, topics might be inferred for content like "bus-route" or "lo-

[3] We used regular expression to map named entities, and Porter stemmer in NLTK to stem all tokens.



(a) *TM-HMM* (b) *TM-HMMS* (c) *TM-HMMSS*

Figure 2: Plate diagrams of proposed models. *TM-HMM* is an HMM with state-wise topic distributions. *TM-HMMS* adds session-wise topic distribution and a source generator. *TM-HMMSS* adds a state-wise source generator. Variable definitions are given in the text.

cations"; and other topics for dialogue acts, like to "ask" or "confirm" information. States could then be *combinations* of these, e.g., a state might express "ask bus route" or "confirm location". This approach also decouples the number of topics from the number of states. Throughout this paper, we denote the number of topics as K and the number of states as T. We index words, turns and dialogues in the same ways as baseline models.

We develop three generative models. In the first variant (*TM-HMM*, Figure 2(a)), we assume every state s in HMM is associated with a distribution over topics $\boldsymbol{\theta}$, and topics generate words $\boldsymbol{w}$ at each utterance. The other two models allow words to be generated from different sources (in addition to states), akin to the *LM-HMMS* model.

TM-HMM generates a dialogue as following:

1: For each utterance n in that dialogue, sample a state s_n based on the previous state s_{n-1}.
2: For each word in utterance n, first draw a topic z from the state-specified distribution over topics $\boldsymbol{\theta}_{s_n}$ conditioned on s_n, then generate word w from the topic-specified distribution over vocabulary $\boldsymbol{\phi}_z$ based on z.

We assume $\boldsymbol{\theta}$'s and $\boldsymbol{\phi}$'s are drawn from corresponding Dirichlet priors, as in *LDA*.

The posterior distributions of state assignment s_n and topic assignment $z_{n,i}$ are

$$p(s_n|\boldsymbol{s}_{-n}, \boldsymbol{z}, \boldsymbol{\alpha}, \boldsymbol{\gamma}) \propto p(s_n|\boldsymbol{s}_{-n}, \boldsymbol{\gamma}) \cdot p(\boldsymbol{z}_n|\boldsymbol{s}, \boldsymbol{z}_{-n}, \boldsymbol{\alpha}), \quad (1)$$

$$p(z_{n,i}|\boldsymbol{s}, \boldsymbol{w}, \boldsymbol{z}_{-(n,i)}, \boldsymbol{\alpha}, \boldsymbol{\beta}) \propto p(z_{n,i}|\boldsymbol{s}, \boldsymbol{z}_{-(n,i)}, \boldsymbol{\alpha}) \cdot p(w_{n,i}|s_n, \boldsymbol{w}_{-(n,i)}, \boldsymbol{z}, \boldsymbol{\beta}),$$

where $\boldsymbol{\alpha}$, $\boldsymbol{\beta}$, $\boldsymbol{\gamma}$ are symmetric Dirichlet priors on state-wise topic distribution $\boldsymbol{\theta}_t$'s, topic-wise word distribution $\boldsymbol{\phi}_t$'s and state transition multinomials, respectively. All probabilities can be computed using collapsed Gibbs sampler for *LDA* (Griffiths and Steyvers, 2004) and *HMM* (Goldwater and Griffiths, 2007). We iteratively sample all parameters until convergence.

3.2 TM-HMMS

TM-HMMS (Figure 2(b)) extends *TM-HMM* to allow words to be generated either from state *LM* (as in *LM-HMM*), or a set of dialogue topics (akin to *LM-HMMS*). Because task-oriented dialogues usually focus on a specific domain, a set of words appears repeatedly throughout a given dialogue. Therefore, the topic distribution is often stable throughout the entire dialogue, and does not vary from turn to turn. For example, in the troubleshooting domain, dialogues about network connections, desktop productivity, and anti-virus software could each map to different session-wide topics. To express this, words in the *TM-HMMS* model are generated either from a dialogue-specific topic distribution, or from a state-specific language model.[4] A distribution over sources is sampled once at the beginning of each dialogue and selects the expected fraction of words generated from different sources.

The generative story for a dialogue session is:

1: At the beginning of each session, draw a distribution over topics $\boldsymbol{\theta}$ and a distribution over word sources $\boldsymbol{\tau}$.
2: For each utterance n in the conversation, draw a state s_n based on previous state s_{n-1}.
3: For each word in utterance n, first choose a word source r according to $\boldsymbol{\tau}$, and then depending on r, generate a word w either from the session-wide topic distribution $\boldsymbol{\theta}$ or the language model specified by the state s_n.

[4]Note that a *TM-HMMS* model with state-specific topic models (instead of state-specific language models) would be subsumed by *TM-HMM*, since one topic could be used as the background topic in *TM-HMMS*.

Again, we impose Dirichlet priors on distributions over topics $\boldsymbol{\theta}$'s and distributions over words $\boldsymbol{\phi}$'s as in *LDA*. We also assume the distributions over sources $\boldsymbol{\tau}$'s are governed by a Beta distribution.

The session-wide topics is slightly different from that used in *LM-HMMS*: *LM-HMMS* was developed for social chats on Twitter where topics are very diffuse and unlikely to repeat; hence often unique to each dialogue. By contrast, our models are designed for task-oriented dialogues which pertain to a given domain where topics are more tightly clustered; thus, in *TM-HMMS* session-wide topics are shared across the corpus.

The posterior distributions of state assignment s_n, word source $r_{n,i}$ and topic assignment $z_{n,i}$ are

$$\begin{aligned}
p(s_n|\boldsymbol{r}, \boldsymbol{s}_{-n}, \boldsymbol{w}, \boldsymbol{\gamma}, \boldsymbol{\pi}) &\propto p(s_n|\boldsymbol{s}_{-n}, \boldsymbol{\gamma}) \\
&\quad \cdot p(\boldsymbol{w}_n|\boldsymbol{r}, \boldsymbol{s}, \boldsymbol{\pi}), \\
p(r_{n,i}|\boldsymbol{r}_{-(n,i)}, \boldsymbol{s}, \boldsymbol{w}, \boldsymbol{\pi}) &\propto p(r_{n,i}|\boldsymbol{r}_{-(n,i)}, \boldsymbol{\pi}) \\
&\quad \cdot p(w_{n,i}|\boldsymbol{r}, \boldsymbol{s}, \boldsymbol{w}_{-(n,i)}, \boldsymbol{z}, \boldsymbol{\beta}), \qquad (2) \\
p(z_{n,i}|\boldsymbol{r}, \boldsymbol{w}, \boldsymbol{z}_{-(n,i)}, \boldsymbol{\alpha}, \boldsymbol{\beta}) &\propto p(z_{n,i}|\boldsymbol{r}, \boldsymbol{z}_{-(n,i)}, \boldsymbol{\alpha}) \\
&\quad \cdot p(w_{n,i}|\boldsymbol{r}, \boldsymbol{w}_{-(n,i)}, \boldsymbol{z}, \boldsymbol{\beta}),
\end{aligned}$$

where $\boldsymbol{\pi}$ is a symmetric Dirichlet prior on session-wise word source distribution $\boldsymbol{\tau}_m$'s, and other symbols are defined above. All these probabilities are Dirichlet-multinomial distributions and therefore can be computed efficiently.

3.3 TM-HMMSS

The *TM-HMMSS* (Figure 2(c)) model modifies *TM-HMMS* to re-sample the distribution over word sources $\boldsymbol{\tau}$ *at every utterance*, instead of once at the beginning of each session. This modification allows the fraction of words drawn from the session-wide topics to vary over the course of the dialogue. This is attractive in task-oriented dialogue, where some sections of the dialogue always follow a similar script, regardless of session topic—for example, the opening, closing, or asking the user if they will take a survey. To support these patterns, *TM-HMMSS* conditions the source generator distribution on the current state.

The generative story of *TM-HMMSS* is very similar to *TM-HMMS*, except the distribution over word sources $\boldsymbol{\tau}$'s are sampled at every state. A dialogue is generated as following:

1: For each session, draw a topic distribution $\boldsymbol{\theta}$.
2: For each utterance n in the conversation, draw a state s_n based on previous state s_{n-1}, and subsequently retrieve the state-specific distribution over word sources $\boldsymbol{\tau}_{s_n}$.
3: For each word in utterance n, first sample a word source r according to $\boldsymbol{\tau}_{s_n}$, and then depending on r, generate a word w either from the session-wide topic distribution $\boldsymbol{\theta}$ or the language model specified by the state s_n.

As in *TM-HMMS*, we assume multinomial distributions $\boldsymbol{\theta}$'s and $\boldsymbol{\phi}$'s are drawn from Dirichlet priors; and $\boldsymbol{\tau}$'s are governed by Beta distributions.

The inference for *TM-HMMSS* is exactly same as the inference for *TM-HMMS*, except the posterior distributions over word source $r_{n,i}$ is now

$$\begin{aligned}
p(r_{n,i}|\boldsymbol{r}_{-(n,i)}, \boldsymbol{s}, \boldsymbol{w}, \boldsymbol{\pi}) &\propto p(r_{n,i}|\boldsymbol{r}_{-(n,i)}, s_n, \boldsymbol{\pi}) \\
&\quad \cdot p(w_{n,i}|\boldsymbol{r}, \boldsymbol{s}, \boldsymbol{w}_{-(n,i)}, \boldsymbol{z}, \boldsymbol{\beta}), \qquad (3)
\end{aligned}$$

where the first term is integrated over all sessions and conditioned on the state assignment.

3.4 Supporting Multiple Parties

Since our primary focus is task-oriented dialogues between two parties, we assume every word source is associated with *two* sets of *LM*s—one for system/agent and another for user/client. This configuration is similar to *PolyLDA* (Mimno et al., 2009) or *LinkLDA* (Yano et al., 2009), such that utterances from different parties are treated as different languages or blog-post and comments pairs. In this work, we implement all models under this setting, but omit details in plate diagrams for the sake of simplicity.

In settings where the agent and client always alternate, each state emits both text before transitioning to the next state. This is the case in the *BusTime* dataset, where the spoken dialogue system enforces strict turn-taking. In settings where agents or client may produce more than one utterance in a row, each state emits either agent text *or* client text, then transitions to the next state. This is the case in the *TechSupport* corpus, where either conversant may send a message at any time.

3.5 Likelihood Estimation

To evaluate performance across different models, we compute the likelihood on held-out test set. For *TM-HMM* model, there are no local dependencies, and we therefore compute the marginal likelihood using the forward algorithm. However, for *TM-HMMS* and *TM-HMMSS* models, the latent topic distribution $\boldsymbol{\theta}$ creates local dependencies, rendering computation of marginal likeli-

hoods intractable. Hence, we use a Chib-style estimator (Wallach et al., 2009). Although it is computationally more expensive, it gives less biased approximation of marginal likelihood, even for finite samples. This ensures likelihood measurements are comparable across models.

4 Experiments

In this section, we examine the effectiveness of our models. We first evaluate our models qualitatively by exploring the inferred state diagram. We then perform quantitative analysis with log likelihood measurements and an ordering task on a held-out test set. We train all models with 80% of the entire dataset and use the rest for testing. We run the Gibbs samplers for 1000 iterations and update all hyper-parameters using slice sampling (Neal, 2003; Wallach, 2008) every 10 iterations. The training likelihood suggest all models converge within $500-800$ iterations. For all Chib-style estimators, we collect 100 samples along the Markov chain to approximate the marginal likelihood.

4.1 Qualitative Evaluation

Figure 3 shows the state diagram for *BusTime* corpus inferred by *TM-HMM* without any supervision.[5] Every dialogue is opened by asking the user to say a bus route, or to say "I'm not sure." It then transits to a state about location, e.g., origin and destination. Both these two states may continue to a confirmation step immediately after. After verifying all the necessary information, the system asks if the user wants "the next few buses".[6] Otherwise, the system follows up with the user on the particular date and time information. After system reads out bus times, the user has options to "repeat" or ask for subsequent schedules.

In addition, we also include the human-annotated dialogue flow in Figure 4 for reference (Williams, 2012). It only illustrates the most common design of system actions, without showing edge cases. Comparing these two figures, the dialogue flow inferred by our model along the most probable path (highlighted in bold red in Figure 3) is consistent with underlying design. Furthermore, our models are able to capture edge cases—omitted for space—through a more general and probabilistic fashion. In summary, our models yield a very similar flowchart to the underlying design in a completely unsupervised way.[7]

Figure 5 shows part of the flowchart for the *TechSupport* corpus, generated by the *TM-HMMSS* model.[8] A conversation usually starts with a welcome message from a customer support agent. Next, clients sometimes report a problem; otherwise, the agent gathers the client's identity. After these preliminaries, the agent usually checks the system version or platform settings. Then, information about the problem is exchanged, and a cycle ensues where agents propose solutions, and clients attempt them, reporting results. Usually, a conversation loops among these states until either the problem is resolved (as the case shown in the figure) or the client is left with a reference number for future follow-up (not shown due to space limit). Although technical support is task-oriented, the scope of possible issues is vast and not prescribed. The table in Figure 5 lists the top ranked words of selected topics—the categories clients often report problems in. It illustrates that, qualitatively, *TM-HMMSS* discovers both problem categories and conversation structures on our data.

As one of the baseline model, we also include a part of flowchart generated by *LM-HMM* model with similar settings of $T = 20$ states. Illustrated by the highlighted states in 6, *LM-HMM* model conflates interactions that commonly occur at the beginning and end of a dialogue—i.e., "acknowledge agent" and "resolve problem", since their underlying language models are likely to produce similar probability distributions over words. By incorporating topic information, our proposed models (e.g., *TM-HMMSS* in Figure 5) are able to enforce the state transitions towards more frequent flow patterns, which further helps to overcome the weakness of language model.

4.2 Quantitative Evaluation

In this section, we evaluate our models using log likelihood and an ordering task on a held-out test set. Both evaluation metrics measure the predictive power of a conversation model.

[5] Recall in *BusTime*, state transitions occur after each *pair* of system/user utterances, so we display them synchronously.

[6] The system was designed this way because most users say "yes" to this question, obviating the date and time.

[7] We considered various ways of making a quantitative evaluation of the inferred state diagram, and proved difficult. Rather than attempt to justify a particular sub-division of each "design states", we instead give several straightforward quantitative evaluations in the next section.

[8] Recall in this corpus, state transitions occur after emitting each agent *or* client utterances, which does *not* necessarily alternate in a dialogue, so we display client request and agent response separately.

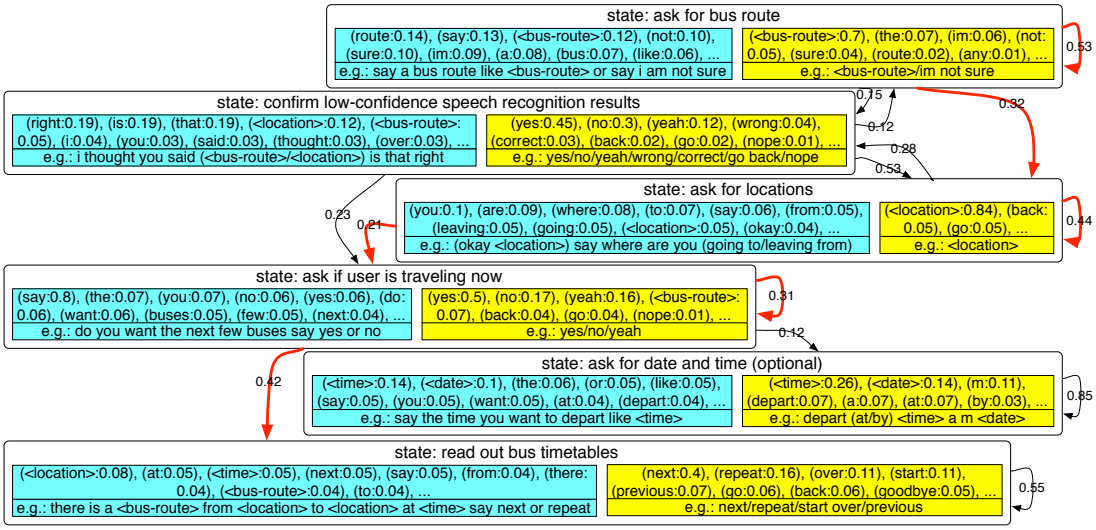


Figure 3: **(Upper)** Part of the flowchart inferred on *BusTime*, by *TM-HMM* model with $K = 10$ topics and $T = 10$ states. The most probable path is highlighted, which is consistent with the underlying design (Figure 4). Cyan blocks are system actions and yellow blocks are user responses. In every block, the upper cell shows the top ranked words marginalized over all topics and the lower cell shows some examples of that state. Transition probability cut-off is 0.1. States are labelled manually.

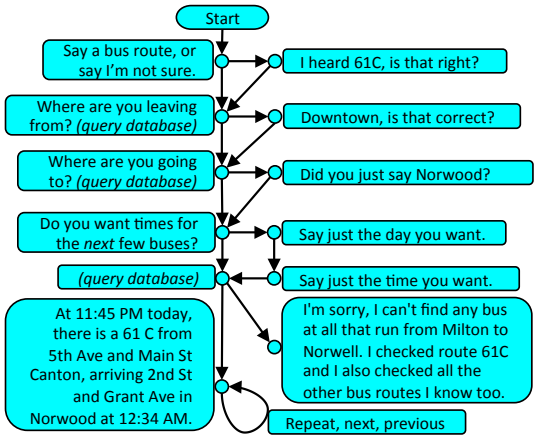

Figure 4: **(Left)** Hand-crafted reference flowchart for *BusTime* (Williams, 2012). Only the most common dialogue flows are displayed. System prompts shown are example paraphrases. Edge cases are not included.

Log Likelihood The likelihood metric measures the probability of generating the test set under a specified model. As shown in Figure 7, our models yield as good or better likelihood than *LM-HMM* and *LM-HMMS* models on both datasets under all settings. For our proposed models, *TM-HMMS* and *TM-HMMSS* perform better than *TM-HMM* on *TechSupport*, but not necessarily on *BusTime*. In addition, we notice that the marginal benefit of *TM-HMMSS* over *TM-HMM* is greater on *TechSupport* dataset, where each dialogue focuses on one of many possible tasks. This coincides with our belief that topics are more conversation dependent and shared across the entire corpus in customer support data—i.e., different clients in different sessions might ask about similar issues.

Ordering Test Ritter et al. (2010) proposes an evaluation based on rank correlation coefficient, which measures the degree of similarity between any two orderings over sequential data. They use Kendall's τ as evaluation metric, which is based on the agreement between pairwise orderings of two sequences (Kendall, 1938). It ranges from -1 to $+1$, where $+1$ indicates an identical ordering and -1 indicates a reverse ordering. The idea is to generate all permutations of the utterances in a dialogue (including true ordering), and compute the log likelihood for each under the model. Then, Kendall's τ is computed between the most probable permutation and true ordering. The result is the average of τ values for all dialogues in test corpus.

Ritter et al. (2010) limits their dataset by choosing Twitter dialogues containing 3 to 6 posts (utterances), making it tractable to enumerate all permutations. However, our datasets are much larger, and enumerating all possible permutations of dialogues with more than 20 or 30 utterances is infeasible. Instead, we incrementally build up the permutation set by adding one random permutation at a time, and taking the most probable permutation after each addition. If this process were continued (intractably!) until all permutations are enumerated, the true value of Kendall's τ test would be reached. In practice, the value appears to plateau after a few dozen measurements.

We present our results in Figure 8. Our models consistently perform as good or better than

Figure 5: Part of flowchart (left) and topic table (right) on *TechSupport* dataset, generated by *TM-HMMSS* model under settings of $K = 20$ topics and $T = 20$ states. The topic table lists top ranked words in issues discussed in the chats. Cyan blocks are system actions and yellow blocks are user responses. In every block, the upper cell shows top ranked words, and the lower cell shows example string patterns of that state. Transition probability cut-off is 0.05. States and topics are labelled manually.

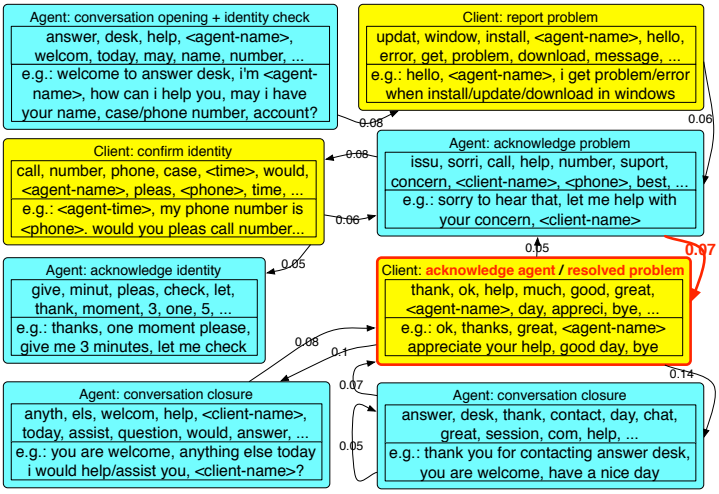

Figure 6: Part of flowchart on *TechSupport* dataset, generated by *LM-HMM* model with $T = 20$ states. Cyan blocks are system actions and yellow blocks are user responses. In every block, the upper cell shows the top ranked words, and the lower cell shows example word sequences or string patterns of that state. Transition probability cut-off is 0.05. States are labelled manually. A poorly-inferred state is highlighted, which seems to conflate the "acknowledge agent" and "resolve problem" states, and *TM-HMMSS* model has properly disentangled (Figure 5).

the baseline models. For *BusTime* data, all models perform relatively well except *LM-HMM* which only indicates weak correlations. *TM-HMM* out-performs all other models under all settings. This is also true for *TechSupport* dataset. *LM-HMMS*, *TM-HMMS* and *TM-HMMSS* models perform considerably well on *BusTime*, but not on *TechSupport* data. These three models allow words to be generated from additional sources other than states. Although this improves log likelihood, it is possible these models encode less information about the state sequences, at least in the more diffuse *TechSupport* data. In summary, under both quantitative evaluation measures, our models advance state-of-the-art, however *which* of our models is best depends on the application.

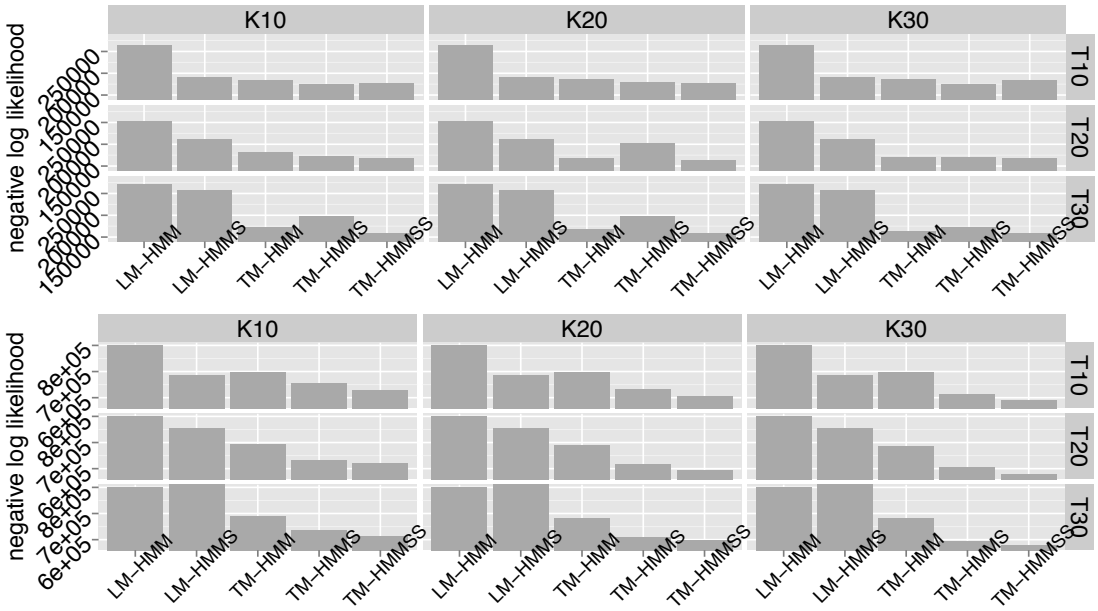

Figure 7: Negative log likelihood on *BusTime* (upper) and *TechSupport* (lower) datasets (smaller is better) under different settings of topics K and states T.

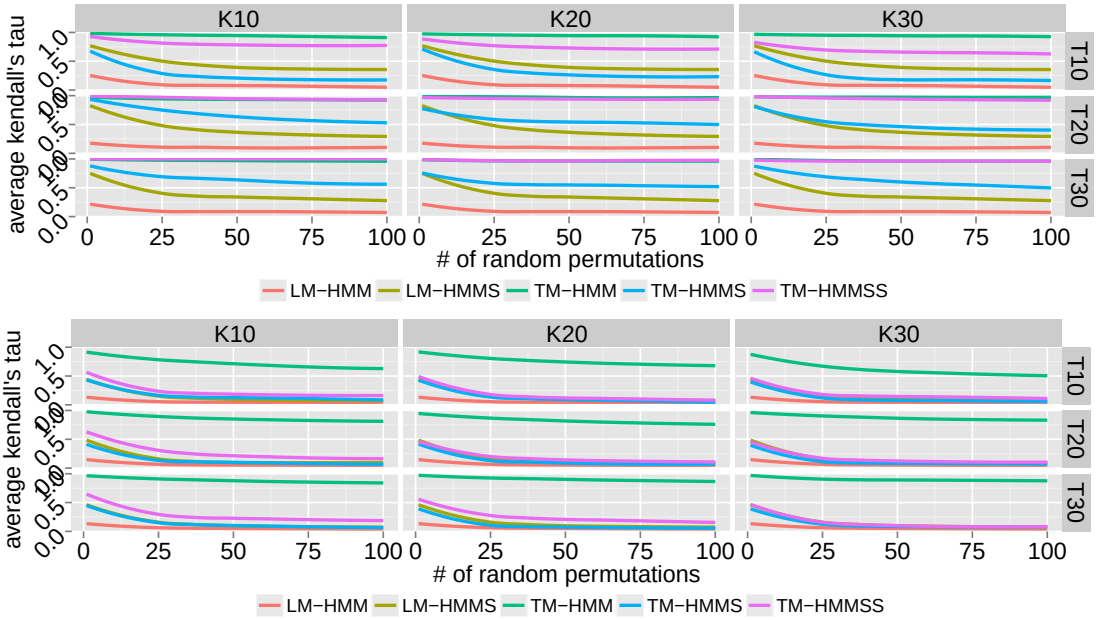

Figure 8: Average Kendall's τ measure on *BusTime* (upper) and *TechSupport* (lower) datasets (larger is better) against number of random permutations, under various settings of topics K and states T.

5 Conclusion and Future Work

We have presented three new unsupervised models to discover latent structures in task-oriented dialogues. We evaluated on two very different corpora—logs from spoken, human-computer dialogues about bus time, and logs of textual, human-human dialogues about technical support. We have shown our models yield superior performance both qualitatively and quantitatively.

One possible avenue for future work is scalability. Parallelization (Asuncion et al., 2012) or online learning (Doucet et al., 2001) could significantly speed up inference. In addition to MCMC, another class of inference method is variational Bayesian analysis (Blei et al., 2003; Beal, 2003), which is inherently easier to distribute (Zhai et al., 2012) and online update (Hoffman et al., 2010).

Acknowledgments

We would like to thank anonymous reviewers and Jordan Boyd-Graber for their valuable comments. We are also grateful to Alan Ritter and Bill Dolan for their helpful discussions; and Kai (Anthony) Lui for providing *TechSupport* dataset.

Learning Structured Perceptrons for Coreference Resolution with Latent Antecedents and Non-local Features

Anders Björkelund and **Jonas Kuhn**
Institute for Natural Language Processing
University of Stuttgart
{anders,jonas}@ims.uni-stuttgart.de

Abstract

We investigate different ways of learning structured perceptron models for coreference resolution when using non-local features and beam search. Our experimental results indicate that standard techniques such as early updates or Learning as Search Optimization (LaSO) perform worse than a greedy baseline that only uses local features. By modifying LaSO to delay updates until the end of each instance we obtain significant improvements over the baseline. Our model obtains the best results to date on recent shared task data for Arabic, Chinese, and English.

1 Introduction

This paper studies and extends previous work using the structured perceptron (Collins, 2002) for complex NLP tasks. We show that for the task of coreference resolution the straightforward combination of beam search and early update (Collins and Roark, 2004) falls short of more limited feature sets that allow for exact search. This contrasts with previous work on, e.g., syntactic parsing (Collins and Roark, 2004; Huang, 2008; Zhang and Clark, 2008) and linearization (Bohnet et al., 2011), and even simpler structured prediction problems, where early updates are not even necessary, such as part-of-speech tagging (Collins, 2002) and named entity recognition (Ratinov and Roth, 2009).

The main reason why early updates underperform in our setting is that the task is too difficult and that the learning algorithm is not able to profit from all training data. Put another way, early updates happen too early, and the learning algorithm rarely reaches the end of the instances as it halts, updates, and moves on to the next instance.

An alternative would be to continue decoding the same instance after the early updates, which is equivalent to *Learning as Search Optimization* (LaSO; Daumé III and Marcu (2005b)). The learning task we are tackling is however further complicated since the target structure is under-determined by the gold standard annotation. Coreferent mentions in a document are usually annotated as sets of mentions, where all mentions in a set are coreferent. We adopt the recently popularized approach of inducing a latent structure within these sets (Fernandes et al., 2012; Chang et al., 2013; Durrett and Klein, 2013). This approach provides a powerful boost to the performance of coreference resolvers, but we find that it does not combine well with the LaSO learning strategy. We therefore propose a modification to LaSO, which delays updates until after each instance. The combination of this modification with non-local features leads to further improvements in the clustering accuracy, as we show in evaluation results on all languages from the CoNLL 2012 Shared Task – Arabic, Chinese, and English. We obtain the best results to date on these data sets.[1]

2 Background

Coreference resolution is the task of grouping referring expressions (or *mentions*) in a text into disjoint *clusters* such that all mentions in a cluster refer to the same entity. An example is given in Figure 1 below, where mentions from two clusters are marked with brackets:

> [Drug Emporium Inc.]$_{a_1}$ said [Gary Wilber]$_{b_1}$ was named CEO of [this drugstore chain]$_{a_2}$. [He]$_{b_2}$ succeeds his father, Philip T. Wilber, who founded [the company]$_{a_3}$ and remains chairman. Robert E. Lyons III, who headed the [company]$_{a_4}$'s Philadelphia region, was appointed president and chief operating officer, succeeding [Gary Wilber]$_{b_3}$.

Figure 1: An excerpt of a document with the mentions from two clusters marked.

[1] Our system is available at http://www.ims.uni-stuttgart.de/~anders/coref.html

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 47–57,
Baltimore, Maryland, USA, June 23-25 2014.

In recent years much work on coreference resolution has been devoted to increasing the expressivity of the classical *mention-pair model*, in which each coreference classification decision is limited to information about two mentions that make up a pair. This shortcoming has been addressed by *entity-mention models*, which relate a candidate mention to the full cluster of mentions predicted to be coreferent so far (for more discussion on the model types, see, e.g., (Ng, 2010)).

Nevertheless, the two best systems in the latest CoNLL Shared Task on coreference resolution (Pradhan et al., 2012) were both variants of the mention-pair model. While the second best system (Björkelund and Farkas, 2012) followed the widely used baseline of Soon et al. (2001), the winning system (Fernandes et al., 2012) proposed the use of a **tree representation**.

The tree-based model of Fernandes et al. (2012) construes the representation of coreference clusters as a rooted tree. Figure 2 displays an example tree over the clusters from Figure 1. Every mention corresponds to a node in the tree, and arcs between mentions indicate that they are coreferent. The tree additionally has a dummy root node. Every subtree under the root node corresponds to a cluster of coreferent mentions.

Since coreference training data is typically not annotated with trees, Fernandes et al. (2012) proposed the use of **latent** trees that are induced during the training phase of a coreference resolver. The latent tree provides more meaningful antecedents for training.[2] For instance, the popular pair-wise instance creation method suggested by Soon et al. (2001) assumes non-branching trees, where the antecedent of every mention is its linear predecessor (i.e., *he*$_{b_2}$ is the antecedent of *Gary Wilber*$_{b_3}$). Comparing the two alternative antecedents of *Gary Wilber*$_{b_3}$, the tree in Figure 2 provides a more reliable basis for training a coreference resolver, as the two mentions of *Gary Wilber* are both proper names and have an exact string match.

3 Representation and Learning

Let $M = \{m_0, m_1, ..., m_n\}$ denote the set of mentions in a document, including the artificial root mention (denoted by m_0). We assume that the mentions are ordered ascendingly with respect to the linear order of the document, where the document root precedes all other mentions.[3] For each mention m_j, let A_j denote the set of potential antecedents. That is, the set of all mentions that precede m_j according to the linear order including the root node, or, $A_j = \{m_i \mid i < j\}$. Finally, let $\mathcal{A}$ denote the set of all antecedent sets $\{A_0, A_1, ..., A_n\}$.

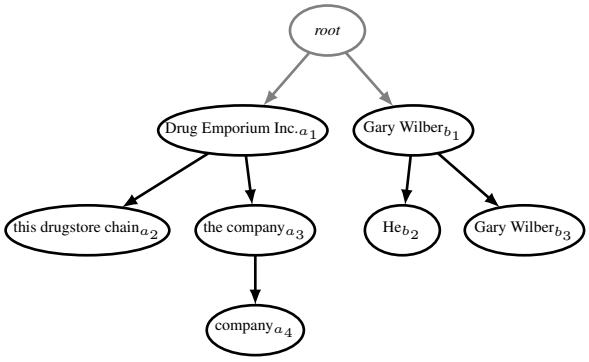

Figure 2: A tree representation of Figure 1.

In the tree model, each mention corresponds to a node, and an antecedent-anaphor pair $\langle a_i, m_i \rangle$, where $a_i \in A_i$, corresponds to a directed edge (or *arc*) pointing from antecedent to anaphor.

The score of an arc $\langle a_i, m_i \rangle$ is defined as the scalar product between a weight vector w and a feature vector $\Phi(\langle a_i, m_i \rangle)$, where Φ is a feature extraction function over an arc (thus extracting features from the antecedent and the anaphor). The score of a coreference tree $y = \{\langle a_1, m_1 \rangle, \langle a_2, m_2 \rangle, ..., \langle a_n, m_n \rangle\}$ is defined as the sum of the scores of all the mention pairs:

$$score(\langle a_i, m_i \rangle) = w \cdot \Phi(\langle a_i, m_i \rangle) \quad (1)$$
$$score(y) = \sum_{\langle a_i, m_i \rangle \in y} score(\langle a_i, m_i \rangle)$$

The objective is to find the output $\hat{y}$ that maximizes the scoring function:

$$\hat{y} = \arg\max_{y \in \mathcal{Y}(\mathcal{A})} score(y) \quad (2)$$

where $\mathcal{Y}(\mathcal{A})$ denotes the set of possible trees given the antecedent sets $\mathcal{A}$. By treating the mentions as nodes in a directed graph and assigning scores to the arcs according to (1), Fernandes et al. (2012) solved the search problem using the Chu-Liu-Edmonds (CLE) algorithm (Chu and Liu, 1965;

[2] We follow standard practice and overload the terms anaphor and antecedent to be any type of mention, i.e., names as well as pronouns. An antecedent is simply the mention to the left of the anaphor.

[3] We impose a total order on mentions. In case of nested mentions, the mention that begins first is assumed to precede the embedded one. If two mentions begin at the same token, the longer one is taken to precede the shorter one.

Edmonds, 1967), which is a maximum spanning tree algorithm that finds the optimal tree over a connected directed graph. CLE, however, has the drawback that the scores of the arcs must remain fixed and can not change depending on other arcs and it is not clear how to include non-local features in a CLE decoder.

3.1 Online learning

We find the weight vector w by online learning using a variant of the structured perceptron (Collins, 2002). Specifically, we use the passive-aggressive (PA) algorithm (Crammer et al., 2006), since we found that this performed slightly better in preliminary experiments.[4]

The structured perceptron iterates over training instances $\langle x_i, y_i \rangle$, where x_i are inputs and y_i are outputs. For each instance it uses the current weight vector w to make a prediction $\hat{y}_i$ given the input x_i. If the prediction is incorrect, the weight vector is updated in favor of the correct structure. Otherwise the weight vector is left untouched. In our setting inputs x_i correspond to documents and outputs y_i are trees over mentions in a document. The training data is, however, not annotated with trees, but only with clusters of mentions. That is, the y_i's are not defined a priori.

3.2 Latent antecedents

In order to have a tree structure to update against, we use the current weight vector and apply the decoder to a constrained antecedent set and obtain a **latent tree** over the mentions in a document, where each mention is assigned a single correct antecedent (Fernandes et al., 2012). We constrain the antecedent sets such that only trees that correspond to the correct clustering can be built. Specifically, let $\tilde{A}_j$ denote the set of correct antecedents for a mention m_j, or

$$\tilde{A}_j = \begin{cases} \{m_0\} \text{ if } m_j \text{ has no correct antecedent} \\ \{a_i \mid \textsc{Coref}(a_i, m_j), a_i \in A_j\} \text{ otherwise} \end{cases}$$

that is, if mention m_j is non-referential or the first mention of its cluster, $\tilde{A}_j$ contains only the document root. Otherwise it is the set of all mentions to the left that belong to the same cluster as m_j. Analogously to $\mathcal{A}$, let $\tilde{\mathcal{A}}$ denote the set of constrained antecedent sets. The latent tree $\tilde{y}$ needed for updates is then defined to be the optimal tree over $\mathcal{Y}(\tilde{\mathcal{A}})$, subject to the current weight vector:

$$\tilde{y} = \arg\max_{y \in \mathcal{Y}(\tilde{\mathcal{A}})} score(y)$$

The intuition behind the latent tree is that during online learning, the weight vector will start favoring latent trees that are easier to learn (such as the one in Figure 2).

Algorithm 1 PA algorithm with latent trees

Input: Training data D, number of iterations T
Output: Weight vector w

1: $w = \overrightarrow{0}$
2: **for** $t \in 1..T$ **do**
3: **for** $\langle M_i, \mathcal{A}_i, \tilde{\mathcal{A}}_i \rangle \in D$ **do**
4: $\hat{y}_i = \arg\max_{\mathcal{Y}(\mathcal{A})} score(y)$ ▷ Predict
5: **if** $\neg$ CORRECT$(\hat{y}_i)$ **then**
6: $\tilde{y}_i = \arg\max_{\mathcal{Y}(\tilde{\mathcal{A}})} score(y)$ ▷ Latent tree
7: $\Delta = \Phi(\hat{y}_i) - \Phi(\tilde{y}_i)$
8: $\tau = \frac{\Delta \cdot w + \text{Loss}(\hat{y}_i)}{\|\Delta\|^2}$ ▷ PA weight
9: $w = w + \tau\Delta$ ▷ PA update
10: **return** w

Algorithm 1 shows pseudocode for the learning algorithm, which we will refer to as the **baseline learning algorithm**. Instead of looping over pairs $\langle x, y \rangle$ of documents and trees, it loops over triples $\langle M, \mathcal{A}, \tilde{\mathcal{A}} \rangle$ that comprise the set of mentions M and the two sets of antecedent candidates (line 3). Moreover, rather than checking that the tree is identical to the latent tree, it only requires the tree to correctly encode the gold clustering (line 5). The update that occurs in lines 7-9 is the passive-aggressive update. A loss function LOSS that quantifies the error in the prediction is used to compute a scalar τ that controls how much the weights are moved in each update. If τ is set to 1, the update reduces to the standard structured perceptron update. The loss function can be an arbitrarily complex function that returns a numerical value of how bad the prediction is. In the simplest case, Hamming loss can be used, i.e., for each incorrect arc add 1. We follow Fernandes et al. (2012) and penalize erroneous root attachments, i.e., mentions that erroneously get the root node as their antecedent, with a loss of 1.5. For all other arcs we use Hamming loss.

4 Incremental Search

We now show that the search problem in (2) can equivalently be solved by the more intuitive **best-first decoder** (Ng and Cardie, 2002), rather than using the CLE decoder. The best-first decoder

[4] We also implement the feature mapping function Φ as a *hash kernel* (Bohnet, 2010) and apply *averaging* (Collins, 2002), though for brevity we omit this from the pseudocode.

works incrementally by making a left-to-right pass over the mentions, selecting for each mention the highest scoring antecedent.

The key aspect that makes the best-first decoder equivalent to the CLE decoder is that all arcs point from left to right, both in this paper and in the work of Fernandes et al. (2012). We sketch a proof that this decoder also returns the highest scoring tree.

First, note that this algorithm indeed returns a tree. This can be shown by assuming the opposite, in which case the tree has to have a cycle. Then there must be a mention that has its antecedent to the right. Though this is not possible since all arcs point from left to right.

Second, this tree is the highest scoring tree. Again, assume the contrary, i.e., that there is a higher scoring tree in $\mathcal{Y}(\mathcal{A})$. This implies that for some mention there is a higher scoring antecedent than the one selected by the decoder. This contradicts the fact that the best-first decoder selects the highest scoring antecedent for each mention.[5]

5 Introducing Non-local Features

Since the best-first decoder makes a left-to-right pass, it is possible to extract features on the partial structure on the left. Such **non-local features** are able to capture information beyond that of a mention and its potential antecedent, e.g., the size of a partially built cluster, or features extracted from the antecedent of the antecedent.

When only local features are used, greedy search (either with CLE or the best-first decoder) suffices to find the highest scoring tree. That is, greedy search provides an exact solution to equation 2. Non-local features, however, render the exact search problem intractable. This is because with non-local features, locally suboptimal (i.e., non-greedy) antecedents for some mentions may lead to a higher total score over a whole document.

In order to keep some options around during search, we extend the best-first decoder with **beam search**. Beam search works incrementally by keeping an *agenda* of *state items*. At each step, all items on the agenda are expanded. The subset of size k (the *beam size*) of the highest scoring expansions are retained and put back into the agenda for the next step. The feature extraction function Φ is also extended such that it also receives the current state s as an argument: $\Phi(\langle m_i, m_j \rangle, s)$. The state encodes the previous decisions and enables Φ to extract features from the partial tree on the left.

We now outline three different ways of learning the weight vector w with non-local features.

5.1 Early updates

The beam search decoder can be plugged into the training algorithm, replacing the calls to $\arg\max$. Since state items leading to the best tree may be pruned from the agenda before the decoder reaches the end of the document, the introduction of non-local features may cause the decoder to return a non-optimal tree. This is problematic as it might cause updates although the correct tree has a higher score than the predicted one. It has previously been observed (Huang et al., 2012) that substantial gains can be made by applying an **early update** strategy (Collins and Roark, 2004): if the correct item is pruned before reaching the end of the document, then stop and update.

While beam search and early updates have been successfully applied to other NLP applications, our task differs in two important aspects: First, coreference resolution is a much more difficult task, which relies on more (world) knowledge than what is available in the training data. In other words, it is unlikely that we can devise a feature set that is informative enough to allow the weight vector to converge towards a solution that lets the learning algorithm see the entire documents during training, at least in the situation when no external knowledge sources are used.

Second, our gold structure is not known but is induced latently, and may vary from iteration to iteration. With non-local features this is troublesome since the best latent tree of a complete document may not necessarily coincide with the best *partial* tree at some intermediate mention m_j, $j < n$, i.e., a mention before the last in a document. We therefore also apply beam search to find the latent tree to have a partial gold structure for every mention in a document.

Algorithm 2 shows pseudocode for the beam search and early update training procedure. The algorithm maintains two parallel agendas, one for gold items and one for predicted items. At every mention, both agendas are expanded and thus cover the same set of mentions. Then the predicted agenda is checked to see if it contains any correct

[5] In case there are multiple maximum spanning trees, the best-first decoder will return one of them. This also holds for the CLE algorithm. With proper definitions, the proof can be constructed to show that both search algorithms return trees belonging to the *set* of maximum spanning trees over a graph.

Algorithm 2 Beam search and early update

Input: Data set D, epochs T, beam size k
Output: weight vector w

```
 1: w = 0⃗
 2: for t ∈ 1..T do
 3:     for ⟨M_i, A_i, Ã_i⟩ ∈ D do
 4:         Agenda_G = {}
 5:         Agenda_P = {}
 6:         for j ∈ 1..n do
 7:             Agenda_G = EXPAND(Agenda_G, Ã_j, m_j, k)
 8:             Agenda_P = EXPAND(Agenda_P, A_j, m_j, k)
 9:             if ¬ CONTAINSCORRECT(Agenda_P) then
10:                 ỹ = EXTRACTBEST(Agenda_G)
11:                 ŷ = EXTRACTBEST(Agenda_P)
12:                 update                          ▷ PA update
13:                 GOTO 3   ▷ Skip and move to next instance
14:         ŷ = EXTRACTBEST(Agenda_P)
15:         if ¬ CORRECT(ŷ) then
16:             ỹ = EXTRACTBEST(Agenda_G)
17:             update                              ▷ PA update
```

item. If there is no correct item in the predicted agenda, search is halted and an update is made against the best item from the gold agenda. The algorithm then moves on to the next document. If the end of a document is reached, the top scoring predicted item is checked for correctness. If it is not, an update is made against the best gold item.

A drawback of early updates is that the remainder of the document is skipped when an early update is applied, effectively discarding some training data.[6] An alternative strategy that makes better use of the training data is to apply the max-violation procedure suggested by Huang et al. (2012). However, since our gold trees change from iteration to iteration, and even inside of a single document, it is not entirely clear with respect to what gold tree the maximum violation should be computed. Initial experiments with max-violation updates indicated that they did not improve much over early updates, and also had a tendency to only consider a smaller portion of the training data.

5.2 LaSO

To make full use of the training data we implemented Learning as Search Optimization (**LaSO**; Daumé III and Marcu, 2005b). It is very similar to early updates, but differs in one crucial respect: When an early update is made, search is continued rather than aborted. Thus the learning algorithm always reaches the end of a document, avoiding the problem that early updates discard parts of the training data.

[6] In fact, after 50 iterations about 70% of the mentions in the training data are still being ignored due to early updates.

Correct items are computed the same way as with early updates, where an agenda of gold items is maintained in parallel. When search is resumed after an intermediate LaSO update, the prediction agenda is re-seeded with gold items (i.e., items that are all correct). This is necessary since the update influences what the partial gold structure looks like, and the gold agenda therefore needs to be recreated from the beginning of the document. Specifically, after each intermediate LaSO update, the gold agenda is expanded repeatedly from the beginning of the document to the point where the update was made, and is then copied over to seed the prediction agenda. In terms of pseudocode, this is accomplished by replacing lines 12 and 13 in Algorithm 2 with the following:

```
12:                 update                          ▷ PA update
13:                 Agenda_G = {}
14:                 for m_i ∈ {m_1, ..., m_j}   ▷ Recreate gold agenda
15:                     Agenda_G = EXPAND(Agenda_G, Ã_i, m_i, k)
16:                 Agenda_P = COPY(Agenda_G)
17:                 GOTO 6                          ▷ Continue
```

5.3 Delayed LaSO updates

When we applied LaSO, we noticed that it performed worse than the baseline learning algorithm when only using local features. We believe that the reason is that updates are made in the middle of documents which means that lexical forms of antecedents are "fresh in memory" of the weight vector. This results in fewer mistakes during training and leads to fewer updates. While this feedback makes it easier during training, such feedback is not available during test time, and the LaSO learning setting therefore mimics the testing setting to a lesser extent.

We also found that LaSO updates change the shape of the latent tree and that the average distance between mentions connected by an arc increased. This problem can also be attributed to how lexical items are fresh in memory. Such trees tend to deviate from the intuition that the latent trees are easier to learn. They also render distance-based features (which are standard practice and generally rather useful) less powerful, as distance in sentences or mentions becomes less of a reliable indicator for coreference.

To cope with this problem, we devised the **delayed LaSO** update, which differs from LaSO only in the respect that it postpones the actual updates until the end of a document. This is accomplished by summing the distance vectors Δ at every point where LaSO would make an update. At

Algorithm 3 Delayed LaSO update

Input: Data set D, iterations T, beam size k
Output: weight vector w

$w = \overrightarrow{0}$
for $t \in 1..T$ **do**
  for $\langle M_i, \mathcal{A}_i, \tilde{\mathcal{A}}_i \rangle \in D$ **do**
    $Agenda_G = \{\}$
    $Agenda_P = \{\}$
    $\Delta_{acc} = \overrightarrow{0}$
    $loss_{acc} = 0$
    for $j \in 1..n$ **do**
      $Agenda_G = \text{EXPAND}(Agenda_G, \tilde{A}_j, m_j, k)$
      $Agenda_P = \text{EXPAND}(Agenda_P, A_j, m_j, k)$
      if $\neg\,\text{CONTAINSCORRECT}(Agenda_P)$ **then**
        $\tilde{y} = \text{EXTRACTBEST}(Agenda_G)$
        $\hat{y} = \text{EXTRACTBEST}(Agenda_P)$
        $\Delta_{acc} = \Delta_{acc} + \Phi(\hat{y}) - \Phi(\tilde{y})$
        $loss_{acc} = loss_{acc} + \text{LOSS}(\hat{y})$
        $Agenda_P = Agenda_G$
    $\hat{y} = \text{EXTRACTBEST}(Agenda_P)$
    if $\neg\,\text{CORRECT}(\hat{y})$ **then**
      $\tilde{y} = \text{EXTRACTBEST}(Agenda_G)$
      $\Delta_{acc} = \Delta_{acc} + \Phi(\hat{y}) - \Phi(\tilde{y})$
      $loss_{acc} = loss_{acc} + \text{LOSS}(\hat{y})$
    if $\Delta_{acc} \neq \overrightarrow{0}$ **then**
      update w.r.t. Δ_{acc} and $loss_{acc}$

the end of a document, an update is made with respect to the sum of all Δ's. Similarly, a running sum of the partial loss is maintained within a document. Since the PA update only depends on the distance vector Δ and the loss, it can be applied with respect to these sums at the end of the document. When only local features are used, this update is equivalent to the updates in the baseline learning algorithm. This follows because greedy search finds the optimal tree when only local features are used. Similarly, using only local features, the beam-based best-first decoder will also return the optimal tree. Algorithm 3 shows the pseudocode for the delayed LaSO learning algorithm.

6 Features

In this section we briefly outline the type of features we use. The feature sets are customized for each language. As a baseline we use the features from Björkelund and Farkas (2012), who ranked second in the 2012 CoNLL shared task and is publicly available. The exact definitions and feature sets that we use are available as part of the download package of our system.

6.1 Local features

Basic features that can be extracted on one or both mentions in a pair include (among others): **Mention type**, which is either root, pronoun, name, or common; **Distance** features, e.g., the distance in sentences or mentions; **Rule-based** features, e.g., StringMatch or SubStringMatch; **Syntax-based** features, e.g., category labels or paths in the syntax tree; **Lexical** features, e.g., the head word of a mention or the last word of a mention.

In order to have a strong local baseline, we applied greedy forward/backward feature selection on the training data using a large set of local feature templates. Specifically, the training set of each language was split into two parts where 75% was used for training, and 25% for testing. Feature templates were incrementally added or removed in order to optimize the mean of MUC, B^3, and $CEAF_e$ (i.e., the CoNLL average).

6.2 Non-local Features

We experimented with non-local features drawn from previous work on entity-mention models (Luo et al., 2004; Rahman and Ng, 2009), however they did not improve performance in preliminary experiments. The one exception is the size of a cluster (Culotta et al., 2007). Additional features we use are

Shape encodes the linear "shape" of a cluster in terms of mention type. For instance, the clusters representing *Gary Wilber* and *Drug Emporium Inc.* from the example in Figure 1, would be represented as RNPN and RNCCC, respectively. Where R, N, P, and C denote the root node, names, pronouns, and common noun phrases, respectively.

Local syntactic context is inspired by the Entity Grid (Barzilay and Lapata, 2008), where the basic assumption is that references to an entity follow particular syntactic patterns. For instance, an entity may be introduced as an object in one sentence, whereas in subsequent sentences it is referred to in subject position. Grammatical functions are approximated by the path in the syntax tree from a mention to its closest S node. The partial paths of a mention and its linear predecessor, given the cluster of the current antecedent, informs the model about the local syntactic context.

Cluster start distance denotes the distance in mentions from the beginning of the document where the cluster of the antecedent in consideration begins.

Additionally, the non-local model also has access to the basic properties of other mentions in the partial tree structure, such as head words. The

non-local features were selected with the same greedy forward strategy as the local features, starting from the optimized local feature sets.

7 Experimental Setup

We apply our model to the CoNLL 2012 Shared Task data, which includes a training, development, and test set split for three languages: Arabic, Chinese and English. We follow the *closed track* setting where systems may only be trained on the provided training data, with the exception of the English gender and number data compiled by Bergsma and Lin (2006). We use automatically extracted mentions using the same mention extraction procedure as Björkelund and Farkas (2012).

We evaluate our system using the CoNLL 2012 scorer, which computes several coreference metrics: MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), and $CEAF_e$ and $CEAF_m$ (Luo, 2005). We also report the CoNLL average (also known as MELA; Denis and Baldridge (2009)), i.e., the arithmetic mean of MUC, B^3, and $CEAF_e$. It should be noted that for B^3 and the CEAF metrics, multiple ways of handling *twinless mentions*[7] have been proposed (Rahman and Ng, 2009; Stoyanov et al., 2009). We use the most recent version of the CoNLL scorer (version 7), which implements the original definitions of these metrics.[8]

Our system is evaluated on the version of the data with automatic preprocessing information (e.g., predicted parse trees). Unless otherwise stated we use 25 iterations of perceptron training and a beam size of 20. We did not attempt to tune either of these parameters. We experiment with two feature sets for each language: the optimized local feature sets (denoted *local*), and the optimized local feature sets extended with non-local features (denoted *non-local*).

8 Results

Learning strategies. We begin by looking at the different learning strategies. Since early updates do not always make use of the complete documents during training, it can be expected that it will require either a very wide beam or more iterations to get up to par with the baseline learning algorithm. Figure 3 shows the CoNLL average on the English development set as a function of number of training iterations with two different beam sizes, 20 and 100, over the local and non-local feature sets. The figure shows that even after 50 iterations, early update falls short of the baseline, even when the early update system has access to more informative non-local features.[9]

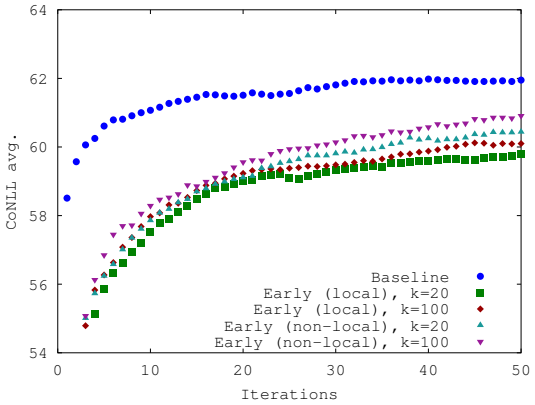

Figure 3: Comparing early update training with the baseline training algorithm.

In Figure 4 we compare early update with LaSO and delayed LaSO on the English development set. The left half uses the local feature set, and the right the extended non-local feature set. Recall that with only local features, delayed LaSO is equivalent to the baseline learning algorithm. As before, early update is considerably worse than other learning strategies. We also see that delayed LaSO outperforms LaSO, both with and without non-local features. Note that plain LaSO with non-local features only barely outperforms the delayed LaSO with only local features (i.e., the baseline), which indicates that only delayed LaSO is able to fully leverage non-local features. From these results we conclude that we are better off when the learning algorithm handles one document at a time, instead of getting feedback within documents.

Local vs. Non-local feature sets. Table 1 displays the differences in F-measures and CoNLL average between the local and non-local systems when applied to the development sets for each language. All metrics improve when more informative non-local features are added to the local feature set. Arabic and English show considerable improvements, and the CoNLL average increases

[7] i.e., mentions that appear in the prediction but not in gold, or the other way around

[8] Available at `http://conll.cemantix.org/2012/software.html`

[9] Although the Early systems still seem to show slight increases after 50 iterations, it needs a considerable number of iterations to catch up with the baseline – after 100 iterations the best early system is still more than half a point behind the baseline.

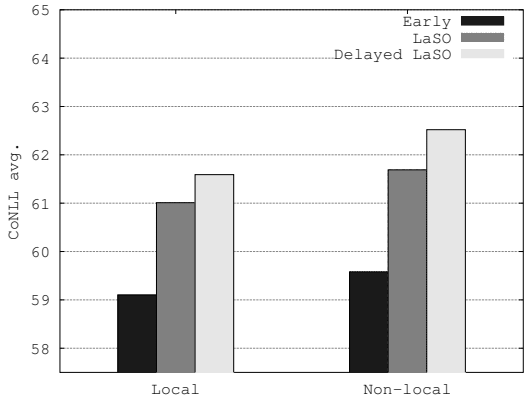

Figure 4: Comparison of learning algorithms evaluated on the English development set.

	MUC	B^3	$CEAF_m$	$CEAF_e$	CoNLL
Arabic					
local	47.33	42.51	49.71	46.49	45.44
non-local	49.31	43.52	50.96	47.18	46.67
Chinese					
local	65.84	57.94	62.23	57.05	60.27
non-local	66.4	57.99	62.37	57.12	60.5
English					
local	69.95	58.7	62.91	56.03	61.56
non-local	70.74	60.03	65.01	56.8	62.52

Table 1: Comparison of local and non-local feature sets on the development sets.

about one point. For Chinese the gains are generally not as pronounced, though the MUC metric goes up by more than half a point.

Final results. In Table 2 we compare the results of the non-local system (*This paper*) to the best results from the CoNLL 2012 Shared Task.[10] Specifically, this includes Fernandes et al.'s (2012) system for Arabic and English (denoted Fernandes), and Chen and Ng's (2012) system for Chinese (denoted C&N). For English we also compare it to the Berkeley system (Durrett and Klein, 2013), which, to our knowledge, is the best publicly available system for English coreference resolution (denoted D&K). As a general baseline, we also include Björkelund and Farkas' (2012) system (denoted B&F), which was the second best system in the shared task. For almost all metrics our system is significantly better than the best competitor. For a few metrics the best competitor outperforms our results for either precision or recall, but in terms of F-measures and the CoNLL average our system is the best for all languages.

[10]Thanks to Sameer Pradhan for providing us with the outputs of the other systems for significance testing.

9 Related Work

On the machine learning side Collins and Roark's (2004) work on the early update constitutes our starting point. The LaSO framework was introduced by Daumé III and Marcu (2005b), but has, to our knowledge, only been applied to the related task of entity detection and tracking (Daumé III and Marcu, 2005a). The theoretical motivation for early updates was only recently explained rigorously (Huang et al., 2012). The delayed LaSO update that we propose decomposes the prediction task of a complex structure into a number of subproblems, each of which guarantee *violation*, using Huang et al.'s (2012) terminology. We believe this is an interesting novelty, as it leverages the complete structures for every training instance during every iteration, and expect it to be applicable also to other structured prediction tasks.

Our approach also resembles imitation learning techniques such as SEARN (Daumé III et al., 2009) and DAGGER (Ross et al., 2011), where the search problem is reduced to a sequence of classification steps that guide the search algorithm through the search space. These frameworks, however, rely on the notion of an *expert policy* which provides an optimal decision at each point during search. In our context that would require antecedents for every mention to be given a priori, rather than using latent antecedents as we do.

Perceptrons for coreference. The perceptron has previously been used to train coreference resolvers either by casting the problem as a binary classification problem that considers pairs of mentions in isolation (Bengtson and Roth, 2008; Stoyanov et al., 2009; Chang et al., 2012, *inter alia*) or in the structured manner, where a clustering for an entire document is predicted in one go (Fernandes et al., 2012). However, none of these works use non-local features. Stoyanov and Eisner (2012) train an Easy-First coreference system with the perceptron to learn a sequence of join operations between arbitrary mentions in a document and accesses non-local features through previous merge operations in later stages. Culotta et al. (2007) also apply online learning in a first-order logic framework that enables non-local features, though using a greedy search algorithm.

Latent antecedents. The use of latent antecedents goes back to the work of Yu and Joachims (2009), although the idea of determining

Table 2: Comparison with other systems on the test sets. Bold numbers indicate significance at the $p < 0.05$ level between the best and the second best systems (according to the CoNLL average) using a Wilcoxon signed rank sum test. We refrain from significance tests on the CoNLL average, as it is an average over other F-measures.

meaningful antecedents for mentions can be traced back to Ng and Cardie (2002) who used a rule-based approach. Latent antecedents have recently gained popularity and were used by two systems in the CoNLL 2012 Shared Task, including the winning system (Fernandes et al., 2012; Chang et al., 2012). Durrett and Klein (2013) present a coreference resolver with latent antecedents that predicts clusterings over entire documents and fit a log-linear model with a custom task-specific loss function using AdaGrad (Duchi et al., 2011). Chang et al. (2013) use a max-margin approach to learn a pairwise model and rely on stochastic gradient descent to circumvent the costly operation of decoding the entire training set in order to compute the gradients and the latent antecedents. None of the aforementioned works use non-local features in their models, however.

Entity-mention models. Entity-mention models that compare a single mention to a (partial) cluster have been studied extensively and several works have evaluated non-local entity-level features (Luo et al., 2004; Yang et al., 2008; Rahman and Ng, 2009). Luo et al. (2004) also apply beam search at test time, but use a static assignment of antecedents and learns log-linear model using batch learning. Moreover, these works alter the basic feature definitions from their pairwise models when introducing entity-level features. This contrasts with our work, as our mention-pair model simply constitutes a special case of the non-local system.

10 Conclusion

We presented experiments with a coreference resolver that leverages non-local features to improve its performance. The application of non-local features requires the use of an approximate search algorithm to keep the problem tractable. We evaluated standard perceptron learning techniques for this setting both using early updates and LaSO. We found that the early update strategy is considerably worse than a local baseline, as it is unable to exploit all training data. LaSO resolves this issue by giving feedback within documents, but still underperforms compared to the baseline as it distorts the choice of latent antecedents.

We introduced a modification to LaSO, where updates are delayed until each document is processed. In the special case where only local features are used, this method coincides with standard structured perceptron learning that uses exact search. Moreover, it is also able to profit from non-local features resulting in improved performance. We evaluated our system on all three languages from the CoNLL 2012 Shared Task and present the best results to date on these data sets.

Abstract

We present a novel technique for learning semantic representations, which extends the distributional hypothesis to multilingual data and joint-space embeddings. Our models leverage parallel data and learn to strongly align the embeddings of semantically equivalent sentences, while maintaining sufficient distance between those of dissimilar sentences. The models do not rely on word alignments or any syntactic information and are successfully applied to a number of diverse languages. We extend our approach to learn semantic representations at the document level, too. We evaluate these models on two cross-lingual document classification tasks, outperforming the prior state of the art. Through qualitative analysis and the study of pivoting effects we demonstrate that our representations are semantically plausible and can capture semantic relationships across languages without parallel data.

1 Introduction

Distributed representations of words provide the basis for many state-of-the-art approaches to various problems in natural language processing today. Such word embeddings are naturally richer representations than those of symbolic or discrete models, and have been shown to be able to capture both syntactic and semantic information. Successful applications of such models include language modelling (Bengio et al., 2003), paraphrase detection (Erk and Padó, 2008), and dialogue analysis (Kalchbrenner and Blunsom, 2013).

Within a monolingual context, the distributional hypothesis (Firth, 1957) forms the basis of most approaches for learning word representations. In this work, we extend this hypothesis to multilingual data and joint-space embeddings. We present a novel unsupervised technique for learning semantic representations that leverages parallel corpora and employs semantic transfer through compositional representations. Unlike most methods for learning word representations, which are restricted to a single language, our approach learns to represent meaning across languages in a shared multilingual semantic space.

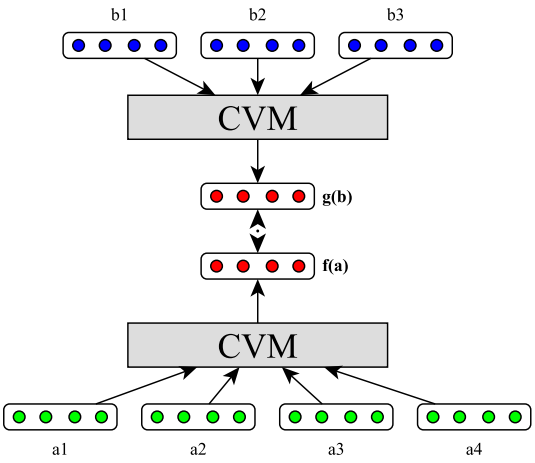

Figure 1: Model with parallel input sentences a and b. The model minimises the distance between the sentence level encoding of the bitext. Any composition functions (CVM) can be used to generate the compositional sentence level representations.

We present experiments on two corpora. First, we show that for cross-lingual document classification on the Reuters RCV1/RCV2 corpora (Lewis et al., 2004), we outperform the prior state of the art (Klementiev et al., 2012). Second, we also present classification results on a massively multilingual corpus which we derive from the TED corpus (Cettolo et al., 2012). The results on this task, in comparison with a number of strong baselines, further demonstrate the relevance of our approach and the success of our method in learning multilingual semantic representations over a wide range of languages.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 58–68,
Baltimore, Maryland, USA, June 23-25 2014.

2 Overview

Distributed representation learning describes the task of learning continuous representations for discrete objects. Here, we focus on learning semantic representations and investigate how the use of multilingual data can improve learning such representations at the word and higher level. We present a model that learns to represent each word in a lexicon by a continuous vector in $\mathbb{R}^d$. Such distributed representations allow a model to share meaning between similar words, and have been used to capture semantic, syntactic and morphological content (Collobert and Weston, 2008; Turian et al., 2010, *inter alia*).

We describe a multilingual objective function that uses a noise-contrastive update between semantic representations of different languages to learn these word embeddings. As part of this, we use a compositional vector model (CVM, henceforth) to compute semantic representations of sentences and documents. A CVM learns semantic representations of larger syntactic units given the semantic representations of their constituents (Clark and Pulman, 2007; Mitchell and Lapata, 2008; Baroni and Zamparelli, 2010; Grefenstette and Sadrzadeh, 2011; Socher et al., 2012; Hermann and Blunsom, 2013, *inter alia*).

A key difference between our approach and those listed above is that we only require sentence-aligned parallel data in our otherwise unsupervised learning function. This removes a number of constraints that normally come with CVM models, such as the need for syntactic parse trees, word alignment or annotated data as a training signal. At the same time, by using multiple CVMs to transfer information between languages, we enable our models to capture a broader semantic context than would otherwise be possible.

The idea of extracting semantics from multilingual data stems from prior work in the field of semantic grounding. Language acquisition in humans is widely seen as grounded in sensory-motor experience (Bloom, 2001; Roy, 2003). Based on this idea, there have been some attempts at using multi-modal data for learning better vector representations of words (e.g. Srivastava and Salakhutdinov (2012)). Such methods, however, are not easily scalable across languages or to large amounts of data for which no secondary or tertiary representation might exist.

Parallel data in multiple languages provides an alternative to such secondary representations, as parallel texts share their semantics, and thus one language can be used to ground the other. Some work has exploited this idea for transferring linguistic knowledge into low-resource languages or to learn distributed representations at the word level (Klementiev et al., 2012; Zou et al., 2013; Lauly et al., 2013, *inter alia*). So far almost all of this work has been focused on learning multilingual representations at the word level. As distributed representations of larger expressions have been shown to be highly useful for a number of tasks, it seems to be a natural next step to attempt to induce these, too, cross-lingually.

3 Approach

Most prior work on learning compositional semantic representations employs parse trees on their training data to structure their composition functions (Socher et al., 2012; Hermann and Blunsom, 2013, *inter alia*). Further, these approaches typically depend on specific *semantic* signals such as sentiment- or topic-labels for their objective functions. While these methods have been shown to work in some cases, the need for parse trees and annotated data limits such approaches to resource-fortunate languages. Our novel method for learning compositional vectors removes these requirements, and as such can more easily be applied to low-resource languages.

Specifically, we attempt to learn semantics from multilingual data. The idea is that, given enough parallel data, a shared representation of two parallel sentences would be forced to capture the common elements between these two sentences. What parallel sentences share, of course, are their semantics. Naturally, different languages express meaning in different ways. We utilise this diversity to abstract further from mono-lingual surface realisations to deeper semantic representations. We exploit this semantic similarity across languages by defining a bilingual (and trivially multilingual) energy as follows.

Assume two functions $f : X \to \mathbb{R}^d$ and $g : Y \to \mathbb{R}^d$, which map sentences from languages x and y onto distributed semantic representations in $\mathbb{R}^d$. Given a parallel corpus C, we then define the energy of the model given two sentences $(a, b) \in C$ as:

$$E_{bi}(a, b) = \|f(a) - g(b)\|^2 \qquad (1)$$

We want to minimize E_{bi} for all semantically equivalent sentences in the corpus. In order to prevent the model from degenerating, we further introduce a noise-constrastive large-margin update which ensures that the representations of non-aligned sentences observe a certain margin from each other. For every pair of parallel sentences (a, b) we sample a number of additional sentence pairs $(\cdot, n) \in C$, where n—with high probability—is not semantically equivalent to a. We use these noise samples as follows:

$$E_{hl}(a, b, n) = [m + E_{bi}(a, b) - E_{bi}(a, n)]_+$$

where $[x]_+ = max(x, 0)$ denotes the standard hinge loss and m is the margin. This results in the following objective function:

$$J(\theta) = \sum_{(a,b)\in\mathcal{C}} \left(\sum_{i=1}^{k} E_{hl}(a, b, n_i) + \frac{\lambda}{2}\|\theta\|^2 \right) \quad (2)$$

where θ is the set of all model variables.

3.1 Two Composition Models

The objective function in Equation 2 could be coupled with any two given vector composition functions f, g from the literature. As we aim to apply our approach to a wide range of languages, we focus on composition functions that do not require any syntactic information. We evaluate the following two composition functions.

The first model, ADD, represents a sentence by the sum of its word vectors. This is a distributed bag-of-words approach as sentence ordering is not taken into account by the model.

Second, the BI model is designed to capture bigram information, using a non-linearity over bigram pairs in its composition function:

$$f(x) = \sum_{i=1}^{n} \tanh\left(x_{i-1} + x_i\right) \quad (3)$$

The use of a non-linearity enables the model to learn interesting interactions between words in a document, which the bag-of-words approach of ADD is not capable of learning. We use the hyperbolic tangent as activation function.

3.2 Document-level Semantics

For a number of tasks, such as topic modelling, representations of objects beyond the sentence level are required. While most approaches to compositional distributed semantics end at the word level, our model extends to document-level learning quite naturally, by recursively applying the composition and objective function (Equation 2) to compose sentences into documents. This is achieved by first computing semantic representations for each sentence in a document. Next, these representations are used as inputs in a higher-level CVM, computing a semantic representation of a document (Figure 2).

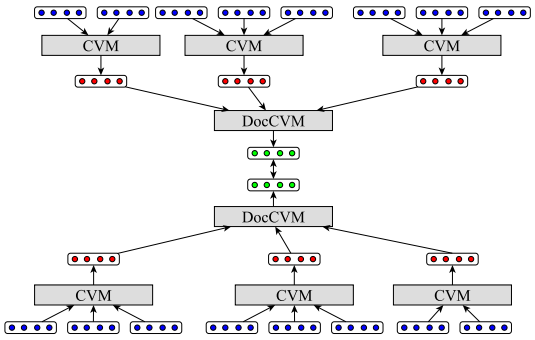

Figure 2: Description of a parallel document-level compositional vector model (DOC). The model recursively computes semantic representations for each sentence of a document and then for the document itself, treating the sentence vectors as inputs for a second CVM.

This recursive approach integrates document-level representations into the learning process. We can thus use corpora of parallel documents—regardless of whether they are sentence aligned or not—to propagate a semantic signal back to the individual words. If sentence alignment is available, of course, the document-signal can simply be combined with the sentence-signal, as we did with the experiments described in §5.3.

This concept of learning compositional representations for documents contrasts with prior work (Socher et al., 2011; Klementiev et al., 2012, *inter alia*) who rely on summing or averaging sentence-vectors if representations beyond the sentence-level are required for a particular task.

We evaluate the models presented in this paper both with and without the document-level signal. We refer to the individual models used as ADD and BI if used without, and as DOC/ADD and DOC/BI is used with the additional document composition function and error signal.

4 Corpora

We use two corpora for learning semantic representations and performing the experiments described in this paper.

The Europarl corpus v7[1] (Koehn, 2005) was used during initial development and testing of our approach, as well as to learn the representations used for the Cross-Lingual Document Classification task described in §5.2. We considered the English-German and English-French language pairs from this corpus. From each pair the final 100,000 sentences were reserved for development.

Second, we developed a massively multilingual corpus based on the TED corpus[2] for IWSLT 2013 (Cettolo et al., 2012). This corpus contains English transcriptions and multilingual, sentence-aligned translations of talks from the TED conference. While the corpus is aimed at machine translation tasks, we use the keywords associated with each talk to build a subsidiary corpus for multilingual document classification as follows.[3]

The development sections provided with the IWSLT 2013 corpus were again reserved for development. We removed approximately 10 percent of the training data in each language to create a test corpus (all talks with $id \geq 1{,}400$). The new training corpus consists of a total of 12,078 parallel documents distributed across 12 language pairs[4]. In total, this amounts to 1,678,219 non-English sentences (the number of unique English sentences is smaller as many documents are translated into multiple languages and thus appear repeatedly in the corpus). Each document (talk) contains one or several keywords. We used the 15 most frequent keywords for the topic classification experiments described in section §5.3.

Both corpora were pre-processed using the set of tools provided by cdec[5] for tokenizing and lowercasing the data. Further, all empty sentences and their translations were removed from the corpus.

5 Experiments

We report results on two experiments. First, we replicate the cross-lingual document classification task of Klementiev et al. (2012), learning distributed representations on the Europarl corpus and evaluating on documents from the Reuters RCV1/RCV2 corpora. Subsequently, we design a multi-label classification task using the TED corpus, both for training and evaluating. The use of a wider range of languages in the second experiments allows us to better evaluate our models' capabilities in learning a shared multilingual semantic representation. We also investigate the learned embeddings from a qualitative perspective in §5.4.

5.1 Learning

All model weights were randomly initialised using a Gaussian distribution (μ=0, σ^2=0.1). We used the available development data to set our model parameters. For each positive sample we used a number of noise samples ($k \in \{1, 10, 50\}$), randomly drawn from the corpus at each training epoch. All our embeddings have dimensionality d=128, with the margin set to m=d.[6] Further, we use L2 regularization with λ=1 and step-size in $\{0.01, 0.05\}$. We use 100 iterations for the RCV task, 500 for the TED single and 5 for the joint corpora. We use the adaptive gradient method, AdaGrad (Duchi et al., 2011), for updating the weights of our models, in a mini-batch setting ($b \in \{10, 50\}$). All settings, our model implementation and scripts to replicate our experiments are available at `http://www.karlmoritz.com/`.

5.2 RCV1/RCV2 Document Classification

We evaluate our models on the cross-lingual document classification (CLDC, henceforth) task first described in Klementiev et al. (2012). This task involves learning language independent embeddings which are then used for document classification across the English-German language pair. For this, CLDC employs a particular kind of supervision, namely using supervised training data in one language and evaluating without further supervision in another. Thus, CLDC can be used to establish whether our learned representations are semantically useful across multiple languages.

We follow the experimental setup described in Klementiev et al. (2012), with the exception that we learn our embeddings using solely the Europarl data and use the Reuters corpora only during for classifier training and testing. Each document in the classification task is represented by the average of the d-dimensional representations of all its sentences. We train the multiclass classifier using an averaged perceptron (Collins, 2002) with the same settings as in Klementiev et al. (2012).

[4] English to Arabic, German, French, Spanish, Italian, Dutch, Polish, Brazilian Portuguese, Romanian, Russian and Turkish. Chinese, Farsi and Slowenian were removed due to the small size of those datasets.

[5] `http://cdec-decoder.org/`

[6] On the RCV task we also report results for d=40 which matches the dimensionality of Klementiev et al. (2012).

Model	en → de	de → en
Majority Class	46.8	46.8
Glossed	65.1	68.6
MT	68.1	67.4
I-Matrix	77.6	71.1
$dim = 40$		
ADD	83.7	71.4
ADD+	86.2	76.9
BI	83.4	69.2
BI+	86.9	74.3
$dim = 128$		
ADD	86.4	74.7
ADD+	87.7	77.5
BI	86.1	79.0
BI+	**88.1**	**79.2**

Table 1: Classification accuracy for training on English and German with 1000 labeled examples on the RCV corpus. Cross-lingual compositional representations (ADD, BI and their multilingual extensions), I-Matrix (Klementiev et al., 2012) translated (MT) and glossed (Glossed) word baselines, and the majority class baseline. The baseline results are from Klementiev et al. (2012).

We present results from four models. The ADD model is trained on 500k sentence pairs of the English-German parallel section of the Europarl corpus. The ADD+ model uses an additional 500k parallel sentences from the English-French corpus, resulting in one million English sentences, each paired up with either a German or a French sentence, with BI and BI+ trained accordingly. The motivation behind ADD+ and BI+ is to investigate whether we can learn better embeddings by introducing additional data from other languages. A similar idea exists in machine translation where English is frequently used to pivot between other languages (Cohn and Lapata, 2007).

The actual CLDC experiments are performed by training on English and testing on German documents and vice versa. Following prior work, we use varying sizes between 100 and 10,000 documents when training the multiclass classifier. The results of this task across training sizes are in Figure 3. Table 1 shows the results for training on 1,000 documents compared with the results published in Klementiev et al. (2012). Our models outperform the prior state of the art, with the BI models performing slightly better than the ADD models. As the relative results indicate, the addition of a second language improves model performance. It it interesting to note that results improve in both directions of the task, even though no additional German data was used for the '+' models.

5.3 TED Corpus Experiments

Here we describe our experiments on the TED corpus, which enables us to scale up to multilingual learning. Consisting of a large number of relatively short and parallel documents, this corpus allows us to evaluate the performance of the DOC model described in §3.2.

We use the training data of the corpus to learn distributed representations across 12 languages. Training is performed in two settings. In the *single* mode, vectors are learnt from a single language pair (en-X), while in the *joint* mode vector-learning is performed on all parallel sub-corpora simultaneously. This setting causes words from all languages to be embedded in a single semantic space.

First, we evaluate the effect of the document-level error signal (DOC, described in §3.2), as well as whether our multilingual learning method can extend to a larger variety of languages. We train DOC models, using both ADD and BI as CVM (DOC/ADD, DOC/BI), both in the *single* and *joint* mode. For comparison, we also train ADD and DOC models without the document-level error signal. The resulting document-level representations are used to train classifiers (system and settings as in §5.2) for each language, which are then evaluated in the paired language. In the English case we train twelve individual classifiers, each using the training data of a single language pair only. As described in §4, we use 15 keywords for the classification task. Due to space limitations, we report cumulative results in the form of F1-scores throughout this paper.

MT System We develop a machine translation baseline as follows. We train a machine translation tool on the parallel training data, using the development data of each language pair to optimize the translation system. We use the cdec decoder (Dyer et al., 2010) with default settings for this purpose. With this system we translate the test data, and then use a Naïve Bayes classifier[7] for the actual experiments. To exemplify, this means the $de{\rightarrow}ar$ result is produced by training a translation system from Arabic to German. The Arabic test set is translated into German. A classifier is then trained

[7]We use the implementation in Mallet (McCallum, 2002)

Table 4: F1-scores on the TED corpus document classification task when training and evaluating on the same language. Baseline embeddings are Senna (Collobert et al., 2011) and Polyglot (Al-Rfou' et al., 2013).

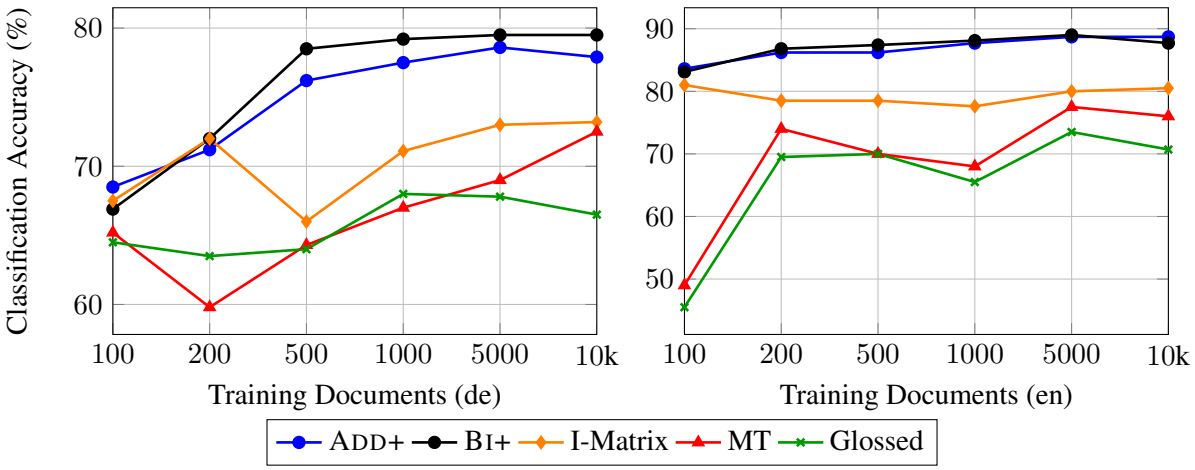

Figure 3: Classification accuracy for a number of models (see Table 1 for model descriptions). The left chart shows results for these models when trained on German data and evaluated on English data, the right chart vice versa.

on the German training data and evaluated on the translated Arabic. While we developed this system as a baseline, it must be noted that the classifier of this system has access to significantly more information (all words in the document) as opposed to our models (one embedding per document), and we do not expect to necessarily beat this system.

The results of this experiment are in Table 2. When comparing the results between the ADD model and the models trained using the document-level error signal, the benefit of this additional signal becomes clear. The *joint* training mode leads to a relative improvement when training on English data and evaluating in a second language. This suggests that the *joint* mode improves the quality of the English embeddings more than it affects the L2-embeddings. More surprising, perhaps, is the relative performance between the ADD and BI composition functions, especially when compared to the results in §5.2, where the BI models relatively consistently performed better. We suspect that the better performance of the additive composition function on this task is related to the smaller amount of training data available which could cause sparsity issues for the bigram model.

As expected, the MT system slightly outperforms our models on most language pairs. However, the overall performance of the models is comparable to that of the MT system. Considering the relative amount of information available during the classifier training phase, this indicates that our learned representations are semantically useful, capturing almost the same amount of information as available to the Naïve Bayes classifier.

We next investigate linguistic transfer across languages. We re-use the embeddings learned with the DOC/ADD *joint* model from the previous experiment for this purpose, and train classifiers on all non-English languages using those embeddings. Subsequently, we evaluate their performance in classifying documents in the remaining languages. Results for this task are in Table 3. While the results across language-pairs might not be very insightful, the overall good performance compared with the results in Table 2 implies that we learnt semantically meaningful vectors and in fact a joint embedding space across thirteen languages.

In a third evaluation (Table 4), we apply the embeddings learnt with out models to a monolingual classification task, enabling us to compare with prior work on distributed representation learning. In this experiment a classifier is trained in one language and then evaluated in the same. We again use a Naïve Bayes classifier on the raw data to establish a reasonable upper bound.

We compare our embeddings with the SENNA embeddings, which achieve state of the art performance on a number of tasks (Collobert et al., 2011). Additionally, we use the Polyglot embeddings of Al-Rfou' et al. (2013), who published word embeddings across 100 languages, including all languages considered in this paper. We represent each document by the mean of its word vectors and then apply the same classifier training and testing regime as with our models. Even though both of these sets of embeddings were trained on much larger datasets than ours, our models outperform these baselines on all languages—even outperforming the Naïve Bayes system on on several

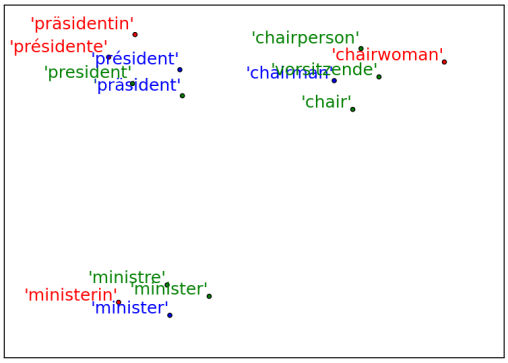

Figure 4: t-SNE projections for a number of English, French and German words as represented by the BI+ model. Even though the model did not use any parallel French-German data during training, it learns semantic similarity between these two languages using English as a pivot, and semantically clusters words across all languages.

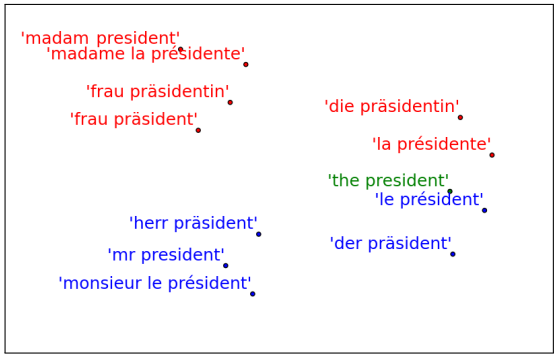

Figure 5: t-SNE projections for a number of short phrases in three languages as represented by the BI+ model. The projection demonstrates linguistic transfer through a pivot by. It separates phrases by gender (red for female, blue for male, and green for neutral) and aligns matching phrases across languages.

languages. While this may partly be attributed to the fact that our vectors were learned on in-domain data, this is still a very positive outcome.

5.4 Linguistic Analysis

While the classification experiments focused on establishing the semantic content of the sentence level representations, we also want to briefly investigate the induced word embeddings. We use the BI+ model trained on the Europarl corpus for this purpose. Figure 4 shows the t-SNE projections for a number of English, French and German words. Even though the model did not use any parallel French-German data during training, it still managed to learn semantic word-word similarity across these two languages.

Going one step further, Figure 5 shows t-SNE projections for a number of short phrases in these three languages. We use the English *the president* and gender-specific expressions *Mr President* and *Madam President* as well as gender-specific equivalents in French and German. The projection demonstrates a number of interesting results: First, the model correctly clusters the words into three groups, corresponding to the three English forms and their associated translations. Second, a separation between genders can be observed, with male forms on the bottom half of the chart and female forms on the top, with the neutral *the president* in the vertical middle. Finally, if we assume a horizontal line going through *the president*, this line could be interpreted as a "gender divide", with male and female versions of one expression mirroring each other on that line. In the case of *the president* and its translations, this effect becomes even clearer, with the neutral English expression being projected close to the mid-point between each other language's gender-specific versions.

These results further support our hypothesis that the bilingual contrastive error function can learn semantically plausible embeddings and furthermore, that it can abstract away from mono-lingual surface realisations into a shared semantic space across languages.

6 Related Work

Distributed Representations Distributed representations can be learned through a number of approaches. In their simplest form, distributional information from large corpora can be used to learn embeddings, where the words appearing within a certain window of the target word are used to compute that word's embedding. This is related to topic-modelling techniques such as LSA (Dumais et al., 1988), LSI, and LDA (Blei et al., 2003), but these methods use a document-level context, and tend to capture the topics a word is used in rather than its more immediate syntactic context.

Neural language models are another popular approach for inducing distributed word representations (Bengio et al., 2003). They have received a lot of attention in recent years (Collobert and Weston, 2008; Mnih and Hinton, 2009; Mikolov et al., 2010, *inter alia*) and have achieved state of the art performance in language modelling. Collobert et al. (2011) further popularised using neural network architectures for learning word embeddings from large amounts of largely unlabelled data by showing the embeddings can then be used to improve standard supervised tasks.

Unsupervised word representations can easily be plugged into a variety of NLP related tasks. Tasks, where the use of distributed representations has resulted in improvements include topic modelling (Blei et al., 2003) or named entity recognition (Turian et al., 2010; Collobert et al., 2011).

Compositional Vector Models For a number of important problems, semantic representations of individual words do not suffice, but instead a semantic representation of a larger structure—e.g. a phrase or a sentence—is required. Self-evidently, sparsity prevents the learning of such representations using the same collocational methods as applied to the word level. Most literature instead focuses on learning composition functions that represent the semantics of a larger structure as a function of the representations of its parts.

Very simple composition functions have been shown to suffice for tasks such as judging bigram semantic similarity (Mitchell and Lapata, 2008). More complex composition functions using matrix-vector composition, convolutional neural networks or tensor composition have proved useful in tasks such as sentiment analysis (Socher et al., 2011; Hermann and Blunsom, 2013), relational similarity (Turney, 2012) or dialogue analysis (Kalchbrenner and Blunsom, 2013).

Multilingual Representation Learning Most research on distributed representation induction has focused on single languages. English, with its large number of annotated resources, has enjoyed most attention. However, there exists a corpus of prior work on learning multilingual embeddings or on using parallel data to transfer linguistic information across languages. One has to differentiate between approaches such as Al-Rfou' et al. (2013), that learn embeddings across a large variety of languages and models such as ours, that learn joint embeddings, that is a projection into a shared semantic space across multiple languages.

Related to our work, Yih et al. (2011) proposed S2Nets to learn joint embeddings of tf-idf vectors for comparable documents. Their architecture optimises the cosine similarity of documents, using relative semantic similarity scores during learning. More recently, Lauly et al. (2013) proposed a bag-of-words autoencoder model, where the bag-of-words representation in one language is used to train the embeddings in another. By placing their vocabulary in a binary branching tree, the probabilistic setup of this model is similar to that of Mnih and Hinton (2009). Similarly, Sarath Chandar et al. (2013) train a cross-lingual encoder, where an autoencoder is used to recreate words in two languages in parallel. This is effectively the linguistic extension of Ngiam et al. (2011), who used a similar method for audio and video data. Hermann and Blunsom (2014) propose a large-margin learner for multilingual word representations, similar to the basic additive model proposed here, which, like the approaches above, relies on a bag-of-words model for sentence representations.

Klementiev et al. (2012), our baseline in §5.2, use a form of multi-agent learning on word-aligned parallel data to transfer embeddings from one language to another. Earlier work, Haghighi et al. (2008), proposed a method for inducing bilingual lexica using monolingual feature representations and a small initial lexicon to bootstrap with. This approach has recently been extended by Mikolov et al. (2013a), Mikolov et al. (2013b), who developed a method for learning transformation matrices to convert semantic vectors of one language into those of another. Is was demonstrated that this approach can be applied to improve tasks related to machine translation. Their CBOW model is also worth noting for its similarities to the ADD composition function used here. Using a slightly different approach, Zou et al. (2013), also learned bilingual embeddings for machine translation.

7 Conclusion

To summarize, we have presented a novel method for learning multilingual word embeddings using parallel data in conjunction with a multilingual objective function for compositional vector models. This approach extends the distributional hypothesis to multilingual joint-space representations. Coupled with very simple composition functions, vectors learned with this method outperform the state of the art on the task of cross-lingual document classification. Further experiments and analysis support our hypothesis that bilingual signals are a useful tool for learning distributed representations by enabling models to abstract away from mono-lingual surface realisations into a deeper semantic space.

Abstract

In this work, we revisit Shared Task 1 from the 2012 *SEM Conference: the automated analysis of negation. Unlike the vast majority of participating systems in 2012, our approach works over explicit and formal representations of propositional semantics, i.e. derives the notion of negation *scope* assumed in this task from the structure of logical-form meaning representations. We relate the task-specific interpretation of (negation) scope to the concept of (quantifier and operator) scope in mainstream underspecified semantics. With reference to an explicit encoding of semantic predicate-argument structure, we can operationalize the annotation decisions made for the 2012 *SEM task, and demonstrate how a comparatively simple system for negation scope resolution can be built from an off-the-shelf deep parsing system. In a system combination setting, our approach improves over the best published results on this task to date.

1 Introduction

Recently, there has been increased community interest in the theoretical and practical analysis of what Morante and Sporleder (2012) call *modality and negation*, i.e. linguistic expressions that modulate the certainty or factuality of propositions. Automated analysis of such aspects of meaning is important for natural language processing tasks which need to consider the truth value of statements, such as for example text mining (Vincze et al., 2008) or sentiment analysis (Lapponi et al., 2012). Owing to its immediate utility in the curation of scholarly results, the analysis of negation and so-called hedges in bio-medical research literature has been the focus of several workshops, as well as the Shared Task at the 2011 Conference on Computational Language Learning (CoNLL).

Task 1 at the First Joint Conference on Lexical and Computational Semantics (*SEM 2012; Morante and Blanco, 2012) provided a fresh, principled annotation of negation and called for systems to analyze negation—detecting cues (affixes, words, or phrases that express negation), resolving their scopes (which parts of a sentence are actually negated), and identifying the negated event or property. The task organizers designed and documented an annotation scheme (Morante and Daelemans, 2012) and applied it to a little more than 100,000 tokens of running text by the novelist Sir Arthur Conan Doyle. While the task and annotations were framed from a semantic perspective, only one participating system actually employed explicit compositional semantics (Basile et al., 2012), with results ranking in the middle of the 12 participating systems. Conversely, the best-performing systems approached the task through machine learning or heuristic processing over *syntactic* and linguistically relatively *coarse-grained* representations; see § 2 below.

Example (1), where ⟨⟩ marks the cue and {} the in-scope elements, illustrates the annotations, including how negation inside a noun phrase can scope over discontinuous parts of the sentence.[1]

(1) {The German} was sent for but professed to {know} ⟨nothing⟩ {of the matter}.

In this work, we return to the 2012 *SEM task from a deliberately semantics-centered point of view, focusing on the hardest of the three sub-problems: scope resolution.[2] Where Morante and Daelemans (2012) characterize negation as an "extra-propositional aspect of meaning" (p. 1563),

[1] Our running example is a truncated variant of an item from the Shared Task training data. The remainder of the original sentence does not form part of the scope of this cue.

[2] Resolving negation scope is a more difficult sub-problem at least in part because (unlike cue and event identification) it is concerned with much larger, non-local and often discontinuous parts of each utterance. This intuition is confirmed by Read et al. (2012), who report results for each sub-problem using gold-standard inputs; in this setup, scope resolution showed by far the lowest performance levels.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 69–78,
Baltimore, Maryland, USA, June 23-25 2014.

we in fact see it as a core piece of compositionally constructed logical-form representations. Though the task-specific concept of scope of negation is not the same as the notion of quantifier and operator scope in mainstream underspecified semantics, we nonetheless find that reviewing the 2012 *SEM Shared Task annotations with reference to an explicit encoding of semantic predicate-argument structure suggests a simple and straightforward operationalization of their concept of negation scope. Our system implements these findings through a notion of functor-argument 'crawling', using as our starting point the underspecified logical-form meaning representations provided by a general-purpose deep parser.

Our contributions are three-fold: Theoretically, we correlate the structures at play in the Morante and Daelemans (2012) view on negation with formal semantic analyses; methodologically, we demonstrate how to approach the task in terms of underspecified, logical-form semantics; and practically, our combined system retroactively 'wins' the 2012 *SEM Shared Task. In the following sections, we review related work (§ 2), detail our own setup (§ 3), and present and discuss our experimental results (§ 4 and § 5, respectively).

2 Related Work

Read et al. (2012) describe the best-performing submission to Task 1 of the 2012 *SEM Conference. They investigated two approaches for scope resolution, both of which were based on syntactic constituents. Firstly, they created a set of 11 heuristics that describe the path from the preterminal of a cue to the constituent whose projection is predicted to match the scope. Secondly they trained an SVM ranker over candidate constituents, generated by following the path from a cue to the root of the tree and describing each candidate in terms of syntactic properties along the path and various surface features. Both approaches attempted to handle discontinuous instances by applying two heuristics to the predicted scope: (a) removing preceding conjuncts from the scope when the cue is in a conjoined phrase and (b) removing sentential adverbs from the scope. The ranking approach showed a modest advantage over the heuristics (with F_1 equal to 77.9 and 76.7, respectively, when resolving the scope of gold-standard cues in evaluation data). Read et al. (2012) noted however that the annotated scopes did not align with the Shared Task–provided constituents for 14% of the instances in the training data, giving an F_1 upper-bound of around 86.0 for systems that depend on those constituents.

Basile et al. (2012) present the only submission to Task 1 of the 2012 *SEM Conference which employed compositional semantics. Their scope resolution pipeline consisted primarily of the C&C parser and Boxer (Curran et al., 2007), which produce Discourse Representation Structures (DRSs). The DRSs represent negation explicitly, including representing other predications as being within the scope of negation. Basile et al. (2012) describe some amount of tailoring of the Boxer lexicon to include more of the Shared Task scope cues among those that produce the negation operator in the DRSs, but otherwise the system appears to directly take the notion of scope of negation from the DRS and project it out to the string, with one caveat: As with the logical-forms representations we use, the DRS logical forms do not include function words as predicates in the semantics. Since the Shared Task gold standard annotations included such arguably semantically vacuous (see Bender, 2013, p. 107) words in the scope, further heuristics are needed to repair the string-based annotations coming from the DRS-based system. Basile et al. resort to counting any words between in-scope tokens which are not themselves cues as in-scope. This simple heuristic raises their F_1 for full scopes from 20.1 to 53.3 on system-predicted cues.

3 System Description

The new system described here is what we call the MRS Crawler. This system operates over the normalized semantic representations provided by the LinGO English Resource Grammar (ERG; Flickinger, 2000).[3] The ERG maps surface strings to meaning representations in the format of Minimal Recursion Semantics (MRS; Copestake et al., 2005). MRS makes explicit predicate-argument relations, as well as partial information about scope (see below). We used the grammar together with one of its pre-packaged conditional Maximum Entropy models for parse ranking, trained on a combination of encyclopedia articles and tourism brochures. Thus, the deep parsing front-end system to our MRS Crawler has not been

[3] In our experiments, we use the 1212 release of the ERG, in combination with the ACE parser (`http://sweaglesw.org/linguistics/ace/`). The ERG and ACE are DELPH-IN resources; see `http://www.delph-in.net`.

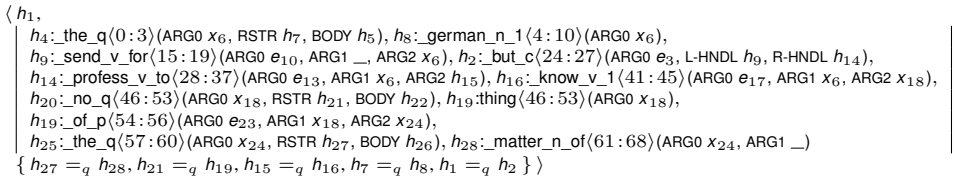

Figure 1: MRS analysis of our running example (1).

adapted to the task or its text type; it is applied in an 'off the shelf' setting. We combine our system with the outputs from the best-performing 2012 submission, the system of Read et al. (2012), firstly by relying on the latter for system negation cue detection,[4] and secondly as a fall-back in system combination as described in § 3.4 below.

Scopal information in MRS analyses delivered by the ERG fixes the scope of operators—such as negation, modals, scopal adverbs (including subordinating conjunctions like *while*), and clause-embedding verbs (e.g. *believe*)—based on their position in the constituent structure, while leaving the scope of quantifiers (e.g. *a* or *every*, but also other determiners) free. From these underspecified representations of possible scopal configurations, a scope resolution component can spell out the full range of fully-connected logical forms (Koller and Thater, 2005), but it turns out that such enumeration is not relevant here: the notion of scope encoded in the Shared Task annotations is not concerned with the relative scope of quantifiers and negation, such as the two possible readings of (2) represented informally below:[5]

(2) Everyone didn't leave.

a. $\forall(x)\neg\text{leave}(x) \sim$ Everyone stayed.

b. $\neg\forall(x)\text{leave}(x) \sim$ At least some stayed.

However, as shown below, the information about fixed scopal elements in an underspecified MRS is sufficient to model the Shared Task annotations.

3.1 MRS Crawling

Fig. 1 shows the ERG semantic analysis for our running example. The heart of the MRS is a multiset of elementary predications (EPs). Each elementary prediction includes a predicate symbol, a label (or 'handle', prefixed to predicates with a colon in Fig. 1), and one or more argument positions, whose values are semantic variables. Eventualities (e_i) in MRS denote states or activities, while instance variables (x_j) typically correspond to (referential or abstract) entities. All EPs have the argument position ARG0, called the *distinguished variable* (Oepen and Lønning, 2006), and no variable is the ARG0 of more than one non-quantifier EP.

The arguments of one EP are linked to the arguments of others either directly (sharing the same variable as their value), or indirectly (through so-called 'handle constraints', where $=_q$ in Fig. 1 denotes equality modulo quantifier insertion). Thus a well-formed MRS forms a connected graph. In addition, the grammar links the EPs to the elements of the surface string that give rise to them, via character offsets recorded in each EP (shown in angle brackets in Fig. 1). For the purposes of the present task, we take a negation cue as our entry point into the MRS graph (as our initial *active* EP), and then move through the graph according to the following simple operations to add EPs to the active set:

Argument Crawling Add to the scope all EPs whose distinguished variable or label is an argument of the active EP; for arguments of type h_k, treat any $=_q$ constraints as label equality.

Label Crawling Add all EPs whose label is identical to that of the active EP.

Functor Crawling Add all EPs that take the distinguished variable or label of the active EP as an argument (directly or via $=_q$ constraints).

Our MRS crawling algorithm is sketched in Fig. 2. To illustrate how the rules work, we will trace their operation in the analysis of example (1), i.e. traverse the EP graph in Fig. 1.

The negation cue is *nothing*, from character position 46 to 53. This leads us to _no_q as our entry point into the graph. Our algorithm states that for this type of cue (a quantifier) the first step is

[4] Read et al. (2012) predicted cues using a closed vocabulary assumption with a supervised classifier to disambiguate instances of cues.

[5] In other words, a possible semantic interpretation of the (string-based) Shared Task annotation guidelines and data is in terms of a quantifier-free approach to meaning representation, or in terms of one where quantifier scope need not be made explicit (as once suggested by, among others, Alshawi, 1992). From this interpretation, it follows that the notion of scope assumed in the Shared Task does not encompass interactions of negation operators and quantifiers.

1: Activate the cue EP
2: **if** the cue EP is a quantifier **then**
3: Activate EPs reached by functor crawling from the distinguished variable (ARG0) of the cue EP
4: **end if**
5: **repeat**
6: **for** each active EP X **do**
7: Activate EPs reached by argument crawling or label crawling unless they are co-modifiers of the negation cue.[a]
8: Activate EPs reached by functor crawling if they are modal verbs, or one of the following subordinating conjunctions reached by ARG1: *whether*, *when*, *because*, *to*, *with*, *although*, *unless*, *until*, or *as*.
9: **end for**
10: **until** a fixpoint is reached (no additional EPs were activated)
11: Deactivate zero-pronoun EPs (from imperative constructions)
12: Apply semantically empty word handling rules (iterate until a fixpoint is reached)
13: Apply punctuation heuristics

Figure 2: Algorithm for scope detection by MRS crawling

[a]Formally: If an EP shares its label with the negation cue, or is a quantifier whose restriction (RSTR) is $=_q$ equated with the label of the negation cue, it cannot be in-scope unless its ARG0 is an argument of the negation cue, or the ARG0 of the negation cue is one of its own arguments. See § 3.3 for elaboration.

functor crawling (see § 3.3 below), which brings _know_v_1 into the scope. We proceed with *argument crawling* and *label crawling*, which pick up _the_q⟨0:3⟩ and _german_n_1 as the ARG1. Further, as the ARG2 of _know_v_1, we reach thing and through recursive invocation we activate _of_p and, in yet another level of recursion, _the_q⟨57:60⟩ and _matter_n_of. At this point, crawling has no more links to follow. Thus, the MRS crawling operations 'paint' a subset of the MRS graph as in-scope for a given negation cue.

3.2 Semantically Empty Word Handling

Our crawling rules operate on semantic representations, but the annotations are with reference to the surface string. Accordingly, we need projection rules to map from the 'painted' MRS to the string. We can use the character offsets recorded in each EP to project the scope to the string. However, the string-based annotations also include words which the ERG treats as semantically vacuous. Thus in order to match the gold annotations, we define a set of heuristics for when to count vacuous words as in scope. In (1), there are no semantically empty words in-scope, so we illustrate these heuristics with another example:

(3) "I trust that {there is} ⟨nothing⟩ {of consequence which I have overlooked}?"

The MRS crawling operations discussed above paint the EPs corresponding to *is*, *thing*, *of*, *consequence*, *I*, and *overlooked* as in-scope (underlined in (3)). Conversely, the ERG treats the words *that*, *there*, *which*, and *have* as semantically empty. Of these, we need to add all except *that* to the scope. Our vacuous word handling rules use the syntactic structure provided by the ERG as scaffolding to help link the scope information gleaned from contentful words to vacuous words. Each node in the syntax tree is initially colored either in-scope or out-of-scope in agreement with the decision made by the crawler about the lexical head of the corresponding subtree. A semantically empty word is determined to be in-scope if there is an in-scope syntax tree node in the right position relative to it, as governed by a short list of templates organized by the type of the semantically empty word (particles, complementizers, non-referential pronouns, relative pronouns, and auxiliary verbs).

As an example, the rule for auxiliary verbs like *have* in our example (3) is that they are in scope when their verb phrase complement is in scope. Since *overlooked* is marked as in-scope by the crawler, the semantically empty *have* becomes in-scope as well. Sometimes the rules need to be iterated. For example, the main rule for relative pronouns is that they are in-scope when they fill a gap in an in-scope constituent; *which* fills a gap in the constituent *have overlooked*, but since *have* is the (syntactic) lexical head of that constituent, the verb phrase is not considered in-scope the first time the rules are tried.

Similar rules deal with *that* (complementizers are in-scope when the complement phrase is an argument of an in-scope verb, which is not the case here) and *there* (non-referential pronouns are in-scope when they are the subject of an in-scope VP, which is true here).

3.3 Re-Reading the Annotation Guidelines

Our MRS crawling algorithm was defined by looking at the annotated data rather than the annotation guidelines for the Shared Task (Morante et al., 2011). Nonetheless, our algorithm can be seen as a first pass formalization of the guidelines. In this section, we briefly sketch how our algorithm corresponds to different aspects of the guidelines.

For negated verbs, the guidelines state that "If the negated verb is the main verb in the sentence, the entire sentence is in scope." (Morante et al., 2011, 17). In terms of our operations defined over semantic representations, this is rendered as follows: all arguments of the negated verb are selected by *argument crawling*, all intersective modifiers by *label crawling*, and *functor crawling* (Fig. 2, line 8) captures modal auxiliaries and non-intersective modifiers. The guidelines treat predicative adjectives under a separate heading from verbs, but describe the same desired annotations (scope over the whole clause; ibid., p. 20). Since these structures are analogous in the semantic representations, the same operations that handle negated verbs also handle negated predicative adjectives correctly.

For negated subjects and objects, the guidelines state that the negation scopes over "all the clause" and "the clause headed by the verb" (Morante et al., 2011, 19), respectively. The examples given in the annotation guidelines suggest that these are in fact meant to refer to the same thing. The negation cue for a negated nominal argument will appear as a quantifier EP in the MRS, triggering line 3 of our algorithm. This *functor crawling* step will get to the verb's EP, and from there, the process is the same as the last two cases.

In contrast to subjects and objects, negation of a clausal argument is not treated as negation of the verb (ibid., p. 18). Since in this case, the negation cue will not be a quantifier in the MRS, there will be no *functor crawling* to the verb's EP.

For negated modifiers, the situation is somewhat more complex, and this is a case where our crawling algorithm, developed on the basis of the annotated data, does not align directly with the guidelines as given. The guidelines state that negated attributive adjectives have scope over the entire NP (including the determiner) (ibid., p. 20) and analogously negated adverbs have scope over the entire clause (ibid., p. 21). However, the annotations are not consistent, especially with respect to the treatment of negated adjectives: while the head noun and determiner (if present) are typically annotated as in scope, other co-modifiers, especially long, post-nominal modifiers (including relative clauses) are not necessarily included:

(4) "A dabbler in science, Mr. Holmes, a picker up of shells on the shores of {the} great ⟨un⟩{known ocean}.

(5) Our client looked down with a rueful face at {his} own ⟨un⟩{conventional appearance}.

(6) Here was {this} ⟨ir⟩{reproachable Englishman} ready to swear in any court of law that the accused was in the house all the time.

(7) {There is}, on the face of it, {something} ⟨un⟩{natural about this strange and sudden friendship between the young Spaniard and Scott Eccles}.

Furthermore, the guidelines treat relative clauses as subordinate clauses and thus negation inside a relative clause is treated as bound to that clause only, and includes neither the head noun of the relative clause nor any of its other dependents in its scope. However, from the perspective of MRS, a negated relative clause is indistinguishable from any other negated modifier of a noun. This treatment of relative clauses (as well as the inconsistencies in other forms of co-modification) is the reason for the exception noted at line 7 of Fig. 2. By disallowing the addition of EPs to the scope if they share the label of the negation cue but are not one of its arguments, we block the head noun's EP (and any EPs only reachable from it) in cases of relative clauses where the head verb inside the relative clause is negated. It also blocks co-modifiers like *great*, *own*, and the phrases headed by *ready* and *about* in (4)–(7). As illustrated in these examples, this is correct some but not all of the time. Having been unable to find a generalization capturing when comodifiers are annotated as in scope, we stuck with this approximation.

For negation within clausal modifiers of verbs, the annotation guidelines have further information, but again, our existing algorithm has the correct behavior: The guidelines state that a negation cue inside of the complement of a subordinating conjunction (e.g. *if*) has scope only over the subordinate clause (ibid., p. 18 and p. 26). The ERG treats all subordinating conjunctions as two-place predicates taking two scopal arguments. Thus, as with clausal complements of clause-embedding verbs, the embedding subordinating conjunction and any other arguments it might have are inaccessible, since functor crawling is restricted to a handful of specific configurations.

As is usually the case with exercises in formalization, our crawling algorithm generalizes beyond what is given explicitly in the annotation guidelines. For example, all arguments that are treated as semantically nominal (including PP arguments where the preposition is semantically null) are treated in the same way as subjects and objects; similarly, all arguments which are semantically clausal (including certain PP arguments) are handled the same way as clausal complements. This is possible because we take advantage of the high degree of normalization that the ERG accomplishes in mapping to the MRS representation.

There are also cases where we are more specific. The guidelines do not handle coordination in detail, except to state that in coordinated clauses negation is restricted to the clause it appears in (ibid., p. 17–18) and to include a few examples of coordination under the heading 'ellipsis'. In the case of VP coordination, our existing algorithm does not need any further elaboration to pick up the subject of the coordinated VP but not the non-negated conjunct, as shown in discussion of (1) in § 3.1 above. In the case of coordination of negated NPs, recall that to reach the main portion of the negated scope we must first apply functor crawling. The functor crawling procedure has a general mechanism to transparently continue crawling up through coordinated structures while blocking future crawling from traversing them again.[6]

On the other hand, there are some cases in the annotation guidelines which our algorithm does not yet handle. We have not yet provided any analysis of the special cases for *save* and *expect* discussed in Morante et al., 2011, pp. 22–23, and also do not have a means of picking out the overt verb in gapping constructions (p. 24).

Finally, we note that even carefully worked out annotation guidelines such as these are never followed perfectly consistently by the human annotators who apply them. Because our crawling algorithm so closely models the guidelines, this puts our system in an interesting position to provide feedback to the Shared Task organizers.

3.4 Fall-Back Configurations

The close match between our crawling algorithm and the annotation guidelines supported by the mapping to MRS provides for very high precision and recall when the analysis engine produces the desired MRS.[7] However, the analysis engine does not always provide the desired analysis, largely because of idiosyncrasies of the genre (e.g. vocatives appearing mid-sentence) that are either not handled by the grammar or not well modeled in the parse selection component. In addition, as noted above, there are a handful of negation cues we do not yet handle. Thus, we also tested fall-back configurations which use scope predictions based on MRS in some cases, and scope predictions from the system of Read et al. (2012) in others.

Our first fall-back configuration (Crawler$_N$ in Table 1) uses MRS-based predictions whenever there is a parse available and the cue is one that our system handles. Sometimes, the analysis picked by the ERG's statistical model is not the correct analysis for the given context. To combat such suboptimal parse selection performance, we investigated using the probability of the top ranked analysis (as determined by the parse selection model and conditioned on the sentence) as a confidence metric. Our second fall-back configuration (Crawler$_P$ in Table 1) uses MRS-based predictions when there is a parse available whose conditional probability is at least 0.5.[8]

4 Experiments

We evaluated the performance of our system using the Shared Task development and evaluation data (respectively CDD and CDE in Table 1). Since we do not attempt to perform cue detection, we report performance using gold cues and also using the system cues predicted by Read et al. (2012). We used the official Shared Task evaluation script to compute all scores.

4.1 Data Sets

The Shared Task data consists of chapters from the *Adventures of Sherlock Holmes* mystery novels and short stories. As such, the text is carefully edited turn-of-the-20th-century British English,[9]

[6] This allows *ate* to be reached in *We ate bread but no fish.*, while preventing *but* and *bread* from being reached, which they otherwise would via argument crawling from *ate*.

[7] And in fact, the task is somewhat noise-tolerant: some parse selection decisions are independent of each other, and a mistake in a part of the analysis far enough away from the negation cue does not harm performance.

[8] This threshold was determined empirically on the development data. We also experimented with other confidence metrics—the probability ratio of the top-ranked and second parse or the entropy over the probability distribution of the top 10 parses—but found no substantive differences.

[9] In contrast, the ERG was engineered for the analysis of contemporary American English, and an anecdotal analysis of parse failures and imperfect top-ranked parses suggests

		Gold Cues						System Cues					
		Scopes			Tokens			Scopes			Tokens		
Set	**Method**	**Prec**	**Rec**	**F_1**	**Prec**	**Rec**	**F_1**	**Prec**	**Rec**	**F_1**	**Prec**	**Rec**	**F_1**
CDD	Ranker	**100.0**	68.5	81.3	84.8	**86.8**	85.8	**91.7**	66.1	76.8	79.5	**84.9**	82.1

	Crawler	**100.0**	44.2	61.3	85.8	68.4	76.1	**87.8**	43.4	58.1	78.8	66.7	72.2
	Crawler$_N$	98.6	56.6	71.9	83.8	88.4	86.1	86.0	54.2	66.5	78.4	85.7	81.9
	Crawler$_P$	98.8	**65.5**	**78.7**	**86.1**	90.4	**88.2**	87.6	**62.7**	**73.1**	**82.6**	88.5	**85.4**
	Oracle	100.0	*70.3*	*82.6*	*89.5*	*93.1*	*91.3*						

Table 1: Scope resolution performance of various configurations over each subset of the Shared Task data. Ranker refers to the system of Read et al. (2012); Crawler refers to our current system in isolation, or falling back to the Ranker prediction either when the sentence is not covered by the parser (Crawler$_N$), or when the parse probability is predicted to be less than 0.5 (Crawler$_P$); finally, Oracle simulates best possible selection among the Ranker and Crawler predictions (and would be ill-defined on system cues).

annotated with token-level information about the cues and scopes in every negated sentence. The training set contains 848 negated sentences, the development set 144, and the evaluation set 235. As there can be multiple usages of negation in one sentence, this corresponds to 984, 173, and 264 instances, respectively.

Being rule-based, our system does not require any training data per se. However, the majority of our rule development and error analysis were performed against the designated training data. We used the designated development data for a single final round of error analysis and corrections. The system was declared frozen before running with the formal evaluation data. All numbers reported here reflect this frozen system.[10]

4.2 Results

Table 1 presents the results of our various configurations in terms of both (a) whole *scopes* (i.e. a true positive is only generated when the predicted scope matches the gold scope exactly) and (b) in-scope *tokens* (i.e. a true positive for every token the system correctly predicts to be in scope). The table also details the performance upper-bound for system combination, in which an oracle selects the system prediction which scores the greater token-wise F_1 for each gold cue.

The low recall levels for Crawler can be mostly attributed to imperfect parser coverage. Crawler$_N$, which falls back just for parse failure brings the recall back up, and results in F_1 levels closer to the system of Read et al. (2012), albeit still not quite advancing the state of the art (except over the development set). Our best results are from Crawler$_P$, which outperforms all other configurations on the development and evaluation sets.

The Oracle results are interesting because they show that there is much more to be gained in combining our semantics-based system with the Read et al. (2012) syntactically-focused system. Further analysis of these results to draw out the patterns of complementary errors and strengths is a promising avenue for future work.

4.3 Error Analysis

To shed more light on specific strengths and weaknesses of our approach, we performed a manual error analysis of scope predictions by Crawler, starting from gold cues so as to focus in-depth analysis on properties specific to scope resolution over MRSs. This analysis was performed on CDD, in order to not bar future work on this task. Of the 173 negation cue instances in CDD, Crawler by itself makes 94 scope predictions that exactly match the gold standard. In comparison, the system of Read et al. (2012) accomplishes 119 exact scope matches, of which 80 are shared with Crawler; in other words, there are 14 cue instances (or 8% of all cues) in which our approach can improve over the best-performing syntax-based submission to the original Shared Task.

that the archaic style in the 2012 *SEM Shared Task texts has a strong adverse effect on the parser.

[10]The code and data are available from `http://www.delph-in.net/crawler/`, for replicability (Fokkens et al., 2013).

We reviewed the 79 negation instances where Crawler made a wrong prediction in terms of exact scope match, categorizing the source of failure into five broad error types:

(1) Annotation Error In 11% of all instances, we consider the annotations erroneous or inconsistent. These judgments were made by two of the authors, who both were familiar with the annotation guidelines and conventions observable in the data. For example, Morante et al. (2011) unambiguously state that subordinating conjunctions shall not be in-scope (8), whereas relative pronouns should be (9), and a negated predicative argument to the copula must scope over the full clause (10):

(8) It was after nine this morning {when we} reached his house and {found} ⟨neither⟩ {you} ⟨nor⟩ {anyone else inside it}.

(9) "We can imagine that in the confusion of flight something precious, something which {he could} ⟨not⟩ {bear to part with}, had been left behind.

(10) He said little about the case, but from that little we gathered that he also was not ⟨dis⟩{satisfied} at the course of events.

(2) Parser Failure Close to 30% of Crawler failures reflect lacking coverage in the ERG parser, i.e. inputs for which the parser does not make available an analysis (within certain bounds on time and memory usage).[11] In this work, we have treated the ERG as an off-the-shelf system, but coverage could certainly be straightforwardly improved by adding analyses for phenomena particular to turn-of-the-20th-century British English.

(3) MRS Inadequacy Another 33% of our false scope predictions are Crawler-external, viz. owing to erroneous input MRSs due to imperfect disambiguation by the parser or other inadequacies in the parser output. Again, these judgments (assigning blame outside our own work) were double-checked by two authors, and we only counted MRS imperfections that actually involve the cue or in-scope elements. Here, we could anticipate improvements by training the parse ranker on in-domain data or otherwise adapting it to this task.

(4) Cue Selection In close to 9% of all cases, there is a valid MRS, but Crawler fails to pick out an initial EP that corresponds to the negation cue. This first type of genuine crawling failure often relates to cues expressed as affixation (11), as well as to rare usages of cue expressions that predominantly occur with different categories, e.g. *neither* as a generalized quantifier (12):

(11) Please arrange your thoughts and let me know, in their due sequence, exactly what those events are {which have sent you out} ⟨un⟩{brushed} and unkempt, with dress boots and waistcoat buttoned awry, in search of advice and assistance.

(12) You saw yourself {how} ⟨neither⟩ {of the inspectors dreamed of questioning his statement}, extraordinary as it was.

[11] Overall parsing coverage on this data is about 86%, but of course all parser failures on sentences containing negation surface in our error analysis of Crawler in isolation.

		Scopes			Tokens		
	Method	**Prec**	**Rec**	**F$_1$**	**Prec**	**Rec**	**F$_1$**
CDE	Boxer	76.1	41.0	53.3	69.2	82.3	75.2
	Crawler	87.8	43.4	58.1	78.8	66.7	72.2
	Crawler$_P$	87.6	62.7	73.1	82.6	88.5	85.4

Table 2: Comparison to Basile et al. (2012).

(5) Crawler Deficiency Finally, a little more than 16% of incorrect predictions we attribute to our crawling rules proper, where we see many instances of under-coverage of MRS elements (13, 14) and a few cases of extending the scope too wide (15). In the examples below, erroneous scope predictions by Crawler are indicated through underlining. Hardly any of the errors in this category, however, involve semantically vacuous tokens.

(13) He in turn had friends among the indoor servants who unite in {their} fear and ⟨dis⟩{like of their master}.

(14) He said little about the case, but from that little we gathered that {he also was} ⟨not⟩ {dissatisfied at the course of events}.

(15) I tell you, sir, {I could}n't move a finger, ⟨nor⟩ {get my breath}, till it whisked away and was gone.

5 Discussion and Comparison

The example in (1) nicely illustrates the strengths of the MRS Crawler and of the abstraction provided by the deep linguistic analysis made possible by the ERG. The negated verb in that sentence is *know*, and its first semantic argument is *The German*. This semantic dependency is directly and explicitly represented in the MRS, but the phrase expressing the dependent is not adjacent to the head in the string. Furthermore, even a system using syntactic structure to model scope would be faced with a more complicated task than our crawling rules: At the level of syntax the dependency is mediated by both verb phrase coordination and the control verb *profess*, as well as by the semantically empty infinitival marker *to*.

The system we propose is very similar in spirit to that of Basile et al. (2012). Both systems map from logical forms with explicit representations of scope of negation out to string-based annotations in the format provided by the Shared Task gold standard. The main points of difference are in the robustness of the system and in the degree of tailoring of both the rules for determining scope on the logical form level and the rules for handling semantically vacuous elements. The system description in Basile et al. (2012) suggests relatively little tailoring at either level: aside from adjustments to the Boxer lexicon to make more negation cues take the form of the negation operator in the DRS, the notion of scope is directly that given in the DRS. Similarly, their heuristic for picking up semantically vacuous words is string-based and straightforward. Our system, on the other hand, models the annotation guidelines more closely in the definition of the MRS crawling rules, and has more elaborated rules for handling semantically empty words. The Crawler alone is less robust than the Boxer-based system, returning no output for 29% of the cues in CDE. These factors all point to higher precision and lower recall for the Crawler compared to the Boxer-based system. At the token level, that is what we see. Since full-scope recall depends on token-level precision, the Crawler does better across the board at the full-scope level. A comparison of the results is shown in Table 2.

A final key difference between our results and those of Basile et al. (2012) is the cascading with a fall-back system. Presumably a similar system combination strategy could be pursued with the Boxer-based system in place of the Crawler.

6 Conclusion and Outlook

Our motivation in this work was to take the design of the 2012 *SEM Shared Task on negation analysis at face value—as an overtly *semantic* problem that takes a central role in our long-term pursuit of *language understanding*. Through both theoretical and practical reflection on the nature of representations at play in this task, we believe we have demonstrated that explicit semantic structure will be a key driver of further progress in the analysis of negation. We were able to closely align two independently developed semantic analyses—the negation-specific annotations of Morante et al. (2011), on the one hand, and the broad-coverage, MRS meaning representations of the ERG, on the other hand. In our view, the conceptual correlation between these two semantic views on negation analysis reinforces their credibility.

Unlike the rather complex top-performing systems from the original 2012 competition, our MRS Crawler is defined by a small set of general rules that operate over general-purpose, explicit meaning representations. Thus, our approach scores high on transparency, adaptability, and replicability. In isolation, the Crawler provides premium precision but comparatively low recall. Its limitations, we conjecture, reflect primarily on ERG parsing challenges and inconsistencies in the target data. In a sense, our approach pushes a larger proportion of the task into the parser, meaning (a) there should be good opportunities for parser adaptation to this somewhat idiosyncratic text type; (b) our results can serve to offer feedback on ERG semantic analyses and parse ranking; and (c) there is a much smaller proportion of very task-specific engineering. When embedded in a confidence-thresholded cascading architecture, our system advances the state of the art on this task, and oracle combination scores suggest there is much remaining room to better exploit the complementarity of approaches in our study. In future work, we will seek to better understand the division of labor between the systems involved through contrastive error analysis and possibly another oracle experiment, constructing gold-standard MRSs for part of the data. It would also be interesting to try a task-specific adaptation of the ERG parse ranking model, for example retraining on the pre-existing treebanks but giving preference to analyses that lead to correct Crawler results downstream.

Acknowledgments

We are grateful to Dan Flickinger, the main developer of the ERG, for many enlightening discussions and continuous assistance in working with the analyses available from the grammar. This work grew out of a discussion with colleagues of the Language Technology Group at the University of Oslo, notably Elisabeth Lien and Jan Tore Lønning, to whom we are indebted for stimulating cooperation. Furthermore, we have benefited from comments by participants of the 2013 DELPH-IN Summit, in particular Joshua Crowgey, Guy Emerson, Glenn Slayden, Sanghoun Song, and Rui Wang.

Logical Inference on Dependency-based Compositional Semantics

Ran Tian **Yusuke Miyao** **Takuya Matsuzaki**
National Institute of Informatics, Japan
{tianran,yusuke,takuya-matsuzaki}@nii.ac.jp

Abstract

Dependency-based Compositional Semantics (DCS) is a framework of natural language semantics with easy-to-process structures as well as strict semantics. In this paper, we equip the DCS framework with logical inference, by defining *abstract denotations* as an abstraction of the computing process of denotations in original DCS. An inference engine is built to achieve inference on abstract denotations. Furthermore, we propose a way to generate on-the-fly knowledge in logical inference, by combining our framework with the idea of tree transformation. Experiments on FraCaS and PASCAL RTE datasets show promising results.

1 Introduction

Dependency-based Compositional Semantics (DCS) provides an intuitive way to model semantics of questions, by using simple dependency-like trees (Liang et al., 2011). It is expressive enough to represent complex natural language queries on a relational database, yet simple enough to be latently learned from question-answer pairs. In this paper, we equip DCS with *logical inference*, which, in one point of view, is "the best way of testing an NLP system's semantic capacity" (Cooper et al., 1996).

It should be noted that, however, a framework primarily designed for question answering is not readily suited for logical inference. Because, answers returned by a query depend on the specific database, but implication is independent of any databases. For example, answers to the question "*What books are read by students?*", should always be a subset of answers to "*What books are ever read by anyone?*", no matter how we store the data of students and how many records of books are there in our database.

Thus, our first step is to fix a notation which abstracts the calculation process of DCS trees, so as to clarify its meaning without the aid of any existing database. The idea is to borrow a minimal set of operators from relational algebra (Codd, 1970), which is already able to formulate the calculation in DCS and define *abstract denotation*, which is an abstraction of the *computation* of denotations guided by DCS trees. Meanings of sentences then can be represented by primary relations among abstract denotations. This formulation keeps the simpleness and computability of DCS trees mostly unaffected; for example, our semantic calculation for DCS trees is parallel to the denotation computation in original DCS.

An inference engine is built to handle inference on abstract denotations. Moreover, to compensate the lack of background knowledge in practical inference, we combine our framework with the idea of tree transformation (Bar-Haim et al., 2007), to propose a way of generating knowledge in logical representation from entailment rules (Szpektor et al., 2007), which are by now typically considered as syntactic rewriting rules.

We test our system on FraCaS (Cooper et al., 1996) and PASCAL RTE datasets (Dagan et al., 2006). The experiments show: (i) a competitive performance on FraCaS dataset; (ii) a big impact of our automatically generated on-the-fly knowledge in achieving high recall for a logic-based RTE system; and (iii) a result that outperforms state-of-the-art RTE system on RTE5 data. Our whole system is publicly released and can be downloaded from `http://kmcs.nii.ac.jp/tianran/tifmo/`.

2 The Idea

In this section we describe the idea of representing natural language semantics by DCS trees, and achieving inference by computing logical relations among the corresponding abstract denotations.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 79–89,
Baltimore, Maryland, USA, June 23-25 2014.

2.1 DCS trees

DCS trees has been proposed to represent natural language semantics with a structure similar to dependency trees (Liang et al., 2011) (Figure 1). For the sentence "*students read books*", imagine a database consists of three tables, namely, a set of students, a set of books, and a set of "reading" events (Table 1). The DCS tree in Figure 1 is interpreted as a command for querying these tables, obtaining "reading" entries whose "SUBJ" field is **student** and whose "OBJ" field is **book**. The result is a set $\{$*John reads Ulysses*, ...$\}$, which is called a *denotation*.

DCS trees can be extended to represent linguistic phenomena such as quantification and coreference, with additional markers introducing additional operations on tables. Figure 2 shows an example with a quantifier "*every*", which is marked as "$\subset$" on the edge (**love**)OBJ−ARG(**dog**) and interpreted as a *division operator* $q_{\subset}^{\text{OBJ}}$ (§2.2). Optimistically, we believe DCS can provide a framework of semantic representation with sufficiently wide coverage for real-world texts.

The strict semantics of DCS trees brings us the idea of applying DCS to logical inference. This is not trivial, however, because DCS works under the assumption that databases are explicitly available. Obviously this is unrealistic for logical inference on unrestricted texts, because we cannot prepare a database for everything in the world. This fact fairly restricts the applicable tasks of DCS.

Our solution is to redefine DCS trees without the aid of any databases, by considering each node of a DCS tree as a content word in a sentence (but may no longer be a table in a specific database), while each edge represents semantic relations between two words. The labels on both ends of an edge, such as SUBJ (subject) and OBJ (object), are considered as *semantic roles* of the corresponding words[1]. To formulate the database querying process defined by a DCS tree, we provide formal semantics to DCS trees by employing *relational algebra* (Codd, 1970) for representing the query. As described below, we represent meanings of sentences with *abstract denotations*, and logical relations among sentences are computed as relations among their abstract denotations. In this way, we can perform inference over formulas of relational algebra, without computing database entries explicitly.

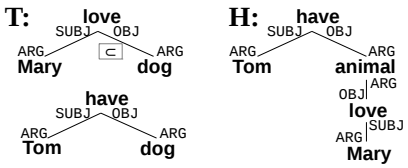

Figure 2: DCS trees of "*Mary loves every dog*" (Left-Up), "*Tom has a dog*" (Left-Down), and "*Tom has an animal that Mary loves*" (Right).

2.2 Abstract denotations

Abstract denotations are formulas constructed from a minimal set of relational algebra (Codd, 1970) operators, which is already able to formulate the database queries defined by DCS trees.

For example, the semantics of "*students read books*" is given by the abstract denotation:

$$F_1 = \textbf{read} \cap (\textbf{student}_{\text{SUBJ}} \times \textbf{book}_{\text{OBJ}}),$$

where **read**, **student** and **book** denote sets represented by these words respectively, and w_r represents the set w considered as the domain of the semantic role r (e.g. $\textbf{book}_{\text{OBJ}}$ is the set of books considered as objects). The operators $\cap$ and $\times$ represent intersection and Cartesian product respectively, both borrowed from relational algebra. It is not hard to see the abstract denotation denotes the intersection of the "*reading*" set (as illustrated by the "*read*" table in Table 1) with the product of "*student*" set and "*book*" set, which results in the same denotation as computed by the DCS tree in Figure 1, i.e. $\{$*John reads Ulysses*, ...$\}$. However, the point is that F_1 itself is an algebraic formula that does not depend on any concrete databases.

Formally, we introduce the following *constants*:

- W: a universal set containing all entities.

[1]The semantic role ARG is specifically defined for denoting nominal predicate.

	example phrase	abstract denotation / statement
compound noun	*pet fish*	**pet** $\cap$ **fish**
modification	*nice day*	**day** $\cap$ ($W_{\text{ARG}} \times$ **nice**$_{\text{MOD}}$)
temporal relation	*boys study at night*	**study** $\cap$ (**boy**$_{\text{SUBJ}} \times$ **night**$_{\text{TIME}}$)
relative clause	*books that students read*	**book** $\cap\, \pi_{\text{OBJ}}$(**read** $\cap$(**student**$_{\text{SUBJ}} \times W_{\text{OBJ}}$))
quantification	*all men die*	**man** $\subset\, \pi_{\text{SUBJ}}$(**die**)
hypernym		**dog** $\subset$ **animal**
derivation	*all criminals commit a crime*	**criminal** $\subset\, \pi_{\text{SUBJ}}$(**commit**$\cap$ ($W_{\text{SUBJ}} \times$ **crime**$_{\text{OBJ}}$))
antonym		**rise** $\|$ **fall**
negation	*no dogs are hurt*	**dog** $\|\, \pi_{\text{OBJ}}$(**hurt**)

Table 2: Abstract denotations and statements

- Content words: a content word (e.g. *read*) defines a set representing the word (e.g. **read** $= \{(x, y) \mid read(x, y)\}$).

In addition we introduce following *functions*:

- $\times$: the Cartesian product of two sets.
- $\cap$: the intersection of two sets.
- π_r: projection onto domain of semantic role r (e.g. $\pi_{\text{OBJ}}(\textbf{read}) = \{y \mid \exists x; read(x, y)\}$). Generally we admit projections onto multiple semantics roles, denoted by π_R where R is a set of semantic roles.
- ι_r: relabeling (e.g. $\iota_{\text{OBJ}}(\textbf{book}) = \textbf{book}_{\text{OBJ}}$).
- $q^r_{\subset}$: the division operator, where $q^r_{\subset}(A, B)$ is defined as the largest set X which satisfies $B_r \times X \subset A$.[2] This is used to formulate universal quantifiers, such as "*Mary loves every dog*" and "*books read by all students*".

An *abstract denotation* is then defined as finite applications of functions on either constants or other abstract denotations.

2.3 Statements

As the semantics of DCS trees is formulated by abstract denotations, the meanings of declarative sentences are represented by *statements* on abstract denotations. Statements are declarations of some relations among abstract denotations, for which we consider the following set relations:

Non-emptiness $A \neq \emptyset$: the set A is not empty.
Subsumption $A \subset B$: set A is subsumed by B.[3]

Roughly speaking, the relations correspond to the logical concepts *satisfiability* and *entailment*.

[2] If A and B has the same dimension, $q_{\subset}(A, B)$ is either $\emptyset$ or $\{*\}$ (0-dimension point set), depending on if $A \subset B$.

[3] Using division operator, subsumption can be represented by non-emptiness, since for sets A, B of the same dimension, $q_{\subset}(A, B) \neq \emptyset \Leftrightarrow A \subset B$.

Abstract denotations and statements are convenient for representing semantics of various types of expressions and linguistic knowledge. Some examples are shown in Table 2.[4]

2.4 Logical inference on DCS

Based on abstract denotations, we briefly describe our process to apply DCS to textual inference.

2.4.1 Natural language to DCS trees

To obtain DCS trees from natural language, we use Stanford CoreNLP[5] for dependency parsing (Socher et al., 2013), and convert Stanford dependencies to DCS trees by pattern matching on POS tags and dependency labels.[6] Currently we use the following semantic roles: `ARG`, `SUBJ`, `OBJ`, `IOBJ`, `TIME` and `MOD`. The semantic role `MOD` is used for any restrictive modifiers. Determiners such as "all", "every" and "each" trigger quantifiers, as shown in Figure 2.

2.4.2 DCS trees to statements

A DCS tree $\mathcal{T} = (\mathcal{N}, \mathcal{E})$ is defined as a rooted tree, where each node $\sigma \in \mathcal{N}$ is labeled with a content word $w(\sigma)$ and each edge $(\sigma, \sigma') \in \mathcal{E} \subset \mathcal{N} \times \mathcal{N}$ is labeled with a pair of semantic roles (r, r')[7]. Here σ is the node nearer to the root. Furthermore, for each edge (σ, σ') we can optionally assign a quantification marker.

Abstract denotation of a DCS tree can be calculated in a bottom-up manner. For example, the abstract denotation of **H** in Figure 2 is calculated from the leaf node **Mary**, and then:

Node **love** (*Mary loves*):
$F_2 = \textbf{love} \cap (\textbf{Mary}_{\text{SUBJ}} \times W_{\text{OBJ}})$
Node **animal** (*Animal that Mary loves*):
$F_3 = \textbf{animal} \cap \pi_{\text{OBJ}}(F_2)$
Node **have** (*Tom has an animal that Mary loves*):
$F_4 = \textbf{have} \cap (\textbf{Tom}_{\text{SUBJ}} \times (F_3)_{\text{OBJ}})$.

Formally, suppose the root σ of a DCS tree $\mathcal{T}$ has children $\tau_1, \ldots, \tau_n$, and edges $(\sigma, \tau_1), \ldots, (\sigma, \tau_n)$ labeled by $(r_1, r'_1), \ldots, (r_n, r'_n)$, respectively. The abstract denotation of $\mathcal{T}$ is defined as:

$$[\![\mathcal{T}]\!] = w(\sigma) \cap (\bigcap_{i=1}^{n} \iota_{r_i}(\pi_{r'_i}([\![\mathcal{T}_{\tau_i}]\!])) \times W_{R_\sigma \setminus r_i}),$$

[4] Negation and disjointness ("$\|$") are explained in §2.5.

[5] `http://nlp.stanford.edu/software/corenlp.shtml`

[6] In (Liang et al., 2011) DCS trees are learned from QA pairs and database entries. We obtain DCS trees from dependency trees, to bypass the need of a concrete database.

[7] The definition differs slightly from the original Liang et al. (2011), mainly for the sake of simplicity and clarity.

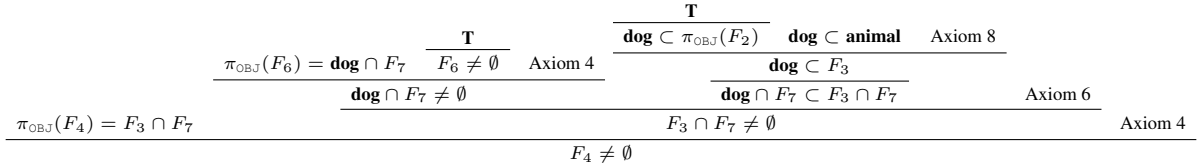

Figure 3: An example of proof using abstract denotations

1. $W \neq \emptyset$	5. $(A \subset B \;\&\; B \subset C) \Rightarrow A \subset C$
2. $A \cap B \subset A$	6. $(A \subset B \;\&\; A \neq \emptyset) \Rightarrow B \neq \emptyset$
3. $B_r \times q^r_{\subset}(A, B) \subset A$	7. $A \subset B \Rightarrow \pi_R(A) \subset \pi_R(B)$
4. $\pi_R(A) \neq \emptyset \Leftrightarrow A \neq \emptyset$	8. $(C \subset A \;\&\; C \subset B) \Rightarrow C \subset A \cap B$

Table 3: An excerpt of axioms

where $\mathcal{T}_{\tau_i}$ is the subtree of $\mathcal{T}$ rooted at τ_i, and R_σ is the set of possible semantic roles for content word $w(\sigma)$ (e.g. $R_{\textbf{love}} = \{\texttt{SUBJ}, \texttt{OBJ}\}$), and $W_{R_\sigma \setminus r_i}$ is the product of W which has dimension $R_\sigma \setminus r_i$ (e.g. $W_{\{\texttt{SUBJ},\texttt{OBJ}\}\setminus\texttt{SUBJ}} = W_{\texttt{OBJ}}$).

When universal quantifiers are involved, we need to add division operators to the formula. If (σ, τ_i) is assigned by a quantification marker "$\subset$"[8], then the abstract denotation is[9]

$$[\![\mathcal{T}]\!] = q^{r_i}_{\subset}(\pi_{R_\sigma \setminus \{r_1,\ldots,r_{i-1}\}}([\![\mathcal{T}']\!]), \pi_{r'_i}([\![\mathcal{T}_{\tau_i}]\!])),$$

where $\mathcal{T}'$ is the same tree as $\mathcal{T}$ except that the edge (σ, τ_i) is removed. For example, the abstract denotation of the first sentence of **T** in Figure 2 (*Mary loves every dog*) is calculated from F_2 (*Mary loves*) as

$$F_5 = q^{\texttt{OBJ}}_{\subset}(\pi_{\texttt{OBJ}}(F_2), \textbf{dog}).$$

After the abstract denotation $[\![\mathcal{T}]\!]$ is calculated, the statement representing the meaning of the sentence is defined as $[\![\mathcal{T}]\!] \neq \emptyset$. For example, the statement of "*students read books*" is $\textbf{read} \cap (\textbf{student}_{\texttt{SUBJ}} \times \textbf{book}_{\texttt{OBJ}}) \neq \emptyset$, and the statement of "*Mary loves every dog*" is $q^{\texttt{OBJ}}_{\subset}(\pi_{\texttt{OBJ}}(F_2), \textbf{dog}) \neq \emptyset$, which is logically equivalent to $\textbf{dog} \subset \pi_{\texttt{OBJ}}(F_2)$.[10]

2.4.3 Logical inference

Since meanings of sentences are represented by statements on abstract denotations, logical inference among sentences is reduced to deriving new relations among abstract denotations. This is done by applying axioms to known statements, and approximately 30 axioms are implemented (Table 3).

[8]Multiple quantifiers can be processed similarly.

[9]The result of $[\![\mathcal{T}]\!]$ depends on the order of the children $\tau_1, \ldots, \tau_n$. Different orders correspond to readings of different quantifier scopes.

[10]See Footnote 2,3.

These are algebraic properties of abstract denotations, among which we choose a set of axioms that can be handled efficiently and enable most common types of inference seen in natural language.

For the example in Figure 2, by constructing the following abstract denotations:

Tom has a dog:

$$F_6 = \textbf{have} \cap (\textbf{Tom}_{\texttt{SUBJ}} \times \textbf{dog}_{\texttt{OBJ}})$$

Objects *that Tom has*:

$$F_7 = \pi_{\texttt{OBJ}}(\textbf{have} \cap (\textbf{Tom}_{\texttt{SUBJ}} \times W_{\texttt{OBJ}})),$$

we can use the lexical knowledge $\textbf{dog} \subset \textbf{animal}$, the statements of **T** (i.e. $\textbf{dog} \subset \pi_{\texttt{OBJ}}(F_2)$ and $F_6 \neq \emptyset$), and the axioms in Table 3,[11] to prove the statement of **H** (i.e. $F_4 \neq \emptyset$) (Figure 3).

We built an inference engine to perform logical inference on abstract denotations as above. In this logical system, we treat abstract denotations as *terms* and statements as *atomic sentences*, which are far more easier to handle than first order predicate logic (FOL) formulas. Furthermore, all implemented axioms are horn clauses, hence we can employ forward-chaining, which is very efficient.

2.5 Extensions

Further extensions of our framework are made to deal with additional linguistic phenomena, as briefly explained below.

Negation To deal with negation in our forward-chaining inference engine, we introduce one more relation on abstract denotations, namely *disjointness* $A \parallel B$, meaning that A and B are disjoint sets. Using disjointness we implemented two types of negations: (i) atomic negation, for each content word w we allow negation $\bar{w}$ of that word, characterized by the property $w \parallel \bar{w}$; and (ii) root negation, for a DCS tree $\mathcal{T}$ and its denotation $[\![\mathcal{T}]\!]$, the negation of $\mathcal{T}$ is represented by $\mathcal{T} \parallel \mathcal{T}$, meaning that $\mathcal{T} = \emptyset$ in its effect.

Selection Selection operators in relational algebra select a subset from a set to satisfy some spe-

[11]Algebraic identities, such as $\pi_{\texttt{OBJ}}(F_4) = F_3 \cap F_7$ and $\pi_{\texttt{OBJ}}(F_6) = \textbf{dog} \cap F_7$, are also axioms.

cific properties. This can be employed to represent linguistic phenomena such as downward monotonicity and generalized quantifiers. In the current system, we implement (i) superlatives, e.g. $s_{highest}(\textbf{mountain} \cap (W_{\texttt{ARG}} \times \textbf{Asia}_{\texttt{MOD}}))$ (the highest mountain in Asia) and (ii) numerics, e.g. $s_{two}(\textbf{pet} \cap \textbf{fish})$ (two pet fish), where s_f is a selection marker. Selection operators are implemented as markers assigned to abstract denotations, with specially designed axioms. For example superlatives satisfy the following property: $A \subset B \ \& \ s_{highest}(B) \subset A \Rightarrow s_{highest}(B) = s_{highest}(A)$. New rules can be added if necessary.

Coreference We use Stanford CoreNLP to resolve coreferences (Raghunathan et al., 2010), whereas coreference is implemented as a special type of selection. If a node σ in a DCS tree $\mathcal{T}$ belongs to a mention cluster m, we take the abstract denotation $[\![\mathcal{T}_\sigma]\!]$ and make a selection $s_m([\![\mathcal{T}_\sigma]\!])$, which is regarded as the abstract denotation of that mention. Then all selections of the same mention cluster are declared to be equal.

3 Generating On-the-fly Knowledge

Recognizing textual entailment (RTE) is the task of determining whether a given textual statement **H** can be inferred by a text passage **T**. For this, our primary textual inference system operates as:

1. For a **T**-**H** pair, apply dependency parsing and coreference resolution.
2. Perform rule-based conversion from dependency parses to DCS trees, which are translated to statements on abstract denotations.
3. Use statements of **T** and linguistic knowledge as premises, and try to prove statements of **H** by our inference engine.

However, this method does not work for real-world datasets such as PASCAL RTE (Dagan et al., 2006), because of the knowledge bottleneck: it is often the case that the lack of sufficient linguistic knowledge causes failure of inference, thus the system outputs "no entailment" for almost all pairs (Bos and Markert, 2005).

The transparent syntax-to-semantics interface of DCS enables us to back off to NLP techniques during inference for catching up the lack of knowledge. We extract fragments of DCS trees as paraphrase candidates, translate them back to linguistic expressions, and apply distributional similarity to judge their validity. In this way, our framework combines distributional and logical semantics, which is also the main subject of Lewis and Steedman (2013) and Beltagy et al. (2013).

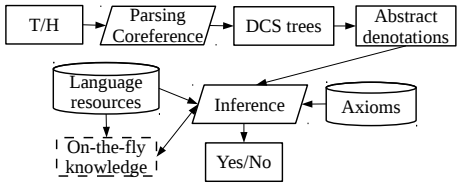

Figure 4: RTE system

As follows, our full system (Figure 4) additionally invokes linguistic knowledge on-the-fly:

4. If **H** is not proven, compare DCS trees of **T** and **H**, and generate path alignments.
5. Aligned paths are evaluated by a similarity score to estimate their likelihood of being paraphrases. Path alignments with scores higher than a threshold are accepted.
6. Convert accepted path alignments into statements on abstract denotations, use them in logical inference as new knowledge, and try to prove **H** again.

3.1 Generating path alignments

On-the-fly knowledge is generated by aligning paths in DCS trees. A path is considered as joining two *germs* in a DCS tree, where a *germ* is defined as a specific semantic role of a node. For example, Figure 5 shows DCS trees of the following sentences (a simplified pair from RTE2-dev):

T: *Tropical storm Debby is blamed for deaths.*
H: *A storm has caused loss of life.*

The germ $\texttt{OBJ}(\textbf{blame})$ and germ $\texttt{ARG}(\textbf{death})$ in DCS tree of **T** are joined by the underscored path. Two paths are aligned if the joined germs are aligned, and we impose constraints on aligned germs to inhibit meaningless alignments, as described below.

3.2 Aligning germs by logical clues

Two germs are aligned if they are both at leaf nodes (e.g. $\texttt{ARG}(\textbf{death})$ in **T** and $\texttt{ARG}(\textbf{life})$ in **H**, Figure 5), or they already have part of their meanings in common, by some logical clues.

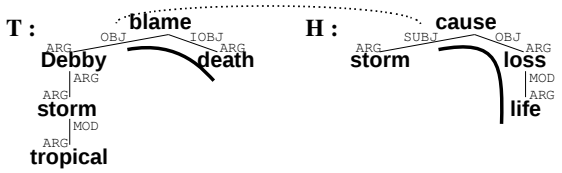

Figure 5: Aligned paths (underscored by the solid lines) and aligned germs (joined by the dotted line)

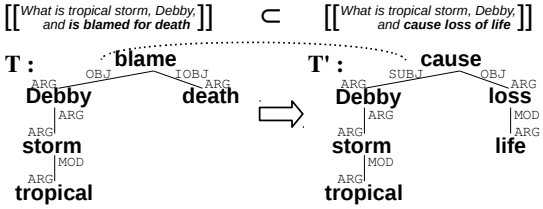

Figure 6: Tree transformation and generated on-the-fly knowledge (subsumption of denotations shown above the trees)

To formulate this properly, we define the abstract denotation of a germ, which, intuitively, represents the meaning of the germ in the specific sentence. The abstract denotation of a germ is defined in a top-down manner: for the root node ρ of a DCS tree $\mathcal{T}$, we define its denotation $[\![\rho]\!]_{\mathcal{T}}$ as the denotation of the entire tree $[\![\mathcal{T}]\!]$; for a non-root node τ and its parent node σ, let the edge (σ, τ) be labeled by semantic roles (r, r'), then define

$$[\![\tau]\!]_{\mathcal{T}} = [\![\mathcal{T}_\tau]\!] \cap (\iota_{r'}(\pi_r([\![\sigma]\!]_{\mathcal{T}})) \times W_{R_\tau \setminus r'}).$$

Now for a germ $r(\sigma)$, the denotation is defined as the projection of the denotation of node σ onto the specific semantic role r: $[\![r(\sigma)]\!]_{\mathcal{T}} = \pi_r([\![\sigma]\!]_{\mathcal{T}})$.

For example, the abstract denotation of germ ARG(**book**) in Figure 1 is defined as $\pi_{\texttt{ARG}}(\textbf{book} \cap \pi_{\texttt{OBJ}}(\textbf{read} \cap (\textbf{student}_{\texttt{SUBJ}} \times \textbf{book}_{\texttt{OBJ}})))$, meaning "*books read by students*". Similarly, denotation of germ OBJ(**blame**) in **T** of Figure 5 indicates the object of "*blame*" as in the sentence "*Tropical storm Debby is blamed for death*", which is a *tropical storm*, is *Debby*, etc. Technically, each germ in a DCS tree indicates a variable when the DCS tree is translated to a FOL formula, and the abstract denotation of the germ corresponds to the set of *consistent values* (Liang et al., 2011) of that variable.

The logical clue to align germs is: if there exists an abstract denotation, other than W, that is a superset of both abstract denotations of two germs, then the two germs can be aligned. A simple example is that ARG(**storm**) in **T** can be aligned to ARG(**storm**) in **H**, because their denotations have a common superset other than W, namely $\pi_{\texttt{ARG}}(\textbf{storm})$. A more complicated example is that OBJ(**blame**) and SUBJ(**cause**) can be aligned, because inference can induce $[\![\texttt{OBJ}(\textbf{blame})]\!]_{\mathbf{T}} = [\![\texttt{ARG}(\textbf{Debby})]\!]_{\mathbf{T}} = [\![\texttt{ARG}(\textbf{storm})]\!]_{\mathbf{T}}$, as well as $[\![\texttt{SUBJ}(\textbf{cause})]\!]_{\mathbf{H}} = [\![\texttt{ARG}(\textbf{storm})]\!]_{\mathbf{H}}$, so they also have the common superset $\pi_{\texttt{ARG}}(\textbf{storm})$. However, for example, logical clues can avoid aligning ARG(**storm**) to ARG(**loss**), which is obviously meaningless.

3.3 Scoring path alignments by similarity

Aligned paths are evaluated by a similarity score, for which we use distributional similarity of the words that appear in the paths (§4.1). Only path alignments with high similarity scores can be accepted. Also, we only accept paths of length ≤ 5, to prevent too long paths to be aligned.

3.4 Applying path alignments

Accepted aligned paths are converted into statements, which are used as new knowledge. The conversion is done by first performing a DCS tree transformation according to the aligned paths, and then declare a subsumption relation between the denotations of aligned germs. For example, to apply the aligned path pair generated in Figure 5, we use it to transform **T** into a new tree **T'** (Figure 6), and then the aligned germs, OBJ(**blame**) in **T** and SUBJ(**cause**) in **T'**, will generate the on-the-fly knowledge: $[\![\texttt{OBJ}(\textbf{blame})]\!]_{\mathbf{T}} \subset [\![\texttt{SUBJ}(\textbf{cause})]\!]_{\mathbf{T'}}$.

Similar to the tree transformation based approach to RTE (Bar-Haim et al., 2007), this process can also utilize lexical-syntactic entailment rules (Szpektor et al., 2007). Furthermore, since the on-the-fly knowledge is generated by transformed pairs of DCS trees, all contexts are preserved: in Figure 6, though the tree transformation can be seen as generated from the entailment rule "*X is blamed for death* → *X causes loss of life*", the generated on-the-fly knowledge, as shown above the trees, only fires with the additional condition that X is a *tropical storm* and is *Debby*. Hence, the process can also be used to generate knowledge from context sensitive rules (Melamud et al., 2013), which are known to have higher quality (Pantel et al., 2007; Clark and Harrison, 2009).

However, it should be noted that using on-the-fly knowledge in logical inference is not a trivial

task. For example, the FOL formula of the rule "*X is blamed for death → X causes loss of life*" is:

$$\forall x; (\exists a; blame(x, a) \ \& \ death(a)) \rightarrow \\ (\exists b, c; cause(x, b) \ \& \ loss(b, c) \ \& \ life(c)),$$

which is not a horn clause. The FOL formula for the context-preserved rule in Figure 6 is even more involved. Still, it can be efficiently treated by our inference engine because as a statement, the formula $[\![\texttt{OBJ}(\textbf{blame})]\!]_{\mathbf{T}} \subset [\![\texttt{SUBJ}(\textbf{cause})]\!]_{\mathbf{T}'}$ is an atomic sentence, more than a horn clause.

4 Experiments

In this section, we evaluate our system on FraCaS (§4.2) and PASCAL RTE datasets (§4.3).

4.1 Language Resources

The lexical knowledge we use are synonyms, hypernyms and antonyms extracted from WordNet[12]. We also add axioms on named entities, stopwords, numerics and superlatives. For example, named entities are singletons, so we add axioms such as $\forall x; (x \subset \textbf{Tom} \ \& \ x \neq \emptyset) \rightarrow \textbf{Tom} \subset x$.

To calculate the similarity scores of path alignments, we use the sum of word vectors of the words from each path, and calculate the cosine similarity. For example, the similarity score of the path alignment "OBJ(**blame**)IOBJ-ARG(**death**) ≈ SUBJ(**cause**)OBJ-ARG(**loss**)MOD-ARG(**life**)" is calculated as the cosine similarity of vectors **blame+death** and **cause+loss+life**. Other structures in the paths, such as semantic roles, are ignored in the calculation. The word vectors we use are from Mikolov et al. (2013)[13] (*Mikolov13*), and additional results are also shown using Turian et al. (2010)[14] (*Turian10*). The threshold for accepted path alignments is set to 0.4, based on preexperiments on RTE development sets.

4.2 Experiments on FraCaS

The FraCaS test suite contains 346 inference problems divided into 9 sections, each focused on a category of semantic phenomena. We use the data by MacCartney and Manning (2007), and experiment on the first section, *Quantifiers*, following Lewis and Steedman (2013). This section has 44 single premise and 30 multi premise problems. Most of the problems do not require lexical knowledge, so we use our primary textual inference system without on-the-fly knowledge nor WordNet, to test the performance of the DCS framework as formal semantics. To obtain the three-valued output (i.e. *yes*, *no*, and *unknown*), we output "*yes*" if **H** is proven, or try to prove the negation of **H** if **H** is not proven. To negate **H**, we use the root negation as described in §2.5. If the negation of **H** is proven, we output "*no*", otherwise we output "*unknown*".

	Single Prem.	Multi Prem.
Lewis13	70	50
MacCartney07	84.1	-
MacCartney08	**97.7**	-
Our Sys.	79.5	**80.0**

Table 4: Accuracy (%) on FraCaS

The result is shown in Table 4. Since our system uses an off-the-shelf dependency parser, and semantic representations are obtained from simple rule-based conversion from dependency trees, there will be only one (right or wrong) interpretation in face of ambiguous sentences. Still, our system outperforms Lewis and Steedman (2013)'s probabilistic CCG-parser. Compared to MacCartney and Manning (2007) and MacCartney and Manning (2008), our system does not need a pretrained alignment model, and it improves by making multi-sentence inferences. To sum up, the result shows that DCS is good at handling universal quantifiers and negations.

Most errors are due to wrongly generated DCS trees (e.g. wrongly assigned semantic roles) or unimplemented quantifier triggers (e.g. "*neither*") or generalized quantifiers (e.g. "*at least a few*"). These could be addressed by future work.

4.3 Experiments on PASCAL RTE datasets

On PASCAL RTE datasets, strict logical inference is known to have very low recall (Bos and Markert, 2005), so on-the-fly knowledge is crucial in this setting. We test the effect of on-the-fly knowledge on RTE2, RTE3, RTE4 and RTE5 datasets, and compare our system with other approaches.

4.3.1 Impact of on-the-fly knowledge

Results on test data are shown in Table 5. When only primary knowledge is used in inference (the first row), recalls are actually very low; After we activate the on-the-fly knowledge, recalls jump to over 50%, with a moderate fall of precision. As a result, accuracies significantly increase.

Table 6: Comparison with other systems

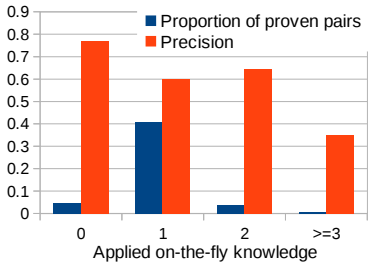

Figure 7: Proportion of proven pairs and their precision, w.r.t. pieces of on-the-fly knowledge.

4.3.2 Comparison to other RTE systems

A comparison between our system and other RTE systems is shown in Table 6. Bos06 (Bos and Markert, 2006) is a hybrid system combining deep features from a theorem prover and a model builder, together with shallow features such as lexical overlap and text length. MacCartney08 (MacCartney and Manning, 2008) uses natural logic to calculate inference relations between two superficially aligned sentences. Clark08 (Clark and Harrison, 2008) is a logic-based system utilizing various resources including WordNet and DIRT paraphrases (Lin and Pantel, 2001), and is tolerant to partially unproven **H** sentences in some degree. All of the three systems pursue a logical approach, while combining various techniques to achieve robustness. The result shows that our system has comparable performance. On the other hand, Wang10 (Wang and Manning, 2010) learns a tree-edit model from training data, and captures entailment relation by tree edit distance. Stern11 (Stern and Dagan, 2011) and Stern12 (Stern et al., 2012) extend this framework to utilize entailment rules as tree transformations. These are more tailored systems using machine learning with many handcrafted features. Still, our unsupervised system outperforms the state-of-the-art on RTE5 dataset.

4.3.3 Analysis

Summing up test data from RTE2 to RTE5, Figure 7 shows the proportion of all proven pairs and their precision. Less than 5% pairs can be proven primarily, with a precision of 77%. Over 40% pairs can be proven by one piece of on-the-fly knowledge, yet pairs do exist in which more than 2 pieces are necessary. The precisions of 1 and 2 pieces on-the-fly knowledge application are over 60%, which is fairly high, given our rough estimation of the similarity score. As a comparison, Dinu and Wang (2009) studied the proportion of proven pairs and precision by applying DIRT rules to tree skeletons in RTE2 and RTE3 data. The proportion is 8% with precision 65% on RTE2, and proportion 6% with precision 72% on RTE3. Applied by our logical system, the noisy on-the-fly knowledge can achieve a precision comparable to higher quality resources such as DIRT.

A major type of error is caused by the ignorance of semantic roles in calculation of similarity scores. For example, though "*Italy beats Kazakhstan*" is not primarily proven from "*Italy is defeated by Kazakhstan*", our system does produce the path alignment "SUBJ(**beat**)OBJ $\approx$ OBJ(**defeat**)SUBJ" with a high similarity score. The impact of such errors depends on the data making methodology, though. It lowers precisions in RTE2 and RTE3 data, particularly in "IE" subtask (where precisions drop under 0.5). On the other hand, it occurs less often in "IR" subtask.

Finally, to see if we "get lucky" on RTE5 data in the choice of word vectors and thresholds, we change the thresholds from 0.1 to 0.7 and draw the precision-recall curve, using two types of word vectors, *Mikolov13* and *Turian10*. As shown in Figure 8, though the precision drops for *Turian10*, both curves show the pattern that our system keeps gaining recall while maintaining precision to a certain level. Not too much "magic" in *Mikolov13* actually: for over 80% pairs, every node in DCS tree of **H** can be covered by a path of length ≤ 5 that

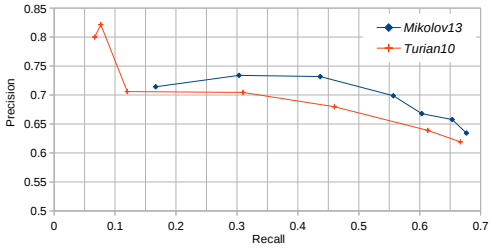

Figure 8: Precision-Recall curve.

has a corresponding path of length ≤ 5 in $\mathbf{T}$ with a similarity score > 0.4.

5 Conclusion and Discussion

We have presented a method of deriving abstract denotation from DCS trees, which enables logical inference on DCS, and we developed a textual inference system based on the framework. Experimental results have shown the power of the representation that allows both strict inference as on FraCaS data and robust reasoning as on RTE data.

Exploration of an appropriate meaning representation for querying and reasoning on knowledge bases has a long history. Description logic, being less expressive than FOL but featuring more efficient reasoning, is used as a theory base for Semantic Web (W3C, 2012). Ideas similar to our framework, including the use of sets in a representation that benefits efficient reasoning, are also found in description logic and knowledge representation community (Baader et al., 2003; Sowa, 2000; Sukkarieh, 2003). To our knowledge, however, their applications to logical inference beyond the use for database querying have not been much explored in the context of NLP.

The pursue of a logic more suitable for natural language inference is not new. For instance, MacCartney and Manning (2008) has implemented a model of natural logic (Lakoff, 1970). While being computationally efficient, various inference patterns are out of the scope of their system.

Much work has been done in mapping natural language into database queries (Cai and Yates, 2013; Kwiatkowski et al., 2013; Poon, 2013). Among these, the (λ-)DCS (Liang et al., 2011; Berant et al., 2013) framework defines algorithms that transparently map a labeled tree to a database querying procedure. Essentially, this is because DCS trees restrict the querying process to a very limited subset of possible operations. Our main contribution, the abstract denotation of DCS trees, can thus be considered as an attempt to characterize a fragment of FOL that is suited for both natural language inference *and* transparent syntax-semantics mapping, through the choice of operations and relations on sets.

We have demonstrated the utility of logical inference on DCS through the RTE task. A wide variety of strategies tackling the RTE task have been investigated (Androutsopoulos and Malakasiotis, 2010), including the comparison of surface strings (Jijkoun and De Rijke, 2005), syntactic and semantic structures (Haghighi et al., 2005; Snow et al., 2006; Zanzotto et al., 2009; Burchardt et al., 2009; Heilman and Smith, 2010; Wang and Manning, 2010), semantic vectors (Erk and Padó, 2009) and logical representations (Bos and Markert, 2005; Raina et al., 2005; Tatu and Moldovan, 2005). Acquisition of basic knowledge for RTE is also a huge stream of research (Lin and Pantel, 2001; Shinyama et al., 2002; Sudo et al., 2003; Szpektor et al., 2004; Fujita et al., 2012; Weisman et al., 2012; Yan et al., 2013). These previous works include various techniques for acquiring and incorporating different kinds of linguistic and world knowledge, and further fight against the knowledge bottleneck problem, e.g. by back-off to shallower representations.

Logic-based RTE systems employ various approaches to bridge knowledge gaps. Bos and Markert (2005) proposes features from a model builder; Raina et al. (2005) proposes an abduction process; Tatu and Moldovan (2006) shows handcrafted rules could drastically improve the performance of a logic-based RTE system.

As such, our current RTE system is at a proof-of-concept stage, in that many of the above techniques are yet to be implemented. Nonetheless, we would like to emphasize that it already shows performance competitive to state-of-the-art systems on one data set (RTE5). Other directions of our future work include further exploitation of the new semantic representation. For example, since abstract denotations are readily suited for data querying, they can be used to verify newly generated assumptions by fact search in a database. This may open a way towards a hybrid approach to RTE wherein logical inference is intermingled with large scale database querying.

A practical and linguistically-motivated approach to compositional distributional semantics

Denis Paperno and **Nghia The Pham** and **Marco Baroni**
Center for Mind/Brain Sciences (University of Trento, Italy)
(denis.paperno|thenghia.pham|marco.baroni)@unitn.it

Abstract

Distributional semantic methods to approximate word meaning with context vectors have been very successful empirically, and the last years have seen a surge of interest in their compositional extension to phrases and sentences. We present here a new model that, like those of Coecke et al. (2010) and Baroni and Zamparelli (2010), closely mimics the standard Montagovian semantic treatment of composition in distributional terms. However, our approach avoids a number of issues that have prevented the application of the earlier linguistically-motivated models to full-fledged, real-life sentences. We test the model on a variety of empirical tasks, showing that it consistently outperforms a set of competitive rivals.

1 Compositional distributional semantics

The research of the last two decades has established empirically that distributional vectors for words obtained from corpus statistics can be used to represent word meaning in a variety of tasks (Turney and Pantel, 2010). If distributional vectors encode certain aspects of word meaning, it is natural to expect that similar aspects of sentence meaning can also receive vector representations, obtained compositionally from word vectors. Developing a practical model of compositionality is still an open issue, which we address in this paper. One approach is to use simple, parameter-free models that perform operations such as pointwise multiplication or summing (Mitchell and Lapata, 2008). Such models turn out to be surprisingly effective in practice (Blacoe and Lapata, 2012), but they have obvious limitations. For instance, symmetric operations like vector addition are insensitive to syntactic structure, therefore meaning differences encoded in word order are lost in composition: *pandas eat bamboo* is identical to *bamboo eats pandas*. Guevara (2010), Mitchell and Lapata (2010), Socher et al. (2011) and Zanzotto et al. (2010) generalize the simple additive model by applying structure-encoding operators to the vectors of two sister nodes before addition, thus breaking the inherent symmetry of the simple additive model. A related approach (Socher et al., 2012) assumes richer lexical representations where each word is represented with a vector and a matrix that encodes its interaction with its syntactic sister. The training proposed in this model estimates the parameters in a supervised setting. Despite positive empirical evaluation, this approach is hardly practical for general-purpose semantic language processing, since it requires computationally expensive approximate parameter optimization techniques, and it assumes task-specific parameter learning whose results are not meant to generalize across tasks.

1.1 The lexical function model

None of the proposals mentioned above, from simple to elaborate, incorporates in its architecture the intuitive idea (standard in theoretical linguistics) that semantic composition is more than a weighted combination of words. Generally one of the components of a phrase, e.g., an adjective, acts as a function affecting the other component (e.g., a noun). This underlying intuition, adopted from formal semantics of natural language, motivated the creation of the *lexical function* model of composition (*lf*) (Baroni and Zamparelli, 2010; Coecke et al., 2010). The lf model can be seen as a projection of the symbolic Montagovian approach to semantic composition in natural language onto the domain of vector spaces and linear operations on them (Baroni et al., 2013). In lf, arguments are vectors and functions taking arguments (e.g., adjectives that combine with nouns) are tensors, with the number of arguments (n) determining the

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 90–99,
Baltimore, Maryland, USA, June 23-25 2014.

order of tensor (n+1). For example, adjectives, as unary functors, are modeled with 2-way tensors, or matrices. Tensor by vector multiplication formalizes function application and serves as the general composition method.

Baroni and Zamparelli (2010) propose a practical and empirically effective way to estimate matrices representing adjectival modifiers of nouns by linear regression from corpus-extracted examples of noun and adjective-noun vectors. Unlike the neural network approach of Socher et al. (2011; 2012), the Baroni and Zamparelli method does not require manually labeled data nor costly iterative estimation procedures, as it relies on automatically extracted phrase vectors and on the analytical solution of the least-squares-error problem.

The same method was later applied to matrix representations of intransitive verbs and determiners (Bernardi et al., 2013; Dinu et al., 2013), always with good empirical results.

The full range of semantic types required for natural language processing, including those of adverbs and transitive verbs, has to include, however, tensors of greater rank. The estimation method originally proposed by Baroni and Zamparelli has been extended to 3-way tensors representing transitive verbs by Grefenstette et al. (2013) with preliminary success. Grefenstette et al.'s method works in two steps. First, one estimates matrices of verb-object phrases from subject and subject-verb-object vectors; next, transitive verb tensors are estimated from verb-object matrices and object vectors.

1.2 Problems with the extension of the lexical function model to sentences

With all the advantages of lf, scaling it up to arbitrary sentences, however, leads to several issues. In particular, it is desirable for all practical purposes to limit representation size. For example, if noun meanings are encoded in vectors of 300 dimensions, adjectives become matrices of 300^2 cells, and transitive verbs are represented as tensors with 300^3=$27,000,000$ dimensions.

Estimating tensors of this size runs into data sparseness issues already for less common transitive verbs. Indeed, in order to train a transitive verb tensor (e.g., *eat*), the method of Grefenstette et al. (2013) requires a sufficient number of distinct verb object phrases with that verb (e.g., *eat cake*, *eat fruits*), each attested in combination with a certain number of subject nouns with sufficient frequency to extract sensible vectors. It is not feasible to obtain enough data points for all verbs in such a training design.

Things get even worse for other categories. Adverbs like *quickly* that modify intransitive verbs have to be represented with 300^{2^2} = $8,100,000,000$ dimensions. Modifiers of transitive verbs would have even greater representation size, which may not be possible to store and learn efficiently.

Another issue is that the same or similar items that occur in different syntactic contexts are assigned different semantic types with incomparable representations. For example, verbs like *eat* can be used in transitive or intransitive constructions (*children eat meat*/*children eat*), or in passive (*meat is eaten*). Since predicate arity is encoded in the order of the corresponding tensor, *eat* and the like have to be assigned different representations (matrix or tensor) depending on the context. Deverbal nouns like *demolition*, often used without mention of who demolished what, would have to get vector representations while the corresponding verbs (*demolish*) would become tensors, which makes immediately related verbs and nouns incomparable. Nouns in general would oscillate between vector and matrix representations depending on argument vs. predicate vs. modifier position (*an animal runs* vs. *this is an animal* vs. *animal shelter*). Prepositions are the hardest, as the syntactic positions in which they occur are most diverse (*park in the dark* vs. *play in the dark* vs. *be in the dark* vs. *a light glowing in the dark*).

In all those cases, the same word has to be mapped to tensors of different orders. Since each of these tensors must be learned from examples individually, their obvious relation is missed. Besides losing the comparability of the semantic contribution of a word across syntactic contexts, we also worsen the data sparseness issues.

The last, and related, point is that for the tensor calculus to work, one needs to model, for each word, each of the constructions in the corpus that the word is attested in. In its pure form lf does not include an emergency backoff strategy when unknown words or constructions are encountered. For example, if we only observe transitive usages of *to eat* in the training corpus, and encounter an intransitive or passive example of it in testing data,

the system would not be able to compose a sentence vector at all. This issue is unavoidable since we don't expect to find all words in all possible constructions even in the largest corpus.

2 The practical lexical function model

As follows from section 1.2, it would be desirable to have a compositional distributional model that encodes function-argument relations but avoids the troublesome high-order tensor representations of the pure lexical function model, with all the practical problems that come with them. We may still want to represent word meanings in different syntactic contexts differently, but at the same time we need to incorporate a formal connection between those representations, e.g., between the transitive and the intransitive instantiations of the verb *to eat*. Last but not least, all items need to include a common aspect of their representation (e.g., a vector) to allow comparison across categories (the case of *demolish* and *demolition*).

To this end, we propose a new model of composition that maintains the idea of function application, while avoiding the complications and rigidity of lf. We call our proposal *practical lexical function* model, or *plf*. In plf, a functional word is not represented by a single tensor of arity-dependent order, but by a vector plus an ordered set of matrices, with one matrix for each argument the function takes. After applying the matrices to the corresponding argument vectors, a single representation is obtained by summing across all resulting vectors.

2.1 Word meaning representation

In plf, all words are represented by a vector, and functional words, such as predicates and modifiers, are also assigned one or more matrices. The general form of a semantic representation for a linguistic unit is an ordered tuple of a vector and $n \in \mathbb{N}$ matrices:[1]

$$\left\langle \vec{x}, \overset{\square}{x}_1, \ldots, \overset{\square}{x}_n \right\rangle$$

The number of matrices in the representation encodes the arity of a linguistic unit, i.e., the number of other units to which it applies as a function. Each matrix corresponds to a function-argument relation, and words have as many matrices as many arguments they take: none for (most) nouns, one for adjectives and intransitive verbs, two for transitives, etc. The matrices formalize argument slot saturation, operating on an argument vector representation through matrix by vector multiplication, as described in the next section.

[1] Matrices associated with term x are symbolized $\overset{\square}{x}$.

dog	$\vec{dog}$
run	$\vec{run}, \overset{\square}{run}$
chase	$\vec{chase}, \overset{\square_s}{chase}, \overset{\square_o}{chase}$
give	$\vec{give}, \overset{\square_s}{give}, \overset{\square_o}{give}, \overset{\square_{io}}{give}$
big	$\vec{big}, \overset{\square}{big}$
very	$\vec{very}, \overset{\square_n}{very}, \overset{\square_a}{very}$
quickly	$\vec{quickly}, \overset{\square_s}{quickly}, \overset{\square_v}{quickly}$

Table 1: Examples of word representations. Subscripts encode, just for mnemonic purposes, the constituent whose vector the matrix combines with: **s**ubject, **o**bject, **i**ndirect **o**bject, **n**oun, **a**djective, **v**erb phrase.

Modifiers of n-ary functors are represented by n+1-ary structures. For instance, we treat adjectives that modify nouns (0-ary) as unary functions, encoded in a vector-matrix pair. Adverbs have different semantic types depending on their syntactic role. Sentential adverbs are unary, while adverbs that modify adjectives (*very*) or verb phrases (*quickly*) are encoded as binary functions, represented by a vector and two matrices. The form of semantic representations we are using is shown in Table 1.[2]

2.2 Semantic composition

Our system incorporates semantic composition via two composition rules, one for combining structures of different arity and the other for symmetric composition of structures with the same arity. These rules incorporate insights of two empirically successful models, lexical function and the simple additive approach, used as the default structure merging strategy.

The first rule is *function application*, illustrated in Figure 1. Table 2 illustrates simple cases of function application. For transitive verbs semantic composition applies iteratively as shown in the derivation of Figure 2. For ternary predicates such

[2] To determine the number and ordering of matrices representing the word in the current syntactic context, our plf implementation relies on the syntactic type assigned to the word in the categorial grammar parse of the sentence.

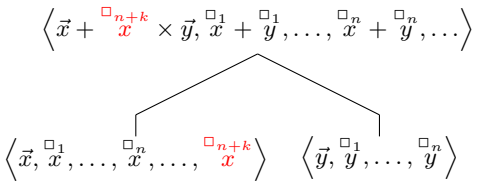

Figure 1: Function application: If two syntactic sisters have different arity, treat the higher-arity sister as the functor. Compose by multiplying the last matrix in the functor tuple by the argument vector and summing the result to the functor vector. Unsaturated matrices are carried up to the composed node, summing across sisters if needed.

dogs	$\vec{dogs}$
run	$\vec{run}, \square run$
dogs run	$\vec{run} + \square run \times \vec{dog}$
house	$\vec{house}$
big	$\vec{big}, \square big$
big house	$\vec{big} + \square big \times \vec{house}$

Table 2: Examples of function application.

as *give* in a ditransitive construction, the first step in the derivation absorbs the innermost argument by multiplying its vector by the third *give* matrix, and then composition proceeds like for transitives.

The second composition rule, *symmetric composition* applies when two syntactic sisters are of the same arity (e.g., two vectors, or two vector-matrix pairs). Symmetric composition simply sums the objects in the two tuples: vector with vector, n-th matrix with n-th matrix.

Symmetric composition is reserved for structures in which the function-argument distinction is problematic. Some candidates for such treatment are coordination and nominal compounds, although we recognize that the headless analysis is

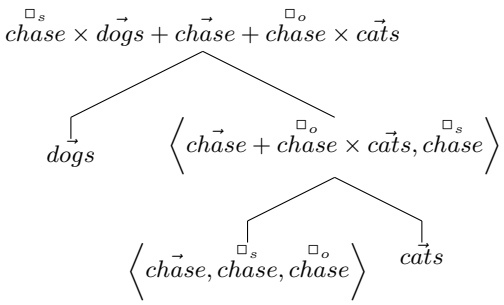

Figure 2: Applying function application twice to derive the representation of a transitive sentence.

sing: $\vec{sing}, \square sing$	dance: $\vec{dance}, \square dance$
sing and dance:	$\vec{sing} + \vec{dance}, \square sing + \square dance$
rice: $\vec{rice}$	cake: $\vec{cake}$
rice cake	$\vec{rice} + \vec{cake}$

Table 3: Examples of symmetric composition.

not the only possible one here. See two examples of Symmetric Composition application in Table 3.

Note that the *sing and dance* composition in Table 3 skips the conjunction. Our current plf implementation treats most grammatical words, including conjunctions, as "empty" elements, that do not project into semantics. This choice leads to some interesting "serendipitous" treatments of various constructions. For example, since the copula is empty, a sentence with a predicative adjective (*cars are red*) is treated in the same way as a phrase with the same adjective in attributive position (*red cars*) – although the latter, being a phrase and not a full sentence, will later be embedded as argument in a larger construction. Similarly, leaving the relative pronoun empty makes *cars that run* identical to *cars run*, although, again, the former will be embedded in a larger construction later in the derivation.

We conclude our brief exposition of plf with an alternative intuition for it: the plf model is also a more sophisticated version of the additive approach, where argument words are adapted by matrices that encode the relation to their functors before the sentence vector is derived by summing.

2.3 Satisfying the desiderata

Let us now outline how plf addresses the shortcomings of lf listed in Section 1.2. First, all issues caused by representation size disappear. An n-ary predicate is no longer encoded as an n+1-way tensor; instead we have a sequence of n matrices. The representation size grows linearly, not exponentially, for higher semantic types, allowing for simpler and more efficient parameter estimation, storage, and computation.

As a consequence of our architecture, we no longer need to perform the complicated step-by-step estimation for elements of higher arity. Indeed, one can estimate each matrix of a complex representation individually using the simple method of Baroni and Zamparelli (2010). For instance, for transitive verbs we estimate the verb-subject combination matrix from subject and verb-

boys	$\vec{boys}$
eat (intrans.)	$\vec{eat}, \overset{\square_s}{eat}$
boys eat	$\overset{\square_s}{eat} \times \vec{boys} + \vec{eat}$
meat	$\vec{meat}$
eat (trans.)	$\vec{eat}, \overset{\square_s}{eat}, \overset{\square_o}{eat}$
boys eat meat	$\overset{\square_s}{eat} \times \vec{boys} + \vec{eat} + \overset{\square_o}{eat} \times \vec{meat}$
(is) eaten (pass.)	$\vec{eat}, \overset{\square_o}{eat}$
meat is eaten	$\vec{eat} + \overset{\square_o}{eat} \times \vec{meat}$

Table 4: The verb *to eat* associated to different sets of matrices in different syntactic contexts.

subject vectors, the verb-object combination matrix from object and verb-object vectors. We expect a reasonably large corpus to feature many occurrences of a verb with a variety of subjects and a variety of objects (but not necessarily a variety of subjects with each of the objects as required by Grefenstette et al.'s training), allowing us to avoid the data sparseness issue.

The semantic representations we propose include a semantic vector for constituents of any semantic type, thus enabling semantic comparison for words of different parts of speech (the case of *demolition* vs. *demolish*).

Finally, the fact that we represent the predicate interaction with each of its arguments in a separate matrix allows for a natural and intuitive treatment of argument alternations. For instance, as shown in Table 4, one can distinguish the transitive and intransitive usages of the verb *to eat* by the presence of the object-oriented matrix of the verb while keeping the rest of the representation intact. To model passive usages, we insert the object matrix of the verb only, which will be multiplied by the syntactic subject vector, capturing the similarity between *eat meat* and *meat is eaten*.

So keeping the verb's interaction with subject and object encoded in distinct matrices not only solves the issues of representation size for arbitrary semantic types, but also provides a sensible built-in strategy for handling a word's occurrence in multiple constructions. Indeed, if we encounter a verb used intransitively which was only attested as transitive in the training corpus, we can simply omit the object matrix to obtain a type-appropriate representation. On the other hand, if the verb occurs with more arguments than usual in testing materials, we can add a default diagonal identity matrix to its representation, signaling agnosticism about how the verb relates to the unexpected argument. This flexibility makes our model suitable to compute vector representations of sentences without stumbling at unseen syntactic usages of words.

To summarize, plf is an extension of the lexical function model that inherits its strengths and overcomes its weaknesses. We still employ a linguistically-motivated notion of semantic composition as function application and use distinct kinds of representations for different semantic types. At the same time, we avoid high order tensor representations, produce semantic vectors for all syntactic constituents, and allow for an elegant and transparent correspondence between different syntactic usages of a lexeme, such as the transitive, the intransitive, and the passive usages of the verb *to eat*. Last but not least, our implementation is suitable for realistic language processing since it allows to produce vectors for sentences of arbitrary size, including those containing novel syntactic configurations.

3 Evaluation

3.1 Evaluation materials

We consider 5 different benchmarks that focus on different aspects of sentence-level semantic composition. The first data set, created by Edward Grefenstette and Mehrnoosh Sadrzadeh and introduced in Kartsaklis et al. (2013), features 200 sentence pairs that were rated for similarity by 43 annotators. In this data set, sentences have fixed adjective-noun-verb-adjective-noun (anvan) structure, and they were built in order to crucially require context-based verb disambiguation (e.g., *young woman filed long nails* is paired with both *young woman smoothed long nails* and *young woman registered long nails*). We also consider a similar data set introduced by Grefenstette (2013), comprising 200 sentence pairs rated by 50 annotators. We will call these benchmarks **anvan1** and **anvan2**, respectively. Evaluation is carried out by computing the Spearman correlation between the annotator similarity ratings for the sentence pairs and the cosines of the vectors produced by the various systems for the same sentence pairs.

The benchmark introduced by The Pham et al. (2013) at the TFDS workshop (**tfds** below) was specifically designed to test compositional methods for their sensitivity to word order and the semantic effect of determiners. The tfds benchmark contains 157 target sentences that are matched with a set of (approximate) paraphrases (8 on av-

erage), and a set of "foils" (17 on average). The foils have high lexical overlap with the targets but very different meanings, due to different determiners and/or word order. For example, the target *A man plays an acoustic guitar* is matched with paraphrases such as *A man plays guitar* and *The man plays the guitar*, and foils such as *The man plays no guitar* and *A guitar plays a man*. A good system should return higher similarities for the comparison with the paraphrases with respect to that with the foils. Performance is assessed through the t-standardized cross-target average of the difference between mean cosine with paraphrases and mean cosine with foils (Pham and colleagues, equivalently, reported non-standardized average and standard deviations).

The two remaining data sets are larger and more 'natural', as they were not constructed by linguists under controlled conditions to focus on specific phenomena. They are aimed at evaluating systems on the sort of free-form sentences one encounters in real-life applications. The **msrvid** data set from the SemEval-2012 Semantic Textual Similarity (STS) task (Agirre et al., 2012) consists of 750 sentence pairs that describe brief videos. Sentence pairs were scored for similarity by 5 subjects each. Following standard practice in paraphrase detection studies (e.g., Blacoe and Lapata (2012)), we use cosine similarity between sentence pairs as computed by one of our systems together with two shallow similarity cues: word overlap between the two sentences and difference in sentence length. We obtain a final similarity score by weighted addition of the 3 cues, with the optimal weights determined by linear regression on separate msrvid train data that were also provided by the SemEval task organizers (before combining, we checked that the collinearity between cues was low). System scores are evaluated by their Pearson correlation with the human ratings.

The final set we use is **onwn**, from the *SEM-2013 STS shared task (Agirre et al., 2013). This set contains 561 pairs of glosses (from the WordNet and OntoNotes databases), rated by 5 judges for similarity. Our main interest in this set stems from the fact that glosses are rarely well-formed full sentences (consider, e.g., *cause something to pass or lead somewhere*; *coerce by violence, fill with terror*). For this reason, they are very challenging for standard parsers. Indeed, we estimated from a sample of 40 onwn glosses that the C&C parser (see below) has only 45% accuracy on this set. Since *plf* needs syntactic information to construct sentence vectors compositionally, we test it on onwn to make sure that it is not overly sensitive to parser noise. Evaluation proceeds as with msrvid (cue weights are determined by 10-fold cross-validation).[3]

3.2 Semantic space construction and composition model implementation

Our source corpus was given by the concatenation of ukWaC (`wacky.sslmit.unibo.it`), a mid-2009 dump of the English Wikipedia (`en.wikipedia.org`) and the British National Corpus (`www.natcorp.ox.ac.uk`), for a total of about 2.8 billion words.

We collected a 30K-by-30K matrix by counting co-occurrence of the 30K most frequent content lemmas (nouns, adjectives and verbs) within a 3-word window. The raw count vectors were transformed into positive Pointwise Mutual Information scores and reduced to 300 dimensions by the Singular Value Decomposition. All vectors were normalized to length 1. This setup was picked without tuning, as we found it effective in previous, unrelated experiments.[4]

We consider four composition models. The **add** (additive) model produces the vector of a sentence by summing the vectors of all content words in it. Similarly, **mult** uses component-wise multiplication of vectors for composition. While these models are very simple, a long experimental tradition has proven their effectiveness (Landauer and Dumais, 1997; Mitchell and Lapata, 2008; Mitchell and Lapata, 2010; Blacoe and Lapata, 2012).

For the **lf** (lexical function) model, we construct functional matrix representations of adjectives, determiners and intransitive verbs. These are trained using Ridge regression with generalized cross-validation from corpus-extracted vectors of nouns,

[3] We did not evaluate on other STS benchmarks since they have characteristics, such as high density of named entities, that would require embedding our compositional models into more complex systems, obfuscating their impact on the overall performance.

[4] With the multiplicative composition model we also tried Nonnegative Matrix Factorization instead of Singular Value Decomposition, because the negative values produced by SVD are potentially problematic for mult. In addition, we repeated the evaluation for the multiplicative and additive models without any form of dimensionality reduction. The overall pattern of results did not change significantly, and thus for consistency we report all models' performance only for the SVD-reduced space.

as input, and phrases including those nouns as output (e.g., the matrix for *red* is trained from corpus-extracted $\langle noun, red\text{-}noun \rangle$ vector pairs). Transitive verb tensors are estimated using the two-step regression procedure outlined by Grefenstette et al. (2013). We did not attempt to train a lf model for the larger and more varied msrvid and onwn data sets, as this would have been extremely time consuming and impractical for all the reasons we discussed in Section 1.2 above.

Training **plf** (practical lexical function) proceeds similarly, but we also build preposition matrices (from $\langle noun, preposition\text{-}noun \rangle$ vector pairs), and for verbs we prepare separate subject and object matrices.

Since syntax guides lf and plf composition, we supplied all test sentences with categorial grammar parses. Every sentence in the anvan1 and anvan2 datasets has the form (subject) Adjective + Noun + Transitive Verb + (object) Adjective + Noun, so parsing them is trivial. All sentences in tfds have a predictable structure that allows perfect parsing with simple finite state rules. In all these cases, applying a general-purpose parser to the data would have, at best, had no impact and, at worst, introduced parsing errors. For msrvid and onwn, we used the output of the C&C parser (Clark and Curran, 2007).

3.3 Results

Table 5 summarizes the performance of our models on the chosen tasks, and compares it to the state of the art reported in previous work, as well as to various strong baselines.

The plf model performs very well on both anvan benchmarks, outperforming not only add and mult, but also the full-fledged lf model. Given that these data sets contain, systematically, transitive verbs, the major difference between plf and lf lies in their representation of the latter. Evidently, the separately-trained subject and object matrices of plf, being less affected by data sparseness than the 3-way tensors of lf, are better able to capture how verbs interact with their arguments. For anvan1, plf is just below the state of the art, which is based on disambiguating the verb vector in context (Kartsaklis and Sadrzadeh, 2013), and lf outperforms the baseline, which consists in using the verb vector only as a proxy to sentence similarity.[5] On anvan2, plf outperforms the best model reported by Grefenstette (2013) (an implementation of the lexical function ideas along the lines of Grefenstette and Sadrzadeh (2011a; 2011b)). And lf is, again, the only model, besides plf, that performs better than the baseline.

models	anvan 1	anvan 2	tfds	msr vid	onwn
add	8	22	-0.2	78	66
mult	8	-4	-2.3	77	55
lf	15	30	**5.90**	NA	NA
plf	**20**	**36**	2.7	**79**	**67**
soa	22	27	11.4	87	75
baseline	8	22	7.9	77	55

Table 5: Performance of composition models on all evaluation sets. Figures of merit follow previous art on each set and are: percentage Spearman coefficients for anvan1 and anvan2, t-standardized average difference between mean cosines with paraphrases and with foils for tfds, percentage Pearson coefficients for msrvid and onwn. State-of-the-art (soa) references: anvan1: Kartsaklis and Sadrzadeh (2013); anvan2: Grefenstette (2013); tfds: The Pham et al. (2013); msrvid: Bär et al. (2012); onwn: Han et al. (2013). Baselines: anvan1/anvan2: verb vectors only; tfds: word overlap; msrvid/onwn: word overlap + sentence length.

In the tfds task, not surprisingly the add and mult models, lacking determiner representations and being order-insensitive, fail to distinguish between true paraphrases and foils (indeed, for the mult model foils are significantly *closer* to the targets than the paraphrases, probably because the latter have lower content word overlap than the foils, that often differ in word order and determiners only). Our plf approach is able to handle determiners and word order correctly, as demonstrated by a highly significant ($p < 0.01$) difference between paraphrase and foil similarity (average difference in cosine .017, standard deviation .077). In this case, however, the traditional lf model (average difference .044, standard deviation .092) outperforms plf. Since determiners are handled identically under the two approaches, the culprit must be word order. We conjecture that the lf 3-way tensor representation of transitive verbs leads to a stronger asymmetry between sentences with in-

[5] We report state of the art from Kartsaklis and Sadrzadeh (2013) rather than Kartsaklis et al. (2013), since only the former used a source corpus that is comparable to ours.

verted arguments, and thus makes this model particularly sensitive to word order differences. Indeed, if we limit evaluation to those foils characterized by word order changes only, lf discriminates between paraphrases and foils even more clearly, whereas the plf difference, while still significant, decreases slightly.

The state-of-the-art row for tfds reports the lf implementation by The Pham et al. (2013), which outperforms ours. The main difference is that Pham and colleagues do not normalize vectors like we do. If we don't normalize, we do get larger differences for our models as well, but consistently lower performance in all other tasks. More worryingly, the simple word overlap baseline reported in the table sports a larger difference than our best model. Clearly, this baseline is exploiting the systematic determiner differences in the foils and, indeed, when it is evaluated on foils where only word order changes its performance is no longer significant.

On msrvid, the plf approach outperforms add and mult, although the difference between the three is not big. Our result stands in contrast with Blacoe and Lapata (2012), the only study we are aware of that compared a sophisticated composition model (Socher et al.'s 2011 model) to add and mult on realistic sentences, which attained the top performance with the simple models for both figures of merit they used.[6] The best 2012 STS system (Bär et al., 2012), obtained 0.87 correlation, but with many more and considerably more complex features than the ones we used here. Indeed, our simple system would have obtained a respectable 25/89 ranking in the STS 2012 msrvid task. Still, we must also stress the impressive performance of our baseline, given by the combination of the word overlap and sentence length cues. This suggests that the msrvid benchmark lacks the lexical and syntactic variety we would like to test our systems on.

Our plf model is again the best on the onwn set (albeit by a small margin over add). This is a very positive result, in the light of the fact that the parser has very low performance on the onwn glosses, thus suggesting that plf can produce sensible semantic vectors from noisy syntactic representations. Here the overlap+length baseline does not perform so well, and again the best STS 2013 system (Han et al., 2013) uses considerably richer knowledge sources and algorithms than ours. Our plf-based method would have reached a respectable 20/90 rank in the STS 2013 onwn task.

As a final remark, in all experiments the running time of plf was only slightly larger than for the simpler models, but orders of magnitude smaller than lf, confirming another practical side of our approach.

4 Conclusion

We introduced an approach to compositional distributional semantics based on a linguistically-motivated syntax-to-semantics type mapping, but simple and flexible enough that it can produce representations of English sentences of arbitrary size and structure.

We showed that our approach is competitive against the more complex lexical function model when evaluated on the simple constructions the latter can be applied to, and it outperforms the additive and multiplicative compositionality models when tested on more realistic benchmarks (where the full-fledged lexical function approach is difficult or impossible to use), even in presence of strong noise in its syntactic input. While our results are encouraging, no current benchmark combines large-scale, real-life data with the syntactic variety on which a syntax-driven approach to semantics such as ours could truly prove its worth. The recently announced SemEval 2014 Task 1[7] is filling exactly this gap, and we look forward to apply our method to this new benchmark, as soon as it becomes available.

One of the strengths of our framework is that it allows for incremental improvement focused on specific constructions. For example, one could add representations for different conjunctions (*and* vs. *or*), train matrices for verb arguments other than subject and direct object, or include new types of modifiers into the model, etc.

While there is potential for local improvements, our framework, which extends and improves on existing compositional semantic vector models, has demonstrated its ability to account for full sentences in a principled and elegant way. Our implementation of the model relies on simple and effi-

[6] We refer here to the results reported in the erratum available at `http://homepages.inf.ed.ac.uk/s1066731/pdf/emnlp2012erratum.pdf`. The add/mult advantage was even more marked in the original paper.

Abstract

Morphological segmentation is an effective sparsity reduction strategy for statistical machine translation (SMT) involving morphologically complex languages. When translating into a segmented language, an extra step is required to desegment the output; previous studies have desegmented the 1-best output from the decoder. In this paper, we expand our translation options by desegmenting n-best lists or lattices. Our novel lattice desegmentation algorithm effectively combines both segmented and desegmented views of the target language for a large subspace of possible translation outputs, which allows for inclusion of features related to the desegmentation process, as well as an unsegmented language model (LM). We investigate this technique in the context of English-to-Arabic and English-to-Finnish translation, showing significant improvements in translation quality over desegmentation of 1-best decoder outputs.

1 Introduction

Morphological segmentation is considered to be indispensable when translating between English and morphologically complex languages such as Arabic. Morphological complexity leads to much higher type to token ratios than English, which can create sparsity problems during translation model estimation. Morphological segmentation addresses this issue by splitting surface forms into meaningful morphemes, while also performing orthographic transformations to further reduce sparsity. For example, the Arabic noun للدول *lldwl* "to the countries" is segmented as *l+* "to" *Aldwl* "the countries". When translating from Arabic, this segmentation process is performed as input preprocessing and is otherwise transparent to the translation system. However, when translating into Arabic, the decoder produces segmented output, which must be **desegmented** to produce readable text. For example, *l+ Aldwl* must be converted to *lldwl*.

Desegmentation is typically performed as a post-processing step that is independent from the decoding process. While this division of labor is useful, the pipeline approach may prevent the desegmenter from recovering from errors made by the decoder. Despite the efforts of the decoder's various component models, the system may produce mismatching segments, such as *s+ hzymp*, which pairs the future particle *s+* "will" with a noun *hzymp* "defeat", instead of a verb. In this scenario, there is no right desegmentation; the post-processor has been dealt a losing hand.

In this work, we show that it is possible to maintain the sparsity-reducing benefit of segmentation while translating directly into unsegmented text. We desegment a large set of possible decoder outputs by processing n-best lists or lattices, which allows us to consider both the segmented and desegmented output before locking in the decoder's decision. We demonstrate that significant improvements in translation quality can be achieved by training a linear model to re-rank this transformed translation space.

2 Related Work

Translating into morphologically complex languages is a challenging and interesting task that has received much recent attention. Most techniques approach the problem by transforming the target language in some manner before training the translation model. They differ in what transformations are performed and at what stage they are reversed. The transformation might take the form of a morphological analysis or a morphological segmentation.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 100–110,
Baltimore, Maryland, USA, June 23-25 2014.

2.1 Morphological Analysis

Many languages have access to morphological analyzers, which annotate surface forms with their lemmas and morphological features. Bojar (2007) incorporates such analyses into a factored model, to either include a language model over target morphological tags, or model the generation of morphological features. Other approaches train an SMT system to predict lemmas instead of surface forms, and then inflect the SMT output as a post-processing step (Minkov et al., 2007; Clifton and Sarkar, 2011; Fraser et al., 2012; El Kholy and Habash, 2012b). Alternatively, one can reparameterize existing phrase tables as exponential models, so that translation probabilities account for source context and morphological features (Jeong et al., 2010; Subotin, 2011). Of these approaches, ours is most similar to the translate-then-inflect approach, except we translate and then desegment. In particular, Toutanova et al. (2008) inflect and re-rank n-best lists in a similar manner to how we desegment and re-rank n-best lists or lattices.

2.2 Morphological Segmentation

Instead of producing an abstract feature layer, morphological segmentation transforms the target sentence by segmenting relevant morphemes, which are then handled as regular tokens during alignment and translation. This is done to reduce sparsity and to improve correspondence with the source language (usually English). Such a segmentation can be produced as a byproduct of analysis (Oflazer and Durgar El-Kahlout, 2007; Badr et al., 2008; El Kholy and Habash, 2012a), or may be produced using an unsupervised morphological segmenter such as Morfessor (Luong et al., 2010; Clifton and Sarkar, 2011). Work on target language morphological segmentation for SMT can be divided into three subproblems: segmentation, desegmentation and integration. Our work is concerned primarily with the integration problem, but we will discuss each subproblem in turn.

The usefulness of a target segmentation depends on its correspondence to the source language. If a morphological feature does not manifest itself as a separate token in the source, then it may be best to leave its corresponding segment attached to the stem. A number of studies have looked into what granularity of segmentation is best suited for a particular language pair (Oflazer and Durgar El-Kahlout, 2007; Badr et al., 2008; Clifton and Sarkar, 2011; El Kholy and Habash, 2012a). Since our focus here is on integrating segmentation into the decoding process, we simply adopt the segmentation strategies recommended by previous work: the Penn Arabic Treebank scheme for English-Arabic (El Kholy and Habash, 2012a), and an unsupervised scheme for English-Finnish (Clifton and Sarkar, 2011).

Desegmentation is the process of converting segmented words into their original surface form. For many segmentations, especially unsupervised ones, this amounts to simple concatenation. However, more complex segmentations, such as the Arabic tokenization provided by MADA (Habash et al., 2009), require further orthographic adjustments to reverse normalizations performed during segmentation. Badr et al. (2008) present two Arabic desegmentation schemes: table-based and rule-based. El Kholy and Habash (2012a) provide an extensive study on the influence of segmentation and desegmentation on English-to-Arabic SMT. They introduce an additional desegmentation technique that augments the table-based approach with an unsegmented language model. Salameh et al. (2013) replace rule-based desegmentation with a discriminatively-trained character transducer. In this work, we adopt the Table+Rules approach of El Kholy and Habash (2012a) for English-Arabic, while concatenation is sufficient for English-Finnish.

Work on integration attempts to improve SMT performance for morphologically complex target languages by going beyond simple pre- and post-processing. Oflazer and Durgar El-Kahlout (2007) desegment 1000-best lists for English-to-Turkish translation to enable scoring with an unsegmented language model. Unlike our work, they *replace* the segmented language model with the unsegmented one, allowing them to tune the linear model parameters by hand. We use both segmented and unsegmented language models, and tune automatically to optimize BLEU.

Like us, Luong et al. (2010) tune on unsegmented references,[1] and translate with both segmented and unsegmented language models for English-to-Finnish translation. However, they adopt a scheme of word-boundary-aware

[1]Tuning on unsegmented references does not require substantial modifications to the standard SMT pipeline. For example, Badr et al. (2008) also tune on unsegmented references by simply desegmenting SMT output before MERT collects sufficient statistics for BLEU.

morpheme-level phrase extraction, meaning that target phrases include only complete words, though those words are segmented into morphemes. This enables full decoder integration, where we do n-best and lattice re-ranking. But it also comes at a substantial cost: when target phrases include only complete words, the system can only generate word forms that were seen during training. In this setting, the sparsity reduction from segmentation helps word alignment and target language modeling, but it does not result in a more expressive translation model. Furthermore, it becomes substantially more difficult to have non-adjacent source tokens contribute morphemes to a single target word. For example, when translating "with his blue car" into the Arabic بسيارته الزرقاء *bsyArth AlzrqA'*, the target word *bsyArth* is composed of three tokens: *b+* "with", *syArp* "car" and *+h* "his". With word-boundary-aware phrase extraction, a phrase pair containing all of "with his blue car" must have been seen in the parallel data to translate the phrase correctly at test time. With lattice desegmentation, we need only to have seen *AlzrqA'* "blue" and the three morphological pieces of *bsyArth* for the decoder and desegmenter to assemble the phrase.

3 Methods

Our goal in this work is to benefit from the sparsity-reducing properties of morphological segmentation while simultaneously allowing the system to reason about the final surface forms of the target language. We approach this problem by augmenting an SMT system built over target segments with features that reflect the desegmented target words. In this section, we describe our various strategies for desegmenting the SMT system's output space, along with the features that we add to take advantage of this desegmented view.

3.1 Baselines

The two obvious baseline approaches each decode using one view of the target language. The **unsegmented** approach translates without segmenting the target. This trivially allows for an unsegmented language model and never makes desegmentation errors. However, it suffers from data sparsity and poor token-to-token correspondence with the source language.

The **one-best desegmentation** approach segments the target language at training time and then desegments the one-best output in post-processing. This resolves the sparsity issue, but does not allow the decoder to take into account features of the desegmented target. To the best of our knowledge, we are the first group to go beyond one-best desegmentation for English-to-Arabic translation. In English-to-Finnish, although alternative integration strategies have seen some success (Luong et al., 2010), the current state-of-the-art performs one-best-desegmentation (Clifton and Sarkar, 2011).

3.2 n-best Desegmentation

The one-best approach can be extended easily by desegmenting n-best lists of segmented decoder output. Doing so enables the inclusion of an unsegmented target language model, and with a small amount of bookkeeping, it also allows the inclusion of features related to the operations performed during desegmentation (see Section 3.4). With new features reflecting the desegmented output, we can re-tune our enhanced linear model on a development set. Following previous work, we will desegment 1000-best lists (Oflazer and Durgar El-Kahlout, 2007).

Once n-best lists have been desegmented, we can tune on unsegmented references as a side-benefit. This could improve translation quality, as it brings our training scenario closer to our test scenario (test BLEU is always measured on unsegmented references). In particular, it could address issues with translation length mismatch. Previous work that has tuned on unsegmented references has reported mixed results (Badr et al., 2008; Luong et al., 2010).

3.3 Lattice Desegmentation

An n-best list reflects a tiny portion of a decoder's search space, typically fixed at 1000 hypotheses. Lattices[2] can represent an exponential number of hypotheses in a compact structure. In this section, we discuss how a lattice from a multi-stack phrase-based decoder such as Moses (Koehn et al., 2007) can be desegmented to enable word-level features.

Finite State Analogy

A phrase-based decoder produces its output from left to right, with each operation appending the translation of a source phrase to a growing target hypothesis. Translation continues un-

[2]Or forests for hierarchical and syntactic decoders.

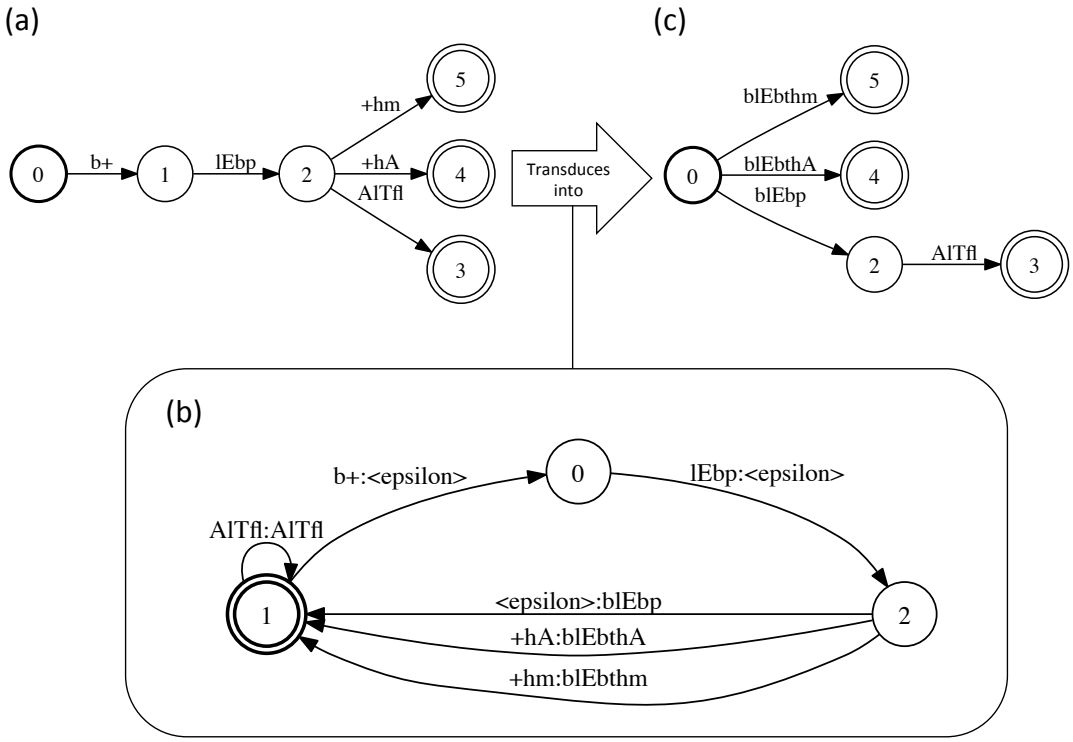

Figure 1: The finite state pipeline for a lattice translating the English fragment "with the child's game". The input morpheme lattice (a) is desegmented by composing it with the desegmenting transducer (b) to produce the word lattice (c). The tokens in (a) are: *b+* "with", *lEbp* "game", *+hm* "their", *+hA* "her", and *AlTfl* "the child".

til each source word has been covered exactly once (Koehn et al., 2003).

The search graph of a phrase-based decoder can be interpreted as a lattice, which can be interpreted as a finite state acceptor over target strings. In its most natural form, such an acceptor emits target phrases on each edge, but it can easily be transformed into a form with one edge per token, as shown in Figure 1a. This is sometimes referred to as a word graph (Ueffing et al., 2002), although in our case the segmented phrase table also produces tokens that correspond to morphemes.

Our goal is to desegment the decoder's output lattice, and in doing so, gain access to a compact, desegmented view of a large portion of the translation search space. This can be accomplished by composing the lattice with a **desegmenting transducer** that consumes morphemes and outputs desegmented words. This transducer must be able to consume every word in our lattice's output vocabulary. We define a word using the following regular expression:

$$\text{[prefix]* [stem] [suffix]* | [prefix]+ [suffix]+} \quad (1)$$

where [prefix], [stem] and [suffix] are non-overlapping sets of morphemes, whose members are easily determined using the segmenter's segment boundary markers.[3] The second disjunct of Equation 1 covers words that have no clear stem, such as the Arabic لـ *lh* "for him", segmented as *l+* "for" *+h* "him". Equation 1 may need to be modified for other languages or segmentation schemes, but our techniques generalize to any definition that can be written as a regular expression.

A desegmenting transducer can be constructed by first encoding our desegmenter as a table that maps morpheme sequences to words. Regardless of whether the original desegmenter was based on concatenation, rules or table-lookup, it can be encoded as a lattice-specific table by applying it to an enumeration of all words found in the lattice. We can then transform that table into a finite state transducer with one path per table entry. Finally, we take the closure of this transducer, so that the resulting machine can transduce any sequence of words. The desegmenting trans-

[3] Throughout this paper, we use "+" to mark morphemes as prefixes or suffixes, as in *w+* or *+h*. In Equation 1 only, we overload "+" as the Kleene cross: $X+ == XX*$.

ducer for our running example is shown in Figure 1b. Note that tokens requiring no desegmentation simply emit themselves. The lattice (Figure 1a) can then be desegmented by composing it with the transducer (1b), producing a desegmented lattice (1c). This is a natural place to introduce features that describe the desegmentation process, such as scores provided by a desegmentation table, which can be incorporated into the desegmenting transducer's edge weights.

We now have a desegmented lattice, but it has not been annotated with an unsegmented (word-level) language model. In order to annotate lattice edges with an n-gram LM, every path coming into a node must end with the same sequence of $(n-1)$ tokens. If this property does not hold, then nodes must be split until it does.[4] This property is maintained by the decoder's recombination rules for the segmented LM, but it is not guaranteed for the desegmented LM. Indeed, the expanded word-level context is one of the main benefits of incorporating a word-level LM. Fortunately, LM annotation as well as any necessary lattice modifications can be performed simultaneously by composing the desegmented lattice with a finite state acceptor encoding the LM (Roark et al., 2011).

In summary, we are given a segmented lattice, which encodes the decoder's translation space as an acceptor over morphemes. We compose this acceptor with a desegmenting transducer, and then with an unsegmented LM acceptor, producing a fully annotated, desegmented lattice. Instead of using a tool kit such as OpenFst (Allauzen et al., 2007), we implement both the desegmenting transducer and the LM acceptor programmatically. This eliminates the need to construct intermediate machines, such as the lattice-specific desegmenter in Figure 1b, and facilitates working with edges annotated with feature vectors as opposed to single weights.

Programmatic Desegmentation

Lattice desegmentation is a non-local lattice transformation. That is, the morphemes forming a word might span several edges, making desegmentation non-trivial. Luong et al. (2010) address this problem by forcing the decoder's phrase table to respect word boundaries, guaranteeing that each desegmentable token sequence is local to an edge. Inspired by the use of non-local features in forest decoding (Huang, 2008), we present an algorithm to find **chains** of edges that correspond to desegmentable token sequences, allowing lattice desegmentation with no phrase-table restrictions. This algorithm can be seen as implicitly constructing a customized desegmenting transducer and composing it with the input lattice on the fly.

Before describing the algorithm, we define some notation. An input morpheme lattice is a triple $\langle n_s, \mathcal{N}, \mathcal{E} \rangle$, where $\mathcal{N}$ is a set of nodes, $\mathcal{E}$ is a set of edges, and $n_s \in \mathcal{N}$ is the start node that begins each path through the lattice. Each edge $e \in \mathcal{E}$ is a 4-tuple $\langle \mathit{from}, \mathit{to}, \mathit{lex}, w \rangle$, where from, $\mathit{to} \in \mathcal{N}$ are head and tail nodes, lex is a single token accepted by this edge, and w is the (potentially vector-valued) edge weight. Tokens are drawn from one of three non-overlapping morpho-syntactic sets: $\mathit{lex} \in \mathit{Prefix} \cup \mathit{Stem} \cup \mathit{Suffix}$, where tokens that do not require desegmentation, such as complete words, punctuation and numbers, are considered to be in Stem. It is also useful to consider the set of all outgoing edges for a node $n.\mathit{out} = \{e \in \mathcal{E} | e.\mathit{from} = n\}$.

With this notation in place, we can define a **chain** c to be a sequence of edges $[e_1 \dots e_l]$ such that for $1 \leq i < l : e_i.\mathit{to} = e_{i+1}.\mathit{from}$. We denote singleton chains with $[e]$, and when unambiguous, we abbreviate longer chains with their start and end node $[e_1.\mathit{from} \rightarrow e_l.\mathit{to}]$. A chain is **valid** if it emits the beginning of a word as defined by the regular expression in Equation 1. A valid chain is **complete** if its edges form an entire word, and if it is part of a path through the lattice that consists only of words. In Figure 1a, the complete chains are $[0 \rightarrow 2]$, $[0 \rightarrow 4]$, $[0 \rightarrow 5]$, and $[2 \rightarrow 3]$. The path restriction on complete chains forces words to be bounded by other words in order to be complete.[5] For example, if we removed the edge $2 \rightarrow 3$ (*AlTfl*) from Figure 1a, then $[0 \rightarrow 2]$ ([*b+ lEbp*]) would cease to be a complete chain, but it would still be a valid chain. Note that in the finite-state analogy, the path restriction is implicit in the composition operation.

Algorithm 1 desegments a lattice by finding all complete chains and replacing each one with a single edge. It maintains a work list of nodes that lie on the boundary between words, and for each node on this list, it launches a depth first search

[4] Or the LM composition can be done dynamically, effectively decoding the lattice with a beam or cube-pruned search (Huang and Chiang, 2007).

[5] Sentence-initial suffix morphemes and sentence-final prefix morphemes represent a special case that we omit for the sake of brevity. Lacking stems, they are left segmented.

Algorithm 1 Desegment a lattice $\langle n_s, \mathcal{N}, \mathcal{E} \rangle$

```
{Initialize output lattice and work list WL}
n'_s = n_s, N' = ∅, E' = ∅, WL = [n_s]
while n = WL.pop() do
  {Work on each node only once}
  if n ∈ N' then continue
  N' = N' ∪ {n}
  {Initialize the chain stack C}
  C = ∅
  for e ∈ n.out do
    if [e] is valid then C.push([e])
  {Depth-first search for complete chains}
  while [e_1, ..., e_l] = C.pop() do
    {Attempt to extend chain}
    for e ∈ e_l.to.out do
      if [e_1 ... e_l, e] is valid then
        C.push([e_1, ..., e_l, e])
      else
        Mark [e_1, ..., e_l] as complete
    {Desegment complete chains}
    if [e_1, ..., e_l] is complete then
      WL.push(e_l.to)
      E' = E' ∪ {deseg([e_1, ..., e_l])}
return ⟨n'_s, N', E'⟩
```

to find all complete chains extending from it. The search recognizes the valid chain c to be complete by finding an edge e such that $c + e$ forms a chain, but not a valid one. By inspection of Equation 1, this can only happen when a prefix or stem follows a stem or suffix, which always marks a word boundary. The chains found by this search are desegmented and then added to the output lattice as edges. The nodes at end points of these chains are added to the work list, as they lie at word boundaries by definition. Note that although this algorithm creates completely new edges, the resulting node set $\mathcal{N}'$ will be a subset of the input node set $\mathcal{N}$. The complement $\mathcal{N} - \mathcal{N}'$ will consist of nodes that are word-internal in all paths through the input lattice, such as node 1 in Figure 1a.

Programmatic LM Integration

Programmatic composition of a lattice with an n-gram LM acceptor is a well understood problem. We use a dynamic program to enumerate all $(n-1)$-word contexts leading into a node, and then split the node into multiple copies, one for each context. With each node corresponding to a single LM context, annotation of outgoing edges with n-gram LM scores is straightforward.

3.4 Desegmentation Features

Our re-ranker has access to all of the features used by the decoder, in addition to a number of features enabled by desegmentation.

Desegmentation Score We use a table-based desegmentation method for Arabic, which is based on segmenting an Arabic training corpus and memorizing the observed transformations to reverse them later. Finnish does not require a table, as all words can be desegmented with simple concatenation. The Arabic table consists of $X \rightarrow Y$ entries, where X is a target morpheme sequence and Y is a desegmented surface form. Several entries may share the same X, resulting in multiple desegmentation options. For the sake of symmetry with the unambiguous Finnish case, we augment Arabic n-best lists or lattices with only the most frequent desegmentation Y.[6] We provide the desegmentation score $\log p(Y|X)$= $\log\left(\frac{\text{count of } X \rightarrow Y}{\text{count of X}}\right)$ as a feature, to indicate the entry's ambiguity in the training data.[7] When an X is missing from the table, we fall back on a set of desegmentation rules (El Kholy and Habash, 2012a) and this feature is set to 0. This feature is always 0 for English-Finnish.

Contiguity One advantage of our approach is that it allows discontiguous source words to translate into a single target word. In order to maintain some control over this powerful capability, we create three binary features that indicate the contiguity of a desegmentation. The first feature indicates that the desegmented morphemes were translated from contiguous source words. The second indicates that the source words contained a single discontiguity, as in a word-by-word translation of the "with his blue car" example from Section 2.2. The third indicates two or more discontiguities.

Unsegmented LM A 5-gram LM trained on unsegmented target text is used to assess the fluency of the desegmented word sequence.

4 Experimental Setup

We train our English-to-Arabic system using 1.49 million sentence pairs drawn from the NIST 2012 training set, excluding the UN data. This training set contains about 40 million Arabic tokens before

[6] Allowing the re-ranker to choose between multiple Ys is a natural avenue for future work.

[7] We also experimented on $\log p(X|Y)$ as an additional feature, but observed no improvement in translation quality.

segmentation, and 47 million after segmentation. We tune on the NIST 2004 evaluation set (1353 sentences) and evaluate on NIST 2005 (1056 sentences). As these evaluation sets are intended for Arabic-to-English translation, we select the first English reference to use as our source text.

Our English-to-Finnish system is trained on the same Europarl corpus as Luong et al. (2010) and Clifton and Sarkar (2011), which has roughly one million sentence pairs. We also use their development and test sets (2000 sentences each).

4.1 Segmentation

For Arabic, morphological segmentation is performed by MADA 3.2 (Habash et al., 2009), using the Penn Arabic Treebank (PATB) segmentation scheme as recommended by El Kholy and Habash (2012a). For both segmented and unsegmented Arabic, we further normalize the script by converting different forms of Alif ا آ أ إ and Ya ى ي to bare Alif ا and dotless Ya ى. To generate the desegmentation table, we analyze the segmentations from the Arabic side of the parallel training data to collect mappings from morpheme sequences to surface forms.

For Finnish, we adopt the Unsup L-match segmentation technique of Clifton and Sarkar (2011), which uses Morfessor (Creutz and Lagus, 2005) to analyze the 5,000 most frequent Finnish words. The analysis is then applied to the Finnish side of the parallel text, and a list of segmented suffixes is collected. To improve coverage, words are further segmented according to their longest matching suffix from the list. As Morfessor does not perform any orthographic normalizations, it can be desegmented with simple concatenation.

4.2 Systems

We align the parallel data with GIZA++ (Och et al., 2003) and decode using Moses (Koehn et al., 2007). The decoder's log-linear model includes a standard feature set. Four translation model features encode phrase translation probabilities and lexical scores in both directions. Seven distortion features encode a standard distortion penalty as well as a bidirectional lexicalized reordering model. A KN-smoothed 5-gram language model is trained on the target side of the parallel data with SRILM (Stolcke, 2002). Finally, we include word and phrase penalties. The decoder uses the default parameters for English-to-Arabic, except that the maximum phrase length is set to 8. For English-to-Finnish, we follow Clifton and Sarkar (2011) in setting the hypothesis stack size to 100, distortion limit to 6, and maximum phrase length to 20.

The decoder's log-linear model is tuned with MERT (Och, 2003). Re-ranking models are tuned using a batch variant of hope-fear MIRA (Chiang et al., 2008; Cherry and Foster, 2012), using the n-best variant for n-best desegmentation, and the lattice variant for lattice desegmentation. MIRA was selected over MERT because we have an in-house implementation that can tune on lattices very quickly. During development, we confirmed that MERT and MIRA perform similarly, as is expected with fewer than 20 features. Both the decoder's log-linear model and the re-ranking models are trained on the same development set. Historically, we have not seen improvements from using different tuning sets for decoding and re-ranking. Lattices are pruned to a density of 50 edges per word before re-ranking.

We test four different systems. Our first baseline is **Unsegmented**, where we train on unsegmented target text, requiring no desegmentation step. Our second baseline is **1-best Deseg**, where we train on segmented target text and desegment the decoder's 1-best output. Starting from the system that produced 1-best Deseg, we then output either 1000-best lists or lattices to create our two experimental systems. The **1000-best Deseg** system desegments, augments and re-ranks the decoder's 1000-best list, while **Lattice Deseg** does the same in the lattice. We augment n-best lists and lattices using the features described in Section 3.4.[8]

We evaluate our system using BLEU (Papineni et al., 2002) and TER (Snover et al., 2006). Following Clark et al. (2011), we report average scores over five random tuning replications to account for optimizer instability. For the baselines, this means 5 runs of decoder tuning. For the desegmenting re-rankers, this means 5 runs of re-ranker tuning, each working on n-best lists or lattices produced by the same (representative) decoder weights. We measure statistical significance using MultEval (Clark et al., 2011), which implements a stratified approximate randomization test to account for multiple tuning replications.

[8] Development experiments on a small-data English-to-Arabic scenario indicated that the Desegmentation Score was not particularly useful, so we exclude it from the main comparison, but include it in the ablation experiments.

5 Results

Tables 1 and 2 report results averaged over 5 tuning replications on English-to-Arabic and English-to-Finnish, respectively. In all scenarios, both 1000-best Deseg and Lattice Deseg significantly outperform the 1-best Deseg baseline ($p < 0.01$).

For English-to-Arabic, 1-best desegmentation results in a 0.7 BLEU point improvement over training on unsegmented Arabic. Moving to lattice desegmentation more than doubles that improvement, resulting in a BLEU score of 34.4 and an improvement of 1.0 BLEU point over 1-best desegmentation. 1000-best desegmentation also works well, resulting in a 0.6 BLEU point improvement over 1-best. Lattice desegmentation is significantly better ($p < 0.01$) than 1000-best desegmentation.

For English-to-Finnish, the Unsup L-match segmentation with 1-best desegmentation does not improve over the unsegmented baseline. The segmentation may be addressing issues with model sparsity, but it is also introducing errors that would have been impossible had words been left unsegmented. In fact, even with our lattice desegmenter providing a boost, we are unable to see a significant improvement over the unsegmented model. As we attempted to replicate the approach of Clifton and Sarkar (2011) exactly by working with their segmented data, this difference is likely due to changes in Moses since the publication of their result. Nonetheless, the 1000-best and lattice desegmenters both produce significant improvements over the 1-best desegmentation baseline, with Lattice Deseg achieving a 1-point improvement in TER. These results match the established state-of-the-art on this data set, but also indicate that there is still room for improvement in identifying the best segmentation strategy for English-to-Finnish translation.

We also tried a similar Morfessor-based segmentation for Arabic, which has an unsegmented test set BLEU of 32.7. As in Finnish, the 1-best desegmentation using Morfessor did not surpass the unsegmented baseline, producing a test BLEU of only 31.4 (not shown in Table 1). Lattice desegmentation was able to boost this to 32.9, slightly above 1-best desegmentation, but well below our best MADA desegmentation result of 34.4. There appears to be a large advantage to using MADA's supervised segmentation in this scenario.

Model	Dev	Test	
	BLEU	BLEU	TER
Unsegmented	24.4	32.7	49.4
1-best Deseg	24.4	33.4	48.6
1000-best Deseg	25.0	34.0	48.0
Lattice Deseg	25.2	34.4	47.7

Table 1: Results for English-to-Arabic translation using MADA's PATB segmentation.

Model	Dev	Test	
	BLEU	BLEU	TER
Unsegmented	15.4	15.1	70.8
1-best Deseg	15.3	14.8	71.9
1000-best Deseg	15.4	15.1	71.5
Lattice Deseg	15.5	15.1	70.9

Table 2: Results for English-to-Finnish translation using unsupervised segmentation.

5.1 Ablation

We conducted an ablation experiment on English-to-Arabic to measure the impact of the various features described in Section 3.4. Table 3 compares different combinations of features using lattice desegmentation. The unsegmented LM alone yields a 0.4 point improvement over the 1-best desegmentation score. Adding contiguity indicators on top of the unsegmented LM results in another 0.6 point improvement. As anticipated, the tuner assigns negative weights to discontiguous cases, encouraging the re-ranker to select a safer translation path when possible. Judging from the output on the NIST 2005 test set, the system uses these discontiguous desegmentations very rarely: only 5% of desegmented tokens align to discontiguous source phrases. Adding the desegmentation score to these two feature groups does not improve performance, confirming the results we observed during development. The desegmentation score would likely be useful in a scenario where we provide multiple desegmentation options to the re-ranker; for now, it indicates only the ambiguity of a fixed choice, and is likely redundant with information provided by the language model.

5.2 Error Analysis

In order to better understand the source of our improvements in the English-to-Arabic scenario, we conducted an extensive manual analysis of the differences between 1-best and lattice deseg-

Features	dev	test
1-best Deseg	24.5	33.4
+ Unsegmented LM	24.9	33.8
+ Contiguity	25.2	34.4
+ Desegmentation Score	25.2	34.3

Table 3: The effect of feature ablation on BLEU score for English-to-Arabic translation with lattice desegmentation.

	Lattice Correct	1-best Correct	Both Incorrect
Clitical	157	71	79
Lexical	61	39	80
Inflectional	37	32	47
Part-of-speech	19	17	11

Table 4: Error analysis for English-to-Arabic translation based on 650 sampled instances.

mentation on our test set. We compared the output of the two systems using the Unix tool *wdiff*, which transforms a solution to the longest-common-subsequence problem into a sequence of multi-word insertions and deletions (Hunt and McIlroy, 1976). We considered adjacent insertion-deletion pairs to be (potentially phrasal) substitutions, and collected them into a file, omitting any unpaired insertions or deletions. We then sampled 650 cases where the two sides of the substitution were deemed to be related, and divided these cases into categories based on how the lattice desegmentation differs from the one-best desegmentation. We consider a phrase to be correct only if it can be found in the reference.

Table 4 breaks down per-phrase accuracy according to four manually-assigned categories: (1) **clitical** – the two systems agree on a stem, but at least one clitic, often a prefix denoting a preposition or determiner, was dropped, added or replaced; (2) **lexical** – a word was changed to a morphologically unrelated word with a similar meaning; (3) **inflectional** – the words have the same stem, but different inflection due to a change in gender, number or verb tense; (4) **part-of-speech** – the two systems agree on the lemma, but have selected different parts of speech.

For each case covering a single phrasal difference, we compare the phrases from each system to the reference. We report the number of instances where each system matched the reference, as well as cases where they were both incorrect. The majority of differences correspond to clitics, whose correction appears to be a major source of the improvements obtained by lattice desegmentation. This category is challenging for the decoder because English prepositions tend to correspond to multiple possible forms when translated into Arabic. It also includes the frequent cases involving the nominal determiner prefix *Al* "the" (left unsegmented by the PATB scheme), and the sentence-initial conjunction *w+* "and". The second most common category is lexical, where the unsegmented LM has drastically altered the choice of translation. The remaining categories show no major advantage for either system.

6 Conclusion

We have explored deeper integration of morphological desegmentation into the statistical machine translation pipeline. We have presented a novel, finite-state-inspired approach to lattice desegmentation, which allows the system to account for a desegmented view of many possible translations, without any modification to the decoder or any restrictions on phrase extraction. When applied to English-to-Arabic translation, lattice desegmentation results in a 1.0 BLEU point improvement over one-best desegmentation, and a 1.7 BLEU point improvement over unsegmented translation. We have also applied our approach to English-to-Finnish translation, and although segmentation in general does not currently help, we are able to show significant improvements over a 1-best desegmentation baseline.

In the future, we plan to explore introducing multiple segmentation options into the lattice, and the application of our method to a full morphological analysis (as opposed to segmentation) of the target language. Eventually, we would like to replace the functionality of factored translation models (Koehn and Hoang, 2007) with lattice transformation and augmentation.

Acknowledgments

Thanks to Ann Clifton for generously providing the data and segmentation for our English-to-Finnish experiments, and to Marine Carpuat and Roland Kuhn for their helpful comments on an earlier draft. This research was supported by the Natural Sciences and Engineering Research Council of Canada.

Abstract

We propose Bilingually-constrained Recursive Auto-encoders (BRAE) to learn semantic phrase embeddings (compact vector representations for phrases), which can distinguish the phrases with different semantic meanings. The BRAE is trained in a way that minimizes the semantic distance of translation equivalents and maximizes the semantic distance of non-translation pairs simultaneously. After training, the model learns how to embed each phrase semantically in two languages and also learns how to transform semantic embedding space in one language to the other. We evaluate our proposed method on two end-to-end SMT tasks (phrase table pruning and decoding with phrasal semantic similarities) which need to measure semantic similarity between a source phrase and its translation candidates. Extensive experiments show that the BRAE is remarkably effective in these two tasks.

1 Introduction

Due to the powerful capacity of feature learning and representation, Deep (multi-layer) Neural Networks (DNN) have achieved a great success in speech and image processing (Kavukcuoglu et al., 2010; Krizhevsky et al., 2012; Dahl et al., 2012).

Recently, statistical machine translation (SMT) community has seen a strong interest in adapting and applying DNN to many tasks, such as word alignment (Yang et al., 2013), translation confidence estimation (Mikolov et al., 2010; Liu et al., 2013; Zou et al., 2013), phrase reordering prediction (Li et al., 2013), translation modelling (Auli et al., 2013; Kalchbrenner and Blunsom, 2013) and language modelling (Duh et al., 2013; Vaswani et al., 2013). Most of these works attempt to improve some components in SMT based on *word embedding*, which converts a word into a dense, low dimensional, real-valued vector representation (Bengio et al., 2003; Bengio et al., 2006; Collobert and Weston, 2008; Mikolov et al., 2013).

However, in the conventional (phrase-based) SMT, phrases are the basic translation units. The models using word embeddings as the direct inputs to DNN cannot make full use of the whole syntactic and semantic information of the phrasal translation rules. Therefore, in order to successfully apply DNN to model the whole translation process, such as modelling the decoding process, learning compact vector representations for the basic phrasal translation units is the essential and fundamental work.

In this paper, we explore the phrase embedding, which represents a phrase (sequence of words) with a real-valued vector. In some previous works, phrase embedding has been discussed from different views. Socher et al. (2011) make the phrase embeddings capture the sentiment information. Socher et al. (2013a) enable the phrase embeddings to mainly capture the syntactic knowledge. Li et al. (2013) attempt to encode the reordering pattern in the phrase embeddings. Kalchbrenner and Blunsom (2013) utilize a simple convolution model to generate phrase embeddings from word embeddings. Mikolov et al. (2013) consider a phrase as an indivisible n-gram. Obviously, these methods of learning phrase embeddings either focus on some aspects of the phrase (e.g. reordering pattern), or impose strong assumptions (e.g. bag-of-words or indivisible n-gram). Therefore, these phrase embeddings are not suitable to fully represent the phrasal translation units in SMT due to the lack of semantic meanings of the phrase.

Instead, we focus on learning phrase embeddings from the view of semantic meaning, so that our phrase embedding can fully represent the phrase and best fit the phrase-based SMT. Assuming the phrase is a meaningful composition

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 111–121,
Baltimore, Maryland, USA, June 23-25 2014.

of its internal words, we propose Bilingually-constrained Recursive Auto-encoders (BRAE) to learn semantic phrase embeddings. The core idea behind is that a phrase and its correct translation should share the same semantic meaning. Thus, they can supervise each other to learn their semantic phrase embeddings. Similarly, non-translation pairs should have different semantic meanings, and this information can also be used to guide learning semantic phrase embeddings.

In our method, the standard recursive auto-encoder (RAE) pre-trains the phrase embedding with an unsupervised algorithm by minimizing the reconstruction error (Socher et al., 2010), while the bilingually-constrained model learns to fine-tune the phrase embedding by minimizing the semantic distance between translation equivalents and maximizing the semantic distance between non-translation pairs.

We use an example to explain our model. As illustrated in Fig. 1, the Chinese phrase on the left and the English phrase on the right are translations with each other. If we learn the embedding of the Chinese phrase correctly, we can regard it as the gold representation for the English phrase and use it to guide the process of learning English phrase embedding. In the other direction, the Chinese phrase embedding can be learned in the same way. This procedure can be performed with an co-training style algorithm so as to minimize the semantic distance between the translation equivalents [1]. In this way, the result Chinese and English phrase embeddings will capture the semantics as much as possible. Furthermore, a transformation function between the Chinese and English semantic spaces can be learned as well.

With the learned model, we can accurately measure the semantic similarity between a source phrase and a translation candidate. Accordingly, we evaluate the BRAE model on two end-to-end SMT tasks (phrase table pruning and decoding with phrasal semantic similarities) which need to check whether a translation candidate and the source phrase are in the same meaning. In phrase table pruning, we discard the phrasal translation rules with low semantic similarity. In decoding with phrasal semantic similarities, we apply the semantic similarities of the phrase pairs as new features during decoding to guide translation candidate selection. The experiments show that up to 72% of the phrase table can be discarded without significant decrease on the translation quality, and in decoding with phrasal semantic similarities up to 1.7 BLEU score improvement over the state-of-the-art baseline can be achieved.

[1]For simplicity, we do not show non-translation pairs here.

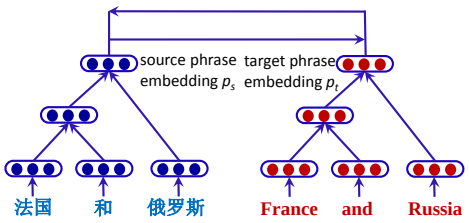

Figure 1: A motivation example for the BRAE model.

In addition, our semantic phrase embeddings have many other potential applications. For instance, the semantic phrase embeddings can be directly fed to DNN to model the decoding process. Besides SMT, the semantic phrase embeddings can be used in other cross-lingual tasks (e.g. cross-lingual question answering) and monolingual applications such as textual entailment, question answering and paraphrase detection.

2 Related Work

Recently, phrase embedding has drawn more and more attention. There are three main perspectives handling this task in monolingual languages.

One method considers the phrases as bag-of-words and employs a convolution model to transform the word embeddings to phrase embeddings (Collobert et al., 2011; Kalchbrenner and Blunsom, 2013). Gao et al. (2013) also use bag-of-words but learn BLEU sensitive phrase embeddings. This kind of approaches does not take the word order into account and loses much information. Instead, our bilingually-constrained recursive auto-encoders not only learn the composition mechanism of generating phrases from words, but also fine tune the word embeddings during the model training stage, so that we can induce the full information of the phrases and internal words.

Another method (Mikolov et al., 2013) deals with the phrases having a meaning that is not a simple composition of the meanings of its individual words, such as *New York Times*. They first find the phrases of this kind. Then, they regard these phrases as indivisible units, and learn their embeddings with the context information. How-

ever, this kind of phrase embedding is hard to capture full semantics since the context of a phrase is limited. Furthermore, this method can only account for a very small part of phrases, since most of the phrases are compositional. In contrast, our method attempts to learn the semantic vector representation for any phrase.

The third method views any phrase as the meaningful composition of its internal words. The recursive auto-encoder is typically adopted to learn the way of composition (Socher et al., 2010; Socher et al., 2011; Socher et al., 2013a; Socher et al., 2013b; Li et al., 2013). They pre-train the RAE with an unsupervised algorithm. And then, they fine-tune the RAE according to the label of the phrase, such as the syntactic category in parsing (Socher et al., 2013a), the polarity in sentiment analysis (Socher et al., 2011; Socher et al., 2013b), and the reordering pattern in SMT (Li et al., 2013). This kind of semi-supervised phrase embedding is in fact performing phrase clustering with respect to the phrase label. For example, in the RAE-based phrase reordering model for SMT (Li et al., 2013), the phrases with the similar reordering tendency (e.g. monotone or swap) are close to each other in the embedding space, such as the prepositional phrases. Obviously, this kind methods of semi-supervised phrase embedding do not fully address the semantic meaning of the phrases. Although we also follow the composition-based phrase embedding, we are the first to focus on the semantic meanings of the phrases and propose a bilingually-constrained model to induce the semantic information and learn transformation of the semantic space in one language to the other.

3 Bilingually-constrained Recursive Auto-encoders

This section introduces the Bilingually-constrained Recursive Auto-encoders (BRAE), that is inspired by two observations. First, the recursive auto-encoder provides a reasonable composition mechanism to embed each phrase. And the semi-supervised phrase embedding (Socher et al., 2011; Socher et al., 2013a; Li et al., 2013) further indicates that phrase embedding can be tuned with respect to the label. Second, even though we have no correct semantic phrase representation as the gold label, the phrases sharing the same meaning provide an indirect but feasible way.

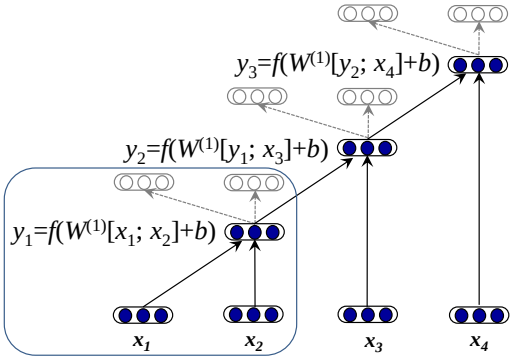

Figure 2: A recursive auto-encoder for a four-word phrase. The empty nodes are the reconstructions of the input.

We will first briefly present the unsupervised phrase embedding, and then describe the semi-supervised framework. After that, we introduce the BRAE on the network structure, objective function and parameter inference.

3.1 Unsupervised Phrase Embedding

3.1.1 Word Vector Representations

In phrase embedding using composition, the word vector representation is the basis and serves as the input to the neural network. After learning word embeddings with DNN (Bengio et al., 2003; Collobert and Weston, 2008; Mikolov et al., 2013), each word in the vocabulary V corresponds to a vector $x \in \mathbb{R}^n$, and all the vectors are stacked into an embedding matrix $L \in \mathbb{R}^{n \times |V|}$.

Given a phrase which is an ordered list of m words, each word has an index i into the columns of the embedding matrix L. The index i is used to retrieve the word's vector representation using a simple multiplication with a binary vector e which is zero in all positions except for the ith index:

$$x_i = Le_i \in \mathbb{R}^n \quad (1)$$

Note that n is usually set empirically, such as $n = 50, 100, 200$. Throughout this paper, $n = 3$ is used for better illustration as shown in Fig. 1.

3.1.2 RAE-based Phrase Embedding

Assuming we are given a phrase $w_1 w_2 \cdots w_m$, it is first projected into a list of vectors $(x_1, x_2, \cdots, x_m)$ using Eq. 1. The RAE learns the vector representation of the phrase by recursively combining two children vectors in a bottom-up manner (Socher et al., 2011). Fig. 2 illustrates an instance of a RAE applied to a binary tree, in

which a standard auto-encoder (in box) is re-used at each node. The standard auto-encoder aims at learning an abstract representation of its input. For two children $c_1 = x_1$ and $c_2 = x_2$, the auto-encoder computes the parent vector y_1 as follows:

$$p = f(W^{(1)}[c_1; c_2] + b^{(1)}) \quad (2)$$

Where we multiply the parameter matrix $W^{(1)} \in \mathbb{R}^{n \times 2n}$ by the concatenation of two children $[c_1; c_2] \in \mathbb{R}^{2n \times 1}$. After adding a bias term $b^{(1)}$, we apply an element-wise activation function such as $f = tanh(\cdot)$, which is used in our experiments. In order to apply this auto-encoder to each pair of children, the representation of the parent p should have the same dimensionality as the c_i's.

To assess how well the parent's vector represents its children, the standard auto-encoder reconstructs the children in a reconstruction layer:

$$[c_1'; c_2'] = f^{(2)}(W^{(2)}p + b^{(2)}) \quad (3)$$

Where c_1' and c_2' are reconstructed children, $W^{(2)}$ and $b^{(2)}$ are parameter matrix and bias term for reconstruction respectively, and $f^{(2)} = tanh(\cdot)$.

To obtain the optimal abstract representation of the inputs, the standard auto-encoder tries to minimize the reconstruction errors between the inputs and the reconstructed ones during training:

$$E_{rec}([c_1; c_2]) = \frac{1}{2}||[c_1; c_2] - [c_1'; c_2']||^2 \quad (4)$$

Given $y_1 = p$, we can use Eq. 2 again to compute y_2 by setting the children to be $[c_1; c_2] = [y_1; x_3]$. The same auto-encoder is re-used until the vector of the whole phrase is generated.

For unsupervised phrase embedding, the only objective is to minimize the sum of reconstruction errors at each node in the optimal binary tree:

$$RAE_\theta(x) = \underset{y \in A(x)}{\operatorname{argmin}} \sum_{s \in y} E_{rec}([c_1; c_2]_s) \quad (5)$$

Where x is the list of vectors of a phrase, and $A(x)$ denotes all the possible binary trees that can be built from inputs x. A greedy algorithm (Socher et al., 2011) is used to generate the optimal binary tree y. The parameters $\theta = (W, b)$ are optimized over all the phrases in the training data.

3.2 Semi-supervised Phrase Embedding

The above RAE is completely unsupervised and can only induce general representations of the multi-word phrases. Several researchers extend the original RAEs to a semi-supervised setting so that the induced phrase embedding can predict a target label, such as polarity in sentiment analysis (Socher et al., 2011), syntactic category in parsing (Socher et al., 2013a) and phrase reordering pattern in SMT (Li et al., 2013).

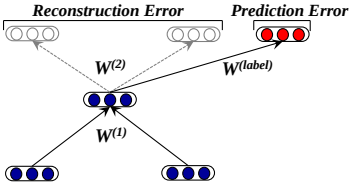

Figure 3: An illustration of a semi-supervised RAE unit. Red nodes show the label distribution.

In the semi-supervised RAE for phrase embedding, the objective function over a (phrase, label) pair (x, t) includes the reconstruction error and the prediction error, as illustrated in Fig. 3.

$$E(x, t; \theta) = \alpha E_{rec}(x, t; \theta) + (1 - \alpha) E_{pred}(x, t; \theta) \quad (6)$$

Where the hyper-parameter α is used to balance the reconstruction and prediction error. For label prediction, the cross-entropy error is usually used to calculate E_{pred}. By optimizing the above objective, the phrases in the vector embedding space will be grouped according to the labels.

3.3 The BRAE Model

We know from the semi-supervised phrase embedding that the learned vector representation can be well adapted to the given label. Therefore, we can imagine that learning semantic phrase embedding is reasonable if we are given gold vector representations of the phrases.

However, no gold semantic phrase embedding exists. Fortunately, we know the fact that the two phrases should share the same semantic representation if they express the same meaning. We can make inference from this fact that if a model can learn the same embedding for any phrase pair sharing the same meaning, the learned embedding must encode the semantics of the phrases and the corresponding model is our desire.

As translation equivalents share the same semantic meaning, we employ high-quality phrase translation pairs as training corpus in this work. Accordingly, we propose the Bilingually-constrained Recursive Auto-encoders (BRAE),

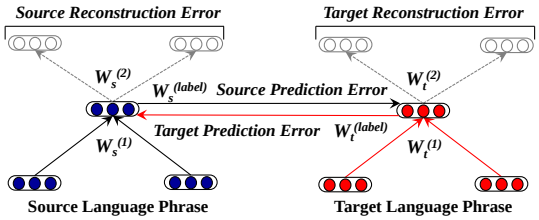

Figure 4: An illustration of the bilingual-constrained recursive auto-encoders. The two phrases are translations with each other.

whose basic goal is to minimize the semantic distance between the phrases and their translations.

3.3.1 The Objective Function

Unlike previous methods, the BRAE model jointly learns two RAEs (Fig. 4 shows the network structure): one for source language and the other for target language. For a phrase pair (s, t), two kinds of errors are involved:

1. **reconstruction error** $E_{rec}(s, t; \theta)$: how well the learned vector representations p_s and p_t represent the phrase s and t respectively?

$$E_{rec}(s, t; \theta) = E_{rec}(s; \theta) + E_{rec}(t; \theta) \quad (7)$$

2. **semantic error** $E_{sem}(s, t; \theta)$: what is the semantic distance between the learned vector representations p_s and p_t?

Since word embeddings for two languages are learned separately and locate in different vector space, we do not enforce the phrase embeddings in two languages to be in the same semantic vector space. We suppose there is a transformation between the two semantic embedding spaces. Thus, the semantic distance is bidirectional: the distance between p_t and the transformation of p_s, and that between p_s and the transformation of p_t. As a result, the overall semantic error becomes:

$$E_{sem}(s, t; \theta) = E_{sem}(s|t, \theta) + E_{sem}(t|s, \theta) \quad (8)$$

Where $E_{sem}(s|t, \theta) = E_{sem}(p_t, f(W_s^l p_s + b_s^l))$ means the transformation of p_s is performed as follows: we first multiply a parameter matrix W_s^l by p_s, and after adding a bias term b_s^l we apply an element-wise activation function $f = tanh(\cdot)$. Finally, we calculate their Euclidean distance:

$$E_{sem}(s|t, \theta) = \frac{1}{2}||p_t - f(W_s^l p_s + b_s^l)||^2 \quad (9)$$

$E_{sem}(t|s, \theta)$ can be calculated in exactly the same way. For the phrase pair (s, t), the joint error is:

$$E(s, t; \theta) = \alpha E_{rec}(s, t; \theta) + (1 - \alpha) E_{sem}(s, t; \theta) \quad (10)$$

The hyper-parameter α weights the reconstruction and semantic error. The final BRAE objective over the phrase pairs training set (S, T) becomes:

$$J_{BRAE} = \frac{1}{N} \sum_{(s,t) \in (S,T)} E(s, t; \theta) + \frac{\lambda}{2}||\theta||^2 \quad (11)$$

3.3.2 Max-Semantic-Margin Error

Ideally, we want the learned BRAE model can make sure that the semantic error for the positive example (a source phrase s and its correct translation t) is much smaller than that for the negative example (the source phrase s and a bad translation t'). However, the current model cannot guarantee this since the above semantic error $E_{sem}(s|t, \theta)$ only accounts for positive ones.

We thus enhance the semantic error with both positive and negative examples, and the corresponding max-semantic-margin error becomes:

$$E^*_{sem}(s|t, \theta) = max\{0, E_{sem}(s|t, \theta) - E_{sem}(s|t', \theta) + 1\} \quad (12)$$

It tries to minimize the semantic distance between translation equivalents and maximize the semantic distance between non-translation pairs simultaneously. Using the above error function, we need to construct a negative example for each positive example. Suppose we are given a positive example (s, t), the correct translation t can be converted into a bad translation t' by replacing the words in t with randomly chosen target language words. Then, a negative example (s, t') is available.

3.3.3 Parameter Inference

Like semi-supervised RAE (Li et al., 2013), the parameters θ in our BRAE model can also be divided into three sets:

θ_L: word embedding matrix L for two languages (Section 3.1.1);

θ_{rec}: recursive auto-encoder parameter matrices $W^{(1)}$, $W^{(2)}$, and bias terms $b^{(1)}$, $b^{(2)}$ for two languages (Section 3.1.2);

θ_{sem}: transformation matrix W^l and bias term b^l for two directions in semantic distance computation (Section 3.3.1).

To have a deep understanding of the parameters, we rewrite Eq. 10:

$$\begin{aligned} E(s,t;\theta) &= \alpha(E_{rec}(s;\theta) + E_{rec}(t;\theta)) \\ &+ (1-\alpha)(E^*_{sem}(s|t,\theta) + E^*_{sem}(t|s,\theta)) \\ &= (\alpha E_{rec}(s;\theta_s) + (1-\alpha)E^*_{sem}(s|t,\theta_s)) \\ &+ (\alpha E_{rec}(t;\theta_t) + (1-\alpha)E^*_{sem}(t|s,\theta_t)) \end{aligned} \quad (13)$$

We can see that the parameters θ can be divided into two classes: θ_s for the source language and θ_t for the target language. The above equation also indicates that the source-side parameters θ_s can be optimized independently as long as the semantic representation p_t of the target phrase t is given to compute $E_{sem}(s|t,\theta)$ with Eq. 9. It is similar for the target-side parameters θ_t.

Assuming the target phrase representation p_t is available, the optimization of the source-side parameters is similar to that of semi-supervised RAE. We apply the Stochastic Gradient Descent (SGD) algorithm to optimize each parameter:

$$\theta_s = \theta_s - \eta \frac{\partial J_s}{\partial \theta_s} \quad (14)$$

In order to run SGD algorithm, we need to solve two problems: one for parameter initialization and the other for partial gradient calculation.

In parameter initialization, θ_{rec} and θ_{sem} for the source language is randomly set according to a normal distribution. For the word embedding L_s, there are two choices. First, L_s is initialized randomly like other parameters. Second, the word embedding matrix L_s is pre-trained with DNN (Bengio et al., 2003; Collobert and Weston, 2008; Mikolov et al., 2013) using large-scale unlabeled monolingual data. We prefer to the second one since this kind of word embedding has already encoded some semantics of the words. In this work, we employ the toolkit Word2Vec (Mikolov et al., 2013) to pre-train the word embedding for the source and target languages. The word embeddings will be fine-tuned in our BRAE model to capture much more semantics.

The partial gradient for one instance is computed as follows:

$$\frac{\partial J_s}{\partial \theta_s} = \frac{\partial E(s|t,\theta_s)}{\partial \theta_s} + \lambda\theta_s \quad (15)$$

Where the source-side error given the target phrase representation includes reconstruction error and updated semantic error:

$$E(s|t,\theta_s) = \alpha E_{rec}(s;\theta_s) + (1-\alpha)E^*_{sem}(s|t,\theta_s) \quad (16)$$

Given the current θ_s, we first construct the binary tree (as illustrated in Fig. 2) for any source-side phrase using the greedy algorithm (Socher et al., 2011). Then, the derivatives for the parameters in the fixed binary tree will be calculated via back-propagation through structures (Goller and Kuchler, 1996). Finally, the parameters will be updated using Eq. 14 and a new θ_s is obtained.

The target-side parameters θ_t can be optimized in the same way as long as the source-side phrase representation p_s is available. It seems a paradox that updating θ_s needs p_t while updating θ_t needs p_s. To solve this problem, we propose an co-training style algorithm which includes three steps:

1. **Pre-training:** applying unsupervised phrase embedding with standard RAE to pre-train the source- and target-side phrase representations p_s and p_t respectively (Section 2.1.2);

2. **Fine-tuning:** with the BRAE model, using target-side phrase representation p_t to update the source-side parameters θ_s and obtain the fine-tuned source-side phrase representation p'_s, and meanwhile using p_s to update θ_t and get the fine-tuned p'_t, and then calculate the joint error over the training corpus;

3. **Termination Check:** if the joint error reaches a local minima or the iterations reach the pre-defined number (25 is used in our experiments), we terminate the training procedure, otherwise we set $p_s = p'_s$, $p_t = p'_t$, and go to step 2.

4 Experiments

With the semantic phrase embeddings and the vector space transformation function, we apply the BRAE to measure the semantic similarity between a source phrase and its translation candidates in the phrase-based SMT. Two tasks are involved in the experiments: phrase table pruning that discards entries whose semantic similarity is very low and decoding with the phrasal semantic similarities as additional new features.

4.1 Hyper-Parameter Settings

The hyper-parameters in the BRAE model include the dimensionality of the word embedding n in Eq. 1, the balance weight α in Eq. 10, λs in Eq. 11, and the learning rate η in Eq. 14.

For the dimensionality n, we have tried three settings $n = 50, 100, 200$ in our experiments. We

empirically set the learning rate $\eta = 0.01$. We draw α from 0.05 to 0.5 with step 0.05, and λs from $\{10^{-6}, 10^{-5}, 10^{-4}, 10^{-3}, 10^{-2}\}$. The overall error of the BRAE model is employed to guide the search procedure. Finally, we choose $\alpha = 0.15$, $\lambda_L = 10^{-2}$, $\lambda_{rec} = 10^{-3}$ and $\lambda_{sem} = 10^{-3}$.

4.2 SMT Setup

We have implemented a phrase-based translation system with a maximum entropy based reordering model using the bracketing transduction grammar (Wu, 1997; Xiong et al., 2006).

The SMT evaluation is conducted on Chinese-to-English translation. Accordingly, our BRAE model is trained on Chinese and English. The bilingual training data from LDC [2] contains 0.96M sentence pairs and 1.1M entity pairs with 27.7M Chinese words and 31.9M English words. A 5-gram language model is trained on the Xinhua portion of the English Gigaword corpus and the English part of bilingual training data. The NIST MT03 is used as the development data. NIST MT04-06 and MT08 (news data) are used as the test data. Case-insensitive BLEU is employed as the evaluation metric. The statistical significance test is performed by the re-sampling approach (Koehn, 2004).

In addition, we pre-train the word embedding with toolkit Word2Vec on large-scale monolingual data including the aforementioned data for SMT. The monolingual data contains 1.06B words for Chinese and 1.12B words for English. To obtain high-quality bilingual phrase pairs to train our BRAE model, we perform forced decoding for the bilingual training sentences and collect the phrase pairs used. After removing the duplicates, the remaining 1.12M bilingual phrase pairs (length ranging from 1 to 7) are obtained.

4.3 Phrase Table Pruning

Pruning most of the phrase table without much impact on translation quality is very important for translation especially in environments where memory and time constraints are imposed. Many algorithms have been proposed to deal with this problem, such as significance pruning (Johnson et al., 2007; Tomeh et al., 2009), relevance pruning (Eck et al., 2007) and entropy-based pruning (Ling et al., 2012; Zens et al., 2012). These algorithms are based on corpus statistics including co-occurrence statistics, phrase pair usage and composition information. For example, the significance pruning, which is proven to be a very effective algorithm, computes the probability named p-value, that tests whether a source phrase s and a target phrase t co-occur more frequently in a bilingual corpus than they happen just by chance. The higher the p-value, the more likely of the phrase pair to be spurious.

Our work has the same objective, but instead of using corpus statistics, we attempt to measure the quality of the phrase pair from the view of semantic meaning. Given a phrase pair (s, t), the BRAE model first obtains their semantic phrase representations (p_s, p_t), and then transforms p_s into target semantic space ${p_s}^*$, p_t into source semantic space ${p_t}^*$. We finally get two similarities $Sim({p_s}^*, p_t)$ and $Sim({p_t}^*, p_s)$. Phrase pairs that have a low similarity are more likely to be noise and more prone to be pruned. In experiments, we discard the phrase pair whose similarity in two directions are smaller than a threshold [3].

Table 1 shows the comparison results between our BRAE-based pruning method and the significance pruning algorithm. We can see a common phenomenon in both of the algorithms: for the first few thresholds, the phrase table becomes smaller and smaller while the translation quality is not much decreased, but the performance jumps a lot at a certain threshold (16 for Significance pruning, 0.8 for BRAE-based one).

Specifically, the Significance algorithm can safely discard 64% of the phrase table at its threshold 12 with only 0.1 BLEU loss in the overall test. In contrast, our BRAE-based algorithm can remove 72% of the phrase table at its threshold 0.7 with only 0.06 BLEU loss in the overall evaluation. When the two algorithms using a similar portion of the phrase table [4] (35% in BRAE and 36% in Significance), the BRAE-based algorithm outperforms the Significance algorithm on all the test sets except for MT04. It indicates that our BRAE model is a good alternative for phrase table pruning. Furthermore, our model is much more in-

[3] To avoid the situation that all the translation candidates for a source phrase are pruned, we always keep the first 10 best according to the semantic similarity.

[4] In the future, we will compare the performance by enforcing the two algorithms to use the same portion of phrase table

Method	Threshold	PhraseTable	MT03	MT04	MT05	MT06	MT08	ALL

Table 1: Comparison between BRAE-based pruning and Significance pruning of phrase table. Threshold means similarity in BRAE and negative-log-p-value in Significance. "ALL" combines the development and test sets. **Bold numbers** denote that the result is better than or comparable to that of baseline. $n = 50$ is used for embedding dimensionality.

tuitive because it is directly based on the semantic similarity.

4.4 Decoding with Phrasal Semantic Similarities

Besides using the semantic similarities to prune the phrase table, we also employ them as two informative features like the phrase translation probability to guide translation hypotheses selection during decoding. Typically, four translation probabilities are adopted in the phrase-based SMT, including phrase translation probability and lexical weights in both directions. The phrase translation probability is based on co-occurrence statistics and the lexical weights consider the phrase as bag-of-words. In contrast, our BRAE model focuses on compositional semantics from words to phrases. Therefore, the semantic similarities computed using our BRAE model are complementary to the existing four translation probabilities.

The semantic similarities in two directions $Sim(p_s{}^*, p_t)$ and $Sim(p_t{}^*, p_s)$ are integrated into our baseline phrase-based model. In order to investigate the influence of the dimensionality of the embedding space, we have tried three different settings $n = 50, 100, 200$.

As shown in Table 2, no matter what n is, the BRAE model can significantly improve the translation quality in the overall test data. The largest improvement can be up to 1.7 BLEU score (MT06 for $n = 50$). It is interesting that with dimensionality growing, the translation performance is not consistently improved. We speculate that using $n = 50$ or $n = 100$ can already distinguish good translation candidates from bad ones.

4.5 Analysis on Semantic Phrase Embedding

To have a better intuition about the power of the BRAE model at learning semantic phrase embeddings, we show some examples in Table 3. Given the BRAE model and the phrase training set, we search from the set the most semantically similar English phrases for any new input English phrase.

The input phrases contain different number of words. The table shows that the unsupervised RAE can at most capture the syntactic property when the phrases are short. For example, the unsupervised RAE finds *do not want* for the input phrase *do not agree*. When the phrase becomes longer, the unsupervised RAE cannot even capture the syntactic property. In contrast, our BRAE model learns the semantic meaning for each phrase no matter whether it is short or relatively long. This indicates that the proposed BRAE model is effective at learning semantic phrase embeddings.

5 Discussions

5.1 Applications of The BRAE model

As the semantic phrase embedding can fully represent the phrase, we can go a step further in the phrase-based SMT and feed the semantic phrase embeddings to DNN in order to model the whole translation process (e.g. derivation structure prediction). We will explore this direction in our future work. Besides SMT, the semantic phrase embeddings can be used in other cross-lingual tasks, such as cross-lingual question answering, since the semantic similarity between phrases in different languages can be calculated accurately.

In addition to the cross-lingual applications, we believe the BRAE model can be applied in many

monolingual NLP tasks which depend on good phrase representations or semantic similarity between phrases, such as named entity recognition, parsing, textual entailment, question answering and paraphrase detection.

5.2 Model Extensions

In fact, the phrases having the same meaning are translation equivalents in different languages, but are paraphrases in one language. Therefore, our model can be easily adapted to learn semantic phrase embeddings using paraphrases.

Our BRAE model still has some limitations. For example, as each node in the recursive auto-encoder shares the same weight matrix, the BRAE model would become weak at learning the semantic representations for long sentences with tens of words. Improving the model to semantically embed sentences is left for our future work.

6 Conclusions and Future Work

This paper has explored the bilingually-constrained recursive auto-encoders in learning phrase embeddings, which can distinguish phrases with different semantic meanings. With the objective to minimize the semantic distance between translation equivalents and maximize the semantic distance between non-translation pairs simultaneously, the learned model can semantically embed any phrase in two languages and can transform the semantic space in one language to the other. Two end-to-end SMT tasks are involved to test the power of the proposed model at learning the semantic phrase embeddings. The experimental results show that the BRAE model is remarkably effective in phrase table pruning and decoding with phrasal semantic similarities.

We have also discussed many other potential applications and extensions of our BRAE model. In the future work, we will explore four directions. 1) we will try to model the decoding process with DNN based on our semantic embeddings of the basic translation units. 2) we are going to learn semantic phrase embeddings with the paraphrase corpus. 3) we will apply the BRAE model in other monolingual and cross-lingual tasks. 4) we plan to learn semantic sentence embeddings by automatically learning different weight matrices for different nodes in the BRAE model.

Abstract

In this paper, instead of designing new features based on intuition, linguistic knowledge and domain, we learn some new and effective features using the deep auto-encoder (DAE) paradigm for phrase-based translation model. Using the unsupervised pre-trained deep belief net (DBN) to initialize DAE's parameters and using the input original phrase features as a teacher for semi-supervised fine-tuning, we learn new semi-supervised DAE features, which are more effective and stable than the unsupervised DBN features. Moreover, to learn high dimensional feature representation, we introduce a natural horizontal composition of more DAEs for large hidden layers feature learning. On two Chinese-English tasks, our semi-supervised DAE features obtain statistically significant improvements of 1.34/2.45 (IWSLT) and 0.82/1.52 (NIST) BLEU points over the unsupervised DBN features and the baseline features, respectively.

1 Introduction

Recently, many new features have been explored for SMT and significant performance have been obtained in terms of translation quality, such as syntactic features, sparse features, and reordering features. However, most of these features are manually designed on linguistic phenomena that are related to bilingual language pairs, thus they are very difficult to devise and estimate.

Instead of designing new features based on intuition, linguistic knowledge and domain, for the first time, Maskey and Zhou (2012) explored the possibility of inducing new features in an unsupervised fashion using deep belief net (DBN) (Hinton et al., 2006) for hierarchical phrase-based translation model. Using the 4 original phrase features in the phrase table as the input features, they pre-trained the DBN by contrastive divergence (Hinton, 2002), and generated new unsupervised DBN features using forward computation. These new features are appended as extra features to the phrase table for the translation decoder.

However, the above approach has two major shortcomings. First, the input original features for the DBN feature learning are too simple, the limited 4 phrase features of each phrase pair, such as bidirectional phrase translation probability and bidirectional lexical weighting (Koehn et al., 2003), which are a bottleneck for learning effective feature representation. Second, it only uses the unsupervised layer-wise pre-training of DBN built with stacked sets of Restricted Boltzmann Machines (RBM) (Hinton, 2002), does not have a training objective, so its performance relies on the empirical parameters. Thus, this approach is unstable and the improvement is limited. In this paper, we strive to effectively address the above two shortcomings, and systematically explore the possibility of learning new features using deep (multilayer) neural networks (DNN, which is usually referred under the name *Deep Learning*) for SMT.

To address the first shortcoming, we adapt and extend some simple but effective phrase features as the input features for new DNN feature learning, and these features have been shown significant improvement for SMT, such as, phrase pair similarity (Zhao et al., 2004), phrase frequency, phrase length (Hopkins and May, 2011), and phrase generative probability (Foster et al., 2010), which also show further improvement for new phrase feature learning in our experiments.

To address the second shortcoming, inspired by the successful use of DAEs for handwritten digits recognition (Hinton and Salakhutdinov, 2006; Hinton et al., 2006), information retrieval (Salakhutdinov and Hinton, 2009; Mirowski et

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 122–132,
Baltimore, Maryland, USA, June 23-25 2014.

al., 2010), and speech spectrograms (Deng et al., 2010), we propose new feature learning using semi-supervised DAE for phrase-based translation model. By using the input data as the teacher, the "semi-supervised" fine-tuning process of DAE addresses the problem of "back-propagation without a teacher" (Rumelhart et al., 1986), which makes the DAE learn more powerful and abstract features (Hinton and Salakhutdinov, 2006). For our semi-supervised DAE feature learning task, we use the unsupervised pre-trained DBN to initialize DAE's parameters and use the input original phrase features as the "teacher" for semi-supervised back-propagation. Compared with the unsupervised DBN features, our semi-supervised DAE features are more effective and stable.

Moreover, to learn high dimensional feature representation, we introduce a natural horizontal composition for DAEs (HCDAE) that can be used to create large hidden layer representations simply by horizontally combining two (or more) DAEs (Baldi, 2012), which shows further improvement compared with single DAE in our experiments.

It is encouraging that, non-parametric feature expansion using gaussian mixture model (GMM) (Nguyen et al., 2007), which guarantees invariance to the specific embodiment of the original features, has been proved as a feasible feature generation approach for SMT. Deep models such as DNN have the potential to be much more representationally efficient for feature learning than shallow models like GMM. Thus, instead of GMM, we use DNN (DBN, DAE and HCDAE) to learn new non-parametric features, which has the similar evolution in speech recognition (Dahl et al., 2012; Hinton et al., 2012). DNN features are learned from the non-linear combination of the input original features, they strong capture high-order correlations between the activities of the original features, and we believe this deep learning paradigm induces the original features to further reach their potential for SMT.

Finally, we conduct large-scale experiments on IWSLT and NIST Chinese-English translation tasks, respectively, and the results demonstrate that our solutions solve the two aforementioned shortcomings successfully. Our semi-supervised DAE features significantly outperform the unsupervised DBN features and the baseline features, and our introduced input phrase features significantly improve the performance of DAE feature learning.

The remainder of this paper is organized as follows. Section 2 briefly summarizes the recent related work about the applications of DNN for SMT tasks. Section 3 presents our introduced input features for DNN feature learning. Section 4 describes how to learn our semi-supervised DAE features for SMT. Section 5 describes and discusses the large-scale experimental results. Finally, we end with conclusions in section 6.

2 Related Work

Recently, there has been growing interest in use of DNN for SMT tasks. Le et al. (2012) improved translation quality of n-gram translation model by using a bilingual neural LM, where translation probabilities are estimated using a continuous representation of translation units in lieu of standard discrete representations. Kalchbrenner and Blunsom (2013) introduced recurrent continuous translation models that comprise a class for purely continuous sentence-level translation models. Auli et al. (2013) presented a joint language and translation model based on a recurrent neural network which predicts target words based on an unbounded history of both source and target words. Liu et al. (2013) went beyond the log-linear model for SMT and proposed a novel additive neural networks based translation model, which overcome some of the shortcomings suffered by the log-linear model: linearity and the lack of deep interpretation and representation in features. Li et al. (2013) presented an ITG reordering classifier based on recursive autoencoders, and generated vector space representations for variable-sized phrases, which enable predicting orders to exploit syntactic and semantic information. Lu et al. (2014) adapted and extended the max-margin based RNN (Socher et al., 2011) into HPB translation with force decoding and converting tree, and proposed a RNN based word topology model for HPB translation, which successfully capture the topological structure of the words on the source side in a syntactically and semantically meaningful order.

However, none of these above works have focused on learning new features automatically with input data, and while learning suitable features (representations) is the superiority of DNN since it has been proposed. In this paper, we systematically explore the possibility of learning new fea-

tures using DNN for SMT.

3 Input Features for DNN Feature Learning

The phrase-based translation model (Koehn et al., 2003; Och and Ney, 2004) has demonstrated superior performance and been widely used in current SMT systems, and we employ our implementation on this translation model. Next, we adapt and extend some original phrase features as the input features for DAE feature learning.

3.1 Baseline phrase features

We assume that source phrase $f = f_1, \cdots, f_{l_f}$ and target phrase $e = e_1, \cdots, e_{l_e}$ include l_f and l_e words, respectively. Following (Maskey and Zhou, 2012), we use the following 4 phrase features of each phrase pair (Koehn et al., 2003) in the phrase table as the first type of input features, bidirectional phrase translation probability ($P(e|f)$ and $P(f|e)$), bidirectional lexical weighting ($Lex(e|f)$ and $Lex(f|e)$),

$$X_1 \rightarrow P(f|e), Lex(f|e), P(e|f), Lex(e|f)$$

3.2 Phrase pair similarity

Zhao et al. (2004) proposed a way of using term weight based models in a vector space as additional evidences for phrase pair translation quality. This model employ phrase pair similarity to encode the weights of content and non-content words in phrase translation pairs. Following (Zhao et al., 2004), we calculate bidirectional phrase pair similarity using cosine distance and BM25 distance as,

$$S_i^{cos}(e,f) = \frac{\sum_{j=1}^{l_e}\sum_{i=1}^{l_f} w_{e_j} p(e_j|f_i) w_{f_i}}{sqrt(\sum_{j=1}^{l_e} w_{e_j}^2) sqrt(\sum_{j=1}^{l_e} {w_a^{e_j}}^2)}$$

$$S_d^{cos}(f,e) = \frac{\sum_{i=1}^{l_f}\sum_{j=1}^{l_e} w_{f_i} p(f_i|e_j) w_{e_j}}{sqrt(\sum_{i=1}^{l_f} w_{f_i}^2) sqrt(\sum_{i=1}^{l_f} {w_a^{f_i}}^2)}$$

where, $p(e_j|f_i)$ and $p(f_i|e_j)$ represents bidirectional word translation probability. w_{f_i} and w_{e_j} are term weights for source and target words, $w_a^{e_j}$ and $w_a^{f_i}$ are the transformed weights mapped from all source/target words to the target/source dimension at word e_j and f_i, respectively.

$$S_i^{bm25}(e,f) = \sum_{i=1}^{l_f} idf_{f_i} \frac{(k_1+1) w_{f_i} (k_3+1) w_a^{f_i}}{(K + w_{f_i})(k_3 + w_a^{f_i})}$$

$$S_d^{bm25}(f,e) = \sum_{j=1}^{l_e} idf_{e_j} \frac{(k_1+1) w_{e_j} (k_3+1) w_a^{e_j}}{(K + w_{e_j})(k_3 + w_a^{e_j})}$$

where, k_1, b, k_3 are set to be 1, 1 and 1000, respectively. $K = k_1((1-b) + J/avg(l))$, and J is the phrase length (l_e or l_f), $avg(l)$ is the average phrase length. Thus, we have the second type of input features

$$X_2 \rightarrow S_i^{cos}(f,e), S_i^{bm25}(f,e), S_d^{cos}(e,f), S_d^{bm25}(e,f)$$

3.3 Phrase generative probability

We adapt and extend bidirectional phrase generative probabilities as the input features, which have been used for domain adaptation (Foster et al., 2010). According to the background LMs, we estimate the bidirectional (source/target side) forward and backward phrase generative probabilities as

$$P_f(f) = P(f_1)P(f_2|f_1)\cdots P(f_{l_f}|f_{l_f-n+1}, \cdots, f_{l_f-1})$$
$$P_f(e) = P(e_1)P(e_2|e_1)\cdots P(e_{l_e}|e_{l_e-n+1}, \cdots, e_{l_e-1})$$
$$P_b(f) = P(f_{l_f})P(f_{l_f-1}|f_{l_f})\cdots P(f_1|f_n, \cdots, f_2)$$
$$P_b(e) = P(e_{l_e})P(e_{l_e-1}|e_{l_e})\cdots P(e_1|e_n, \cdots, e_2)$$

where, the bidirectional forward and backward[1] background 4-gram LMs are trained by the corresponding side of bilingual corpus[2]. Then, we have the third type of input features

$$X_3 \rightarrow P_f(e), P_b(e), P_f(f), P_b(f)$$

3.4 Phrase frequency

We consider bidirectional phrase frequency as the input features, and estimate them as

$$P(f) = \frac{count(f)}{\sum_{|f_i|=|f|} count(f_i)}$$

$$P(e) = \frac{count(e)}{\sum_{|e_j|=|e|} count(e_j)}$$

where, the $count(f)$/$count(e)$ are the total number of phrase f/e appearing in the source/target side of the bilingual corpus, and the denominator are the total number of the phrases whose length are equal to $|f|$/$|e|$, respectively. Then, we have the forth type of input features

$$X_4 \rightarrow P(f), P(e)$$

[1] Backward LM has been introduced by Xiong et al. (2011), which successfully capture both the preceding and succeeding contexts of the current word, and we estimate the backward LM by inverting the order in each sentence in the training data from the original order to the reverse order.

[2] This corpus is used to train the translation model in our experiments, and we will describe it in detail in section 5.1.

3.5 Phrase length

Phrase length plays an important role in the translation process (Koehn, 2010; Hopkins and May, 2011). We normalize bidirectional phrase length by the maximum phrase length, and introduce them as the last type of input features

$$X_5 \rightarrow l_e^n, l_f^n$$

In summary, except for the first type of phrase feature X_1 which is used by (Maskey and Zhou, 2012), we introduce another four types of effective phrase features X_2, X_3, X_4 and X_5. Now, the input original phrase features X includes 16 features in our experiments, as follows,

$$X \rightarrow X_1, X_2, X_3, X_4, X_5$$

We build the DAE network where the first layer with visible nodes equaling to 16, and each visible node v_i corresponds to the above original features X in each phrase pair.

4 Semi-Supervised Deep Auto-encoder Features Learning for SMT

Each translation rule in the phrase-based translation model has a set number of features that are combined in the log-linear model (Och and Ney, 2002), and our semi-supervised DAE features can also be combined in this model. In this section, we design our DAE network with various network structures for new feature learning.

4.1 Learning a Deep Belief Net

Inspired by (Maskey and Zhou, 2012), we first learn a deep generative model for feature learning using DBN. DBN is composed of multiple layers of latent variables with the first layer representing the visible feature vectors, which is built with stacked sets of RBMs (Hinton, 2002).

For a RBM, there is full connectivity between layers, but no connections within either layer. The connection weight W, hidden layer biases c and visible layer biases b can be learned efficiently using the contrastive divergence (Hinton, 2002; Carreira-Perpinan and Hinton, 2005). When given a hidden layer h, factorial conditional distribution of visible layer v can be estimated by

$$P(v = 1|h) = \sigma(b + h^T W^T)$$

where σ denotes the logistic sigmoid. Given v, the element-wise conditional distribution of h is

$$P(h = 1|v) = \sigma(c + v^T W)$$

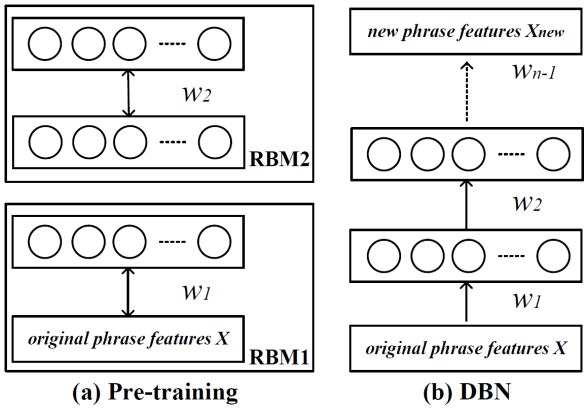

Figure 1: Pre-training consists of learning a stack of RBMs, and these RBMs create an unsupervised DBN.

The two conditional distributions can be shown to correspond to the generative model,

$$P(v, h) = \frac{1}{Z} exp(-E(v, h))$$

where,

$$Z = \sum_{v,h} e^{-E(v,h)}$$

$$E(v, h) = -b^T v - c^T h - v^T W h$$

After learning the first RBM, we treat the activation probabilities of its hidden units, when they are being driven by data, as the data for training a second RBM. Similarly, a n_{th} RBM is built on the output of the $n - 1_{th}$ one and so on until a sufficiently deep architecture is created. These n RBMs can then be composed to form a DBN in which it is easy to infer the states of the n_{th} layer of hidden units from the input in a single forward pass (Hinton et al., 2006), as shown in Figure 1. This greedy, layer-by-layer pre-training can be repeated several times to learn a deep, hierarchical model (DBN) in which each layer of features captures strong high-order correlations between the activities of features in the layer below.

To deal with real-valued input features X in our task, we use an RBM with Gaussian visible units (GRBM) (Dahl et al., 2012) with a variance of 1 on each dimension. Hence, $P(v|h)$ and $E(v, h)$ in the first RBM of DBN need to be modified as

$$P(v|h) = \mathcal{N}(v; b + h^T W^T, I)$$

$$E(v, h) = \frac{1}{2}(v - b)^T (v - b) - c^T h - v^T W h$$

where I is the appropriate identity matrix.

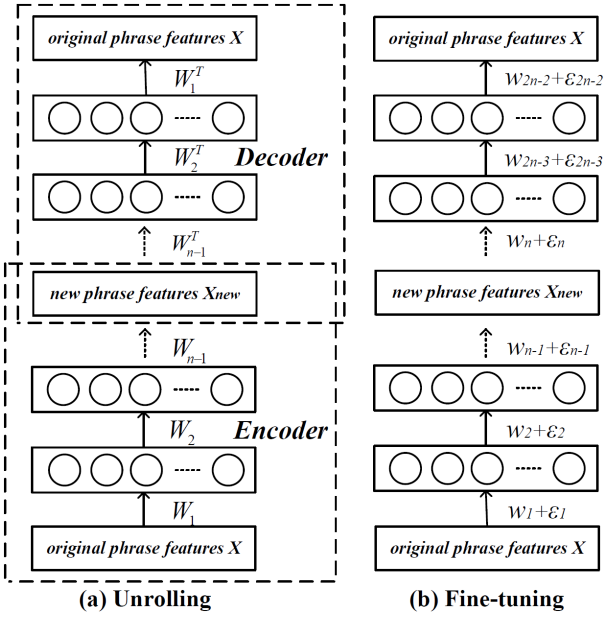

Figure 2: After the unsupervised pre-training, the DBNs are "unrolled" to create a semi-supervised DAE, which is then fine-tuned using back-propagation of error derivatives.

To speed-up the pre-training, we subdivide the entire phrase pairs (with features X) in the phrase table into small mini-batches, each containing 100 cases, and update the weights after each mini-batch. Each layer is greedily pre-trained for 50 epochs through the entire phrase pairs. The weights are updated using a learning rate of 0.1, momentum of 0.9, and a weight decay of 0.0002 $\times$ weight $\times$ learning rate. The weight matrix W are initialized with small random values sampled from a zero-mean normal distribution with variance 0.01.

After the pre-training, for each phrase pair in the phrase table, we generate the DBN features (Maskey and Zhou, 2012) by passing the original phrase features X through the DBN using forward computation.

4.2 From DBN to Deep Auto-encoder

To learn a semi-supervised DAE, we first "unroll" the above n layer DBN by using its weight matrices to create a deep, 2n-1 layer network whose lower layers use the matrices to "encode" the input and whose upper layers use the matrices in reverse order to "decode" the input (Hinton and Salakhutdinov, 2006; Salakhutdinov and Hinton, 2009; Deng et al., 2010), as shown in Figure 2. The layer-wise learning of DBN as above must be treated as a pre-training stage that finds a good region of the parameter space, which is used to initialize our DAE's parameters. Starting in this region, the DAE is then fine-tuned using average squared error (between the output and input) back-propagation to minimize reconstruction error, as to make its output as equal as possible to its input.

For the fine-tuning of DAE, we use the method of conjugate gradients on larger mini-batches of 1000 cases, with three line searches performed for each mini-batch in each epoch. To determine an adequate number of epochs and to avoid over-fitting, we fine-tune on a fraction phrase table and test performance on the remaining validation phrase table, and then repeat fine-tuning on the entire phrase table for 100 epochs.

We experiment with various values for the noise variance and the threshold, as well as the learning rate, momentum, and weight-decay parameters used in the pre-training, the batch size and epochs in the fine-tuning. Our results are fairly robust to variations in these parameters. The precise weights found by the pre-training do not matter as long as it finds a good region of the parameter space from which to start the fine-tuning.

The fine-tuning makes the feature representation in the central layer of the DAE work much better (Salakhutdinov and Hinton, 2009). After the fine-tuning, for each phrase pair in the phrase table, we estimate our DAE features by passing the original phrase features X through the "encoder" part of the DAE using forward computation.

To combine these learned features (DBN and DAE feature) into the log-linear model, we need to eliminate the impact of the non-linear learning mechanism. Following (Maskey and Zhou, 2012), these learned features are normalized by the average of each dimensional respective feature set. Then, we append these features for each phrase pair to the phrase table as extra features.

4.3 Horizontal Composition of Deep Auto-encoders (HCDAE)

Although DAE can learn more powerful and abstract feature representation, the learned features usually have smaller dimensionality compared with the dimensionality of the input features, such as the successful use for handwritten digits recognition (Hinton and Salakhutdinov, 2006; Hinton et al., 2006), information retrieval (Salakhutdinov and Hinton, 2009; Mirowski et al., 2010), and

16-32-32-16-8-4-2	16-32-32-16-16-8-4	16-32-32-32-16-16-8

Table 1: Details of the used network structure. For example, the architecture 16-32-16-2 (4 layers' network depth) corresponds to the DAE with 16-dimensional input features (X) (input layer), 32/16 hidden units (first/second hidden layer), and 2-dimensional output features (new DAE features) (output layer). During the fine-tuning, the DAE's network structure becomes 16-32-16-2-16-32-16. Correspondingly, 4-16-8-2 and 6(8)-16-8-2 represent the input features are X_1 and X_1+X_i.

speech spectrograms (Deng et al., 2010). Moreover, although we have introduced another four types of phrase features (X_2, X_3, X_4 and X_5), the only 16 features in X are a bottleneck for learning large hidden layers feature representation, because it has limited information, the performance of the high-dimensional DAE features which are directly learned from single DAE is not very satisfactory.

To learn high-dimensional feature representation and to further improve the performance, we introduce a natural horizontal composition for DAEs that can be used to create large hidden layer representations simply by horizontally combining two (or more) DAEs (Baldi, 2012), as shown in Figure 3. Two single DAEs with architectures $16/m_1/16$ and $16/m_2/16$ can be trained and the hidden layers can be combined to yield an expanded hidden feature representation of size $m_1 + m_2$, which can then be fed to the subsequent layers of the overall architecture. Thus, these new $m_1 + m_2$-dimensional DAE features are added as extra features to the phrase table.

Differences in m_1- and m_2-dimensional hidden representations could be introduced by many different mechanisms (e.g., learning algorithms, initializations, training samples, learning rates, or distortion measures) (Baldi, 2012). In our task, we introduce differences by using different initializations and different fractions of the phrase table.

5 Experiments and Results

5.1 Experimental Setup

We now test our DAE features on the following two Chinese-English translation tasks.

IWSLT. The bilingual corpus is the Chinese-English part of Basic Traveling Expression corpus (BTEC) and China-Japan-Korea (CJK) corpus (0.38M sentence pairs with 3.5/3.8M Chinese/English words). The LM corpus is the English side of the parallel data (BTEC, CJK and CWMT08[3]) (1.34M sentences). Our development set is IWSLT 2005 test set (506 sentences), and our test set is IWSLT 2007 test set (489 sentences).

NIST. The bilingual corpus is LDC[4] (3.4M sentence pairs with 64/70M Chinese/English words). The LM corpus is the English side of the parallel data as well as the English Gigaword corpus (LDC2007T07) (11.3M sentences). Our development set is NIST 2005 MT evaluation set (1084 sentences), and our test set is NIST 2006 MT evaluation set (1664 sentences).

We choose the Moses (Koehn et al., 2007) framework to implement our phrase-based machine system. The 4-gram LMs are estimated by the SRILM toolkit with modified Kneser-Ney

Table 2: The translation results by adding new DNN features (DBN feature (Maskey and Zhou, 2012), our proposed DAE and HCDAE feature) as extra features to the phrase table on two tasks. "DBN_X_1_xf", "DBN_X_xf", "DAE_X_1_xf" and "DAE_X_xf" represent that we use DBN and DAE, input features X_1 and X, to learn x-dimensional features, respectively. "HCDAE_X_x+xf" represents horizontally combining two DAEs and each DAE has the same x-dimensional learned features. All improvements on two test sets are statistically significant by the bootstrap resampling (Koehn, 2004). *: significantly better than the baseline ($p < 0.05$), **: significantly better than "DBN_X_1_xf" or "DBN_X_xf" ($p < 0.01$), ***: significantly better than "DAE_X_1_xf" or "DAE_X_xf" ($p < 0.01$), ****: significantly better than "HCDAE_X_x+xf" ($p < 0.01$), +: significantly better than "X_2+X_3+X_4+X_5" ($p < 0.01$).

discounting. We perform pairwise ranking optimization (Hopkins and May, 2011) to tune feature weights. The translation quality is evaluated by case-insensitive IBM BLEU-4 metric.

The baseline translation models are generated by Moses with default parameter settings. In the contrast experiments, our DAE and HCDAE features are appended as extra features to the phrase table. The details of the used network structure in our experiments are shown in Table 1.

5.2 Results

Table 2 presents the main translation results. We use DBN, DAE and HCDAE (with 6 layers' network depth), input features X_1 and X, to learn 2-, 4- and 8-dimensional features, respectively. From the results, we can get some clear trends:

1. Adding new DNN features as extra features significantly improves translation accuracy (row 2-17 vs. 1), with the highest increase of 2.45 (IWSLT) and 1.52 (NIST) (row 14 vs. 1) BLEU points over the baseline features.

2. Compared with the unsupervised DBN features, our semi-supervised DAE features are more effective for translation decoder (row 3 vs. 2; row 5 vs. 4; row 8 vs. 7; row 11 vs. 10; row 13 vs. 12; row 16 vs. 15). Specially, Table 3 shows the variance distributions of the learned each dimensional DBN and DAE feature, our DAE features have bigger variance distributions which means

Table 4: The effectiveness of our introduced input features. "DAE_X_1+X_i_4f" represents that we use DAE, input features $X_1 + X_i$, to learn 4-dimensional features. *: significantly better than "DAE_X_1_4f" ($p < 0.05$).

our DAE features have more discriminative power, and also their variance distributions are more stable.

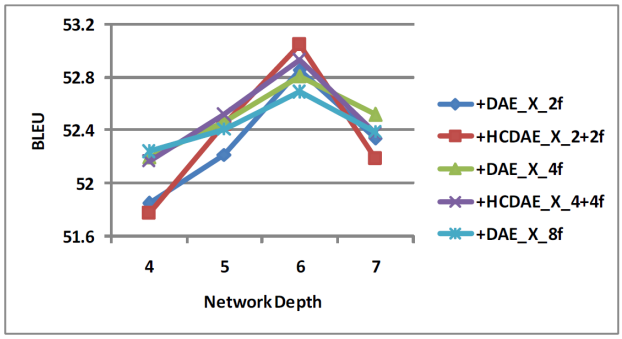
3. HCDAE outperforms single DAE for high dimensional feature learning (row 6 vs. 5; row 9 vs. 8; row 14 vs. 13; row 17 vs. 16), and further improve the performance of DAE feature learning, which can also somewhat address the bring shortcoming of the limited input features.

4. Except for the phrase feature X_1 (Maskey and Zhou, 2012), our introduced input features X significantly improve the DAE feature learning (row 11 vs. 3; row 13 vs. 5; row 16 vs. 8). Specially, Table 4 shows the detailed effectiveness of our introduced input features for DAE feature learning, and the results show that each type of features are very effective for DAE feature learning.

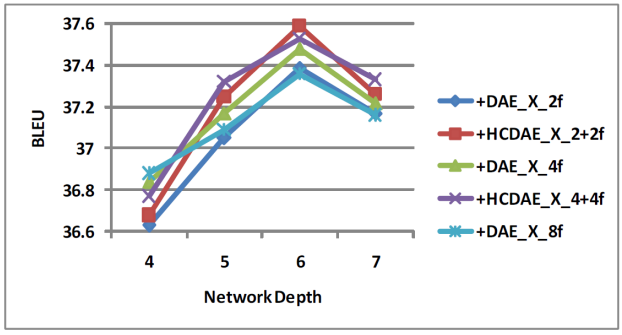
5. Adding the original features (X_2, X_3, X_4 and X_5) and DAE/HCDAE features together can further improve translation performance (row 19-23 vs. 18), with the highest increase of 3.16 (IWSLT) and 2.06 (NIST) (row 21 vs. 1) BLEU points over the baseline features. DAE and HCDAE features are learned from the non-linear combination of the original features, they strong capture high-order correlations between the activities of the original features, as to be further interpreted to reach their potential for SMT. We suspect these learned fea-

tures are complementary to the original features.

5.3 Analysis



(a) IWSLT



(b) NIST

Figure 5: The compared results of using single DAE and the HCDAE for feature learning on two development sets.

Figure 4 shows our DAE features are not only more effective but also more stable than DBN features with various network structures. Also, adding more input features (X vs. X_1) not only significantly improves the performance of DAE feature learning, but also slightly improves the performance of DBN feature learning.

Figure 5 shows there is little change in the performance of using single DAE to learn different dimensional DAE features, but the 4-dimensional features work more better and more stable. HCDAE outperforms the single DAE and learns high-dimensional representation more effectively, especially for the peak point in each condition.

Figures 5 also shows the best network depth for DAE feature learning is 6 layers. When the network depth of DBN is 7 layers, the network depth of corresponding DAE during the fine-tuning is 13 layers. Although we have pre-trained the corresponding DBN, this DAE network is so deep, the fine-tuning does not work very well and typically finds poor local minima. We suspect this leads to the decreased performance.

6 Conclusions

In this paper, instead of designing new features based on intuition, linguistic knowledge and domain, we have learned new features using the DAE for the phrase-based translation model. Using the unsupervised pre-trained DBN to initialize DAE's parameters and using the input original phrase features as the "teacher" for semi-supervised back-propagation, our semi-supervised DAE features are more effective and stable than the unsupervised DBN features (Maskey and Zhou, 2012). Moreover, to further improve the performance, we introduce some simple but effective features as the input features for feature learning. Lastly, to learn high dimensional feature representation, we introduce a natural horizontal composition of two DAEs for large hidden layers feature learning.

On two Chinese-English translation tasks, the results demonstrate that our solutions solve the two aforementioned shortcomings successfully. Firstly, our DAE features obtain statistically significant improvements of 1.34/2.45 (IWSLT) and 0.82/1.52 (NIST) BLEU points over the DBN features and the baseline features, respectively. Secondly, compared with the baseline phrase features X_1, our introduced input original phrase features X significantly improve the performance of not only our DAE features but also the DBN features.

The results also demonstrate that DNN (DAE and HCDAE) features are complementary to the original features for SMT, and adding them together obtain statistically significant improvements of 3.16 (IWSLT) and 2.06 (NIST) BLEU points over the baseline features. Compared with the original features, DNN (DAE and HCDAE) features are learned from the non-linear combination of the original features, they strong capture high-order correlations between the activities of the original features, and we believe this deep learning paradigm induces the original features to further reach their potential for SMT.

Abstract

Statistical Machine Translation (SMT) usually utilizes contextual information to disambiguate translation candidates. However, it is often limited to contexts within sentence boundaries, hence broader topical information cannot be leveraged. In this paper, we propose a novel approach to learning topic representation for parallel data using a neural network architecture, where abundant topical contexts are embedded via topic relevant monolingual data. By associating each translation rule with the topic representation, topic relevant rules are selected according to the distributional similarity with the source text during SMT decoding. Experimental results show that our method significantly improves translation accuracy in the NIST Chinese-to-English translation task compared to a state-of-the-art baseline.

1 Introduction

Making translation decisions is a difficult task in many Statistical Machine Translation (SMT) systems. Current translation modeling approaches usually use context dependent information to disambiguate translation candidates. For example, translation sense disambiguation approaches (Carpuat and Wu, 2005; Carpuat and Wu, 2007) are proposed for phrase-based SMT systems. Meanwhile, for hierarchical phrase-based or syntax-based SMT systems, there is also much work involving rich contexts to guide rule selection (He et al., 2008; Liu et al., 2008; Marton and Resnik, 2008; Xiong et al., 2009). Although these methods are effective and proven successful in many SMT systems, they only leverage within-sentence contexts which are insufficient in exploring broader information. For example, the word *driver* often means "the operator of a motor vehicle" in common texts. But in the sentence "Finally, we write the user response to the buffer, i.e., pass it to our driver", we understand that *driver* means "computer program". In this case, people understand the meaning because of the IT topical context which goes beyond sentence-level analysis and requires more relevant knowledge. Therefore, it is important to leverage topic information to learn smarter translation models and achieve better translation performance.

Topic modeling is a useful mechanism for discovering and characterizing various semantic concepts embedded in a collection of documents. Attempts on topic-based translation modeling include topic-specific lexicon translation models (Zhao and Xing, 2006; Zhao and Xing, 2007), topic similarity models for synchronous rules (Xiao et al., 2012), and document-level translation with topic coherence (Xiong and Zhang, 2013). In addition, topic-based approaches have been used in domain adaptation for SMT (Tam et al., 2007; Su et al., 2012), where they view different topics as different domains. One typical property of these approaches in common is that they only utilize parallel data where document boundaries are explicitly given. In this way, the topic of a sentence can be inferred with document-level information using off-the-shelf topic modeling toolkits such as Latent Dirichlet Allocation (LDA) (Blei et al., 2003) or Hidden Topic Markov Model (HTMM) (Gruber et al., 2007). Most of them also assume that the input must be in document level. However, this situation does not always happen since there is considerable amount of parallel data which does not have document boundaries. In addition, contemporary SMT systems often works on sentence level rather than document level due to the efficiency. Although we can easily apply LDA at the

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 133–143,
Baltimore, Maryland, USA, June 23-25 2014.

sentence level, it is quite difficult to infer the topic accurately with only a few words in the sentence. This makes previous approaches inefficient when applied them in real-world commercial SMT systems. Therefore, we need to devise a systematical approach to enriching the sentence and inferring its topic more accurately.

In this paper, we propose a novel approach to learning topic representations for sentences. Since the information within the sentence is insufficient for topic modeling, we first enrich sentence contexts via Information Retrieval (IR) methods using content words in the sentence as queries, so that topic-related monolingual documents can be collected. These topic-related documents are utilized to learn a specific topic representation for each sentence using a neural network based approach. Neural network is an effective technique for learning different levels of data representations. The levels inferred from neural network correspond to distinct levels of concepts, where high-level representations are obtained from low-level bag-of-words input. It is able to detect correlations among any subset of input features through non-linear transformations, which demonstrates the superiority of eliminating the effect of noisy words which are irrelevant to the topic. Our problem fits well into the neural network framework and we expect that it can further improve inferring the topic representations for sentences.

To incorporate topic representations as translation knowledge into SMT, our neural network based approach directly optimizes similarities between the source language and target language in a compact topic space. This underlying topic space is learned from sentence-level parallel data in order to share topic information across the source and target languages as much as possible. Additionally, our model can be discriminatively trained with a large number of training instances, without expensive sampling methods such as in LDA or HTMM, thus it is more practicable and scalable. Finally, we associate the learned representation to each bilingual translation rule. Topic-related rules are selected according to distributional similarity with the source text, which helps hypotheses generation in SMT decoding. We integrate topic similarity features in the log-linear model and evaluate the performance on the NIST Chinese-to-English translation task. Experimental results demonstrate that our model significantly improves translation accuracy over a state-of-the-art baseline.

2 Background: Deep Learning

Deep learning is an active topic in recent years which has triumphed in many machine learning research areas. This technique began raising public awareness in the mid-2000s after researchers showed how a multi-layer feed-forward neural network can be effectively trained. The training procedure often involves two phases: a layer-wise unsupervised pre-training phase and a supervised fine-tuning phase. For pre-training, Restricted Boltzmann Machine (RBM) (Hinton et al., 2006), auto-encoding (Bengio et al., 2006) and sparse coding (Lee et al., 2006) are most frequently used. Unsupervised pre-training trains the network one layer at a time and helps guide the parameters of the layer towards better regions in parameter space (Bengio, 2009). Followed by fine-tuning in this parameter region, deep learning is able to achieve state-of-the-art performance in various research areas, including breakthrough results on the ImageNet dataset for objective recognition (Krizhevsky et al., 2012), significant error reduction in speech recognition (Dahl et al., 2012), etc.

Deep learning has also been successfully applied in a variety of NLP tasks such as part-of-speech tagging, chunking, named entity recognition, semantic role labeling (Collobert et al., 2011), parsing (Socher et al., 2011a), sentiment analysis (Socher et al., 2011b), etc. Most NLP research converts a high-dimensional and sparse binary representation into a low-dimensional and real-valued representation. This low-dimensional representation is usually learned from huge amount of monolingual texts in the pre-training phase, and then fine-tuned towards task-specific criterion. Inspired by previous successful research, we first learn sentence representations using topic-related monolingual texts in the pre-training phase, and then optimize the bilingual similarity by leveraging sentence-level parallel data in the fine-tuning phase.

3 Topic Similarity Model with Neural Network

In this section, we explain our neural network based topic similarity model in detail, as well as how to incorporate the topic similarity features into SMT decoding procedure. Figure 1 sketches the high-level overview which illustrates how to

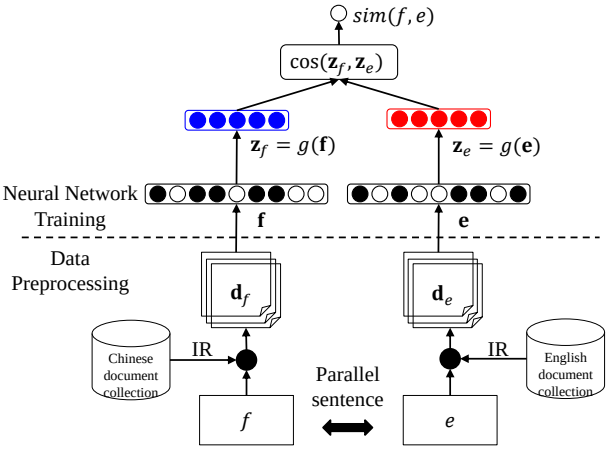

Figure 1: Overview of neural network based topic similarity model.

learn topic representations using sentence-level parallel data. Given a parallel sentence pair $\langle f, e \rangle$, the first step is to treat f and e as queries, and use IR methods to retrieve relevant documents to enrich contextual information for them. Specifically, the ranking model we used is a Vector Space Model (VSM), where the query and document are converted into tf-idf weighted vectors. The most relevant N documents $\mathbf{d}_f$ and $\mathbf{d}_e$ are retrieved and converted to a high-dimensional, bag-of-words input $\mathbf{f}$ and $\mathbf{e}$ for the representation learning[1].

There are two phases in our neural network training process: pre-training and fine-tuning. In the pre-training phase (Section 3.1), we build two neural networks with the same structure but different parameters to learn a low-dimensional representation for sentences in two different languages. Then, in the fine-tuning phase (Section 3.2), our model directly optimizes the similarity of two low-dimensional representations, so that it highly correlates to SMT decoding. Finally, the learned representation is used to calculate similarities which are integrated as features in SMT decoding procedure (Section 3.3).

3.1 Pre-training using denoising auto-encoder

In the pre-training phase, we leverage neural network structures to transform high-dimensional sparse vectors to low-dimensional dense vectors. The topic similarity is calculated on top of the learned dense vectors. This dense representation should preserve the information from the bag-of-words input, meanwhile alleviate data sparse problem. Therefore, we use a specially designed mechanism called auto-encoder to solve this problem. Auto-encoder (Bengio et al., 2006) is one of the basic building blocks of deep learning. Assuming that the input is a n-of-V binary vector $\mathbf{x}$ representing the bag-of-words (V is the vocabulary size), an auto-encoder consists of an encoding process $g(\mathbf{x})$ and a decoding process $h(g(\mathbf{x}))$. The objective of the auto-encoder is to minimize the reconstruction error $\mathcal{L}(h(g(\mathbf{x})), \mathbf{x})$. Our goal is to learn a low-dimensional vector which can preserve information from the original n-of-V vector.

One problem with auto-encoder is that it treats all words in the same way, making no distinguishment between function words and content words. The representation learned by auto-encoders tends to be influenced by the function words, thereby it is not robust. To alleviate this problem, Vincent et al. (2008) proposed the Denoising Auto-Encoder (DAE), which aims to reconstruct a clean, "repaired" input from a corrupted, partially destroyed vector. This is done by corrupting the initial input $\mathbf{x}$ to get a partially destroyed version $\tilde{\mathbf{x}}$. DAE is capable of capturing the global structure of the input while ignoring the noise. In our task, for each sentence, we treat the retrieved N relevant documents as a single large document and convert it to a bag-of-words vector $\mathbf{x}$ in Figure 2. With DAE, the input $\mathbf{x}$ is manually corrupted by applying masking noise (randomly mask 1 to 0) and getting $\tilde{\mathbf{x}}$. Denoising training is considered as "filling in the blanks" (Vincent et al., 2010), which means the masking components can be recovered from the non-corrupted components. For example, in IT related texts, if the word *driver* is masked, it should be predicted through hidden units in neural networks by active signals such as "buffer", "user response", etc.

In our case, the encoding process transforms the corrupted input $\tilde{\mathbf{x}}$ into $g(\tilde{\mathbf{x}})$ with two layers: a linear layer connected with a non-linear layer. Assuming that the dimension of the $g(\tilde{\mathbf{x}})$ is L, the linear layer forms a $L \times V$ matrix W which projects the n-of-V vector to a L-dimensional hidden layer. After the bag-of-words input has been transformed, they are fed into a subsequent layer to model the highly non-linear relations among words:

$$\mathbf{z} = f(W\tilde{\mathbf{x}} + \mathbf{b}) \quad (1)$$

where $\mathbf{z}$ is the output of the non-linear layer, $\mathbf{b}$ is a

[1]We use $\mathbf{f}$ and $\mathbf{e}$ to denote the n-of-V vector converted from the retrieved documents.

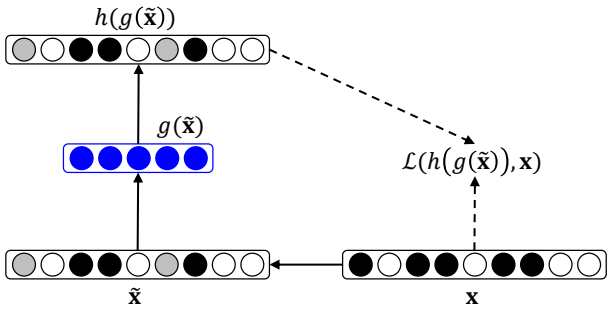

Figure 2: Denoising auto-encoder with a bag-of-words input.

L-length bias vector. $f(\cdot)$ is a non-linear function, where common choices include sigmoid function, hyperbolic function, "hard" hyperbolic function, rectifier function, etc. In this work, we use the rectifier function as our non-linear function due to its efficiency and better performance (Glorot et al., 2011):

$$rec(x) = \begin{cases} x & \text{if } x > 0 \\ 0 & \text{otherwise} \end{cases} \quad (2)$$

The decoding process consists of a linear layer and a non-linear layer with similar network structures, but different parameters. It transforms the L-dimensional vector $g(\tilde{\mathbf{x}})$ to a V-dimensional vector $h(g(\tilde{\mathbf{x}}))$. To minimize reconstruction error with respect to $\tilde{\mathbf{x}}$, we define the loss function as the L2-norm of the difference between the uncorrupted input and reconstructed input:

$$\mathcal{L}(h(g(\tilde{\mathbf{x}})), \mathbf{x}) = \|h(g(\tilde{\mathbf{x}})) - \mathbf{x}\|_2 \quad (3)$$

Multi-layer neural networks are trained with the standard back-propagation algorithm (Rumelhart et al., 1988). The gradient of the loss function is calculated and back-propagated to the previous layer to update its parameters. Training neural networks involves many factors such as the learning rate and the length of hidden layers. We will discuss the optimization of these parameters in Section 4.

3.2 Fine-tuning with parallel data

In the fine-tuning phase, we stack another layer on top of the two low-dimensional vectors to maximize the similarity between source and target languages. The similarity scores are integrated into the standard log-linear model for making translation decisions. Since the vectors from DAE are trained using information from monolingual training data independently, these vectors may be inadequate to measure bilingual topic similarity due to their different topic spaces. Therefore, in this stage, parallel sentence pairs are used to help connecting the vectors from different languages because they express the same topic. In fact, the objective of fine-tuning is to discover a latent topic space which is shared by both languages as much as possible. This shared topic space is particularly useful when the SMT decoder tries to match the source texts and translation candidates in the target language.

Given a parallel sentence pair $\langle f, e \rangle$, the DAE learns representations for f and e respectively, as $\mathbf{z}_f = g(\mathbf{f})$ and $\mathbf{z}_e = g(\mathbf{e})$ in Figure 1. We then take two vectors as the input to calculate their similarity. Consequently, the whole neural network can be fine-tuned towards the supervised criteria with the help of parallel data. The similarity score of the representation pair $\langle \mathbf{z}_f, \mathbf{z}_e \rangle$ is defined as the cosine similarity of the two vectors:

$$\begin{aligned} sim(f, e) &= \cos(\mathbf{z}_f, \mathbf{z}_e) \\ &= \frac{\mathbf{z}_f \cdot \mathbf{z}_e}{\|\mathbf{z}_f\| \|\mathbf{z}_e\|} \end{aligned} \quad (4)$$

Since a parallel sentence pair should have the same topic, our goal is to maximize the similarity score between the source sentence and target sentence. Inspired by the contrastive estimation method (Smith and Eisner, 2005), for each parallel sentence pair $\langle f, e \rangle$ as a positive instance, we select another sentence pair $\langle f', e' \rangle$ from the training data and treat $\langle f, e' \rangle$ as a negative instance. To make the similarity of the positive instance larger than the negative instance by some margin η, we utilize the following pairwise ranking loss:

$$\mathcal{L}(f, e) = \max\{0, \eta - sim(f, e) + sim(f, e')\} \quad (5)$$

where $\eta = \frac{1}{2} - sim(f, f')$. The rationale behind this criterion is, the smaller $sim(f, f')$ is, the more we should penalize negative instances.

To effectively train the model in this task, negative instances must be selected carefully. Since different sentences may have very similar topic distributions, we select negative instances that are dissimilar with the positive instances based on the following criteria:

1. For each positive instance $\langle f, e \rangle$, we select e' which contains at least 30% different content words from e.

2. If we cannot find such e', remove $\langle f, e\rangle$ from the training instances for network learning.

The model minimizes the pairwise ranking loss across all training instances:

$$\mathcal{L} = \sum_{\langle f,e\rangle} \mathcal{L}(f, e) \tag{6}$$

We used standard back-propagation algorithm to further fine-tune the neural network parameters W and $\mathbf{b}$ in Equation (1). The learned neural networks are used to obtain sentence topic representations, which will be further leveraged to infer topic representations of bilingual translation rules.

3.3 Integration into SMT decoding

We incorporate the learned topic similarity scores into the standard log-linear framework for SMT. When a synchronous rule $\langle \alpha, \gamma\rangle$ is extracted from a sentence pair $\langle f, e\rangle$, a triple instance $\mathcal{I} = (\langle \alpha, \gamma\rangle, \langle f, e\rangle, c)$ is collected for inferring the topic representation of $\langle \alpha, \gamma\rangle$, where c is the count of rule occurrence. Following (Chiang, 2007), we give a count of one for each phrase pair occurrence and a fractional count for each hierarchical phrase pair. The topic representation of $\langle \alpha, \gamma\rangle$ is then calculated as the weighted average:

$$\mathbf{z}_\alpha = \frac{\sum_{(\langle \alpha,\gamma\rangle,\langle f,e\rangle,c)\in\mathcal{T}} \{c \times \mathbf{z}_f\}}{\sum_{(\langle \alpha,\gamma\rangle,\langle f,e\rangle,c)\in\mathcal{T}} \{c\}} \tag{7}$$

$$\mathbf{z}_\gamma = \frac{\sum_{(\langle \alpha,\gamma\rangle,\langle f,e\rangle,c)\in\mathcal{T}} \{c \times \mathbf{z}_e\}}{\sum_{(\langle \alpha,\gamma\rangle,\langle f,e\rangle,c)\in\mathcal{T}} \{c\}} \tag{8}$$

where $\mathcal{T}$ denotes all instances for the rule $\langle \alpha, \gamma\rangle$, $\mathbf{z}_\alpha$ and $\mathbf{z}_\gamma$ are the source-side and target-side topic vectors respectively.

By measuring the similarity between the source texts and bilingual translation rules, the SMT decoder is able to encourage topic relevant translation candidates and penalize topic irrelevant candidates. Therefore, it helps to train a smarter translation model with the embedded topic information. Given a source sentence s to be translated, we define the similarity as follows:

$$Sim(\mathbf{z}_s, \mathbf{z}_\alpha) = \cos(\mathbf{z}_s, \mathbf{z}_\alpha) \tag{9}$$

$$Sim(\mathbf{z}_s, \mathbf{z}_\gamma) = \cos(\mathbf{z}_s, \mathbf{z}_\gamma) \tag{10}$$

where $\mathbf{z}_s$ is the topic representation of s. The similarity calculated against $\mathbf{z}_\alpha$ or $\mathbf{z}_\gamma$ denotes the source-to-source or the source-to-target similarity.

We also consider the topic sensitivity estimation since general rules have flatter distributions while topic-specific rules have sharper distributions. A standard entropy metric is used to measure the sensitivity of the source-side of $\langle \alpha, \gamma\rangle$ as:

$$Sen(\alpha) = -\sum_{i=1}^{|\mathbf{z}_\alpha|} z_{\alpha i} \times \log z_{\alpha i} \tag{11}$$

where $z_{\alpha i}$ is a component in the vector $\mathbf{z}_\alpha$. The target-side sensitivity $Sen(\gamma)$ can be calculated in a similar way. The larger the sensitivity is, the more topic-specific the rule manifests.

In addition to traditional SMT features, we add new topic-related features into the standard log-linear framework. For the SMT system, the best translation candidate $\hat{e}$ is given by:

$$\hat{e} = \arg\max_e P(e|f) \tag{12}$$

where the translation probability is given by:

$$\begin{aligned} P(e|f) &\propto \sum_i w_i \cdot \log \phi_i(f, e) \\ &= \underbrace{\sum_j w_j \cdot \log \phi_j(f, e)}_{\text{Standard}} + \underbrace{\sum_k w_k \cdot \log \phi_k(f, e)}_{\text{Topic related}} \end{aligned} \tag{13}$$

where $\phi_j(f, e)$ is the standard feature function and w_j is the corresponding feature weight. $\phi_k(f, e)$ is the topic-related feature function and w_k is the feature weight. The detailed feature description is as follows:

Standard features: Translation model, including translation probabilities and lexical weights for both directions (4 features), 5-gram language model (1 feature), word count (1 feature), phrase count (1 feature), NULL penalty (1 feature), number of hierarchical rules used (1 feature).

Topic-related features: rule similarity scores (2 features), rule sensitivity scores (2 features).

4 Experiments

4.1 Setup

We evaluate the performance of our neural network based topic similarity model on a Chinese-to-English machine translation task. In neural network training, a large number of monolingual documents are collected in both source and target languages. The documents are mainly from two domains: news and weblog. We use Chinese and

English Gigaword corpus (Version 5) which are mainly from news domain. In addition, we also collect weblog documents with a variety of topics from the web. The total data statistics are presented in Table 1. These documents are built in the format of inverted index using Lucene[2], which can be efficiently retrieved by the parallel sentence pairs. The most relevant N documents are collected, where we experiment with $N = \{1, 5, 10, 20, 50\}$.

Domain	Chinese		English	
	Docs	Words	Docs	Words
News	5.7M	5.4B	9.9M	25.6B
Weblog	2.1M	8B	1.2M	2.9B
Total	7.8M	13.4B	11.1M	28.5B

Table 1: Statistics of monolingual data, in numbers of documents and words (main content). "M" refers to million and "B" refers to billion.

We implement a distributed framework to speed up the training process of neural networks. The network is learned with mini-batch asynchronous gradient descent with the adaptive learning rate procedure called AdaGrad (Duchi et al., 2011). We use 32 model replicas in each iteration during the training. The model parameters are averaged after each iteration and sent to each replica for the next iteration. The vocabulary size for the input layer is 100,000, and we choose different lengths for the hidden layer as $L = \{100, 300, 600, 1000\}$ in the experiments. In the pre-training phase, all parallel data is fed into two neural networks respectively for DAE training, where network parameters W and $\mathbf{b}$ are randomly initialized. In the fine-tuning phase, for each parallel sentence pair, we randomly select other ten sentence pairs which satisfy the criterion as negative instances. These training instances are leveraged to optimize the similarity of two vectors.

In SMT training, an in-house hierarchical phrase-based SMT decoder is implemented for our experiments. The CKY decoding algorithm is used and cube pruning is performed with the same default parameter settings as in Chiang (2007). The parallel data we use is released by LDC[3]. In total, the datasets contain nearly 1.1 million sentence pairs. Translation models are trained over the parallel data that is automatically word-aligned using GIZA++ in both directions, and the diag-grow-final heuristic is used to refine symmetric word alignment. An in-house language modeling toolkit is used to train the 5-gram language model with modified Kneser-Ney smoothing (Kneser and Ney, 1995). The English monolingual data used for language modeling is the same as in Table 1. The NIST 2003 dataset is the development data. The testing data consists of NIST 2004, 2005, 2006 and 2008 datasets. The evaluation metric for the overall translation quality is case-insensitive BLEU4 (Papineni et al., 2002). The reported BLEU scores are averaged over 5 times of running MERT (Och, 2003). A statistical significance test is performed using the bootstrap re-sampling method (Koehn, 2004).

4.2 Baseline

The baseline is a re-implementation of the Hiero system (Chiang, 2007). The phrase pairs that appear only once in the parallel data are discarded because most of them are noisy. We also use the fix-discount method in Foster et al. (2006) for phrase table smoothing. This implementation makes the system perform much better and the translation model size is much smaller.

We compare our method with the LDA-based approach proposed by Xiao et al. (2012). In (Xiao et al., 2012), the topic of each sentence pair is exactly the same as the document it belongs to. Since some of our parallel data does not have document-level information, we rely on the IR method to retrieve the most relevant document and simulate this approach. The PLDA toolkit (Liu et al., 2011) is used to infer topic distributions, which takes 34.5 hours to finish.

4.3 Effect of retrieved documents and length of hidden layers

We illustrate the relationship among translation accuracy (BLEU), the number of retrieved documents (N) and the length of hidden layers (L) on different testing datasets. The results are shown in Figure 3. The best translation accuracy is achieved when N=10 for most settings. This confirms that enriching the source text with topic-related documents is very useful in determining topic representations, thereby help to guide the synchronous rule selection. However, we find that as N becomes larger in the experiments, e.g. N=50, the translation accuracy drops drastically. As more documents are retrieved, less relevant information

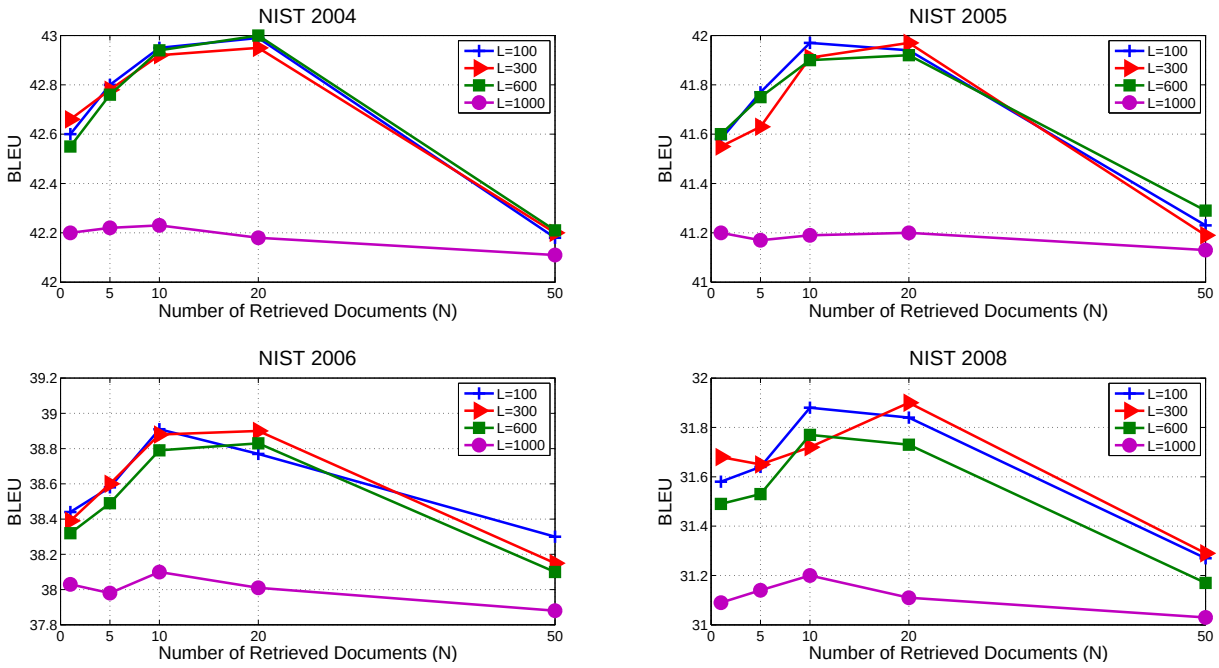

Figure 3: End-to-end translation results (BLEU%) using all standard and topic-related features, with different settings on the number of retrieved documents N and the length of hidden layers L.

is also used to train the neural networks. Irrelevant documents bring so many unrelated topic words hence degrade neural network learning performance.

Another important factor is the length of hidden layers L in the network. In deep learning, this parameter is often empirically tuned with human efforts. As shown in Figure 3, the translation accuracy is better when L is relatively small. Actually, there is no obvious distinction of the performance when L is less than 600. However, when L equals 1,000, the translation accuracy is inferior to other settings. The main reason is that parameters in the neural networks are too many to be effectively trained. As we know when L=1000, there are a total of $100,000 \times 1,000$ parameters between the linear and non-linear layers in the network. Limited training data prevents the model from getting close to the global optimum. Therefore, the model is likely to fall in local optima and lead to unacceptable representations.

4.4 Effect of topic related features

We evaluate the performance of adding new topic-related features to the log-linear model and compare the translation accuracy with the method in (Xiao et al., 2012). To make different methods comparable, we set the dimension of topic representation as 100 for all settings. This takes 10 hours in pre-training phase and 22 hours in fine-tuning phase. Table 2 shows how the accuracy is improved with more features added. The results confirm that topic information is indispensable for SMT since both (Xiao et al., 2012) and our neural network based method significantly outperforms the baseline system. Our method improves 0.86 BLEU points at most and 0.76 BLEU points on average over the baseline. We observe that source-side similarity is more effective than target-side similarity, but their contributions are cumulative. This proves that bilingually induced topic representation with neural network helps the SMT system disambiguate translation candidates. Furthermore, rule sensitivity features improve SMT performance compared with only using similarity features. Because topic-specific rules usually have a larger sensitivity score, they can beat general rules when they obtain the same similarity score against the input sentence. Finally, when all new features are integrated, the performance is the best, preforming substantially better than (Xiao et al., 2012) with 0.39 BLEU points on average.

It is worth mentioning that the performance of (Xiao et al., 2012) is similar to the settings with N=1 and L=100 in Figure 3. This is not simply coincidence since we can interpret their approach as a special case in our neural network method: when a parallel sentence pair has

Settings	NIST 2004	NIST 2005	NIST 2006	NIST 2008	Average
Baseline	42.25	41.21	38.05	31.16	38.17
(Xiao et al., 2012)	42.58	41.61	38.39	31.58	38.54
Sim(Src)	42.51	41.55	38.53	31.57	38.54
Sim(Trg)	42.43	41.48	38.4	31.49	38.45
Sim(Src+Trg)	42.7	41.66	38.66	31.66	38.67
Sim(Src+Trg)+Sen(Src)	42.77	41.81	38.85	31.73	38.79
Sim(Src+Trg)+Sen(Trg)	42.85	41.79	38.76	31.7	38.78
Sim(Src+Trg)+Sen(Src+Trg)	**42.95**	**41.97**	**38.91**	**31.88**	**38.93**

Table 2: Effectiveness of different features in BLEU% ($p < 0.05$), with N=10 and L=100. "Sim" denotes the rule similarity feature and "Sen" denotes rule sensitivity feature. "Src" and "Trg" means utilizing source-side/target-side rule topic vectors to calculate similarity or sensitivity, respectively. The "Average" setting is the averaged result of four datasets.

document-level information, that document will be retrieved for training; otherwise, the most relevant document will be retrieved from the monolingual data. Therefore, our method can be viewed as a more general framework than previous LDA-based approaches.

4.5 Discussion

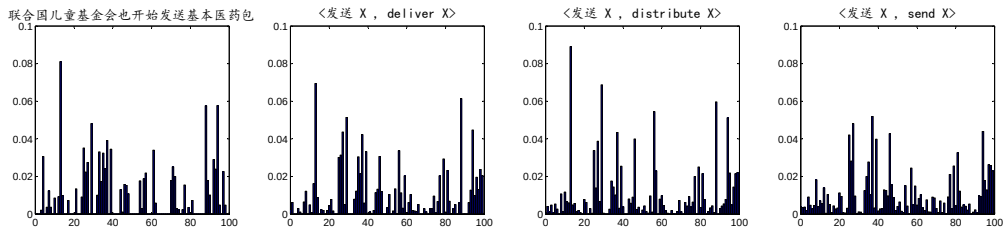
In this section, we give a case study to explain why our method works. An example of translation rule disambiguation for a sentence from the NIST 2005 dataset is shown in Figure 4. We find that the topic of this sentence is about "rescue after a natural disaster". Under this topic, the Chinese rule "发送 X" should be translated to "deliver X" or "distribute X". However, the baseline system prefers "send X" rather than those two candidates. Although the translation probability of "send X" is much higher, it is inappropriate in this context since it is usually used in IT texts. For example, ⟨发送邮件, send emails⟩, ⟨发送信息, send messages⟩ and ⟨发送数据, send data⟩. In contrast, with our neural network based approach, the learned topic distributions of "deliver X" or "distribute X" are more similar with the input sentence than "send X", which is shown in Figure 4. The similarity scores indicate that "deliver X" and "distribute X" are more appropriate to translate the sentence. Therefore, adding topic-related features is able to keep the topic consistency and substantially improve the translation accuracy.

5 Related Work

Topic modeling was first leveraged to improve SMT performance in (Zhao and Xing, 2006; Zhao and Xing, 2007). They proposed a bilingual topical admixture approach for word alignment and assumed that each word-pair follows a topic-specific model. They reported extensive empirical analysis and improved word alignment accuracy as well as translation quality. Following this work, (Xiao et al., 2012) extended topic-specific lexicon translation models to hierarchical phrase-based translation models, where the topic information of synchronous rules was directly inferred with the help of document-level information. Experiments show that their approach not only achieved better translation performance but also provided a faster decoding speed compared with previous lexicon-based LDA methods.

Another direction of approaches leveraged topic modeling techniques for domain adaptation. Tam et al. (2007) used bilingual LSA to learn latent topic distributions across different languages and enforce one-to-one topic correspondence during model training. They incorporated the bilingual topic information into language model adaptation and lexicon translation model adaptation, achieving significant improvements in the large-scale evaluation. (Su et al., 2012) investigated the relationship between out-of-domain bilingual data and in-domain monolingual data via topic mapping using HTMM methods. They estimated phrase-topic distributions in translation model adaptation and generated better translation quality. Recently, Chen et al. (2013) proposed using vector space model for adaptation where genre resemblance is leveraged to improve translation accuracy. We also investigated multi-domain adaptation where explicit topic information is used to train domain specific models (Cui et al., 2013).

Generally, most previous research has leveraged conventional topic modeling techniques such as LDA or HTMM. In our work, a novel neural network based approach is proposed to infer topic representations for parallel data. The advantage of



Rules	$P(\gamma\|\alpha)$	$Sim(\mathbf{z}_s, \mathbf{z}_\alpha)$
⟨发送 X, deliver X⟩	0.0237	0.8469
⟨发送 X, distribute X⟩	0.0546	0.8268
⟨发送 X, send X⟩	0.2464	0.6119

our method is that it is applicable to both sentence-level and document-level SMT, since we do not place any restrictions on the input. In addition, our method directly maximizes the similarity between parallel sentence pairs, which is ideal for SMT decoding. Compared to document-level topic modeling which uses the topic of a document for all sentences within the document (Xiao et al., 2012), our contributions are:

- We proposed a more general approach to leveraging topic information for SMT by using IR methods to get a collection of related documents, regardless of whether or not document boundaries are explicitly given.
- We used neural networks to learn topic representations more accurately, with more practicable and scalable modeling techniques.
- We directly optimized bilingual topic similarity in the deep learning framework with the help of sentence-level parallel data, so that the learned representation could be easily used in SMT decoding procedure.

6 Conclusion and Future Work

In this paper, we propose a neural network based approach to learning bilingual topic representation for SMT. We enrich contexts of parallel sentence pairs with topic related monolingual data and obtain a set of documents to represent sentences. These documents are converted to a bag-of-words input and fed into neural networks. The learned low-dimensional vector is used to obtain the topic representations of synchronous rules. In SMT decoding, appropriate rules are selected to best match source texts according to their similarity in the topic space. Experimental results show that our approach is promising for SMT systems to learn a better translation model. It is a significant improvement over the state-of-the-art Hiero system, as well as a conventional LDA-based method.

In the future research, we will extend our neural network methods to address document-level translation, where topic transition between sentences is a crucial problem to be solved. Since the translation of the current sentence is usually influenced by the topic of previous sentences, we plan to leverage recurrent neural networks to model this phenomenon, where the history translation information is naturally combined in the model.

Abstract

In this paper, we address the problem of web-domain POS tagging using a two-phase approach. The first phase learns representations that capture regularities underlying web text. The representation is integrated as features into a neural network that serves as a scorer for an easy-first POS tagger. Parameters of the neural network are trained using guided learning in the second phase. Experiment on the SANCL 2012 shared task show that our approach achieves 93.15% average tagging accuracy, which is the best accuracy reported so far on this data set, higher than those given by ensembled syntactic parsers.

1 Introduction

Analysing and extracting useful information from the web has become an increasingly important research direction for the NLP community, where many tasks require part-of-speech (POS) tagging as a fundamental preprocessing step. However, state-of-the-art POS taggers in the literature (Collins, 2002; Shen et al., 2007) are mainly optimized on the the Penn Treebank (PTB), and when shifted to web data, tagging accuracies drop significantly (Petrov and McDonald, 2012).

The problem we face here can be considered as a special case of *domain adaptation*, where we have access to labelled data on the source domain (PTB) and unlabelled data on the target domain (web data). Exploiting useful information from the web data can be the key to improving web domain tagging. Towards this end, we adopt the idea of learning representations which has been demonstrated useful in capturing hidden regularities underlying the raw input data (web text, in our case).

Our approach consists of two phrases. In the pre-training phase, we learn an encoder that converts the web text into an intermediate representation, which acts as useful features for prediction tasks. We integrate the learned encoder with a set of well-established features for POS tagging (Ratnaparkhi, 1996; Collins, 2002) in a single neural network, which is applied as a scorer to an easy-first POS tagger. We choose the easy-first tagging approach since it has been demonstrated to give higher accuracies than the standard left-to-right POS tagger (Shen et al., 2007; Ma et al., 2013).

In the fine-tuning phase, the parameters of the network are optimized on a set of labelled training data using guided learning. The learned model preserves the property of preferring to tag *easy* words first. To our knowledge, we are the first to investigate guided learning for neural networks.

The idea of learning representations from unlabelled data and then fine-tuning a model with such representations according to some supervised criterion has been studied before (Turian et al., 2010; Collobert et al., 2011; Glorot et al., 2011). While most previous work focus on in-domain sequential labelling or cross-domain classification tasks, we are the first to learn representations for web-domain structured prediction. Previous work treats the learned representations either as model parameters that are further optimized in supervised fine-tuning (Collobert et al., 2011) or as fixed features that are kept unchanged (Turian et al., 2010; Glorot et al., 2011). In this work, we investigate both strategies and give empirical comparisons in the cross-domain setting. Our results suggest that while both strategies improve in-domain tagging accuracies, keeping the learned representation unchanged consistently results in better cross-domain accuracies.

We conduct experiments on the official data set provided by the SANCL 2012 shared task (Petrov and McDonald, 2012). Our method achieves a 93.15% average accuracy across the web-domain, which is the best result reported so far on this data

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 144–154,

set, higher than those given by ensembled syntactic parsers. Our code will be publicly available at https://github.com/majineu/TWeb.

2 Learning from Web Text

Unsupervised learning is often used for training encoders that convert the input data to abstract representations (i.e. encoding vectors). Such representations capture hidden properties of the input, and can be used as features for supervised tasks (Bengio, 2009; Ranzato et al., 2007). Among the many proposed encoders, we choose the restricted Boltzmann machine (RBM), which has been successfully used in many tasks (Lee et al., 2009b; Hinton et al., 2006). In this section, we give some background on RBMs and then show how they can be used to learn representations of the web text.

2.1 Restricted Boltzmann Machine

The RBM is a type of graphical model that contains two layers of binary stochastic units $\mathbf{v} \in \{0,1\}^V$ and $\mathbf{h} \in \{0,1\}^H$, corresponding to a set of visible and hidden variables, respectively. The RBM defines the joint probability distribution over $\mathbf{v}$ and $\mathbf{h}$ by an energy function

$$E(\mathbf{v},\mathbf{h}) = -\mathbf{c}'\mathbf{h} - \mathbf{b}'\mathbf{v} - \mathbf{h}'\mathbf{W}\mathbf{v}, \qquad (1)$$

which is factorized by a visible bias $\mathbf{b} \in \mathbb{R}^V$, a hidden bias $\mathbf{c} \in \mathbb{R}^H$ and a weight matrix $\mathbf{W} \in \mathbb{R}^{H\times V}$. The joint distribution $P(\mathbf{v},\mathbf{h})$ is given by

$$P(\mathbf{v},\mathbf{h}) = \frac{1}{Z}\exp(E(\mathbf{v},\mathbf{h})), \qquad (2)$$

where Z is the partition function.

The affine form of E with respect to $\mathbf{v}$ and $\mathbf{h}$ implies that the visible variables are conditionally independent with each other given the hidden layer units, and vice versa. This yields the conditional distribution:

$$P(\mathbf{v}|\mathbf{h}) = \prod_{j=1}^{V} P(v_j|\mathbf{h}) \quad P(\mathbf{h}|\mathbf{v}) = \prod_{i=1}^{H} P(h_i|\mathbf{v})$$

$$P(v_j = 1|\mathbf{h}) = \sigma(\mathbf{b}_j + W_{.j}\mathbf{h}) \qquad (3)$$

$$P(h_i = 1|\mathbf{v}) = \sigma(\mathbf{c}_j + W_{i.}\mathbf{v}) \qquad (4)$$

Here σ denotes the sigmoid function. Parameters of RBMs $\theta = \{\mathbf{b},\mathbf{c},\mathbf{W}\}$ can be trained efficiently using contrastive divergence learning (CD), see (Hinton, 2002) for detailed descriptions of CD.

2.2 Encoding Web Text with RBM

Most of the indicative features for POS disambiguation can be found from the words and word combinations within a local context (Ratnaparkhi, 1996; Collins, 2002). Inspired by this observation, we apply the RBM to learn feature representations from word n-grams. More specifically, given the i^{th} word w_i of a sentence, we apply RBMs to model the joint distribution of the n-gram $(w_{i-l},\cdots,w_{i+r})$, where l and r denote the left and right window, respectively. Note that the visible units of RBMs are binary. While in our case, each visible variable corresponds to a word, which may take on tens-of-thousands of different values. Therefore, the RBM need to be re-factorized to make inference tractable.

We utilize the Word Representation RBM (WRRBM) factorization proposed by Dahl et al. (2012). The basic idea is to share word representations across different positions in the input n-gram while using position-dependent weights to distinguish between different word orders.

Let w_k be the k-th entry of lexicon L, and $\mathbf{w}_k$ be its *one-hot* representation (i.e., only the k-th component of $\mathbf{w}_k$ is 1, and all the others are 0). Let $\mathbf{v}^{(j)}$ represents the j-th visible variable of the WRRBM, which is a vector of length $|L|$. Then $\mathbf{v}^{(j)} = \mathbf{w}_k$ means that the j-th word in the n-gram is w_k. Let $\mathbf{D} \in \mathbb{R}^{D\times|L|}$ be a projection matrix, then $\mathbf{D}\mathbf{w}_k$ projects w_k into a D-dimensional real value vector (embedding). For each position j, there is a weight matrix $\mathbf{W}^{(j)} \in \mathbb{R}^{H\times D}$, which is used to model the interaction between the hidden layer and the word projection in position j. The visible biases are also shared across different positions ($b^{(j)} = b\ \forall j$) and the energy function is:

$$E(\mathbf{v},\mathbf{h}) = -\mathbf{c}'\mathbf{h} - \sum_{j=1}^{n}(\mathbf{b}'\mathbf{v}^{(j)} + \mathbf{h}'\mathbf{W}^{(j)}\mathbf{D}\mathbf{v}^{(j)}), \qquad (5)$$

which yields the conditional distributions:

$$P(\mathbf{v}|\mathbf{h}) = \prod_{j=1}^{n} P(\mathbf{v}^{(j)}|\mathbf{h}) \quad P(\mathbf{h}|\mathbf{v}) = \prod_{i=1} P(h_i|\mathbf{v})$$

$$P(h_i = 1|\mathbf{v}) = \sigma(c_i + \sum_{j=1}^{n}\mathbf{W}_{i.}^{(j)}\mathbf{D}\mathbf{v}^{(j)}) \qquad (6)$$

$$P(\mathbf{v}^{(j)} = \mathbf{w}_k|\mathbf{h}) = \frac{1}{Z}\exp(\mathbf{b}'\mathbf{w}_k + \mathbf{h}'\mathbf{W}^{(j)}\mathbf{D}\mathbf{w}_k) \qquad (7)$$

Again Z is the partition function.

The parameters $\{\mathbf{b}, \mathbf{c}, \mathbf{D}, \mathbf{W}^{(1)}, \ldots, \mathbf{W}^{(n)}\}$ can be trained using a Metropolis-Hastings-based CD variant and the learned word representations also capture certain syntactic information; see Dahl et al. (2012) for more details.

Note that one can stack standard RBMs on top of a WRRBM to construct a Deep Belief Network (DBN). By adopting greedy layer-wise training (Hinton et al., 2006; Bengio et al., 2007), DBNs are capable of modelling higher order non-linear relations between the input, and has been demonstrated to improve performance for many computer vision tasks (Hinton et al., 2006; Bengio et al., 2007; Lee et al., 2009a). However, in this work we do not observe further improvement by employing DBNs. This may partly be due to the fact that unlike computer vision tasks, the input structure of POS tagging or other sequential labelling tasks is relatively simple, and a single non-linear layer is enough to model the interactions within the input (Wang and Manning, 2013).

3 Neural Network for POS Disambiguation

We integrate the learned WRRBM into a neural network, which serves as a scorer for POS disambiguation. The main challenge to designing the neural network structure is: on the one hand, we hope that the model can take the advantage of information provided by the learned WRRBM, which reflects general properties of web texts, so that the model generalizes well in the web domain; on the other hand, we also hope to improve the model's discriminative power by utilizing well-established POS tagging features, such as those of Ratnaparkhi (1996).

Our approach is to leverage the two sources of information in one neural network by combining them though a shared output layer, as shown in Figure 1. Under the output layer, the network consists of two modules: *the web-feature module*, which incorporates knowledge from the pre-trained WRRBM, and *the sparse-feature module*, which makes use of other POS tagging features.

3.1 The Web-Feature Module

The web-feature module, shown in the lower left part of Figure 1, consists of a input layer and two hidden layers. The input for the this module is the word n-gram $(w_{i-l}, \ldots, w_{i+r})$, the form of which

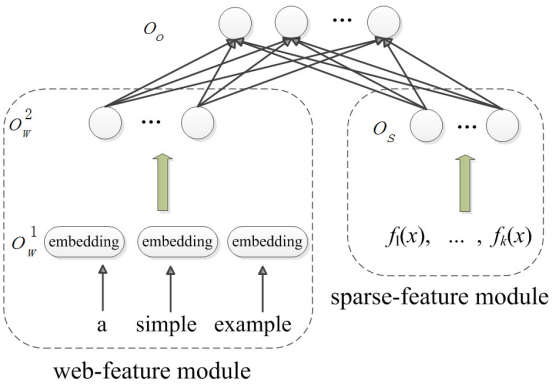

Figure 1: The proposed neural network. The web-feature module (lower left) and sparse-feature module (lower right) are combined by a shared output layer (upper).

is identical to the training data of the pre-trained WRRBM.

The first layer is a linear projection layer, where each word in the input is projected into a D-dimensional real value vector using the projection operation described in Section 2.2. The output of this layer $\mathbf{o}_w^1$ is the concatenation of the projections of $w_{i-l}, \ldots, w_{i+r}$:

$$\mathbf{o}_w^1 = \begin{pmatrix} \mathbf{M}_w^1 \mathbf{w}_{i-l} \\ \vdots \\ \mathbf{M}_w^1 \mathbf{w}_{i+r} \end{pmatrix} \tag{8}$$

Here $\mathbf{M}_w^1$ denotes the parameters of the first layer of the web-feature module, which is a $D \times |L|$ projection matrix.

The second layer is a sigmoid layer to model non-linear relations between the word projections:

$$\mathbf{o}_w^2 = \sigma(\mathbf{M}_w^2 \mathbf{o}_w^1 + \mathbf{b}_w^2) \tag{9}$$

Parameters of this layer include: a bias vector $\mathbf{b}_w^2 \in \mathbb{R}^H$ and a weight matrix $\mathbf{M}_w^2 \in \mathbb{R}^{H \times nD}$.

The web-feature module enables us to explore the learned WRRBM in various ways. First, it allows us to investigate knowledge from the WRRBM incrementally. We can choose to use only the *word* representations of the learned WRRBM. This can be achieved by initializing only the first layer of the web module with the projection matrix $\mathbf{D}$ of the learned WRRBM:

$$\mathbf{M}_w^1 \leftarrow \mathbf{D}. \tag{10}$$

Alternatively, we can choose to use the hidden states of the WRRBM, which can be treated as the

representations of the input *n-gram*. This can be achieved by *also* initializing the parameters of the second layer of the web-feature module using the position-dependent weight matrix and hidden bias of the learned WRRBM:

$$\mathbf{b}_w^2 \leftarrow \mathbf{c} \tag{11}$$

$$\mathbf{M}_w^2 \leftarrow (\mathbf{W}^{(1)}, \ldots, \mathbf{W}^{(n)}) \tag{12}$$

Second, the web-feature module also allows us to make a comparison between whether or not to further adjust the pre-trained representation in the supervised fine-tuning phase, which corresponds to the supervised learning strategies of Turian et al. (2010) and Collobert et al. (2011), respectively. To our knowledge, no investigations have been presented in the literature on this issue.

3.2 The Sparse-Feature Module

The sparse-feature module, as shown in the lower right part of Figure 1, is designed to incorporate commonly-used tagging features. The input for this module is a vector of boolean values $\Phi(x) = (f_1(x), \ldots, f_k(x))$, where x denotes the partially tagged input sentence and $f_i(x)$ denotes a feature function, which returns 1 if the corresponding feature fires and 0 otherwise. The first layer of this module is a linear transformation layer, which converts the high dimensional sparse vector into a fixed-dimensional real value vector:

$$\mathbf{o}_s = \mathbf{M}_s \Phi(x) + \mathbf{b}_s \tag{13}$$

Depending on the specific task being considered, the output of this layer can be further fed to other non-linear layers, such as a sigmoid or hyperbolic tangent layer, to model more complex relations. For POS tagging, we found that a simple linear layer yields satisfactory accuracies.

The web-feature and sparse-feature modules are combined by a linear output layer, as shown in the upper part of Figure 1. The value of each unit in this layer denotes the score of the corresponding POS tag.

$$\mathbf{o}_o = \mathbf{M}_o \begin{pmatrix} \mathbf{o}_w \\ \mathbf{o}_s \end{pmatrix} + \mathbf{b}_o \tag{14}$$

In some circumstances, probability distribution over POS tags might be a more preferable form of output. Such distribution can be easily obtained by adding a soft-max layer on top of the output layer to perform a local normalization, as done by Collobert et al. (2011).

Algorithm 1 Easy-first POS tagging

Input: x a sentence of m words $w_1, \ldots, w_m$
Output: tag sequence of x

1: $\mathbf{U} \leftarrow [w_1, \ldots, w_m]$ // untagged words
2: **while** $\mathbf{U} \neq []$ **do**
3: $(\hat{w}, \hat{t}) \leftarrow \arg\max_{(w,t) \in \mathbf{U} \times \mathbf{T}} S(w, t)$
4: $\hat{w}.t \leftarrow \hat{t}$
5: $\mathbf{U} \leftarrow \mathbf{U}/[\hat{w}]$ // remove $\hat{w}$ from $\mathbf{U}$
6: **end while**
7: **return** $[w_1.t, \ldots, w_m.t]$

4 Easy-first POS tagging with Neural Network

The neural network proposed in Section 3 is used for POS disambiguation by the easy-first POS tagger. Parameters of the network are trained using guided learning, where learning and search interact with each other.

4.1 Easy-first POS tagging

Pseudo-code of easy-first tagging is shown in Algorithm 1. Rather than tagging a sentence from left to right, easy-first tagging is based on a deterministic process, repeatedly selecting the *easiest* word to tag. Here "easiness" is evaluated based on a statistical model. At each step, the algorithm adopts a scorer, the neural network in our case, to assign a score to each possible word-tag pair (w, t), and then selects the highest score one $(\hat{w}, \hat{t})$ to tag (i.e., tag $\hat{w}$ with $\hat{t}$). The algorithm repeats until all words are tagged.

4.2 Training

The training algorithm repeats for several iterations over the training data, which is a set of sentences labelled with gold standard POS tags. In each iteration, the procedure shown in Algorithm 2 is applied to each sentence in the training set.

At each step during the processing of a training example, the algorithm calculates a *margin loss* based on two word-tag pairs $(\overline{w}, \overline{t})$ and $(\hat{w}, \hat{t})$ (line 4 $\sim$ line 6). $(\overline{w}, \overline{t})$ denotes the word-tag pair that has the highest model score among those that are *inconsistent* with the gold standard, while $(\hat{w}, \hat{t})$ denotes the one that has the highest model score among those that are *consistent* with the gold standard. If the loss is zero, the algorithm continues to process the next untagged word. Otherwise, parameters are updated using back-propagation.

The standard back-propagation algorithm

(Rumelhart et al., 1988) cannot be applied directly. This is because the standard loss is calculated based on a *unique* input vector. This condition does not hold in our case, because $\hat{w}$ and $\overline{w}$ may refer to different words, which means that the margin loss in line 6 of Algorithm 2 is calculated based on two different input vectors, denoted by $\langle\hat{w}\rangle$ and $\langle\overline{w}\rangle$, respectively.

We solve this problem by decomposing the margin loss in line 6 into two parts:

- $1 + nn(\overline{w}, \bar{t})$, which is associated with $\langle\overline{w}\rangle$;
- $-nn(\hat{w}, \hat{t})$, which is associated with $\langle\hat{w}\rangle$.

In this way, two separate back-propagation updates can be used to update the model's parameters (line 8 $\sim$ line 11). For the special case where $\hat{w}$ and $\overline{w}$ do refer to the same word w, it can be easily verified that the two separate back-propagation updates equal to the standard back-propagation with a loss $1 + nn(w, \bar{t}) - nn(w, \hat{t})$ on the input $\langle w\rangle$.

The algorithm proposed here belongs to a general framework named *guided learning*, where search and learning interact with each other. The algorithm learns not only a local classifier, but also the inference order. While previous work (Shen et al., 2007; Zhang and Clark, 2011; Goldberg and Elhadad, 2010) apply guided learning to train a linear classifier by using variants of the perceptron algorithm, we are the first to combine guided learning with a neural network, by using a margin loss and a modified back-propagation algorithm.

5 Experiments

5.1 Setup

Our experiments are conducted on the data set provided by the SANCL 2012 shared task, which aims at building a single robust syntactic analysis system across the web-domain. The data set consists of labelled data for both the source (Wall Street Journal portion of the Penn Treebank) and target (web) domains. The web domain data can be further classified into five sub-domains, including emails, weblogs, business reviews, news groups and Yahoo!Answers. While emails and weblogs are used as the development sets, reviews, news groups and Yahoo!Answers are used as the final test sets. Participants are not allowed to use web-domain labelled data for training. In addition to labelled data, a large amount of unlabelled data on the web domain is also provided. Statistics

Algorithm 2 Training over one sentence

Input: (x, t) a tagged sentence, neural net nn
Output: updated neural net nn'

1: $\mathbf{U} \leftarrow [w_1, \ldots, w_m]$ // untagged words
2: $\mathbf{R} \leftarrow [(w_1, t_1), \ldots, (w_m, t_m)]$ // reference
3: **while** $\mathbf{U} \neq []$ **do**
4: $\quad(\overline{w}, \bar{t}) \leftarrow \arg\max_{(w,t)\in(\mathbf{U}\times\mathbf{T}/\mathbf{R})} nn(w, t)$
5: $\quad(\hat{w}, \hat{t}) \leftarrow \arg\max_{(w,t)\in\mathbf{R}} nn(w, t)$
6: $\quad loss \leftarrow \max(0, 1 + nn(\overline{w}, \bar{t}) - nn(\hat{w}, \hat{t}))$
7: $\quad$**if** $loss > 0$ **then**
8: $\quad\quad\hat{e} \leftarrow nn$.BackPropErr$(\langle\hat{w}\rangle, -nn(\hat{w}, \hat{t}))$

15: **end while**
16: **return** nn

about labelled and unlabelled data are summarized in Table 1 and Table 2, respectively.

The raw web domain data contains much noise, including spelling error, emotions and inconsistent capitalization. Following some participants (Le Roux et al., 2012), we conduct simple preprocessing steps to the input of the development and the test sets[1]

- Neutral quotes are transformed to opening or closing quotes.
- Tokens starting with "www.", "http." or ending with ".org", ".com" are converted to a "#URL" symbol
- Repeated punctuations such as "!!!!" are collapsed into one.
- Left brackets such as "<","{" and "[" are converted to "-LRB-". Similarly, right brackets are converted to "-RRB-"
- Upper cased words that contain more than 4 letters are lowercased.
- Consecutive occurrences of one or more digits within a word are replaced with "#DIG"

We apply the same preprocessing steps to all the unlabelled data. In addition, following Dahl et

[1]The preprocessing steps make use of no POS knowledge, and does not bring any unfair advantages to the participants.

trigram	$L(w_i) \odot t_{i-2} \odot t_{i-1}$, $L(w_i) \odot t_{i-1} \odot t_{i+1}$, $L(w_i) \odot t_{i+1} \odot t_{i+2}$

Table 3: Feature templates, where w_i denotes the current word. $H(w)$ and $C(w)$ indicates whether w contains hyphen and upper case letters, respectively. $L(w)$ denotes a lowercased w.

al. (2012) and Turian et al. (2010), we also lowercased all the unlabelled data and removed those sentences that contain less than 90% a-z letters.

The tagging performance is evaluated according to the official evaluation metrics of SANCL 2012. The tagging accuracy is defined as the percentage of words (punctuations included) that are correctly tagged. The averaged accuracies are calculated across the web domain data.

We trained the WRRBM on web-domain data of different sizes (number of sentences). The data sets are generated by first concatenating all the cleaned unlabelled data, then selecting sentences evenly across the concatenated file.

For each data set, we investigate an extensive set of combinations of hyper-parameters: the n-gram window (l, r) in $\{(1,1),(2,1),(1,2),(2,2)\}$; the hidden layer size in $\{200, 300, 400\}$; the learning rate in $\{0.1, 0.01, 0.001\}$. All these parameters are selected according to the averaged accuracy on the development set.

5.2 Baseline

We reimplemented the greedy easy-first POS tagger of Ma et al. (2013), which is used for all the experiments. While the tagger of Ma et al. (2013) utilizes a linear scorer, our tagger adopts the neural network as its scorer. The neural network of our baseline tagger only contains the sparse-feature module. We use this baseline to examine the performance of a tagger trained purely on the source domain. Feature templates are shown in Table 3, which are based on those of Ratnaparkhi (1996) and Shen et al. (2007).

Accuracies of the baseline tagger are shown in the upper part of Table 6. Compared with the performance of the official baseline (row 4 of Table 6), which is evaluated based on the output of BerkeleyParser (Petrov et al., 2006; Petrov and Klein, 2007), our baseline tagger achieves comparable accuracies on both the source and target domain data. With data preprocessing, the average accuracy boosts to about 92.02 on the test set of the target domain. This is consistent with previous work (Le Roux et al., 2011), which found that for noisy data such as web domain text, data cleaning is a effective and necessary step.

5.3 Exploring the Learned Knowledge

As mentioned in Section 3.1, the knowledge learned from the WRRBM can be investigated incrementally, using *word representation*, which corresponds to initializing only the projection layer of web-feature module with the projection matrix of the learned WRRBM, or *ngram-level representation*, which corresponds to initializing both the projection and sigmoid layers of the web-feature module by the learned WRRBM. In each case, there can be two different **training strategies** depending on whether the learned representations are further adjusted or kept unchanged during the fine-turning phrase. Experimental results under the 4 combined settings on the development sets are illustrated in Figure 2, 3 and 4, where the

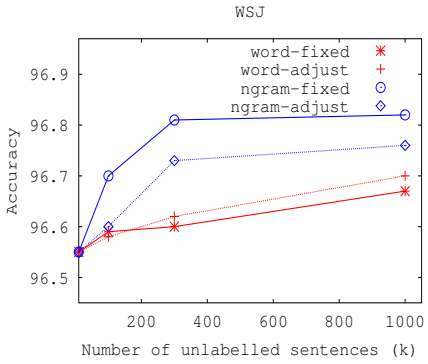

Figure 2: Tagging accuracies on the source-domain data. "word" and "ngram" denote using word representations and n-gram representations, respectively. "fixed" and "adjust" denote that the learned representation are kept unchanged or further adjusted in supervised learning, respectively.

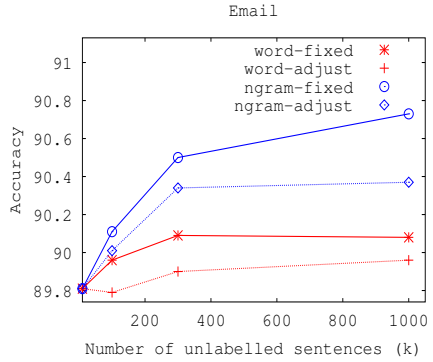

Figure 3: Accuracies on the email domain.

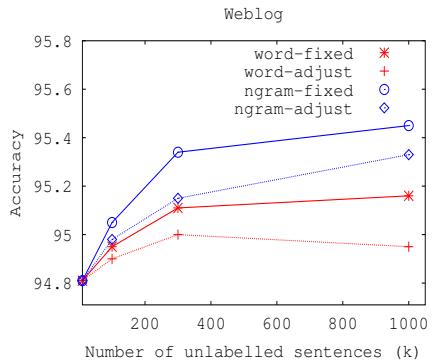

Figure 4: Accuracies on the weblog domain.

x-axis denotes the size of the training data and y-axis denotes tagging accuracy.

5.3.1 Effect of the Training Strategy

From Figure 2 we can see that when knowledge from the pre-trained WRRBM is incorporated, both the **training strategies** ("word-fixed" vs "word-adjusted", "ngram-fixed" vs "ngram-adjusted") improve accuracies on the source domain, which is consistent with previous findings (Turian et al., 2010; Collobert et al., 2011). In addition, adjusting the learned representation or keeping them fixed does not result in too much difference in tagging accuracies.

method	all	non-oov	oov
baseline	89.81	92.42	65.64
word-adjust	+0.09	−0.05	+1.38
word-fix	+0.11	+0.13	+1.73
ngram-adjust	+0.53	+0.52	+0.53
ngram-fix	+0.69	+0.60	+2.30

Table 4: Performance on the email domain.

On the web-domain data, shown in Figure 3 and 4, we found that leaving the learned representation unchanged ("word-fixed", "ngram-fixed") yields consistently higher performance gains. This result is to some degree expected. Intuitively, unsupervised pre-training moves the parameters of the WRRBM towards the region where properties of the *web domain* data are properly modelled. However, since fine-tuning is conducted with respect to the *source domain*, adjusting the parameters of the pre-trained representation towards optimizing source domain tagging accuracies would disrupt its ability in modelling the web domain data. Therefore, a better idea is to keep the representation unchanged so that we can learn a function that maps the general web-text properties to its syntactic categories.

5.3.2 Word and N-gram Representation

From Figures 2, 3 and 4, we can see that adopting the ngram-level representation consistently achieves better performance compared with using word representations only ("word-fixed" vs "ngram-fixed", "word-adjusted" vs "ngram-adjusted"). This result illustrates that the ngram-level knowledge captures more complex interactions of the web text, which cannot be recovered by using only word embeddings. Similar result was reported by Dahl et al. (2012), who found that using both the word embeddings and the hidden units of a tri-gram WRRBM as additional features for a CRF chunker yields larger improvements than using word embeddings only.

Finally, more detailed accuracies under the 4 settings on the email domain are shown in Table 4. We can see that the improvement of using word

		RBM-E	RBM-W	RBM-M
+acc%	Emails	+0.73	+0.37	+0.69
	Weblog	+0.31	+0.52	+0.54
cov%	Emails	95.24	92.79	93.88
	Weblog	90.21	97.74	94.77

Table 5: Effect of unlabelled data. "+acc" denotes improvement in tagging accuracy and "cov" denotes the lexicon coverages.

representations mainly comes from better accuracy of out-of-vocabulary (oov) words. By contrast, using n-gram representations improves the performance on both oov and non-oov.

5.4 Effect of Unlabelled Domain Data

In some circumstances, we may know beforehand that the target domain data belongs to a certain sub-domain, such as the email domain. In such cases, it might be desirable to train WRRBM using data only on that domain. We conduct experiments to test whether using the target domain data to train the WRRBM yields better performance compared with using mixed data from all sub-domains.

We trained 3 WRRBMs using the email domain data (RBM-E), weblog domain data (RBM-W) and mixed domain data (RBM-M), respectively, with each data set consisting of 300k sentences. Tagging performance and lexicon coverages of each data set on the development sets are shown in Table 5. We can see that using the target domain data achieves similar improvements compared with using the mixed data. However, for the email domain, RBM-W yields much smaller improvement compared with RBM-E, and vice versa. From the lexicon coverages, we can see that the sub-domains varies significantly. The results suggest that using mixed data can achieve almost as good performance as using the target sub-domain data, while using mixed data yields a much more robust tagger across all sub-domains.

5.5 Final Results

The best result achieved by using a 4-gram WRRBM, $(w_{i-2}, \ldots, w_{i+1})$, with 300 hidden units learned on 1,000k web domain sentences are shown in row 3 of Table 6. Performance of the top 2 systems of the SANCL 2012 task are also shown in Table 6. Our greedy tagger achieves 93% tagging accuracy, which is significantly better than the baseline's 92.02% accuracy ($p < 0.05$ by McNemar's test). Moreover, we achieve the highest tagging accuracy reported so far on this data set, surpassing those achieved using parser combinations based on self-training (Tang et al., 2012; Le Roux et al., 2012). In addition, different from Le Roux et al. (2012), we do not use any external resources in data cleaning.

6 Related Work

Learning representations has been intensively studied in computer vision tasks (Bengio et al., 2007; Lee et al., 2009a). In NLP, there is also much work along this line. In particular, Collobert et al. (2011) and Turian et al. (2010) learn word embeddings to improve the performance of in-domain POS tagging, named entity recognition, chunking and semantic role labelling. Yang et al. (2013) induce bi-lingual word embeddings for word alignment. Zheng et al. (2013) investigate Chinese character embeddings for joint word segmentation and POS tagging. While those approaches mainly explore token-level representations (word or character embeddings), using WRRBM is able to utilize both word and n-gram representations.

Titov (2011) and Glorot et al. (2011) propose to learn representations from the mixture of both source and target domain unlabelled data to improve cross-domain sentiment classification. Titov (2011) also propose a regularizer to constrain the inter-domain variability. In particular, their regularizer aims to minimize the Kullback-Leibler (KL) distance between the marginal distributions of the learned representations on the source and target domains.

Their work differs from ours in that their approaches learn representations from the feature vectors for sentiment classification, which might be of thousands of dimensions. Such high dimensional input gives rise to high computational cost and it is not clear whether those approaches can be applied to large scale unlabelled data, with hundreds of millions of training examples. Our method learns representations from only word n-grams with n ranging from 3 to 5, which can be easily applied to large scale-data. In addition, while Titov (2011) and Glorot et al. (2011) use the learned representation to improve cross-domain classification tasks, we are the first to apply it to cross-domain structured prediction.

Blitzer et al. (2006) propose to induce shared representations for domain adaptation, which is based on the alternating structure optimization

Table 6: Main results. "baseline-raw" and "baseline-clean" denote performance of our baseline tagger on the raw and cleaned data, respectively. "best-clean" is best performance achieved using a 4-gram WRRBM. The lower part shows accuracies of the official baseline and that of the top 2 participants.

(ASO) method of Ando and Zhang (2005). The idea is to project the original feature representations into low dimensional representations, which yields a high-accuracy classifier on the target domain. The new representations are induced based on the auxiliary tasks defined on unlabelled data together with a dimensionality reduction technique. Such auxiliary tasks can be specific to the supervised task. As pointed out by Plank (2009), for many NLP tasks, defining the auxiliary tasks is a non-trivial engineering problem. Compared with Blitzer et al. (2006), the advantage of using RBMs is that it learns representations in a pure unsupervised manner, which is much simpler.

Besides learning representations, another line of research addresses domain-adaptation by instance re-weighting (Bickel et al., 2007; Jiang and Zhai, 2007) or feature re-weighting (Satpal and Sarawagi, 2007). Those methods assume that each example x that has a non-zero probability on the source domain must have a non-zero probability on the target domain, and vice-versa. As pointed out by Titov (2011), such an assumption is likely to be too restrictive since most NLP tasks adopt word-based or lexicon-based features that vary significantly across different domains.

Regarding using neural networks for sequential labelling, our approach shares similarity with that of Collobert et al. (2011). In particular, we both use a non-linear layer to model complex relations underling word embeddings. However, our network differs from theirs in the following aspects. Collobert et al. (2011) model the dependency between neighbouring tags in a generative manner, by employing a transition score A_{ij}. Training the score involves a forward process of complexity $O(nT^2)$, where T denotes the number of tags. Our model captures such a dependency in a discriminative manner, by just adding tag-related features to the sparse-feature module. In addition, Collobert et al. (2011) train their network by maximizing the training set likelihood, while our approach is to minimize the margin loss using guided learning.

7 Conclusion

We built a web-domain POS tagger using a two-phase approach. We used a WRRBM to learn the representation of the web text and incorporate the representation in a neural network, which is trained using guided learning for easy-first POS tagging. Experiment showed that our approach achieved significant improvement in tagging the web domain text. In addition, we found that keeping the learned representations unchanged yields better performance compared with further optimizing them on the source domain data. We release our tools at https://github.com/majineu/TWeb.

For future work, we would like to investigate the two-phase approach to more challenging tasks, such as web domain syntactic parsing. We believe that high-accuracy web domain taggers and parsers would benefit a wide range of downstream tasks such as machine translation[2].

8 Acknowledgements

We would like to thank Hugo Larochelle for his advices on re-implementing WRRBM. We also thank Nan Yang, Shujie Liu and Tong Xiao for the fruitful discussions, and three anonymous reviewers for their insightful suggestions. Abstract

Discussion forums have evolved into a dependable source of knowledge to solve common problems. However, only a minority of the posts in discussion forums are solution posts. Identifying solution posts from discussion forums, hence, is an important research problem. In this paper, we present a technique for unsupervised solution post identification leveraging a so far unexplored textual feature, that of lexical correlations between problems and solutions. We use translation models and language models to exploit lexical correlations and solution post character respectively. Our technique is designed to not rely much on structural features such as post metadata since such features are often not uniformly available across forums. Our clustering-based iterative solution identification approach based on the EM-formulation performs favorably in an empirical evaluation, beating the only unsupervised solution identification technique from literature by a very large margin. We also show that our unsupervised technique is competitive against methods that require supervision, outperforming one such technique comfortably.

1 Introduction

Discussion forums have become a popular knowledge source for finding solutions to common problems. StackOverflow[1], a popular discussion forum for programmers is among the top-100 most visited sites globally[2]. Now, there are discussion forums for almost every major product ranging from automobiles[3] to gadgets such as those of Mac[4] or Samsung[5]. These typically start with a registered user posting a question/problem[6] to which other users respond. Typical response posts include solutions or clarification requests, whereas feedback posts form another major category of forum posts. As is the case with any community of humans, discussion forums have their share of inflammatory remarks too. Mining problem-solution pairs from discussion forums has attracted much attention from the scholarly community in the recent past. Since the first post most usually contains the problem description, identifying its solutions from among the other posts in the thread has been the focus of many recent efforts (e.g., (Gandhe et al., 2012; Hong and Davison, 2009)). Extracting problem-solution pairs from forums enables the usage of such knowledge in knowledge reuse frameworks such as case-based reasoning (Kolodner, 1992) that use problem-solution pairs as raw material. In this paper, we address the problem of unsupervised solution post identification[7] from discussion forums.

Among the first papers to address the solution identification problem was the unsupervised approach proposed by (Cong et al., 2008). It employs a graph propagation method that prioritizes posts that are (a) more similar to the problem post, (b) more similar to other posts, and (c) authored by a more authoritative user, to be labeled as solution posts. Though seen to be effective in identifying solutions from travel forums, the first two assumptions, (a) and (b), were seen to be not very

[6] We use problem and question, as well as solution and answer interchangeably in this paper.

[7] This problem has been referred to as *answer extraction* by some papers earlier. However, we use *solution identification* to refer to the problem since *answer* and *extraction* have other connotations in the Question-Answering and Information Extraction communities respectively.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 155–164,
Baltimore, Maryland, USA, June 23-25 2014.

reliable in solution identification in other kinds of discussion boards. (Catherine et al., 2012) reports a study that illustrates that non-solution posts are, on an average, as similar to the problem as solution posts in technical forums. The second assumption (i.e., (b) above) was also not seen to be useful in discussion forums since posts that are highly similar to other posts were seen to be complaints, repetitive content being more pervasive among complaint posts than solutions (Catherine et al., 2013). Having exhausted the two obvious textual features for solution identification, subsequent approaches have largely used the presence of lexical cues signifying solution-like narrative (e.g., instructive narratives such as *"check the router for any connection issues"*) as the primary content-based feature for solution identification.

All solution identification approaches since (Cong et al., 2008) have used supervised methods that require training data in the form of labeled solution and non-solution posts. The techniques differ from one another mostly in the non-textual features that are employed in representing posts. A variety of high precision assumptions such as *solution post typically follows a problem post* (Qu and Liu, 2011), *solution posts are likely to be within the first few posts*, *solution posts are likely to have been acknowledged by the problem post author* (Catherine et al., 2012), *users with high authoritativeness are likely to author solutions* (Hong and Davison, 2009), and so on have been seen to be useful in solution identification. Being supervised methods, the above assumptions are implicitly factored in by including the appropriate feature (e.g., post position in thread) in the feature space so that the learner may learn the correlation (e.g., solution posts typically are among the first few posts) using the training data. Though such assumptions on structural features, if generic enough, may be built into unsupervised techniques to aid solution identification, the variation in availability of such features across forums limits the usage of models that rely heavily on structural features. For example, some forums employ chronological order based flattening of threads (Seo et al., 2009) making reply-to information unavailable; models that harness reply-to features would then have limited utility on identifying solutions within such flattened threads. On medical forums, privacy considerations may force forum data to be dumped without author information, making a host of author-id based features unavailable. On datasets that contain data from across forums, the model may have to be aware of the absence of certain features in subsets of the data, or be modeled using features that are available on all threads.

Our Contribution: We propose an unsupervised method for solution identification. The cornerstone of our technique is the usage of a hitherto unexplored textual feature, *lexical correlations between problems and solutions*, that is exploited along with language model based characterization of solution posts. We model the lexical correlation and solution post character using regularized translation models and unigram language models respectively. To keep our technique applicable across a large variety of forums with varying availability of non-textual features, we design it to be able to work with *minimal availability of non-textual features*. In particular, we show that by using post position as the only non-textual feature, we are able to achieve accuracies comparable to supervision-based approaches that use many structural features (Catherine et al., 2013).

2 Related Work

In this section, we provide a brief overview of previous work related to our problem. Though most of the answer/solution identification approaches proposed so far in literature are supervised methods that require a labeled training corpus, there are a few that require limited or no supervision. Table 1 provides an overview of some of the more recent solution identification techniques from literature, with a focus on some features that we wish to highlight. The common observation that most problem-solving discussion threads have a problem description in the first post has been explicitly factored into many techniques; knowing the problem/question is important for solution identification since author relations between problem and other posts provide valuable cues for solution identification. Most techniques use a variety of such features as noted in Section 1. SVMs have been the most popular method for supervised and semi-supervised learning for the task of solution identification.

Of particular interest to us are approaches that use limited or no supervision, since we focus on unsupervised solution identification in this paper.

Table 1: Summary of Some Solution Identification Techniquess

The **only** unsupervised approach for the task, that from (Cong et al., 2008), uses a graph propagation method on a graph modeled using posts as vertices, and relies on the assumptions that posts that bear high similarity to the problem and other posts and those authored by authoritative users are more likely to be solution posts. Some of those assumptions, as mentioned in Section 1, were later found to be not generalizable to beyond travel forums. The semi-supervised approach presented in (Catherine et al., 2013) uses a few labeled threads to bootstrap SVM based learners which are then co-trained in an iterative fashion. In addition to various features explored in literature, they use acknowledgement modeling so that posts that have been acknowledged positively may be favored for being labeled as solutions.

We will use translation and language models in our method for solution identification. Usage of translation models for modeling the correlation between textual problems and solutions have been explored earlier starting from the answer retrieval work in (Xue et al., 2008) where new queries were conceptually expanded using the translation model to improve retrieval. Translation models were also seen to be useful in segmenting incident reports into the problem and solution parts (Deepak et al., 2012); we will use an adaptation of the generative model presented therein, for our solution extraction formulation. Entity-level translation models were recently shown to be useful in modeling correlations in QA archives (Singh, 2012).

3 Problem Definition

Let a thread $\mathcal{T}$ from a discussion forum be made up of t posts. Since we assume, much like many other earlier papers, that the first post is the problem post, the task is to identify which among the remaining $t-1$ posts are solutions. There could be multiple (most likely, different) solutions within the same thread. We may now model the thread $\mathcal{T}$ as $t-1$ post pairs, each pair having the problem post as the first element, and one of the $t-1$ remaining posts (i.e., reply posts in $\mathcal{T}$) as the second element. Let $\mathcal{C} = \{(p_1, r_1), (p_2, r_2), \ldots, (p_n, r_n)\}$ be the set of such problem-reply pairs from across threads in the discussion forum. We are interested in finding a subset $\mathcal{C}'$ of $\mathcal{C}$ such that most of the pairs in $\mathcal{C}'$ are problem-solution pairs, and most of those in $\mathcal{C} - \mathcal{C}'$ are not so. In short, we would like to find problem-solution pairs from $\mathcal{C}$ such that the F-measure[8] for solution identification is maximized.

4 Our Approach

4.1 The Correlation Assumption

Central to our approach is the assumption of lexical correlation between the problem and solution

[8] http://en.wikipedia.org/wiki/F1_score

texts. At the word level, this translates to assuming that there exist word pairs such that the presence of the first word in the problem part predicts the presence/absence of the second word in the solution part well. Though not yet harnessed for solution identification, the correlation assumption is not at all novel. Infact, the assumption that similar problems have similar solutions (of which the correlation assumption is an offshoot) forms the foundation of case-based reasoning systems (Kolodner, 1992), a kind of knowledge reuse systems that could be the natural consumers of problem-solution pairs mined from forums. The usage of translation models in QA retrieval (Xue et al., 2008; Singh, 2012) and segmentation (Deepak et al., 2012) were also motivated by the correlation assumption. We use an IBM Model 1 translation model (Brown et al., 1990) in our technique; simplistically, such a model m may be thought of as a 2-d associative array where the value $m[w_1][w_2]$ is directly related to the probability of w_1 occuring in the problem when w_2 occurs in the solution.

4.2 Generative model for Solution Posts

Consider a unigram language model $\mathcal{S}_S$ that models the lexical characteristics of solution posts, and a translation model $\mathcal{T}_S$ that models the lexical correlation between problems and solutions. Our generative model models the reply part of a (p, r) pair (in which r is a solution) as being generated from the statistical models in $\{\mathcal{S}_S, \mathcal{T}_S\}$ as follows.

- For each word w_s occuring in r,
  1. Choose $z \sim U(0, 1)$
  2. If $z \leq \lambda$, Choose $w \sim Mult(\mathcal{S}_S)$
  3. Else, Choose $w \sim Mult(\mathcal{T}_S^p)$

where $\mathcal{T}_S^p$ denotes the multionomial distribution obtained from $\mathcal{T}_S$ conditioned over the words in the post p; this is obtained by assigning each candidate solution word w a weight equal to $avg\{\mathcal{T}_S[w'][w]|w' \in p\}$, and normalizing such weights across all solution words. *In short, each solution word is assumed to be generated from the language model or the translation model (conditioned on the problem words) with a probability of λ and $1 - \lambda$ respectively, thus accounting for the correlation assumption.* The generative model above is similar to the proposal in (Deepak et al., 2012), adapted suitably for our scenario. We model non-solution posts similarly with the sole difference being that they would be sampled from the analogous models $\mathcal{S}_N$ and $\mathcal{T}_N$ that characterize behavior of non-solution posts.

Example: Consider the following illustrative example of a problem and solution post:

- *Problem:* I am unable to surf the web on the BT public wifi.
- *Solution:* Maybe, you should try disconnecting and rejoining the network.

Of the solution words above, generic words such as *try* and *should* could probably be explained by (i.e., sampled from) the solution language model, whereas *disconnect* and *rejoin* could be correlated well with *surf* and *wifi* and hence are more likely to be supported better by the translation model.

4.3 Clustering-based Approach

We propose a clustering based approach so as to cluster each of the (p, r) pairs into either the *solution* cluster or the *non-solution* cluster. The objective function that we seek to maximize is the following:

$$\sum_{(p,r)\in\mathcal{C}} \begin{cases} F((p,r),\mathcal{S}_S,\mathcal{T}_S) & \textit{if label((p,r))=S} \\ F((p,r),\mathcal{S}_N,\mathcal{T}_N) & \textit{if label((p,r))=N} \end{cases} \quad (1)$$

$F((p, r), \mathcal{S}, \mathcal{T})$ indicates the conformance of the (p, r) pair (details in Section 4.3.1) with the generative model that uses the $\mathcal{S}$ and $\mathcal{T}$ models as the language and translation models respectively. The clustering based approach labels each (p, r) pair as either solution (i.e., S) or non-solution (i.e., N). Since we do not know the models or the labelings to start with, we use an iterative approach modeled on the EM meta-algorithm (Dempster et al., 1977) involving iterations, each comprising of an E-step followed by the M-step. For simplicity and brevity, instead of deriving the EM formulation, we illustrate our approach by making an analogy with the popular K-Means clustering (MacQueen, 1967) algorithm that also uses the EM formulation and crisp assignments of data points like we do. K-Means is a clustering algorithm that clusters objects represented as multi-dimensional points into k clusters where each cluster is represented by the centroid of all its members. Each iteration in K-Means starts off with assigning each

	In K-Means	In Our Approach
Data	Multi-dimensional Points	(p, r) pairs
Cluster Model	Respective Centroid Vector	Respective $\mathcal{S}$ and $\mathcal{T}$ Models for each cluster
Initialization	Random Choice of Centroids	Models learnt using (p, r) pairs labeled using the Post Position of r
E-Step	$label(d) = \arg\min_i dist(d, centroid_i)$	$label((p, r)) = \arg\max_i F((p, r), \mathcal{S}_i, \mathcal{T}_i)$ (Sec 4.3.1), and learn solution word source probabilities (Sec 4.3.2)
M-Step	$centroid_i = avg\{d \mid label(d) = i\}$	Re-learn $\mathcal{S}_S$ and $\mathcal{T}_S$ using pairs labeled S $\mathcal{S}_N$ and $\mathcal{T}_N$ using pairs labeled N (Sec 4.3.3)
Output	The clustering of points	(p, r) pairs labeled as S

Table 2: Illustrating Our Approach wrt K-Means Clustering

data object to its nearest centroid, followed by re-computing the centroid vector based on the assignments made. The analogy with K-Means is illustrated in Table 2.

Though the analogy in Table 2 serves to provide a high-level picture of our approach, the details require further exposition. In short, our approach is a 2-way clustering algorithm that uses two pairs of models, $[\mathcal{S}_S, \mathcal{T}_S]$ and $[\mathcal{S}_N, \mathcal{T}_N]$, to model solution pairs and non-solution pairs respectively. At each iteration, the post-pairs are labeled as either solution (S) or non-solution (N) based on which pair of models they better conform to. Within the same iteration, the four models are then re-learnt using the labels and other side information. At the end of the iterations, the pairs labeled S are output as solution pairs. We describe the various details in separate subsections herein.

4.3.1 E-Step: Estimating Labels

As outlined in Table 2, each (p, r) pair would be assigned to one of the classes, solution or non-solution, based on whether it conforms better with the solution models (i.e., $\mathcal{S}_S$ & $\mathcal{T}_S$) or non-solution models ($\mathcal{S}_N$ & $\mathcal{T}_N$), as determined using the $F((p, r), \mathcal{S}, \mathcal{T})$ function, i.e.,

$$label((p, r)) = \arg\max_{i \in \{S,N\}} F((p, r), \mathcal{S}_i, \mathcal{T}_i)$$

$F(.)$ falls out of the generative model:

$$F((p, r), \mathcal{S}, \mathcal{T}) = \prod_{w \in r} \lambda \times \mathcal{S}[w] + (1 - \lambda) \times \mathcal{T}^p[w]$$

where $\mathcal{S}[w]$ denotes the probability of w from $\mathcal{S}$ and $\mathcal{T}^p[w]$ denotes the probability of w from the multinomial distribution derived from $\mathcal{T}$ conditioned over the words in p, as in Section 4.2.

4.3.2 E-Step: Estimating Reply Word Source

Since the language and translation models operate at the word level, the objective function entails that we let the models learn based on their fractional contribution of the words from the language and translation models. Thus, we estimate the proportional contribution of each word from the language and translation models too, in the E-step. The fractional contributions of the word $w \in r$ in the (p, r) pair labeled as solution (i.e., S) is as follows:

$$f^{(p,r)}_{\mathcal{S}_S}(w) = \frac{\mathcal{S}_S[w]}{\mathcal{S}_S[w] + \mathcal{T}^p_S[w]}$$

$$f^{(p,r)}_{\mathcal{T}_S}(w) = \frac{\mathcal{T}^p_S[w]}{\mathcal{S}_S[w] + \mathcal{T}^p_S[w]}$$

The fractional contributions are just the actual supports for the word w, normalized by the total contribution for the word from across the two models. Similar estimates, $f^{(p,r)}_{\mathcal{S}_N}(.)$ and $f^{(p,r)}_{\mathcal{S}_N}(.)$ are made for reply words from pairs labeled N. In our example from Section 4.2, words such as *rejoin* are likely to get higher $f^{(p,r)}_{\mathcal{T}_S}(.)$ scores due to being better correlated with problem words and consequently better supported by the translation model; those such as *try* may get higher $f^{(p,r)}_{\mathcal{S}_S}(.)$ scores.

4.3.3 M-Step: Learning Models

We use the labels and reply-word source estimates from the E-step to re-learn the language and translation models in this step. As may be obvious from the ensuing discussion, those pairs labeled as solution pairs are used to learn the $\mathcal{S}_S$ and $\mathcal{T}_S$ models and those labeled as non-solution pairs are

used to learn the models with subscript N. We let each reply word contribute as much to the respective language and translation models according to the estimates in Section 4.3.2. In our example, if the word *disconnect* is assigned a source probability of 0.9 and 0.1 for the translation and language models respectively, the virtual document-pair from (p, r) that goes into the training of the respective $\mathcal{T}$ model would assume that *disconnect* occurs in r with a frequency of 0.9; similarly, the respective $\mathcal{S}$ would account for *disconnect* with a frequency of 0.1. Though fractional word frequencies are not possible in real documents, statistical models can accomodate such fractional frequencies in a straightforward manner. The language models are learnt only over the r parts of the (p, r) pairs since they are meant to characterize reply behavior; on the other hand, translation models learn over both p and r parts to model correlation.

Regularizing the $\mathcal{T}$ models: In our formulation, the language and translation models may be seen as competing for "ownership" of reply words. Consider the post and reply vocabularies to be of sizes A and B respectively; then, the translation model would have $A \times B$ variables, whereas the unigram language model has only B variables. This gives the translation model an implicit edge due to having more parameters to tune to the data, putting the language models at a disadvantage. To level off the playing field, we use a regularization[9] operation in the learning of the translation models. The IBM Model 1 learning process uses an internal EM approach where the E-step estimates the alignment vector for each problem word; this vector indicates the distribution of alignments of the problem word across the solution words. In our example, an example alignment vector for *wifi* could be: $\{rejoin : 0.4, network : 0.4, disconnect : 0.1, \ldots\}$. Our regularization method uses a parameter τ to discard the long tail in the alignment vector by resetting entries having a value $\leq \tau$ to 0.0 followed by re-normalizing the alignment vector to add up to 1.0. Such pruning is performed at each iteration in the learning of the translation model, so that the following M-steps learn the probability matrix according to such modified alignment vectors.

The semantics of the τ parameter may be intuitively outlined. If we would like to allow alignment vectors to allow a problem word to align with upto two reply words, we would need to set τ to a value close to $0.5 (= \frac{1}{2})$; ideally though, to allow for the mass consumed by an almost inevitable long tail of very low values in the alignment vector, we would need to set it to slightly lower than 0.5, say 0.4.

[9]We use the word *regularization* in a generic sense to mean adapting models to avoid overfitting; in particular, it may be noted that we are not using popular regularization methods such as L1-regularization.

Alg. 1 ***Clustering-based Solution Identification***

Input. $\mathcal{C}$, a set of (p, r) pairs
Output. $\mathcal{C}'$, the set of identified solution pairs

Initialization
1. $\forall (p, r) \in \mathcal{C}$
2. $\quad if(r.postpos = 2)\ label((p, r)) = S$
3. $\quad else\ label((p, r)) = N$
4. Learn $\mathcal{S}_S$ & $\mathcal{T}_S$ using pairs labeled S
5. Learn $\mathcal{S}_N$ & $\mathcal{T}_N$ using pairs labeled N

EM Iterations
6. $while(not\ converged \wedge \#Iterations < 10)$
   E-Step:
7. $\quad \forall (p, r) \in \mathcal{C}$
8. $\quad label((p, r)) = \arg\max_i F((p, r), \mathcal{S}_i, \mathcal{T}_i)$
9. $\quad \forall w \in r$
10. $\quad\quad Estimate\ f^{(p,r)}_{\mathcal{S}_{label(p,r)}}(w)\ ,\ f^{(p,r)}_{\mathcal{T}_{label(p,r)}}(w)$
    M-Step:
11. $\quad$ Learn $\mathcal{S}_S$ & $\mathcal{T}_S$ from pairs labeled S using the $f^{(p,r)}_{\mathcal{S}_S}(.)\ f^{(p,r)}_{\mathcal{T}_S}(.)$ estimates
12. $\quad$ Learn $\mathcal{S}_N$ & $\mathcal{T}_N$ from pairs labeled N using the $f^{(p,r)}_{\mathcal{S}_N}(.)\ f^{(p,r)}_{\mathcal{T}_N}(.)$ estimates

Output
13. Output (p, r) pairs from $\mathcal{C}$ with $label((p, r)) = S$ as $\mathcal{C}'$

4.3.4 Initialization

K-Means clustering mostly initializes centroid vectors randomly; however, it is non-trivial to initialize the complex translation and language models randomly. Moreover, an initialization such that the $\mathcal{S}_S$ and $\mathcal{T}_S$ models favor the solution pairs more than the non-solution pairs is critical so that they may progressively lean towards modeling solution behaviour better across iterations. Towards this, we make use of a structural feature; in particular, adapting the hypothesis that solutions occur in the first N posts (Ref. (Catherine et al., 2012)), *we label the pairs that have the the reply from the second post (note that the first post is assumed to be the problem post) in the thread as a solution*

post, and all others as non-solution posts. Such an initialization along with uniform reply word source probabilities is used to learn the initial estimates of the $\mathcal{S}_S$, $\mathcal{T}_S$, $\mathcal{S}_N$ and $\mathcal{T}_N$ models to be used in the E-step for the first iteration. We will show that we are able to effectively perform solution identification using our approach by exploiting just one structural feature, the post position, as above. However, we will also show that we can exploit other features as and when available, to deliver higher accuracy clusterings.

4.3.5 Method Summary

The overall method comprising the steps that have been described is presented in Algorithm 1. The initialization using the post position (Ref. Sec 4.3.4) is illustrated in Lines 1-5, whereas the EM-iterations form Steps 6 through 12. Of these, the E-step incorporates labeling (Line 8) as described in Sec 4.3.1 and reply-word source estimation (Line 10) detailed in Sec 4.3.2. The models are then re-learnt in the M-Step (Lines 11-12) as outlined in Sec 4.3.3. At the end of the iterations that may run up to 10 times if the labelings do not stabilize earlier, the pairs labeled S are output as identified solutions (Line 13).

Time Complexity: Let n denote $|\mathcal{C}|$, and the number of unique words in each problem and reply post be a and b respectively. We will denote the vocabulary size of problem posts as A and that of reply posts as B. Learning of the language and translation models in each iteration costs $\mathcal{O}(nb + B)$ and $\mathcal{O}(k'(nab + AB))$ respectively (assuming the translation model learning runs for k' iterations). The E-step labeling and source estimation cost $\mathcal{O}(nab)$ each. For k iterations of our algorithm, this leads to an overall complexity of $\mathcal{O}(kk'(nab + AB))$.

5 Experimental Evaluation

We use a crawl of 140k threads from Apple Discussion forums[10]. Out of these, 300 threads (comprising 1440 posts) were randomly chosen and each post was manually tagged as either solution or non-solution by the authors of (Catherine et al., 2013) (who were kind enough to share the data with us) with an inter-annotator agreement[11] of 0.71. On an average, 40% of replies in each thread and 77% of first replies were seen to be solutions,

Table 4: Sample $\mathcal{T}_S$ and $\mathcal{S}_S$ Estimates

leading to an F-measure of 53% for our initialization heuristic. We use the F-measure[12] for solution identification, as the primary evaluation measure. While we vary the various parameters separately in order to evaluate the trends, we use a dataset of 800 threads (containing the 300 labeled threads) and set $\lambda = 0.5$ and $\tau = 0.4$ unless otherwise mentioned. Since we have only 300 labeled threads, accuracy measures are reported on those (like in (Catherine et al., 2013)). We pre-process the post data by stemming words (Porter, 1980).

5.1 Quality Evaluation

In this study, we compare the performance of our method under varying settings of λ against the only unsupervised approach for solution identification from literature, that from (Cong et al., 2008). We use an independent implementation of the technique using Kullback-Leibler Divergence (Kullback, 1997) as the similarity measure between posts; KL-Divergence was seen to perform best in the experiments reported in (Cong et al., 2008).

Table 3 illustrates the comparative performance

[12] http://en.wikipedia.org/wiki/F1_score

Technique		Precision	Recall	F-Measure
Unsupervised Graph Propagation (Cong et al., 2008)		29.7 %	55.6 %	**38.7 %**
Our Method with only Translation Models ($\lambda = 0.0$)		41.8 %	86.8 %	**56.5 %**
Our Method with only Language Models ($\lambda = 1.0$)		63.2 %	62.1 %	**62.6 %**
Our Method with Both Models ($\lambda = 0.5$)		61.3 %	66.9 %	**64.0 %**
Methods using **Supervision** (Catherine et al., 2013)	ANS CT	40.6 %	88.0 %	**55.6 %**
	ANS-ACK PCT	56.8 %	84.1 %	**67.8%**

Table 3: Quality Evaluation

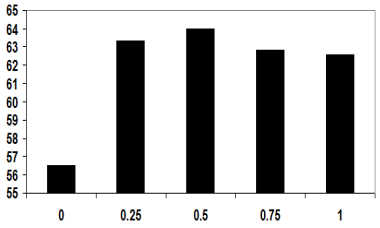

Figure 2: F% (Y) vs. λ (X)

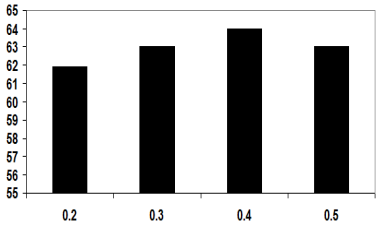

Figure 3: F% (Y) vs. τ (X)

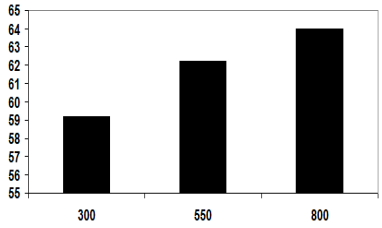

Figure 4: F% (Y) vs. #Threads (X)

on various quality metrics, of which F-Measure is typically considered most important. Our pure-LM[13] setting (i.e., $\lambda = 1$) was seen to perform up to 6 F-Measure points better than the pure-TM[14] setting (i.e., $\lambda = 0$), whereas the uniform mix is seen to be able to harness both to give a 1.4 point (i.e., 2.2%) improvement over the pure-LM case. The comparison with the approach from (Cong et al., 2008) illustrates that our method is very clearly the superior method for solution identification outperforming the former by large margins on all the evaluation measures, with the improvement on F-measure being more than 25 points.

Comparison wrt Methods from (Catherine et al., 2013): Table 3 also lists the performance of SVM-based methods from (Catherine et al., 2013) that use supervised information for solution identification, to help put the performance of our technique in perspective. Of the two methods therein, ANS CT is a more general method that uses two views (structural and lexical) of solutions which are then co-trained. ANS-ACK PCT is an enhanced method that requires author-id information and a means of classifying posts as acknowledgements (which is done using additional supervision); a post being acknowledged by the problem author is then used as a signal to enhance the solution-ness of a post. In the absence of author information (such as may be common in privacy-constrained domains such as medical forums) and extrinsic information to enable identify acknowledgements, ANS CT is the only technique available. Our technique is seen to outperform ANS CT by a respectable margin (8.6 F-measure points) while trailing behind the enhanced ANS-ACK PCT method with a reasonably narrow 3.8 F-measure point margin. Thus, our unsupervised method is seen to be a strong competitor even for techniques using supervision outlined in (Catherine et al., 2013), illustrating the effectiveness of LM and TM modeling of reply posts.

Across Iterations: For scenarios where computation is at a premium, it is useful to know how quickly the quality of solution identification stabilizes, so that the results can be collected after fewer iterations. Figure 1 plots the F-measure across iterations for the run with $\lambda = 0.5, \tau = 0.4$ setting, where the F-measure is seen to stabilize in as few as 4-5 iterations. Similar trends were observed for other runs as well, confirming that the run may be stopped as early as after the fourth iteration without considerable loss in quality.

Example Estimates from LMs and TMs: In order to understand the behavior of the statistical models, we took the highest 100 entries from both $\mathcal{S}_S$ and $\mathcal{T}_S$ and attempted to qualitatively evaluate semantics of the words (or word pairs) corresponding to those. Though the stemming made it hard to make sense of some entries, we present some of the understandable entries from among

[13]Language Model
[14]Translation Model

the top-100 in Table 4. The first three entries from $\mathcal{T}_S$ deal with connection issues for which *adaptor* or *guest account* related solutions are proposed, whereas the remaining have something to do with the *mac translator app* and *rebuilding* libraries after an *update*. The top words from $\mathcal{S}_S$ include imperative words and words from solutions to common issues that include actions pertaining to the *router* or *password*.

5.2 Varying Parameter Settings

We now analyse the performance of our approach against varying parameter settings. In particular, we vary λ and τ values and the dataset size, and experiment with some initialization variations.

Varying λ: λ is the weighting parameter that indicates the fraction of weight assigned to LMs (vis-a-vis TMs). As may be seen from Figure 2, the quality of the results as measured by the F-measure is seen to peak around the middle (i.e., $\lambda = 0.5$), and decline slowly towards either extreme, with a sharp decline at $\lambda = 0$ (i.e., pure-TM setting). This indicates that a uniform mix is favorable; however, if one were to choose only one type of model, usage of LMs is seen to be preferable than TMs.

Varying τ: τ is directly related to the extent of pruning of TMs, in the regularization operation; all values in the alignment vector $\leq \tau$ are pruned. Thus, each problem word is roughly allowed to be aligned with at most $\sim \frac{1}{\tau}$ solution words. The trends from Figure 3 suggests that allowing a problem word to be aligned to up to 2.5 solution words (i.e., $\tau = 0.4$) is seen to yield the best performance though the quality decline is graceful towards either side of the $[0.1, 0.5]$ range.

Varying Data Size: Though more data always tends to be beneficial since statistical models benefit from redundancy, the marginal utility of additional data drops to very small levels beyond a point; we are interested in the amount of data beyond which the quality of solution identification flattens out. Figure 4 suggests that there is a sharp improvement in quality while increasing the amount of data from 300 threads (i.e., 1440 (p, r) pairs) to 550 (2454 pairs), whereas the increment is smaller when adding another 250 pairs (total of 3400 pairs). Beyond 800 threads, the F-measure was seen to flatten out rapidly and stabilize at $\sim 64\%$.

Initialization: In Apple discussion forums, posts by Apple employees that are labeled with the *Apple employees* tag (approximately $\sim 7\%$ of posts in our dataset) tend to be solutions. So are posts that are marked *Helpful* ($\sim 3\%$ of posts) by other users. Being specific to Apple forums, we did not use them for initialization in experiments so far with the intent of keeping the technique generic. However, when such posts are initialized as solutions (in addition to first replies as we did earlier), the F-score for solution identification for our technique was seen to improve slightly, to 64.5% (from 64%). Thus, our technique is able to exploit any extra solution identifying structural features that are available.

6 Conclusions and Future Work

We considered the problem of unsupervised solution post identification from discussion forum threads. Towards identifying solutions to the problem posed in the initial post, we proposed the usage of a hitherto unexplored textual feature for the solution identification problem; that of lexical correlations between problems and solutions. We model and harness lexical correlations using translation models, in the company of unigram language models that are used to characterize reply posts, and formulate a clustering-based EM approach for solution identification. We show that our technique is able to effectively identify solutions using just one non-content based feature, the post position, whereas previous techniques in literature have depended heavily on structural features (that are not always available in many forums) and supervised information. Our technique is seen to outperform the sole unsupervised solution identification technique in literature, by a large margin; further, our method is even seen to be competitive to recent methods that use supervision, beating one of them comfortably, and trailing another by a narrow margin. In short, our empirical analysis illustrates the superior performance and establishes our method as the method of choice for unsupervised solution identification.

Exploration into the usage of translation models to aid other operations in discussion forums such as proactive word suggestions for solution authoring would be interesting direction for follow-up work. Discovery of problem-solution pairs in cases where the problem post is not known beforehand, would be a challenging problem to address.

Abstract

While user attribute extraction on social media has received considerable attention, existing approaches, mostly supervised, encounter great difficulty in obtaining gold standard data and are therefore limited to predicting unary predicates (e.g., gender). In this paper, we present a weakly-supervised approach to user profile extraction from Twitter. Users' profiles from social media websites such as Facebook or Google Plus are used as a distant source of supervision for extraction of their attributes from user-generated text. In addition to traditional linguistic features used in distant supervision for information extraction, our approach also takes into account network information, a unique opportunity offered by social media. We test our algorithm on three attribute domains: *spouse*, *education* and *job*; experimental results demonstrate our approach is able to make accurate predictions for users' attributes based on their tweets.[1]

1 Introduction

The overwhelming popularity of online social media creates an opportunity to display given aspects of oneself. Users' profile information in social networking websites such as Facebook[2] or Google Plus[3] provides a rich repository personal information in a structured data format, making it amenable to automatic processing. This includes, for example, users' jobs and education, and provides a useful source of information for applications such as search[4], friend recommendation, online advertising, computational social science and more.

Table 1: Examples of Twitter message clues for user profile inference.

Although profiles exist in an easy-to-use, structured data format, they are often sparsely populated; users rarely fully complete their online profiles. Additionally, some social networking services such as Twitter don't support this type of structured profile data. It is therefore difficult to obtain a reasonably comprehensive profile of a user, or a reasonably complete facet of information (say, education level) for a class of users. While many users do not explicitly list all their personal information in their online profile, their user generated content often contains strong evidence to suggest many types of user attributes, for example education, spouse, and employment (See Table 1). Can one use such information to infer more details? In particular, can one exploit indirect clues from an unstructured data source like Twitter to obtain rich, structured user profiles?

In this paper we demonstrate that it is feasible to automatically extract Facebook-style pro-

[1]Both code and data are available at http://aclweb.org/aclwiki/index.php?title=Profile_data

files directly from users' tweets, thus making user profile data available in a structured format for upstream applications. We view user profile inference as a structured prediction task where both text and network information are incorporated. Concretely, we cast user profile prediction as binary relation extraction (Brin, 1999), e.g., SPOUSE(User$_i$, User$_j$), EDUCATION(User$_i$, Entity$_j$) and EMPLOYER(User$_i$, Entity$_j$). Inspired by the concept of distant supervision, we collect training tweets by matching attribute ground truth from an outside "knowledge base" such as Facebook or Google Plus.

One contribution of the work presented here is the creation of the first large-scale dataset on three general Twitter user profile domains (i.e., EDUCATION, JOB, SPOUSE). Experiments demonstrate that by simultaneously harnessing both text features and network information, our approach is able to make accurate user profile predictions. We are optimistic that our approach can easily be applied to further user attributes such as HOBBIES and INTERESTS (MOVIES, BOOKS, SPORTS or STARS), RELIGION, HOMETOWN, LIVING LOCATION, FAMILY MEMBERS and so on, where training data can be obtained by matching ground truth retrieved from multiple types of online social media such as Facebook, Google Plus, or LinkedIn. Our contributions are as follows:

- We cast user profile prediction as an information extraction task.
- We present a large-scale dataset for this task gathered from various structured and unstructured social media sources.
- We demonstrate the benefit of jointly reasoning about users' social network structure when extracting their profiles from text.
- We experimentally demonstrate the effectiveness of our approach on 3 relations: SPOUSE, JOB and EDUCATION.

The remainder of this paper is organized as follows: We summarize related work in Section 2. The creation of our dataset is described in Section 3. The details of our model are presented in Section 4. We present experimental results in Section 5 and conclude in Section 6.

2 Related Work

While user profile inference from social media has received considerable attention (Al Zamal et al., 2012; Rao and Yarowsky, 2010; Rao et al., 2010; Rao et al., 2011), most previous work has treated this as a classification task where the goal is to predict unary predicates describing attributes of the user. Examples include gender (Ciot et al., 2013; Liu and Ruths, 2013; Liu et al., 2012), age (Rao et al., 2010), or political polarity (Pennacchiotti and Popescu, 2011; Conover et al., 2011).

A significant challenge that has limited previous efforts in this area is the lack of available training data. For example, researchers obtain training data by employing workers from Amazon Mechanical Turk to manually identify users' gender from profile pictures (Ciot et al., 2013). This approach is appropriate for attributes such as *gender* with a small numbers of possible values (e.g., *male* or *female*), for which the values can be directly identified. However for attributes such as *spouse* or *education* there are many possible values, making it impossible to manually search for gold standard answers within a large number of tweets which may or may not contain sufficient evidence.

Also related is the Twitter user timeline extraction algorithm of Li and Cardie (2013). This work is not focused on user attribute extraction, however.

Distant Supervision Distant supervision, also known as weak supervision, is a method for learning to extract relations from text using ground truth from an existing database as a source of supervision. Rather than relying on mention-level annotations, which are expensive and time consuming to generate, distant supervision leverages readily available structured data sources as a weak source of supervision for relation extraction from related text corpora (Craven et al., 1999). For example, suppose $r(e_1, e_2) = IsIn(Paris, France)$ is a ground tuple in the database and s ="Paris is the capital of France" contains synonyms for both "Paris" and "France", then we assume that s may express the fact $r(e_1, e_2)$ in some way and can be used as positive training examples. In addition to the wide use in text entity relation extraction (Mintz et al., 2009; Ritter et al., 2013; Hoffmann et al., 2011; Surdeanu et al., 2012; Takamatsu et al., 2012), distant supervision has been applied to multiple

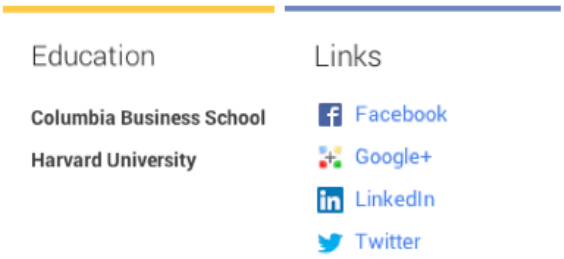

Figure 1: Illustration of Goolge Plus "knowledge base".

Figure 2: Example of fetching tweets containing entity **USC** mention from **Miranda Cosgrove** (an American actress and singer-songwriter)'s twitter stream.

fields such as protein relation extraction (Craven et al., 1999; Ravikumar et al., 2012), event extraction from Twitter (Benson et al., 2011), sentiment analysis (Go et al., 2009) and Wikipedia infobox generation (Wu and Weld, 2007).

Homophily Online social media offers a rich source of network information. McPherson et al. (2001) discovered that people sharing more attributes such as background or hobby have a higher chance of becoming friends in social media. This property, known as HOMOPHILY (summarized by the proverb "birds of a feather flock together") (Al Zamal et al., 2012) has been widely applied to community detection (Yang and Leskovec, 2013) and friend recommendation (Guy et al., 2010) on social media. In the user attribute extraction literature, researchers have considered neighborhood context to boost inference accuracy (Pennacchiotti and Popescu, 2011; Al Zamal et al., 2012), where information about the degree of their connectivity to their pre-labeled users is included in the feature vectors. A related algorithm by Mislove et al. (2010) crawled Facebook profiles of 4,000 Rice University students and alumni and inferred attributes such as major and year of matriculation purely based on network information. Mislove's work does not consider the users' text stream, however. As we demonstrate below, relying solely on network information is not enough to enable inference about attributes.

3 Dataset Creation

We now describe the generation of our distantly supervised training dataset in detail. We make use of Google Plus and Freebase to obtain ground facts and extract positive/negative bags of postings from users' twitter streams according to the ground facts.

Education/Job We first used the Google Plus API[5] (shown in Figure 1) to obtain a seed set of users whose profiles contain both their education/job status and a link to their twitter account.[6] Then, we fetched tweets containing the mention of the education/job entity from each correspondent user's twitter stream using Twitter's search API[7] (shown in Figure 2) and used them to construct positive bags of tweets expressing the associated attribute, namely EDUCATION(User$_i$, Entity$_j$), or EMPLOYER(User$_i$, Entity$_j$). The Freebase API[8] is employed for alias recognition, to match terms such as "Harvard University", "Harvard", "Harvard U" to a single The remainder of each corresponding user's entire Twitter feed is used as negative training data.[9]

We expanded our dataset from the seed users according to network information provided by Google Plus and Twitter. Concretely, we crawled circle information of users in the seed set from both their Twitter and Google Plus accounts and performed a matching to pick out shared users between one's Twitter follower list and Google Plus Circle. This process assures friend identity and avoids the problem of name ambiguity when matching accounts across websites. Among candidate users, those who explicitly display Job or Education information on Google Plus are preserved. We then gathered positive and negative data as described above.

Dataset statistics are presented in Table 2. Our

[5] https://developers.google.com/+/api/

[6] An unambiguous twitter account link is needed here because of the common phenomenon of name duplication.

[7] https://twitter.com/search

[8] http://wiki.freebase.com/wiki/Freebase_API

[9] Due to Twitter user timeline limit, we crawled at most 3200 tweets for each user.

education dataset contains 7,208 users, 6,295 of which are connected to others in the network. The positive training set for the EDUCATION is comprised of 134,060 tweets.

Spouse Facebook is the only type of social media where spouse information is commonly displayed. However, only a tiny amount of individual information is publicly accessible from Facebook Graph API[10]. To obtain ground truth for the spouse relation at large scale, we turned to Freebase[11], a large, open-domain database, and gathered instances of the /PEOPLE/PERSON/SPOUSE relation. Positive/negative training tweets are obtained in the same way as was previously described for EDUCATION and JOB. It is worth noting that our Spouse dataset is not perfect, as individuals retrieved from Freebase are mostly celebrities, and thus it's not clear whether this group of people are representative of the general population.

SPOUSE is an exception to the "homophily" effect. But it exhibits another unique property, known as, REFLEXIVITY: fact $IsSpouseOf(e_1, e_2)$ and $IsSpouseOf(e_2, e_1)$ will hold or not hold at the same time. Given training data expressing the tuple $IsSpouseOf(e_1, e_2)$ from user e_1's twitter stream, we also gather user e_2's tweet collection, and fetch tweets with the mention of e_1. We augment negative training data from e_2 as in the case of Education and Job. Our Spouse dataset contains 1,636 users, where there are 554 couples (1108 users). Note that the number of positive entities (3,121) is greater than the number of users as (1) one user can have multiple spouses at different periods of time (2) multiple entities may point to the same individual, e.g., BarackObama, Barack Obama and Barack.

4 Model

We now describe our approach to predicting user profile attributes.

4.1 Notation

Message X: Each user $i \in [1, I]$ is associated with his Twitter ID and his tweet corpus X_i. X_i is comprised of a collection of tweets $X_i = \{x_{i,j}\}_{j=1}^{j=N_i}$, where N_i denotes the number of tweets user i published.

[10] https://developers.facebook.com/docs/graph-api/

[11] http://www.freebase.com/

	Education	Job	Spouse
#Users	7,208	1,806	1,636
#Users Connected	6,295	1,407	1,108
#Edges	11,167	3,565	554
#Pos Entities	451	380	3121
#Pos Tweets	124,801	65,031	135,466
#Aver Pos Tweets per User	17.3	36.6	82.8
#Neg Entity	6,987,186	4,405,530	8,840,722
#Neg Tweets	16,150,600	10,687,403	12,872,695

Table 2: Statistics for our Dataset

Tweet Collection L_i^e: L_i^e denotes the collection of postings containing the mention of entity e from user i. $L_i^e \subset X_i$.

Entity attribute indicator $z_{i,e}^k$ and $z_{i,x}^k$: For each entity $e \in X_i$, there is a boolean variable $z_{i,e}^k$, indicating whether entity e expresses attribute k of user i. Each posting $x \in L_i^e$ is associated with attribute indicator $z_{i,x}^k$ indicating whether posting x expresses attribute k of user i. $z_{i,e}^k$ and $z_{i,x}^k$ are observed during training and latent during testing.

Neighbor set F_i^k: F_i^k denotes the neighbor set of user i. For Education $(k = 0)$ and Job $(k = 1)$, F_i^k denotes the group of users within the network that are in friend relation with user i. For Spouse attribute, F_i^k denote current user's spouse.

4.2 Model

The distant supervision assumes that if entity e corresponds to an attribute for user i, at least one posting from user i's Twitter stream containing a mention of e might express that attribute. For user-level attribute prediction, we adopt the following two strategies:

(1) GLOBAL directly makes aggregate (entity) level prediction for $z_{i,e}^k$, where features for all tweets from L_i^e are aggregated to one vector for training and testing, following Mintz et al. (2009).

(2) LOCAL makes local tweet-level predictions for each tweet $z_{i,x}^e$, $x \in L_i^k$ in the first place, making the stronger assumption that all mentions of an entity in the users' profile are expressing the associated attribute. An aggregate-level decision $z_{i,e}^k$ is then made from the deterministic OR operators.

$$z_{i,x}^e = \begin{cases} 1 & \exists x \in L_i^e, \mathbf{s.t.} z_{i,x}^k = 1 \\ 0 & \text{Otherwise} \end{cases} \quad (1)$$

The rest of this paper describes GLOBAL in detail. The model and parameters with LOCAL are identical to those in GLOBAL except that LOCAL

encode a tweet-level feature vector rather than an aggregate one. They are therefore excluded for brevity. For each attribute k, we use a model that factorizes the joint distribution as product of two distributions that separately characterize text features and network information as follows:

$$\Psi(z_{i,e}^k, X_i, F_i^k : \Theta) \propto \Psi_{text}(z_{i,e}^k, X_i)\Psi_{Neigh}(z_{i,e}^k, F_i^k) \quad (2)$$

Text Factor We use $\Psi^{text}(z_e^k, X_i)$ to capture the text related features which offer attribute clues:

$$\Psi_{text}(z_e^k, , X_i) = \exp[(\Theta_{text}^k)^T \cdot \psi_{text}(z_{i,e}^k, X_i)] \quad (3)$$

The feature vector $\psi_{text}(z_{i,e}^k, X_i)$ encodes the following standard general features:

- Entity-level: whether begins with capital letter, length of entity.
- Token-level: for each token $t \in e$, word identity, word shape, part of speech tags, name entity tags.
- Conjunctive features for a window of k (k=1,2) words and part of speech tags.
- Tweet-level: All tokens in the correspondent tweet.

In addition to general features, we employ attribute-specific features, such as whether the entity matches a bag of words observed in the list of universities, colleges and high schools for *Education* attribute, whether it matches terms in a list of companies for *Job* attribute[12]. Lists of universities and companies are taken from knowledge base NELL[13].

Neighbor Factor For Job and Education, we bias friends to have a larger possibility to share the same attribute. $\Psi_{Neigh}(z_{i,e}^k, F_i^k)$ captures such influence from friends within the network:

$$\Psi_{Neigh}(z_{i,e}^k, F_i^k) = \prod_{j \in F_i^k} \Phi_{Neigh}(z_e^k, X_j)$$

$$\Phi_{Neigh}(z_{i,e}^k, X_j) = \exp[(\Theta_{Neigh}^k)^T \cdot \psi_{Neigh}(z_{i,e}^k, X_j)] \quad (4)$$

Features we explore include the whether entity e is also the correspondent attribute with neighbor user j, i.e., $\mathbf{I}(z_{j,k}^e = 0)$ and $\mathbf{I}(z_{j,k}^e = 1)$.

[12]Freebase is employed for alias recognition.

[13]http://rtw.ml.cmu.edu/rtw/kbbrowser/

Input: Tweet Collection $\{X_i\}$, Neighbor set $\{F_i^k\}$

Initialization:

• for each user i:

for each candidate entity $e \in X_i$

$z_{i,e}^k = \text{argmax}_{z'} \Psi(z', X_i)$ from text features

End Initialization

while not convergence:

• for each user i:

update attribute values for $j \in F_i^k$

for each candidate entity $e \in X_i$

$z_{i,e}^k = \text{argmax}_{z'} \Psi(z', X_i, F_i^k)$

end while:

Figure 3: Inference for NEIGH-LATENT setting.

For Spouse, we set $F_i^{spouse} = \{e\}$ and the neighbor factor can be rewritten as:

$$\Psi_{Neigh}(z_{i,e}^k, X_j) = \Psi_{Neigh}(C_i, X_e) \quad (5)$$

It characterizes whether current user C_i to be the spouse of user e (if e corresponds to a Twitter user). We expect clues about whether C_i being entity e's spouse from e's Twitter corpus will in turn facilitate the spouse inference procedure of user i. $\psi_{Neigh}(C_i, X_e)$ encodes $\mathbf{I}(C_i \in S_e)$, $\mathbf{I}(C_i \notin S_e)$. Features we explore also include whether C_i's twitter ID appears in e's corpus.

4.3 Training

We separately trained three classifiers regarding the three attributes. All variables are observed during training; we therefore take a feature-based approach to learning structure prediction models inspired by structure compilation (Liang et al., 2008). In our setting, a subset of the features (those based on network information) are computed based on predictions that will need to be made at test time, but are observed during training. This simplified approach to learning avoids expensive inference; at test time, however, we still need to jointly predict the best attribute values for friends as is described in section 4.4.

4.4 Inference

Job and Education Our inference algorithm for Job/Education is performed on two settings, depending on whether neighbor information is

observed (NEIGH-OBSERVED) or latent (NEIGH-LATENT). Real world applications, where network information can be partly retrieved from all types of social networks, can always falls in between.

Inference in the NEIGH-OBSERVED setting is trivial; for each entity $e \in G_i$, we simply predict it's candidate attribute values using Equ.6.

$$z_{i,e}^k = \underset{z'}{\operatorname{argmax}}\, \Psi(z', X_i, F_i^k) \tag{6}$$

For NEIGH-LATENT setting, attributes for each node along the network are treated latent and user attribute prediction depends on attributes of his neighbors. The objective function for joint inference would be difficult to optimize exactly, and algorithms for doing so would be unlikely to scale to network of the size we consider. Instead, we use a sieve-based greedy search approach to inference (shown in Figure 3) inspired by recent work on coreference resolution (Raghunathan et al., 2010). Attributes are initialized using only text features, maximizing $\Psi_{text}(e, X_i)$, and ignoring network information. Then for each user we iteratively re-estimate their profile given both their text features and network features (computed based on the current predictions made for their friends) which provide additional evidence.

In this way, highly confident predictions will be made strictly from text in the first round, then the network can either support or contradict low confidence predictions as more decisions are made. This process continues until no changes are made at which point the algorithm terminates. We empirically found it to work well in practice. We expect that NEIGH-OBSERVED performs better than NEIGH-LATENT since the former benefits from gold network information.

Spouse For Spouse inference, if candidate entity e has no correspondent twitter account, we directly determine $z_{i,e}^k = \operatorname{argmax}_{z'} \Psi(z', X_i)$ from text features. Otherwise, the inference of $z_{i,e}^k$ depends on the z_{e,C_i}^k. Similarly, we initialize $z_{i,e}^k$ and z_{e,C_i}^k by maximizing text factor, as we did for Education and Job. Then we iteratively update z^k given by the rest variables until convergence.

5 Experiments

In this Section, we present our experimental results in detail.

	Education	Job
AFFINITY	74.3	14.5

Table 3: Affinity values for Education and Job.

5.1 Preprocessing and Experiment Setup

Each tweet posting is tokenized using Twitter NLP tool introduced by Noah's Ark[14] with # and @ separated following tokens. We assume that attribute values should be either name entities or terms following @ and #. Name entities are extracted using Ritter et al.'s NER system (2011). Consecutive tokens with the same named entity tag are chunked (Mintz et al., 2009). Part-of-speech tags are assigned based on Owoputi et al's tweet POS system (Owoputi et al., 2013).

Data is divided in halves. The first is used as training data and the other as testing data.

5.2 Friends with Same Attribute

Our network intuition is that users are much more likely to be friends with other users who share attributes, when compared to users who have no attributes in common. In order to statistically show this, we report the value of AFFINITY defined by Mislove et al (2010), which is used to quantitatively evaluate the degree of HOMOPHILY in the network. AFFINITY is the ratio of the fraction of links between attribute (k)-sharing users (S_k), relative to what is expected if attributes are randomly assigned in the network (E_k).

$$\begin{aligned} S_k &= \frac{\sum_i \sum_{j \in F_i^k} \mathbf{I}(P_i^k = P_j^k)}{\sum_i \sum_{j \in F_i^k} \mathbf{I}} \\ E_k &= \frac{\sum_m T_m^k (T_m^k - 1)}{U^k (U^k - 1)} \end{aligned} \tag{7}$$

where T_m^k denotes the number of users with m value for attribute k and $U^k = \sum_m T_m^k$. Table 3 shows the affinity value of the Education and Job. As we can see, the property of HOMOPHILY indeed exists among users in the social network with respect to Education and Job attribute, as significant affinity is observed. In particular, the affinity value for Education is 74.3, implying that users connected by a link in the network are 74.3 times more likely affiliated in the same school than as expected if education attributes are randomly assigned. It is interesting to note that Education exhibits a much stronger HOMOPHILY property than

[14] https://code.google.com/p/ark-tweet-nlp/downloads/list

Job. Such affinity demonstrates that our approach that tries to take advantage of network information for attribute prediction of holds promise.

5.3 Evaluation and Discussion

We evaluate settings described in Section 4.2 i.e., GLOBAL setting, where user-level attribute is predicted directly from jointly feature space and LOCAL setting where user-level prediction is made based on tweet-level prediction along with different inference approaches described in Section 4.4, i.e. NEIGH-OBSERVED and NEIGH-LATENT, regarding whether neighbor information is observed or latent.

Baselines We implement the following baselines for comparison and use identical processing techniques for each approach for fairness.

- **Only-Text:** A simplified version of our algorithm where network/neighbor influence is ignored. Classifier is trained and tested only based on text features.
- **NELL:** For Job and Education, candidate is selected as attribute value once it matches bag of words in the list of universities or companies borrowed from NELL. For Education, the list is extended by alias identification based on Freebase. For Job, we also fetch the name abbreviations[15]. NELL is only implemented for Education and Job attribute.

For each setting from each approach, we report the (P)recision, (R)ecall and (F)1-score. For LOCAL setting, we report the performance for both entity-level prediction (Entity) and posting-level prediction (Tweet). Results for Education, Job and Spouse from different approaches appear in Table 4, 5 and 6 respectively.

Local or Global For horizontal comparison, we observe that GLOBAL obtains a higher Precision score but a lower Recall than LOCAL(ENTITY). This can be explained by the fact that LOCAL(U) sets $z_{i,e}^{k} = 1$ once one posting $x \in L_i^e$ is identified as attribute related, while GLOBAL tend to be more meticulous by considering the conjunctive feature space from all postings.

Homophile effect In agreement with our expectation, NEIGH-OBSERVED performs better than NEIGH-LATENT since erroneous predictions in NEIGH-LATENT setting will have negative influence on further prediction during the greedy search process. Both NEIGH-OBSERVED and NEIGH-LATENT where network information is harnessed, perform better than **Only-Text**, which the prediction is made independently on user's text features. The improvement of NEIGH-OBSERVED over **Only-Text** is 22.7% and 6.4% regarding F-1 score for Education and Job respectively, which further illustrate the usefulness of making use of Homophile effect for attribute inference on online social media. It is also interesting to note the improvement much more significant in Education inference than Job inference. This is in accord with what we find in Section 5.2, where education network exhibits stronger HOMOPHILE property than Job network, enabling a significant benefit for education inference, but limited for job inference.

Spouse prediction also benefits from neighboring effect and the improvement is about 12% for LOCAL(ENTITY) setting. Unlike Education and Job prediction, for which in NEIGH-OBSERVED setting all neighboring variables are observed, network variables are hidden during spouse prediction. By considering network information, the model benefits from evident clues offered by tweet corpus of user e's spouse when making prediction for e, but also suffers when erroneous decision are made and then used for downstream predictions.

NELL Baseline Notably, NELL achieves highest Recall score for Education inference. It is also worth noting that most of education mentions that NELL fails to retrieve are those involve irregular spellings, such as HarvardUniv and Cornell_U, which means Recall score for NELL baseline would be even higher if these irregular spellings are recognized in a more sophisticated system. The reason for such high recall is that as our ground truths are obtained from Google plus, the users from which are mostly affiliated with decent schools found in NELL dictionary. However, the high recall from NELL is sacrificed at precision, as users can mention school entities in many of situations, such as paying a visit or reporting some relevant news. NELL will erroneously classify these cases as attribute mentions.

NELL does not work out for Job, with a fairly poor 0.0156 F1 score for LOCAL(ENTITY) and 0.163 for LOCAL(TWEET). Poor precision is expected for as users can mention firm entity in a great many of situations. The recall score for

Table 6: Results for Spouse Prediction

NELL in job inference is also quite low as job related entities exhibit a greater diversity of mentions, many of which are not covered by the NELL dictionary.

Vertical Comparison: Education, Job and Spouse Job prediction turned out to be much more difficult than Education, as shown in Tables 4 and 5. Explanations are as follows: (1) Job contains a much greater diversity of mentions than Education. Education inference can benefit a lot from the dictionary relevant feature which Job may not. (2) Education mentions are usually associated with clear evidence such as homework, exams, studies, cafeteria or books, while situations are much more complicated for job as vocabularies are usually specific for different types of jobs. (3) The boundary between a user working in and a fun for a specific operation is usually ambiguous. For example, a Google engineer may constantly update information about outcome products of Google, so does a big fun. If the aforementioned engineer barely tweets about working conditions or colleagues (which might still be ambiguous), his tweet collection, which contains many of mentions about outcomes of Google product, will be significantly similar to tweets published by a Google fun. Such nuisance can be partly solved by the consideration of network information, but not totally.

The relatively high F1 score for spouse prediction is largely caused by the great many of non-individual related entities in the dataset, the identification of which would be relatively simpler. A deeper look at the result shows that the classifier frequently makes wrong decisions for entities such as userID and name entities. Significant as some spouse relevant features are, such as love, husband, child, in most circumstances, spouse mentions are extremely hard to recognize. For example, in tweets "Check this out, @alancross, it's awesome `bit.ly/1bnjYHh`." or "Happy Birthday @alancross !". *alancross* can reasonably be any option among current user's friend, colleague, parents, child or spouse. Repeated mentions add no confidence. Although we can identify *alancross* as spouse attribute once it jointly appear with other strong spouse indicators, they are still many cases where they never co-appear. How to integrate more useful side information for spouse recognition constitutes our future work.

6 Conclusion and Future Work

In this paper, we propose a framework for user attribute inference on Twitter. We construct the publicly available dataset based on distant supervision and experiment our model on three useful user profile attributes, i.e., Education, Job and Spouse. Our model takes advantage of network information on social network. We will keep updating the dataset as more data is collected.

One direction of our future work involves exploring more general categories of user profile at-

tributes, such as interested books, movies, hometown, religion and so on. Facebook would an ideal ground truth knowledge base. Another direction involves incorporating richer feature space for better inference performance, such as multi-media sources (i.e. pictures and video).

Abstract

Consider a person trying to spread an important message on a social network. He/she can spend hours trying to craft the message. Does it actually matter? While there has been extensive prior work looking into predicting popularity of social-media content, the effect of wording per se has rarely been studied since it is often confounded with the popularity of the author and the topic. To control for these confounding factors, we take advantage of the surprising fact that there are many pairs of tweets containing the *same* url and written by the *same* user but employing different wording. Given such pairs, we ask: which version attracts more retweets? This turns out to be a more difficult task than predicting popular topics. Still, humans can answer this question better than chance (but far from perfectly), and the computational methods we develop can do better than both an average human and a strong competing method trained on non-controlled data.

1 Introduction

How does one make a message "successful"? This question is of interest to many entities, including political parties trying to *frame* an issue (Chong and Druckman, 2007), and individuals attempting to make a point in a group meeting. In the first case, an important type of success is achieved if the national conversation adopts the rhetoric of the party; in the latter case, if other group members repeat the originating individual's point.

The massive availability of online messages, such as posts to social media, now affords researchers new means to investigate at a very large scale the factors affecting message propagation, also known as adoption, sharing, spread, or virality. According to prior research, important features include characteristics of the originating author (e.g., verified Twitter user or not, author's messages' past success rate), the author's social network (e.g., number of followers), message timing, and message content or topic (Artzi et al., 2012; Bakshy et al., 2011; Borghol et al., 2012; Guerini et al., 2011; Guerini et al., 2012; Hansen et al., 2011; Hong et al., 2011; Lakkaraju et al., 2013; Milkman and Berger, 2012; Ma et al., 2012; Petrović et al., 2011; Romero et al., 2013; Suh et al., 2010; Sun et al., 2013; Tsur and Rappoport, 2012). Indeed, it's not surprising that one of the most retweeted tweets of all time was from user BarackObama, with 40M followers, on November 6, 2012: "Four more years. [link to photo]".

Our interest in this paper is the effect of alternative message *wording*, meaning *how* the message is said, rather than what the message is about. In contrast to the identity/social/timing/topic features mentioned above, wording is one of the few factors directly under an author's control when he or she seeks to convey a **fixed** piece of content. For example, consider a speaker at the ACL business meeting who has been tasked with proposing that Paris be the next ACL location. This person cannot on the spot become ACL president, change the shape of his/her social network, wait until the next morning to speak, or campaign for Rome instead; but he/she can craft the message to be more humorous, more informative, emphasize certain aspects instead of others, and so on. In other words, we investigate whether a different choice of words affects message propagation, *controlling for user and topic*: would user BarackObama have gotten significantly more (or fewer) retweets if he had used some alternate wording to announce his re-election?

Although we cannot create a parallel universe

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 175–185,
Baltimore, Maryland, USA, June 23-25 2014.

Table 1: Topic- and author-controlled (TAC) pairs. Topic control = inclusion of the same URL.

author	tweets	#retweets

in which BarackObama tweeted something else[1], fortunately, a surprising characteristic of Twitter allows us to run a fairly analogous *natural experiment*: external forces serendipitously provide an environment that resembles the desired controlled setting (DiNardo, 2008). Specifically, *it turns out to be unexpectedly common for the same user to post different tweets regarding the same URL* — a good proxy for fine-grained topic[2] — within a relatively short period of time.[3] Some example pairs are shown in Table 1; we see that the paired tweets may differ dramatically, going far beyond word-for-word substitutions, so that quite interesting changes can be studied.

Looking at these examples, can one in fact tell from the wording which tweet in a topic- and author-controlled pair will be more successful? The answer may not be a priori clear. For example, for the first pair in the table, one person we asked found t_1's invocation of a "scandal" to be more attention-grabbing; but another person preferred t_2 because it is more informative about the URL's content and includes "fight media portrayal". In an Amazon Mechanical Turk (AMT) experiment (§4), we found that humans achieved an average accuracy of 61.3%: not that high, but better than chance, indicating that it is somewhat possible for humans to predict greater message spread from different deliveries of the same information.

Buoyed by the evidence of our AMT study that wording effects exist, we then performed a battery of experiments to seek generally-applicable, non-Twitter-specific features of more successful phrasings. §5.1 applies hypothesis testing (with Bonferroni correction to ameliorate issues with multiple comparisons) to investigate the utility of features like informativeness, resemblance to headlines, and conformity to the community norm in language use. §5.2 further validates our findings via prediction experiments, including on completely fresh held-out data, used only once and after an array of standard cross-validation experiments.[4] We achieved 66.5% cross-validation accuracy and 65.6% held-out accuracy with a combination of our custom features and bag-of-words. Our classifier fared significantly better than a number of baselines, including a strong classifier trained on the most- and least-retweeted tweets that was even granted access to author and timing metadata.

2 Related work

The idea of using carefully controlled experiments to study effective communication strategies dates back at least to Hovland et al. (1953). Recent studies range from examining what characteristics of *New York Times* articles correlate with high re-sharing rates (Milkman and Berger, 2012) to looking at how differences in description affect the spread of content-controlled videos or images (Borghol et al., 2012; Lakkaraju et al., 2013). Simmons et al. (2011) examined the variation of quotes from different sources to examine how textual memes mutate as people pass them along, but did not control for author. Predicting the "success" of various texts such as novels and movie quotes has been the aim of additional prior work not already mentioned in §1 (Ashok et al., 2013; Louis and Nenkova, 2013; Danescu-Niculescu-Mizil et al., 2012; Pitler and Nenkova, 2008; McIntyre and Lapata, 2009). To our knowledge, there have been no large-scale studies exploring wording effects in a both topic- and author-controlled setting. Employing such controls, we find that predicting the more effective alternative wording is much harder than the previously well-studied problem of pre-

[1] Cf. the Music Lab "multiple universes" experiment to test the randomness of popularity (Salganik et al., 2006).

[2] Although hashtags have been used as coarse-grained topic labels in prior work, for our purposes, we have no assurance that two tweets both using, say, "#Tahrir" would be attempting to express the same message but in different words. In contrast, see the same-URL examples in Table 1.

[3] Moreover, Twitter presents tweets to a reader in strict chronological order, so that there are no algorithmic-ranking effects to compensate for in determining whether readers saw a tweet. And, Twitter accumulates retweet counts for the entire retweet cascade and displays them for the original tweet at the root of the propagation tree, so we can directly use Twitter's retweet counts to compare the entire reach of the different versions.

[4] And after crossing our fingers.

dicting popular content when author or topic can freely vary.

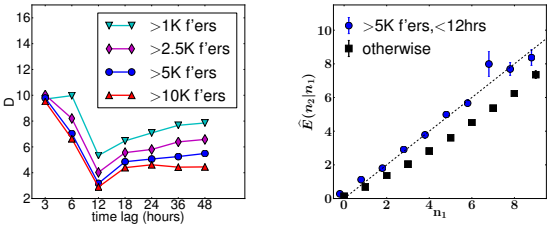
Related work regarding the features we considered is deferred to §5.1 (features description).

3 Data

Our main dataset was constructed by first gathering 1.77M topic- and author-controlled (henceforth *TAC*) tweet pairs[5] differing in more than just spacing.[6] We accomplished this by crawling timelines of 236K user ids that appear in prior work (Kwak et al., 2010; Yang and Leskovec, 2011) via the Twitter API. This crawling process also yielded 632K TAC pairs whose only difference was spacing, and an additional 558M "unpaired" tweets; as shown later in this paper, we used these extra corpora for computing language models and other auxiliary information. We applied non-obvious but important filtering — described later in this section — to control for other external factors and to reduce ambiguous cases. This brought us to a set of 11,404 pairs, with the *gold-standard* labels determined by which tweet in each pair was the one that received more retweets according to the Twitter API. We then did a second crawl to get an additional 1,770 pairs to serve as a held-out dataset. The corresponding tweet IDs are available online at `http://chenhaot.com/pages/wording-for-propagation.html`. (Twitter's terms of service prohibit sharing the actual tweets.)

Throughout, we refer to the textual content of the earlier tweet within a TAC pair as t_1, and of the later one as t_2. We denote the number of retweets received by each tweet by n_1 and n_2, respectively. We refer to the tweet with higher (lower) n_i as the "better (worse)" tweet.

Using "identical" pairs to determine how to compensate for follower-count and timing effects. In an ideal setting, differences between n_1 and n_2 would be determined solely by differences in wording. But even with a TAC pair, retweets might exhibit a temporal bias because of the chronological order of tweet presentation (t_1 might enjoy a first-mover advantage (Borghol et al., 2012) because it is the "original"; alternatively,



(a) For *identical* TAC pairs, retweet-count deviation vs. time lag between t_1 and t_2, for the author follower-counts given in the legend.

(b) Avg. n_2 vs. n_1 for identical TAC pairs, highlighting our chosen time-lag and follower thresholds. Bars: standard error. Diagonal line: $\hat{E}(n_2|n_1) = n_1$.

Figure 1: (a): The ideal case where $n_2 = n_1$ when $t_1 = t_2$ is best approximated when t_2 occurs within 12 hours of t_1 and the author has at least 10,000 or 5,000 followers. (b): in our chosen setting (blue circles), n_2 indeed tends to track n_1, whereas otherwise (black squares), there's a bias towards retweeting t_1.

t_2 might be preferred because retweeters consider t_1 to be "stale"). Also, the number of followers an author has can have complicated indirect effects on which tweets are read (space limits preclude discussion).

We use the 632K TAC pairs wherein t_1 and t_2 are *identical*[7] to check for such confounding effects: we see how much n_2 deviates from n_1 in such settings, since if wording were the only explanatory factor, the retweet rates for identical tweets ought to be equal. Figure 1(a) plots how the time lag between t_1 and t_2 and the author's follower-count affect the following deviation estimate:

$$D = \sum_{0 \leqslant n_1 < 10} |\hat{E}(n_2|n_1) - n_1|,$$

where $\hat{E}(n_2|n_1)$ is the average value of n_2 over pairs whose t_1 is retweeted n_1 times. (Note that the number of pairs whose t_1 is retweeted n_1 times decays exponentially with n_1; hence, we condition on n_1 to keep the estimate from being dominated by pairs with $n_1 = 0$, and do not consider $n_1 \geqslant 10$ because there are too few such pairs to estimate $\hat{E}(n_2|n_1)$ reliably.) Figure 1(a) shows that the setting where we (i) minimize the confounding effects of time lag and author's follower-count and (ii) maximize the amount of data to work with

[5] No data collection/processing was conducted at Google.

[6] The total excludes: tweets containing multiple URLs; tweets from users posting about the same URL more than five times (since such users might be spammers); the third, fourth, or fifth version for users posting between three and five tweets for the same URL; retweets (as identified by Twitter's API or by beginning with "RT @"); non-English tweets.

[7] Identical up to spacing: Twitter prevents exact copies by the same author appearing within a short amount of time, but some authors work around this by inserting spaces.

is: when t_2 occurs within 12 hours after t_1 and the author has more than 5,000 followers. Figure 1(b) confirms that for identical TAC pairs, our chosen setting indeed results in n_2 being on average close to n_1, which corresponds to the desired setting where wording is the dominant differentiating factor.[8]

Focus on meaningful and general changes. Even after follower-count and time-lapse filtering, we still want to focus on TAC pairs that (i) exhibit significant/interesting textual changes (as exemplified in Table 1, and as opposed to typo corrections and the like), and (ii) have n_2 and n_1 sufficiently different so that we are confident in which t_i is better at attracting retweets. To take care of (i), we discarded the 50% of pairs whose similarity was above the median, where similarity was tf-based cosine.[9] For (ii), we sorted the remaining pairs by $n_2 - n_1$ and retained only the top and bottom 5%.[10] Moreover, to ensure that we do not overfit to the idiosyncrasies of particular authors, we cap the number of pairs contributed by each author to 50 before we deal with (ii).

4 Human accuracy on TAC pairs

We first ran a pilot study on Amazon Mechanical Turk (AMT) to determine whether humans can identify, based on wording differences alone, which of two topic- and author- controlled tweets is spread more widely. Each of our 5 AMT tasks involved a disjoint set of 20 randomly-sampled TAC pairs (with t_1 and t_2 randomly reordered); subjects indicated "which tweet would other people be more likely to retweet?", provided a short justification for their binary response, and clicked a checkbox if they found that their choice was a "close call". We received 39 judgments per pair in aggregate from 106 subjects total (9 people completed all 5 tasks). The subjects' justifications were of very high quality, convincing us that they all did the task in good faith[11]. Two examples for the third TAC pair in Table 1 were: "[t_1 makes] the cause relate-able to some people, therefore showing more of an appeal as to why should they click the link and support" and, expressing the opposite view, "I like [t_2] more because [t_1] starts out with a generalization that doesn't affect me and try to make me look like I had that experience before".

If we view the set of 3900 binary judgments for our 100-TAC-pair sample as constituting independent responses, then the accuracy for this set is 62.4% (rising to 63.8% if we exclude the 587 judgments deemed "close calls"). However, if we evaluate the accuracy of the *majority* response among the 39 judgments per pair, the number rises to 73%. The accuracy of the majority response generally increases with the dominance of the majority, going above 90% when at least 80% of the judgments agree (although less than a third of the pairs satisfied this criterion).

Alternatively, we can consider the average accuracy of the 106 subjects: 61.3%, which is better than chance but far from 100%. (Variance was high: one subject achieved 85% accuracy out of 20 pairs, but eight scored below 50%.) This result is noticeably lower than the 73.8%-81.2% reported by Petrović et al. (2011), who ran a similar experiment involving two subjects and 202 tweet pairs, but where the pairs were *not* topic- or author-controlled.[12]

We conclude that even though propagation prediction becomes more challenging when topic and author controls are applied, humans can still to some degree tell which wording attracts more retweets. Interested readers can try this out themselves at `http://chenhaot.com/retweetedmore/quiz`.

5 Experiments

We now investigate computationally what wording features correspond to messages achieving a broader reach. We start (§5.1) by introducing a set of generally-applicable and (mostly) non-Twitter-specific features to capture our intuitions about what might be better ways to phrase a message. We then use hypothesis testing (§5.1) to evaluate the importance of each feature for message prop-

[8] We also computed the Pearson correlation between n_1 and n_2, even though it can be dominated by pairs with smaller n_1. The correlation is 0.853 for "$> 5K$ f'ers, <12hrs", clearly higher than the 0.305 correlation for "otherwise".

[9] Idf weighting was not employed because changes to frequent words are of potential interest. Urls, hashtags, @-mentions and numbers were normalized to [url], [hashtag], [at], and [num] before computing similarity.

[10] For our data, this meant $n_2 - n_1 \geqslant 10$ or $\leqslant -15$. Cf. our median number of retweets: 30.

[11] We also note that the feedback we got was quite positive, including: "...It's fun to make choices between close tweets and use our subjective opinion. Thanks and best of luck with your research" and "This was very interesting and really made me think about how I word my own tweets. Great job on this survey!". We only had to exclude one person (not counted among the 106 subjects), doing so because he or she gave the same uninformative justification for all pairs.

[12] The accuracy range stems from whether author's social features were supplied and which subject was considered.

Table 2: Notational conventions for tables in §5.1.

One-sided paired t-test for feature efficacy	
↑↑↑↑: p<1e-20	↓↓↓↓: p>1-1e-20
↑↑↑ : p<0.001	↓↓↓ : p>0.999
↑↑ : p<0.01	↓↓ : p>0.99
↑ : p<0.05	↓ : p>0.95
∗: passes our Bonferroni correction	

One-sided binomial test for feature increase (Do authors prefer to 'raise' the feature in t_2?)

YES : t_2 has a higher feature score than t_1, $\alpha = .05$
NO : t_2 has a lower feature score than t_1, $\alpha = .05$
(x%): $\%(f_2 > f_1)$, if sig. larger or smaller than 50%

agation and the extent to which authors employ it, followed by experiments on a prediction task (§5.2) to further examine the utility of these features.

5.1 Features: efficacy and author preference

What kind of phrasing helps message propagation? Does it work to explicitly ask people to share the message? Is it better to be short and concise or long and informative? We define an array of features to capture these and other messaging aspects. We then examine (i) how effective each feature is for attracting more retweets; and (ii) whether authors prefer applying a given feature when issuing a second version of a tweet.

First, for each feature, we use a one-sided paired t-test to test whether, on our 11K TAC pairs, our score function for that feature is larger in the better tweet versions than in the worse tweet versions, for significance levels $\alpha = .05, .01, .001,$ 1e-20. Given that we did 39 tests in total, there is a risk of obtaining false positives due to multiple testing (Dunn, 1961; Benjamini and Hochberg, 1995). To account for this, we also report significance results for the conservatively Bonferroni-corrected ("BC") significance level α = 0.05/39=1.28e-3.

Second, we examine author preference for applying a feature. We do so because one (but by no means the only) reason authors post t_2 after having already advertised the same URL in t_1 is that these authors were dissatisfied with the amount of attention t_1 got; in such cases, the changes may have been specifically intended to attract more retweets. We measure author preference for a feature by the percentage of our TAC pairs[13] where t_2 has more "occurrences" of the feature than t_1, which we denote by "$\%(f_2 > f_1)$". We use the one-sided binomial test to see whether $\%(f_2 > f_1)$ is significantly larger (or smaller) than 50%.

[13] For our preference experiments, we added in pairs where $n_2 - n_1$ was not in the top or bottom 5% (cf. §3, meaningful changes), since to measure author preference it's not necessary that the retweet counts differ significantly.

Table 3: Explicit requests for sharing (where only occurrences POS-tagged as verbs count, according to the Gimpel et al. (2011) tagger).

	effective?	author-preferred?
rt	↑↑↑↑ *	——
retweet	↑↑↑↑ *	YES (59%)
spread	↑↑↑ *	YES (56%)
please	↑↑↑ *	——
pls	↑	——
plz	↑↑	——

Table 4: Informativeness.

	effective?	author-preferred?
length (chars)	↑↑↑↑ *	YES (54%)
verb	↑↑↑↑ *	YES (56%)
noun	↑↑↑↑ *	——
adjective	↑↑↑ *	YES (51%)
adverb	↑↑↑ *	YES (55%)
proper noun	↑↑↑ *	NO (45%)
number	↑↑↑↑ *	NO (48%)
hashtag	↑	——
@-mention	↓↓↓ *	YES (53%)

Not surprisingly, it helps to ask people to share. (See Table 3; the notation for all tables is explained in Table 2.) The basic sanity check we performed here was to take as features the number of occurrences of the verbs 'rt', 'retweet', 'please', 'spread', 'pls', and 'plz' to capture explicit requests (e.g. "please retweet").

Informativeness helps. (Table 4) Messages that are more informative have increased *social exchange value* (Homans, 1958), and so may be more worth propagating. One crude approximation of informativeness is length, and we see that length helps.[14] In contrast, Simmons et al. (2011) found that shorter versions of memes are more likely to be popular. The difference may result from TAC-pair changes being more drastic than the variations that memes undergo.

A more refined informativeness measure is counts of the parts of speech that correspond to content. Our POS results, gathered using a Twitter-specific tagger (Gimpel et al., 2011), echo those of Ashok et al. (2013) who looked at predict-

[14] Of course, simply inserting garbage isn't going to lead to more retweets, but adding more information generally involves longer text.

Table 5: Conformity to the community and one's own past, measured via scores assigned by various language models.

	effective?	author-preferred?
twitter unigram	↑↑↑ *	YES (54%)
twitter bigram	↑↑↑ *	YES (52%)
personal unigram	↑↑↑ *	YES (52%)
personal bigram	———	NO (48%)

ing the success of books. The diminished effect of hashtag inclusion with respect to what has been reported previously (Suh et al., 2010; Petrović et al., 2011) presumably stems from our topic and author controls.

Be like the community, and be true to yourself (in the words you pick, but not necessarily in how you combine them). (Table 5) Although distinctive messages may attract attention, messages that conform to expectations might be more easily accepted and therefore shared. Prior work has explored this tension: Lakkaraju et al. (2013), in a content-controlled study, found that the more upvoted Reddit image titles balance novelty and familiarity; Danescu-Niculescu-Mizil et al. (2012) (henceforth DCKL'12) showed that the memorability of movie quotes corresponds to higher lexical distinctiveness but lower POS distinctiveness; and Sun et al. (2013) observed that deviating from one's own past language patterns correlates with more retweets.

Keeping in mind that the authors in our data have at least 5000 followers[15], we consider two types of language-conformity constraints an author might try to satisfy: to be similar to what is normal in the Twitter community, and to be similar to what his or her followers expect. We measure a tweet's similarity to expectations by its score according to the relevant language model, $\frac{1}{|T|}\sum_{x\in T}\log(p(x))$, where T refers to either all the unigrams (unigram model) or all and only bigrams (bigram model).[16] We trained a Twitter-community language model from our 558M unpaired tweets, and personal language models from each author's tweet history.

Imitate headlines. (Table 6) News headlines are often intentionally written to be both informative and attention-getting, so we introduce the idea of scoring by a language model built from New York Times headlines.[17]

Table 6: LM-based resemblance to headlines.

	effective?	author-preferred?
headline unigram	↑↑	YES (53%)
headline bigram	↑↑↑↑ *	YES (52%)

Table 7: Retweet score.

	effective?	author-preferred?
rt score	↑↑ *	NO (49%)
verb rt score	↑↑↑↑ *	——
noun rt score	↑↑↑ *	——
adjective rt score	↑	YES (50%)
adverb rt score	↑	YES (51%)
proper noun rt score	———	NO (48%)

Use words associated with (non-paired) retweeted tweets. (Table 7) We expect that provocative or sensationalistic tweets are likely to make people react. We found it difficult to model provocativeness directly. As a rough approximation, we check whether the changes in t_2 with respect to t_1 (which share the same topic and author) involve words or parts-of-speech that are associated with high retweet rate in a very large separate sample of unpaired tweets (retweets and replies discarded). Specifically, for each word w that appears more than 10 times, we compute the probability that tweets containing w are retweeted more than once, denoted by $rs(w)$. We define the *rt score* of a tweet as $max_{w\in T} rs(w)$, where T is all the words in the tweet, and the *rt score* of a particular POS tag z in a tweet as $max_{w\in T \& \mathrm{tag}(w)=z} rs(w)$.

Include positive and/or negative words. (Table 8) Prior work has found that including positive or negative sentiment increases message propagation (Milkman and Berger, 2012; Godes et al., 2005; Heath et al., 2001; Hansen et al., 2011). We measured the occurrence of positive and negative words as determined by the connotation lexicon of Feng et al. (2013) (better coverage than LIWC). Measuring the occurrence of both *simultaneously* was inspired by Riloff et al. (2013).

Refer to other people (but not your audience). (Table 9) First-person has been found useful for success before, but in the different domains of scientific abstracts (Guerini et al., 2012) and books (Ashok et al., 2013).

[15] This is not an artificial restriction on our set of authors; a large follower count means (in principle) that our results draw on a large sample of decisions whether to retweet or not.

[16] The tokens [at], [hashtag], [url] were ignored in the unigram-model case to prevent their undue influence, but retained in the bigram model to capture longer-range usage ("combination") patterns.

[17] To test whether the results stem from similarity to *news* rather than headlines per se, we constructed a NYT-text LM, which proved less effective. We also tried using Gawker headlines (often said to be attention-getting) but pilot studies revealed insufficient vocabulary overlap with our TAC pairs.

Table 8: Sentiment (contrast is measured by presence of both positive and negative sentiments).

	effective?	author-preferred?
positive	↑↑↑ *	——
negative	↑↑↑ *	——
contrast	↑↑↑ *	——

Table 9: Pronouns.

	effective?	author-preferred?
1st person singular	——	YES (51%)
1st person plural	——	YES (52%)
2nd person	——	YES (57%)
3rd person singular	↑↑	YES (55%)
3rd person plural	↑	YES (58%)

Generality helps. (Table 10) DCKL'12 posited that movie quotes are more shared in the culture when they are general enough to be used in multiple contexts. We hence measured the presence of indefinite articles vs. definite articles.

The easier to read, the better. (Table 11) We measure readability by using Flesch reading ease (Flesch, 1948) and Flesch-Kincaid grade level (Kincaid et al., 1975), though they are not designed for short texts. We use negative grade level so that a larger value indicates easier texts to read.

Final question: Do authors prefer to do what is effective? Recall that we use binomial tests to determine author preference for applying a feature more in t_2. Our preference statistics show that author preferences in many cases are aligned with feature efficacy. But there are several notable exceptions: for example, authors tend to increase the use of @-mentions and 2nd person pronouns even though they are ineffective. On the other hand, they did not increase the use of effective ones like proper nouns and numbers; nor did they tend to increase their rate of sentiment-bearing words. Bearing in mind that changes in t_2 may not always be intended as an effort to improve t_1, it is still interesting to observe that there are some contrasts between feature efficacy and author preferences.

5.2 Predicting the "better" wording

Here, we further examine the collective efficacy of the features introduced in §5.1 via their performance on a binary prediction task: given a TAC pair (t_1, t_2), did t_2 receive more retweets?

Our approach. We group the features introduced in §5.1 into 16 lexicon-based features (Table 3, 8, 9, 10), 9 informativeness features (Table 4), 6 language model features (Table 5, 6), 6 rt score features (Table 7), and 2 readability features (Table 11). We refer to all 39 of them together as *custom* features. We also consider tagged bag-of-words ("BOW") features, which includes all the unigram (word:POS pair) and bigram features that appear more than 10 times in the cross-validation data. This yields 3,568 unigram features and 4,095 bigram features, for a total of 7,663 so-called *1,2-gram features*. Values for each feature are normalized by linear transformation across all tweets in the training data to lie in the range $[0, 1]$.[18]

Table 10: Generality.

	effective?	author-preferred?
indefinite articles (a,an)	↑↑↑ *	——
definite articles (the)	——	YES (52%)

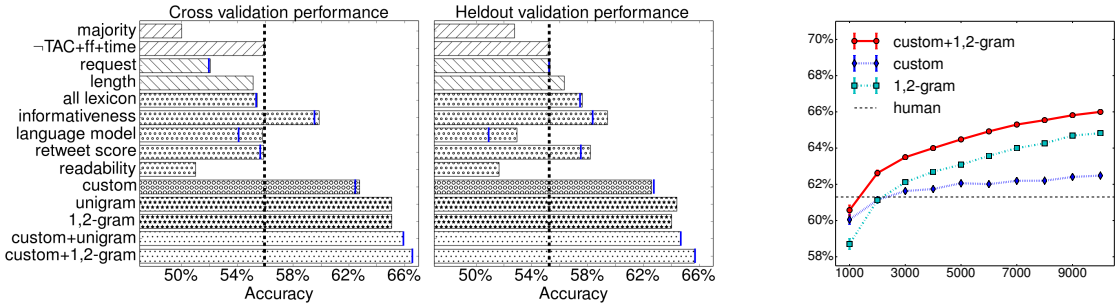
Table 11: Readability.

	effective?	author-preferred?
reading ease	↑↑	YES (52%)
negative grade level	↑	YES (52%)

For a given TAC pair, we construct its feature vector as follows. For each feature being considered, we compute its normalized value for each tweet in the pair and take the difference as the feature value for this pair. We use L2-regularized logistic regression as our classifier, with parameters chosen by cross validation on the training data. (We also experimented with SVMs. The performance was very close, but mostly slightly lower.)

A strong non-TAC alternative, with social information and timing thrown in. One baseline result we would like to establish is whether the topic and author controls we have argued for, while intuitively compelling for the purposes of trying to determine the best way for a given author to present some fixed content, are really necessary in practice. To test this, we consider an alternative binary L2-regularized logistic-regression classifier that is trained on unpaired data, specifically, on the collection of 10,000 most retweeted tweets (gold-standard label: positive) plus the 10,000 least retweeted tweets (gold-standard label: negative) that are neither retweets nor replies. Note that this alternative thus is granted, by design, roughly *twice* the training instances that our classifiers have, as a result of having roughly the same number of tweets, since our instances are pairs. Moreover, we additionally include the tweet author's follower count, and the day and hour of posting, as features. We refer to this alternative classifier as $\neg$*TAC+ff+time*. (Mnemonic: "ff" is used in bibliographic contexts as an abbreviation

[18] We also tried normalization by *whitening*, but it did not lead to further improvements.



(a) Cross-validation and heldout accuracy for various feature sets. Blue lines inside bars: performance when custom features are restricted to those that pass our Bonferroni correction (no line for readability because no readability features passed). Dashed vertical line: ¬TAC+ff+time performance.

(b) Cross-validation accuracy vs data size. Human performance was estimated from a disjoint set of 100 pairs (see §4).

Figure 2: Accuracy results. Pertinent significance results are as follows. In cross-validation, custom+1,2-gram is significantly better than ¬TAC+ff+time (p=0) and 1,2-gram (p=3.8e-7). In heldout validation, custom+1,2-gram is significantly better than ¬TAC+ff+time (p=3.4e-12) and 1,2-gram (p=0.01) but not unigram (p=0.08), perhaps due to the small size of the heldout set.

for "and the following".) We apply it to a tweet pair by computing whether it gives a higher score to t_2 or not.

Baselines. To sanity-check whether our classifier provides any improvement over the simplest methods one could try, we also report the performance of the majority baseline, our request-for-sharing features, and our character-length feature.

Performance comparison. We compare the accuracy (percentage of pairs whose labels were correctly predicted) of our approach against the competing methods. We report 5-fold cross validation results on our balanced set of 11,404 TAC pairs and on our completely disjoint heldout data[19] of 1,770 TAC pairs; this set was never examined during development, and there are no authors in common between the two testing sets.

Figure 2(a) summarizes the main results. While ¬TAC+ff+time outperforms the majority baseline, using all the features we proposed beats ¬TAC+ff+time by more than 10% in both cross-validation (66.5% vs 55.9%) and heldout validation (65.6% vs 55.3%). We outperform the average human accuracy of 61% reported in our Amazon Mechanical Turk experiments (for a different data sample); ¬TAC+ff+time fails to do so.

The importance of topic and author control can be seen by further investigation of ¬TAC+ff+time's performance. First, note that it yields an accuracy of around 55% on our alternate-version-selection task,[20] even though its cross-validation accuracy on the larger most- and least-retweeted unpaired tweets averages out to a high 98.8%. Furthermore, note the superior performance of unigrams trained on TAC data vs ¬TAC+ff+time — which is similar to our unigrams but trained on a larger but non-TAC dataset that included metadata. Thus, TAC pairs are a useful data source even for non-custom features. (We also include individual feature comparisons later.)

Informativeness is the best-performing custom feature group when run in isolation, and outperforms all baselines, as well as ¬TAC+ff+time; and we can see from Figure 2(a) that this is not due just to length. The combination of all our 39 custom features yields approximately 63% accuracy in both testing settings, significantly outperforming informativeness alone ($p<0.001$ in both cases). Again, this is higher than our estimate of average human performance.

Not surprisingly, the TAC-trained BOW features (unigram and 1,2-gram) show impressive predictive power in this task: many of our custom features can be captured by bag-of-word features, in a way. Still, the best performance is achieved

[19] To construct this data, we used the same criteria as in §3: written by authors with more than 5000 followers, posted within 12 hours, $n_2 - n_1 \geqslant 10$ or $\leqslant -15$, and cosine similarity threshold value the same as in §3, cap of 50 on number of pairs from any individual author.

[20] One might suspect that the problem is that ¬TAC+ff+time learns from its training data to overrely on follower-count, since that is presumably a good feature for non-TAC tweets, and for this reason suffers when run on TAC data where follower-counts are by construction non-informative. But in fact, we found that removing the follower-count feature from ¬TAC+ff+time and re-training did not lead to improved performance. Hence, it seems that it is the non-controlled nature of the alternate training data that explains the drop in performance.

by combining our custom and 1,2-gram features together, to a degree statistically significantly better than using 1,2-gram features alone.

Finally, we remark on our Bonferroni correction. Recall that the intent of applying it is to avoid false positives. However, in our case, Figure 2(a) shows that our potentially "false" positives — features whose effectiveness did not pass the Bonferroni correction test — actually do raise performance in our prediction tests.

Size of training data. Another interesting observation is how performance varies with data size. For $n = 1000, 2000, \ldots, 10000$, we randomly sampled n pairs from our 11,404 pairs, and computed the average cross-validation accuracy on the sampled data. Figure 2(b) shows the averages over 50 runs of the aforementioned procedure. Our custom features can achieve good performance with little data, in the sense that for sample size 1000, they outperform BOW features; on the other hand, BOW features quickly surpass them. Across the board, the custom+1,2-gram features are consistently better than the 1,2-gram features alone.

Top features. Finally, we examine some of the top-weighted individual features from our approach and from the competing ¬TAC+ff+time classifier. The top three rows of Table 12 show the best custom and best and worst unigram features for our method; the bottom two rows show the best and worst unigrams for ¬TAC+ff+time. Among custom features, we see that community and personal language models, informativeness, retweet scores, sentiment, and generality are represented. As for unigram features, not surprisingly, "rt" and "retweet" are top features for both our approach and ¬TAC+ff+time. However, the other unigrams for the two methods seem to be a bit different in spirit. Some of the unigrams determined to be most poor only by our method appear to be both surprising and yet plausible in retrospect: "icymi" (abbreviation for "in case you missed it") tends to indicate a direct repetition of older information, so people might prefer to retweet the earlier version; "thanks" and "sorry" could correspond to personal thank-yous and apologies not meant to be shared with a broader audience, and similarly @-mentioning another user may indicate a tweet intended only for that person. The appearance of [hashtag] in the best ¬TAC+ff+time unigrams is consistent with prior research in non-TAC settings (Suh et al., 2010; Petrović et al., 2011).

Table 12: Features with largest coefficients, delimited by commas. POS tags omitted for clarity.

Our approach	
best 15 custom	twitter bigram, length (chars), rt (the word), retweet (the word), verb, verb retweet score, personal unigram, proper noun, number, noun, positive words, please (the word), proper noun retweet score, indefinite articles (a,an), adjective
best 20 unigrams	rt, retweet, [num], breaking, is, win, never, ., people, need, official, officially, are, please, november, world, girl, !!!, god, new
worst 20 unigrams	:, [at], icymi, also, comments, half, ?, earlier, thanks, sorry, highlights, bit, point, update, last, helping, peek, what, haven't, debate

worst 20 unigrams	:, ..., boss, foundation, ?, ∼, others, john, roll, ride, appreciate, page, drive, correct, full, ', looks, @ (not as [at]), sales, hurts

6 Conclusion

In this work, we conducted the first large-scale topic- and author-controlled experiment to study the effects of wording on information propagation.

The features we developed to choose the better of two alternative wordings posted better performance than that of all our comparison algorithms, including one given access to author and timing features but trained on non-TAC data, and also bested our estimate of average human performance. According to our hypothesis tests, helpful wording heuristics include adding more information, making one's language align with both community norms and with one's prior messages, and mimicking news headlines. Readers may try out their own alternate phrasings at `http://chenhaot.com/retweetedmore/` to see what a simplified version of our classifier predicts.

In future work, it will be interesting to examine how these features generalize to longer and more extensive arguments. Moreover, understanding the underlying psychological and cultural mechanisms that establish the effectiveness of these features is a fundamental problem of interest.

Inferring User Political Preferences from Streaming Communications

Abstract

Existing models for social media personal analytics assume access to thousands of messages per user, even though most users author content only sporadically over time. Given this sparsity, we: (i) leverage content from the local neighborhood of a user; (ii) evaluate batch models as a function of size and the amount of messages in various types of neighborhoods; and (iii) estimate the amount of time and tweets required for a dynamic model to predict user preferences. We show that even when limited or no self-authored data is available, language from friend, retweet and user mention communications provide sufficient evidence for prediction. When updating models over time based on Twitter, we find that political preference can be often be predicted using roughly 100 tweets, depending on the context of user selection, where this could mean hours, or weeks, based on the author's tweeting frequency.

1 Introduction

Inferring latent user attributes such as gender, age, and political preferences (Rao et al., 2011; Zamal et al., 2012; Cohen and Ruths, 2013) automatically from personal communications and social media including emails, blog posts or public discussions has become increasingly popular with the web getting more social and volume of data available. Resources like Twitter[1] or Facebook[2] become extremely valuable for studying the underlying properties of such informal communications because of its volume, dynamic nature, and diverse population (Lunden, 2012; Smith, 2013).

[1]http://www.demographicspro.com/
[2]http://www.wolframalpha.com/facebook/

The existing batch models for predicting latent user attributes rely on thousands of tweets per author (Rao et al., 2010; Conover et al., 2011; Pennacchiotti and Popescu, 2011a; Burger et al., 2011; Zamal et al., 2012; Nguyen et al., 2013). However, most Twitter users are less prolific than those examined in these works, and thus do not produce the thousands of tweets required to obtain their levels of accuracy e.g., the median number of tweets produced by a random Twitter user per day is 10. Moreover, recent changes to Twitter API querying rates further restrict the speed of access to this resource, effectively reducing the amount of data that can be collected in a given time period.

In this paper we analyze and go beyond static models formulating personal analytics in social media as a streaming task. We first evaluate batch models that are cognizant of low-resource prediction setting described above, maximizing the efficiency of content in calculating personal analytics. To the best of our knowledge, this is the first work that makes explicit the tradeoff between accuracy and cost (manifest as calls to the Twitter API), and optimizes to a different tradeoff than state-of-the-art approaches, seeking maximal performance when limited data is available. In addition, we propose streaming models for personal analytics that dynamically update user labels based on their stream of communications which has been addressed previously by Van Durme (2012b). Such models better capture the real-time nature of evidence being used in latent author attribute predictions tasks. Our main contributions include:

- develop low-resource and real-time dynamic approaches for personal analytics using as an example the prediction of political preference of Twitter users;
- examine the relative utility of six different notions of "similarity" between users in an implicit Twitter social network for personal analytics;

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 186–196,
Baltimore, Maryland, USA, June 23-25 2014.

- experiments are performed across multiple datasets supporting the prediction of political preference in Twitter, to highlight the significant differences in performance that arise from the underlying collection and annotation strategies.

2 Identifying Twitter Social Graph

Twitter users interact with one another and engage in direct communication in different ways e.g., using retweets, user mentions e.g., *@youtube* or hashtags e.g., *#tcot*, in addition to having explicit connections among themselves such as following, friending. To investigate all types of social relationships between Twitter users and construct Twitter social graphs we collect lists of followers and friends, and extract user mentions, hashtags, replies and retweets from communications.[3]

2.1 Social Graph Definition

Lets define an attributed, undirected graph $G = (V, E)$, where V is a set of vertices and E is a set of edges. Each vertex v_i represents someone in a communication graph i.e., *communicant*: here a Twitter user. Each vertex is attributed with a feature vector $\vec{f}(v_i)$ which encodes communications e.g., tweets available for a given user. Each vertex is associated with a latent attribute $a(v_i)$, in our case it is binary $a(v_i) \in \{D, R\}$, where D stands for Democratic and R for Republican users. Each edge $e_{ij} \in E$ represents a connection between v_i and v_j, $e_{ij} = (v_i, v_j)$ and defines different social circles between Twitter users e.g., follower (f), friend (b), user mention (m), hashtag (h), reply (y) and retweet (w). Thus, $E \in V^{(2)} \times \{f, b, h, m, w, y\}$. We denote a set of edges of a given type as $\phi_r(E)$ for $r \in \{f, b, h, m, w, y\}$. We denote a set of vertices adjacent to v_i by social circle type r as $N_r(v_i)$ which is equivalent to $\{v_j \mid e_{ij} \in \phi_r(E)\}$. Following Filippova (2012) we refer to $N_r(v_i)$ as v_i's social circle, otherwise known as a neighborhood. In most cases, we only work with a sample of a social circle, denoted by $N'_r(v_i)$ where $|N'_r(v_i)| = k$ is its size for v_i.

Figure 1 presents an example of a social graph derived from Twitter. Notably, users from different social circles can be shared across the users of the same or different classes e.g., a user v_j can be

[3]The code and detailed explanation on how we collected all six types of user neighbors and their communications using Twitter API can be found here: http://www.cs.jhu.edu/ svitlana/

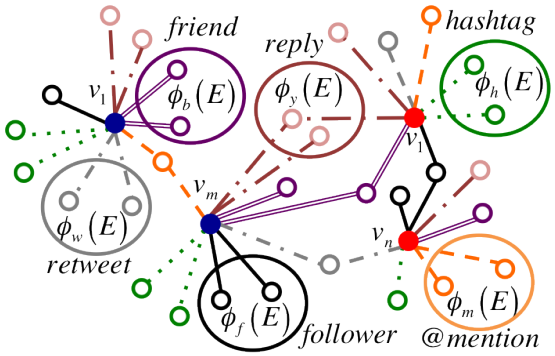

Figure 1: An example of a social graph with follower, friend, @mention, reply, retweet and hashtag social circles for each user of interest e.g., blue: Democratic, red: Republican.

in both follower circle $v_j \in N_f(v_i), v_i \in D$ and retweet circle $v_j \in N_w(v_k), v_k \in R$.

2.2 Candidate-Centric Graph

We construct candidate-centric graph G_{cand} by looking into following relationships between the users and Democratic or Republican candidates during the 2012 US Presidential election. In the Fall of 2012, leading up to the elections, we randomly sampled $n = 516$ Democratic and $m = 515$ Republican users. We labeled users as Democratic if they exclusively follow both Democratic candidates[4] – BarackObama and JoeBiden but do not follow both Republican candidates – MittRomney and RepPaulRyan and vice versa. We collectively refer to D and R as our "users of interest" for which we aim to predict political preference. For each such user we collect recent tweets and randomly sample their immediate $k = 10$ neighbors from follower, friend, user mention, reply, retweet and hashtag social circles.

2.3 Geo-Centric Graph

We construct a geo-centric graph G_{geo} by collecting $n = 135$ Democratic and $m = 135$ Republican users from the Maryland, Virginia and Delaware region of the US with self-reported political preference in their biographies. Similar to the candidate-centric graph, for each user we collect recent tweets and randomly sample user social circles in the Fall of 2012. We collect this data to get a sample of politically less active users compared to the users from candidate-centric graph.

2.4 ZLR Graph

We also consider a G_{ZLR} graph constructed from a dataset previously used for political affiliation

[4]As of Oct 12, 2012, the number of followers for Obama, Biden, Romney and Ryan were 2m, 168k, 1.3m and 267k.

classification (Zamal et al., 2012). This dataset consists of 200 Republican and 200 Democratic users associated with 925 tweets on average per user.[5] Each user has on average 6155 friends with 642 tweets per friend. Sharing restrictions and rate limits on Twitter data collection only allowed us to recreate a semblance of ZLR data[6] – 193 Democratic and 178 Republican users with 1K tweets per user, and 20 neighbors of four types including follower, friends, user mention and retweet with 200 tweets per neighbor for each user of interest.

3 Batch Models

Baseline User Model As input we are given a set of vertices representing users of interest $v_i \in V$ along with feature vectors $\vec{f}(v_i)$ derived from content authored by the user of interest. Each user is associated with a non-zero number of publicly posted tweets. Our goal is assign to a category each user of interest v_i based on $\vec{f}(v_i)$. Here we focus on a binary assignment into the categories Democratic D or Republican R. The log-linear model[7] for such binary classification is:

$$\Phi_{v_i} = \begin{cases} D & (1+\exp[-\vec{\theta}\cdot\vec{f}(v_i)])^{-1} \geq 0.5, \\ R & \text{otherwise.} \end{cases} \tag{1}$$

where features are normalized word ngram counts extracted from v_i's tweets $\vec{f}_t(v_i) : D \times t(v_i) \rightarrow \mathbb{R}$.

The proposed baseline model follows the same trends as the existing state-of-the-art approaches for user attribute classification in social media as described in Section 8. Next we propose to extend the baseline model by taking advantage of language in user social circles as describe below.

Neighbor Model As input we are given user-local neighborhood $N_r(v_i)$, where r is a neighborhood type. Besides the neighborhood's type r, each is characterized by:

- the number of communications per neighbor $\vec{f}_t(N_r)$, $t = \{5, 10, 15, 25, 50, 100, 200\}$;
- the order of the social circle – the number of neighbors per user of interest $|N_r| = deg(v_i)$, $n = \{1, 2, 5, 10\}$.

Our goal is to classify users of interest using evidence (e.g., communications) from their local neighborhood $\sum_n \vec{f}_t[N_r(v_i)] \equiv \vec{f}(N_r)$ as Democratic or Republican. The corresponding log-linear model is defined as:

$$\Phi_{N_r} = \begin{cases} D & (1+\exp[-\vec{\theta}\cdot\vec{f}(N_r)])^{-1} \geq 0.5, \\ R & \text{otherwise.} \end{cases} \tag{2}$$

To check whether our static models are cognizant of low-resource prediction settings we compare the performance of the user model from Eq.1 and the neighborhood model from Eq.2. Following the streaming nature of social media, we see the scarce available resource as the number of requests allowed per day to the Twitter API. Here we abstract this to a model assumption where we receive one tweet t_k at a time and aim to maximize classification performance with as few tweets per user as possible:[8]

- for the baseline user model:

$$\underset{k}{\text{minimize}} \quad \sum_k t_k(v_i), \tag{3}$$

- for the neighborhood model:

$$\underset{k}{\text{minimize}} \quad \sum_n \sum_k t_k[N_r(v_i)]. \tag{4}$$

4 Streaming Models

We rely on straightforward Bayesian rule update to our batch models in order to simulate a real-time streaming prediction scenario as a first step beyond the existing models as shown in Figure 2.

The model makes predictions of a latent user attribute e.g., Republican under a model assumption of sequentially arriving, independent and identically distributed observations $T = (t_1, \ldots, t_k)$[9]. The model dynamically updates posterior probability estimates $p(a(v_i) = R|t_k)$ for a given user

[5]The original dataset was collected in 2012 and has been recently released at http://icwsm.cs.mcgill.ca/. Political labels are extracted from http://www.wefollow.com as described by Pennacchiotti and Popescu (2011b).

[6]This inability to perfectly replicate prior work based on Twitter is a recognized problem throughout the community of computational social science, arising from the data policies of Twitter itself, it is not specific to this work.

[7]We use log-linear models over reasonable alternatives such as perceptron or SVM, following the practice of a wide range of previous work in related areas (Smith, 2004; Liu et al., 2005; Poon et al., 2009) including text classification in social media (Van Durme, 2012b; Yang and Eisenstein, 2013).

[8]The separate issue is that many authors simply don't tweet very often. For instance, 85.3% of all Twitter users post less than one update per day as reported at http://www.sysomos.com/insidetwitter/. Thus, their communications are scare even if we could get all of them without rate limiting from Twitter API.

[9]Given the dynamic character of online discourse it will clearly be of interest in the future to consider models that go beyond the iid assumption.

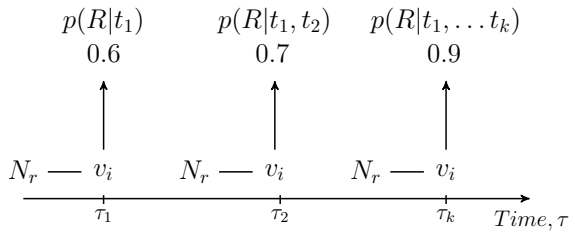

Figure 2: Stream-based classification of an attribute $a(v_i) \in \{R, D\}$ given a stream of communications $t_1, t_2, \ldots, t_k$ authored by a user v_i or user immediate neighbors from N_r social circles at time $\tau_1, \tau_2, \ldots, \tau_k$.

v_i as an additional evidence t_k is acquired, as defined in a general form below for any latent attribute $a(v_i) \in A$ given the tweets T of user v_i:

$$p(a(v_i) = x \in A \mid T) = \frac{p(T \mid a(v_i) = x) \cdot p(a(v_i) = x)}{\sum_{y \in A} p(T \mid a(v_i) = y) \cdot p(a(v_i) = y)} = \frac{\prod_k p(t_k \mid a(v_i) = x) \cdot p(a(v_i) = x)}{\sum_{y \in A} \prod_k p(t_k \mid a(v_i) = y) \cdot p(a(v_i) = y),} \quad (5)$$

where y is the number of all possible attribute values, and k is the number of tweets per user.

For example, to predict user political preference, we start with a prior $P(R) = 0.5$, and sequentially update the posterior $p(R \mid T)$ by accumulating evidence from the likelihood $p(t_k|R)$:

$$p(R \mid T) = \frac{\prod_k p(t_k|R) \cdot p(R)}{\prod_k P(t_k|R) \cdot p(R) + \prod_k P(t_k|D) \cdot p(D).} \quad (6)$$

Our goal is to maximize posterior probability estimates given a stream of communications for each user in the data over (a) time τ and (b) the number of tweets T. For that, for each user we take tweets that arrive continuously over time and apply two different streaming models:

- **User Model with Dynamic Updates:** relies exclusively on user tweets $t_1^{(v_i)}, \ldots, t_k^{(v_i)}$ following the order they arrive over time τ, where for each user v_i we dynamically update the posterior $p(R \mid t_1^{(v_i)}, \ldots, t_k^{(v_i)})$.
- **User-Neighbor Model with Dynamic Updates:** relies on both neighbor N_r communications including friend, follower, retweet, user mention and user tweets $t_1^{(v_i)}, \ldots, t_k^{(N_r)}$ following the order they arrive over time τ; here we dynamically update the posterior probability $p(R \mid t_1^{(v_i)}, \ldots, t_k^{(N_r)})$.

5 Experimental Setup

We design a set of experiments to analyze static and dynamic models for political affiliation classification defined in Sections 3 and 4.

5.1 Batch Classification Experiments

We first answer whether communications from user-local neighborhoods can help predict political preference for the user. To explore the contribution of different neighborhood types we learn static user and neighbor models on G_{cand}, G_{geo} and G_{ZLR} graphs. We also examine the ability of our static models to predict user political preferences in low-resource setting e.g., 5 tweets.

The existing models follow a standard setup when either user or neighbor tweets are available during train and test. For a static neighbor model we go beyond that, and train our the model on all data available per user, but only apply part of the data at the test time, pushing the boundaries of how little is truly required for classification. For example, we only use follower tweets for G^{test}, but we use tweets from all types of neighbors for G^{train}. Such setup will simulate different real-world prediction scenarios which have not been previously explored, to our knowledge e.g., when a user has a private profile or has not tweeted yet, and only user neighbor tweets are available.

We experiment with our static neighbor model defined in Eq.2 with the aim to:

1. evaluate neighborhood size influence, we change the number of neighbors and try $n = [1, 2, 5, 10]$ neighbor(s) per user;
2. estimate neighbor content influence, we alternate the amount of content per neighbor and try $t = [5, 10, 15, 25, 50, 100, 200]$ tweets.

We perform 10-fold cross validation[10] and run 100 random restarts for every n and t parameter combination. We compare our static neighbor and user models using the cost functions from Eq.3 and Eq.4. For all experiments we use `LibLinear` (Fan et al., 2008), integrated in the `Jerboa` toolkit (Van Durme, 2012a). Both models defined in Eq.1 and Eq.2 are learned using normalized count-based word ngram features extracted from either user or neighbor tweets.[11]

[10] For each fold we split the data into 3 parts: 70% train, 10% development and 20% test.

[11] For brevity we omit reporting results for bigram and trigram features, since unigrams showed superior performance.

5.2 Streaming Classification Experiments

We evaluate our models with dynamic Bayesian updates on a continuous stream of communications over time as shown in Figure 2. Unlike static model experiments, we are not modeling the influence of the number of neighbors or the amount of content per neighbor. Here, we order user and neighbor communication streams by real world time of posting and measure changes in posterior probabilities over time. The main purpose of these experiments is to quantitatively evaluate (1) the number of tweets and (2) the amount of real world time it takes to observe enough evidence on Twitter to make reliable predictions.

We experiment with log-linear models defined in Eq. 1 and 2 and continuously estimate the posterior probabilities $P(R \mid T)$ as defined in Eq.6. We average the posterior probability results over the users in G_{cand}, G_{geo} and G_{ZLR} graphs. We train streaming models on an attribute balanced subset of tweets for each user v_i excluding v_i's tweets (or v_i's neighbor tweets for a joint model). This setup is similar to leave-one-out classification. The classifier is learned using binary word ngram features extracted from user or user-neighbor communications. We prefer binary to normalized count-based features to overcome sparsity issues caused by making predictions on each tweet individually.

6 Static Classification Results

6.1 Modeling User Content Influence

We investigate classification decision probabilities for our static user model Φ_{v_i} by making predictions on a random set of 5 vs. 100 tweets per user. To our knowledge only limited work on personal analytics (Burger et al., 2011; Van Durme, 2012b) have performed this straight-forward comparison. For that purpose, we take a random partition containing 100 users of G_{cand} graph and perform four independent classification experiments – two runs using 5 and two runs using 100 tweets per user.

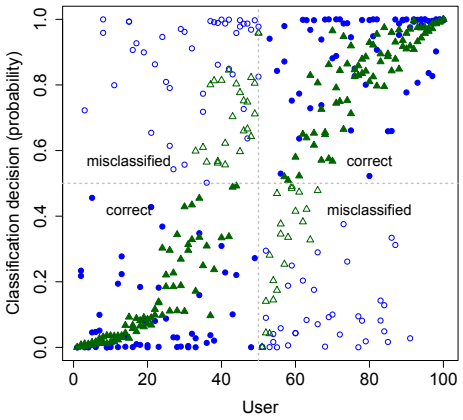

Figure 3: Classification probabilities for Φ_{v_i} estimated over 100 users in G_{cand} tested on 5 (blue) vs. 100 (green) tweets per user where Republican = 1, Democratic = 0, filled markers = correctly classified, not filled = misclassified users.

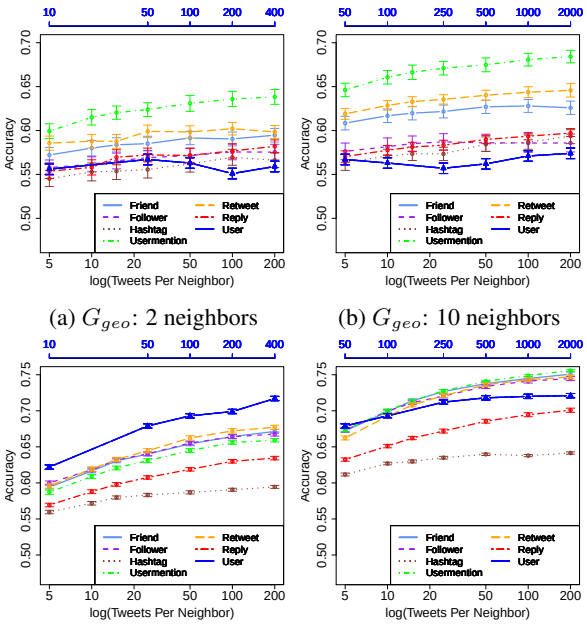


(a) G_{geo}: 2 neighbors (b) G_{geo}: 10 neighbors

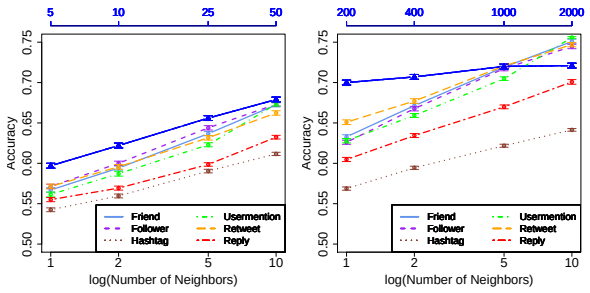
(c) G_{cand}: 2 neighbors (d) G_{cand}: 10 neighbors

Figure 4: Modeling the influence of the number of tweets per neighbor t=[5, .., 200] for G_{cand} and G_{geo} graphs.

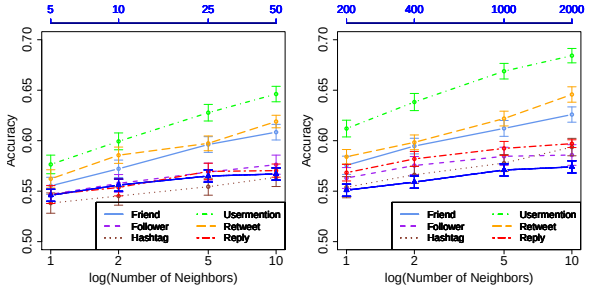
Figure 3 demonstrates that more tweets during prediction time lead to higher accuracy by showing that more users with 100 tweets are correctly classified e.g., filled green markers in the right upper quadrant are true Republicans and in the left lower quadrant are true Democrats. Moreover, a lot of users with 100 tweets are close to 0.5 decision probability which suggests that the classifier is just uncertain rather then being completely off, e.g., misclassified Republican users with 5 tweets (not filled blue markers in the right lower quadrant) are close to 0. These results follow naturally from the underlying feature representation: having more tweets per user leads to a lower variance estimate of a target multinomial distribution. The more robustly this distribution is estimated (based on having more tweets) the more confident we should be in the classifier output.

6.2 Modeling Neighbor Content Influence

Here we discuss the results for our static neighborhood model. We study the influence of the neighborhood type r and size in terms of the number of neighbors n and tweets t per neighbor.



(a) G_{cand}: 5 tweets (b) G_{cand}: 200 tweets



(c) G_{geo}: 5 tweets (d) G_{geo}: 200 tweets

Figure 5: Modeling the influence of the number of neighbors per user n=[1, .., 10] for G_{cand} and G_{geo} graphs.

In Figure 4 we present accuracy results for G_{cand} and G_{geo} graphs. Following Eq.3 and 4, we spent an equal amount of resources to obtain 100 user tweets and 10 tweets from 10 neighbors. We annotate these 'points of equal number of communications' with a line on top marked with a corresponding number of user tweets.

We show that three of six social circles – friend, retweet and user-mention yield better accuracy compared to the user model for all graphs when $t \geq 250$. Thus, for effectively classifying a given user v_i it is better to take 200 tweets each from 10 neighbors rather than 2,000 tweets from the user.

The best accuracy for G_{cand} is 0.75 for friend, follower, retweet and user-mention neighborhoods which is 0.03 higher than the user baseline; for G_{geo} is 0.67 for user-mention and 0.64 for retweet circles compared to 0.57 for the user model; for G_{ZLR} is 0.863 for retweet and 0.849 for friend circles which is 0.11 higher that the user baseline. Finally, similarly to the results for the user model given in Figure 3, increasing the number of tweets per neighbor from 5 to 200 leads to a significant gain in performance for all neighborhood types.

6.3 Modeling Neighborhood Size

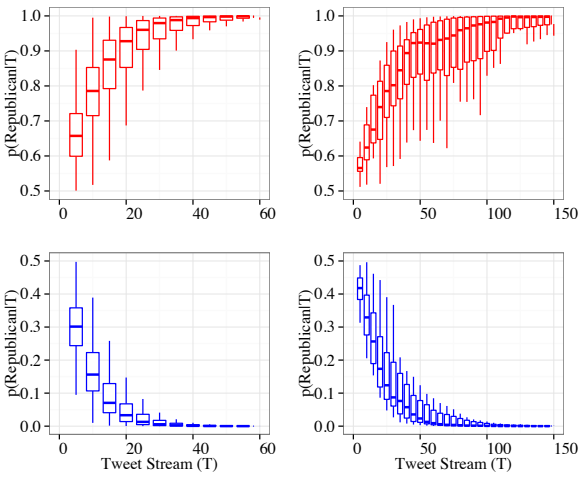
In Figure 5 we present accuracy results to show neighborhood size influence on classification performance for G_{geo} and G_{cand} graphs. Our results demonstrate that even small changes to the neighborhood size n lead to better performance which does not support the claims by Zamal et al. (2012). We demonstrate that increasing the size of the neighborhood leads to better performance across six neighborhood types. Friend, user mention and retweet neighborhoods yield the highest accuracy for all graphs. We observe that when the number of neighbors is $n = 1$, the difference in accuracy across all neighborhood types is less significant but for $n \geq 2$ it becomes more significant.

7 Streaming Classification Results

7.1 Modeling Dynamic Posterior Updates from a User Stream

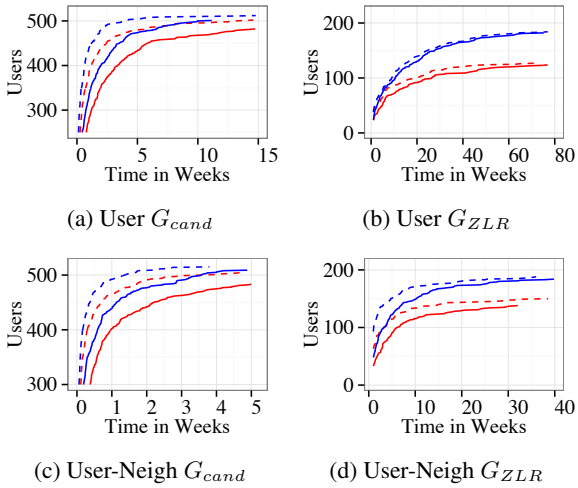
Figures 6a and 6b demonstrate dynamic user model prediction results averaged over users from G_{cand} and G_{ZLR} graphs. Each figure outlines changes in sequential average probability estimates $p_\mu(R \mid T)$ for each individual self-authored tweet t_k as defined in Eq. 6. The average probability estimates $p_\mu(R \mid T)$ are reported for every 5 tweets in a stream $T = (t_1, \ldots t_k)$ as $\frac{\sum_n P(R|t_k)}{n}$, where n is the total number of users with the same attribute R or D. We represent $p_\mu(R \mid T)$ as a box and whisker plot with the median, lower and upper quantiles to show the variance; the length of whiskers indicate lower and upper extreme values.

We find similar behavior across all three graphs. In particular, the posterior estimates converge faster when predicting Democratic than Republican users but it has been trained on an equal number of tweets per class. We observe that average posterior estimates $P_\mu(R \mid T)$ converge faster to 0



(a) User G_{cand} (b) User G_{ZLR}

Figure 6: Streaming classification results from user communications for G_{cand} and G_{ZLR} graphs averaged over every 5 tweets (red - Republican, blue - Democratic).



(a) User G_{cand} (b) User G_{ZLR}

(c) User-Neigh G_{cand} (d) User-Neigh G_{ZLR}

Figure 7: Time needed for (a) - (b) dynamic user model and (c) - (d) joint user-neighbor model to infer political preferences of Democratic (blue) and Republican (red) users at 75% (dotted line) and 95% (solid line) accuracy levels.

(Democratic) than to 1 (Republican) in Figures 6a and 6b. It suggests that language of Democrats is more expressive of their political preference than language of Republicans. For example, frequent politically influenced terms used widely by Democratic users include *faith4liberty, constitutionally, pass, vote2012, terroristic.*

The variance for average posterior estimates decreases when the number of tweets increases for all three datasets. Moreover, we detect that $P_\mu(R|T)$ estimates for users in G_{cand} converge 2-3 times faster in terms of number of tweets than for users in G_{ZLR}. The lowest convergence is detected for G_{geo} where after $t_k = 250$ tweets the average posterior estimate $P_\mu(R \mid t_k) = 0.904 \pm 0.044$ and $P_\mu(D \mid t_k) = 0.861 \pm 0.008$. It means that users in G_{cand} are more politically vocal compared to users in G_{ZLR} and G_{geo}. As a result, less active users in G_{geo} just need more than 250 tweets to converge to a true 0 or 1 class. These results are coherent with the outcomes for our static models shown in Figures 4 and 5. These findings further confirm that differences in performance are caused by various biases present in the data due to distinct sampling and annotation approaches.

Figure 7a and 7b illustrate the amount of time required for the user model to infer political preferences estimated for 1,031 users in G_{cand} and 371 users in G_{ZLR}. The amount of time needed can be evaluated for different accuracy levels e.g., 0.75 and 0.95. Thus, with 75% accuracy we classify:

- 100 ($\sim$20%) Republican users in 3.6 hours and Democratic users in 2.2 hours for G_{cand};
- 100 ($\sim$56%) R users in 20 weeks and 100 ($\sim$52%) D users in 8.9 weeks for G_{ZLR} which is 800 times longer that for G_{cand};
- 100 ($\sim$75%) R users in 12 weeks and 80 ($\sim$60%) D users in 19 weeks for G_{geo}.

Such extreme divergences in the amount of time required for classification across all graphs should be of strong interest to researchers concerned with latent attribute prediction tasks because Twitter users produce messages with extremely different frequencies. In our case, users in G_{ZLR} tweet approximately 800 times less frequently than users in G_{cand}.

7.2 Modeling Dynamic Posterior Updates from a Joint User-Neighbor Stream

We estimate dynamic posterior updates from a joint stream of user and neighbor communications in G_{geo}, G_{cand} and G_{ZLR} graphs. To make a fair comparison with a streaming user model, we start with the same user tweet $t_0(v_i)$. Then instead of waiting for the next user tweet we rely on any neighbor tweets that appear until the user produces the next tweet $t_1(v_i)$. We rely on communications from four types of neighbors such as friends, followers, retweets and user mentions.

The convergence rate for the average posterior probability estimates $P_\mu(R|T)$ depending on the number of tweets is similar to the user model results presented in Figure 6. However, for G_{geo} the variance for $P_\mu(R|T)$ is higher for Democratic users; for G_{ZLR} $P_\mu(R|T) \rightarrow 1$ for Republicans in less than 110 tweets which is $\Delta t = 40$ tweets faster than the user model; for G_{cand} the convergence for both $P_\mu(R|T) \rightarrow 1$ and $P_\mu(D|T) \rightarrow 0$ is not significantly different than the user model.

Figures 7c and 7d show the amount of time required for a joint user-neighbor model to infer political preferences estimated for users in G_{cand} and G_{ZLR}. We find that with 75% accuracy we can classify 100 users for:

- G_{cand}: Republican users in 23 minutes and Democratic users in 10 minutes;
- G_{ZLR}: R users in 3.2 weeks and D users in 1.1 weeks which is 7 times faster on average across attributes than for the user model;
- G_{geo}: R users in 1.2 weeks and D users in 3.5 weeks which is on average 6 times faster across attributes than for the user model.

Similar or better $P_\mu(R|T)$ convergence in terms of the number of tweets and, especially, in the amount of time needed for user and user-neighbor

models further confirms that neighborhood content is useful for political preference prediction. Moreover, communications from a joint stream allow to make an inference up to 7 times faster.

8 Related Work

Supervised Batch Approaches The vast majority of work on predicting latent user attributes in social media apply supervised static SVM models for discrete categorical e.g., gender and regression models for continuous attributes e.g., age with lexical bag-of-word features for classifying user gender (Garera and Yarowsky, 2009; Rao et al., 2010; Burger et al., 2011; Van Durme, 2012b), age (Rao et al., 2010; Nguyen et al., 2011; Nguyen et al., 2013) or political orientation. We present an overview of the existing models for political preference prediction in Table 1.

Bergsma et al. (2012) following up on Rao's work (2010) on adding socio-linguistic features to improve gender, ethnicity and political preference prediction show that incorporating stylistic and syntactic information to the bag-of-word features improves gender classification.

Other methods characterize Twitter users by applying limited amounts of network structure information in addition to lexical features. Conover et al. (2011) rely on identifying strong partisan clusters of Democratic and Republican users in a Twitter network based on retweet and user mention degree of connectivity, and then combine this clustering information with the follower and friend neighborhood size features. Pennacchiotti et al. (2011a; 2011b) focus on user behavior, network structure and linguistic features. Similar to our work, they assume that users from a particular class tend to reply and retweet messages of the users from the same class. We extend this assumption and study other relationship types e.g., friends, user mentions etc. Recent work by Wong et al. (2013) investigates tweeting and retweeting behavior for political learning during 2012 US Presidential election. The most similar work to ours is by Zamal et al. (2012), where the authors apply features from the tweets authored by a user's friend to infer attributes of that user. In this paper, we study different types of user social circles in addition to a friend network.

Table 1: Overview of the existing approaches for political preference classification in Twitter.

Additionally, using social media for mining political opinions (O'Connor et al., 2010a; Maynard and Funk, 2012) or understanding sociopolitical trends and voting outcomes (Tumasjan et al., 2010; Gayo-Avello, 2012; Lampos et al., 2013) is becoming a common practice. For instance, Lampos et al. (2013) propose a bilinear user-centric model for predicting voting intentions in the UK and Australia from social media data. Other works explore political blogs to predict what content will get the most comments (Yano et al., 2013) or analyze communications from Capitol Hill[12] to predict campaign contributors based on this content (Yano and Smith, 2013).

Unsupervised Batch Approaches Bergsma et al. (2013) show that large-scale clustering of user names improves gender, ethnicity and location classification on Twitter. O'Connor et al. (2010b) following the work by Eisenstein (2010) propose a Bayesian generative model to discover demographic language variations in Twitter. Rao et al. (2011) suggest a hierarchical Bayesian model which takes advantage of user name morphology for predicting user gender and ethnicity. Golbeck et al. (2010) incorporate Twitter data in a spatial model of political ideology.

Streaming Approaches Van Durme (2012b) proposed streaming models to predict user gender in Twitter. Other works suggested to process

[12]http://www.tweetcongress.org

text streams for a variety of NLP tasks e.g., real-time opinion mining and sentiment analysis in social media (Pang and Lee, 2008), named entity disambiguation (Sarmento et al., 2009), statistical machine translation (Levenberg et al., 2011), first story detection (Petrović et al., 2010), and unsupervised dependency parsing (Goyal and Daumé, 2011). Massive Online Analysis (MOA) toolkit developed by Bifet et al. (2010) is an alternative to the Jerboa package used in this work developed by Van Durme (2012a). MOA has been effectively used to detect sentiment changes in Twitter streams (Bifet et al., 2011).

9 Conclusions and Future Work

In this paper, we extensively examined state-of-the-art static approaches and proposed novel models with dynamic Bayesian updates for streaming personal analytics on Twitter. Because our streaming models rely on communications from Twitter users and content from various notions of user-local neighborhood they can be effectively applied to real-time dynamic data streams. Our results support several key findings listed below.

Neighborhood content is useful for personal analytics. Content extracted from various notions of a user-local neighborhood can be as effective or more effective for political preference classification than user self-authored content. This may be an effect of 'sparseness' of relevant user data, in that users talk about politics very sporadically compared to a random sample of their neighbors.

Substantial signal for political preference prediction is distributed in the neighborhood. Querying for more neighbors per user is more beneficial than querying for extra content from the existing neighbors e.g., 5 tweets from 10 neighbors leads to higher accuracy than 25 tweets from 2 neighbors or 50 tweets from 1 neighbor. This may be also the effect of data heterogeneity in social media compared to e.g., political debate text (Thomas et al., 2006). These findings demonstrate that a substantial signal is distributed over the neighborhood content.

Neighborhoods constructed from friend, user mention and retweet relationships are most effective. Friend, user mention and retweet neighborhoods show the best accuracy for predicting political preferences of Twitter users. We think that friend relationships are more effective than e.g., follower relationships because it is very likely that users share common interests and preferences with their friends, e.g. Facebook friends can even be used to predict a user's credit score.[13] User mentions and retweets are two primary ways of interaction on Twitter. They both allow to share information e.g., political news, events with others and to be involved in direct communication e.g., live political discussions, political groups.

Streaming models are more effective than batch models for personal analytics. The predictions made using dynamic models with Bayesian updates over user and joint user-neighbor communication streams demonstrate higher performance with lower resources spent compared to the batch models. Depending on user political involvement, expressiveness and activeness, the perfect prediction (approaching 100% accuracy) can be made using only 100 - 500 tweets per user.

Generalization of the classifiers for political preference prediction. This work raises a very important but under-explored problem of the generalization of classifiers for personal analytics in social media, also recently discussed by Cohen and Ruth (2013). For instance, the existing models developed for political preference prediction are all trained on Twitter data but report significantly different results even for the same baseline models trained using bag-of-word lexical features as shown in Table 1. In this work we experiment with three different datasets. Our results for both static and dynamic models show that the accuracy indeed depends on the way the data was constructed. Therefore, publicly available datasets need to be released for a meaningful comparison of the approaches for personal analytics in social media.

In future work, we plan to incorporate iterative model updates from newly classified communications similar to online perceptron-style updates. In addition, we aim to experiment with neighborhood-specific classifiers applied towards the tweets from neighborhood-specific streams e.g., friend classifier used for friend tweets, retweet classifier applied to retweet tweets etc.

Abstract

Much of the recent work on dependency parsing has been focused on solving inherent combinatorial problems associated with rich scoring functions. In contrast, we demonstrate that highly expressive scoring functions can be used with substantially simpler inference procedures. Specifically, we introduce a sampling-based parser that can easily handle arbitrary global features. Inspired by SampleRank, we learn to take guided stochastic steps towards a high scoring parse. We introduce two samplers for traversing the space of trees, Gibbs and Metropolis-Hastings with Random Walk. The model outperforms state-of-the-art results when evaluated on 14 languages of non-projective CoNLL datasets. Our sampling-based approach naturally extends to joint prediction scenarios, such as joint parsing and POS correction. The resulting method outperforms the best reported results on the CATiB dataset, approaching performance of parsing with gold tags.[1]

1 Introduction

Dependency parsing is commonly cast as a maximization problem over a parameterized scoring function. In this view, the use of more expressive scoring functions leads to more challenging combinatorial problems of finding the maximizing parse. Much of the recent work on parsing has been focused on improving methods for solving the combinatorial maximization inference problems. Indeed, state-of-the-art results have been obtained by adapting powerful tools from optimization (Martins et al., 2013; Martins et al., 2011; Rush and Petrov, 2012). We depart from this view and instead focus on using highly expressive scoring functions with substantially simpler inference procedures. The key ingredient in our approach is how learning is coupled with inference. Our combination outperforms the state-of-the-art parsers and remains comparable even if we adopt their scoring functions.

Rich scoring functions have been used for some time. They first appeared in the context of reranking (Collins, 2000), where a simple parser is used to generate a candidate list which is then reranked according to the scoring function. Because the number of alternatives is small, the scoring function could in principle involve arbitrary (global) features of parse trees. The power of this methodology is nevertheless limited by the initial set of alternatives from the simpler parser. Indeed, the set may already omit the gold parse. We dispense with the notion of a candidate set and seek to exploit the scoring function more directly.

In this paper, we introduce a sampling-based parser that places few or no constraints on the scoring function. Starting with an initial candidate tree, our inference procedure climbs the scoring function in small (cheap) stochastic steps towards a high scoring parse. The proposal distribution over the moves is derived from the scoring function itself. Because the steps are small, the complexity of the scoring function has limited impact on the computational cost of the procedure. We explore two alternative proposal distributions. Our first strategy is akin to Gibbs sampling and samples a new head for each word in the sentence, modifying one arc at a time. The second strategy relies on a provably correct sampler for first-order scores (Wilson, 1996), and uses it within a Metropolis-Hastings algorithm for general scoring functions. It turns out that the latter optimizes the

score more efficiently than the former.

Because the inference procedure is so simple, it is important that the parameters of the scoring function are chosen in a manner that facilitates how we climb the scoring function in small steps. One way to achieve this is to make sure that improvements in the scoring functions are correlated with improvements in the quality of the parse. This approach was suggested in the SampleRank framework (Wick et al., 2011) for training structured prediction models. This method was originally developed for a sequence labeling task with local features, and was shown to be more effective than state-of-the-art alternatives. Here we apply SampleRank to parsing, applying several modifications such as the proposal distributions mentioned earlier.

The benefits of sampling-based learning go beyond stand-alone parsing. For instance, we can use the framework to correct preprocessing mistakes in features such as part-of-speech (POS) tags. In this case, we combine the scoring function for trees with a stand-alone tagging model. When proposing a small move, i.e., sampling a head of the word, we can also jointly sample its POS tag from a set of alternatives provided by the tagger. As a result, the selected tag is influenced by a broad syntactic context above and beyond the initial tagging model and is directly optimized to improve parsing performance. Our joint parsing-tagging model provides an alternative to the widely-adopted pipeline setup.

We evaluate our method on benchmark multilingual dependency corpora. Our method outperforms the Turbo parser across 14 languages on average by 0.5%. On four languages, we top the best published results. Our method provides a more effective mechanism for handling global features than reranking, outperforming it by 1.3%. In terms of joint parsing and tagging on the CATiB dataset, we nearly bridge (88.38%) the gap between independently predicted (86.95%) and gold tags (88.45%). This is better than the best published results in the 2013 SPMRL shared task (Seddah et al., 2013), including parser ensembles.

2 Related Work

Earlier works on dependency parsing focused on inference with tractable scoring functions. For instance, a scoring function that operates over each single dependency can be optimized using the maximum spanning tree algorithm (McDonald et al., 2005). It was soon realized that using higher order features could be beneficial, even at the cost of using approximate inference and sacrificing optimality. The first successful approach in this arena was reranking (Collins, 2000; Charniak and Johnson, 2005) on constituency parsing. Reranking can be combined with an arbitrary scoring function, and thus can easily incorporate global features over the entire parse tree. Its main disadvantage is that the output parse can only be one of the few parses passed to the reranker.

Recent work has focused on more powerful inference mechanisms that consider the full search space (Zhang and McDonald, 2012; Rush and Petrov, 2012; Koo et al., 2010; Huang, 2008). For instance, Nakagawa (2007) deals with tractability issues by using sampling to approximate marginals. Another example is the dual decomposition (DD) framework (Koo et al., 2010; Martins et al., 2011). The idea in DD is to decompose the hard maximization problem into smaller parts that can be efficiently maximized and enforce agreement among these via Lagrange multipliers. The method is essentially equivalent to linear programming relaxation approaches (Martins et al., 2009; Sontag et al., 2011), and also similar in spirit to ILP approaches (Punyakanok et al., 2004).

A natural approach to approximate global inference is via search. For instance, a transition-based parsing system (Zhang and Nivre, 2011) incrementally constructs a parsing structure using greedy beam-search. Other approaches operate over full trees and generate a sequence of candidates that successively increase the score (Daumé III et al., 2009; Li et al., 2013; Wick et al., 2011). Our work builds on one such approach — SampleRank (Wick et al., 2011), a sampling-based learning algorithm. In SampleRank, the parameters are adjusted so as to guide the sequence of candidates closer to the target structure along the search path. The method has been successfully used in sequence labeling and machine translation (Haddow et al., 2011). In this paper, we demonstrate how to adapt the method for parsing with rich scoring functions.

3 Sampling-Based Dependency Parsing with Global Features

In this section, we introduce our novel sampling-based dependency parser which can incorporate

arbitrary global features. We begin with the notation before addressing the decoding and learning algorithms. Finally, we extend our model to a joint parsing and POS correction task.

3.1 Notations

We denote sentences by x and the corresponding dependency trees by $y \in \mathcal{Y}(x)$. Here $\mathcal{Y}(x)$ is the set of valid (projective or non-projective) dependency trees for sentence x. We use x_j to refer to the jth word of sentence x, and h_j to the head word of x_j. A training set of size N is given as a set of pairs $\mathcal{D} = \{(x^{(i)}, y^{(i)})\}_{i=1}^{N}$ where $y^{(i)}$ is the ground truth parse for sentence $x^{(i)}$.

We parameterize the scoring function $s(x, y)$ as

$$s(x, y) = \theta \cdot f(x, y) \tag{1}$$

where $f(x, y)$ is the feature vector associated with tree y for sentence x. We do not make any assumptions about how the feature function decomposes. In contrast, most state-of-the-art parsers operate under the assumption that the feature function decomposes into a sum of simpler terms. For example, in the second-order MST parser (McDonald and Pereira, 2006), all the feature terms involve arcs or consecutive siblings. Similarly, parsers based on dual decomposition (Martins et al., 2011; Koo et al., 2010) assume that $s(x, y)$ decomposes into a sum of terms where each term can be maximized over y efficiently.

3.2 Decoding

The decoding problem consists of finding a valid dependency tree $y \in \mathcal{Y}(x)$ that maximizes the score $s(x, y) = \theta \cdot f(x, y)$ with parameters θ. For scoring functions that extend beyond first-order arc preferences, finding the maximizing non-projective tree is known to be NP-hard (McDonald and Pereira, 2006). We find a high scoring tree through sampling, and (later) learn the parameters θ so as to further guide this process.

Our sampler generates a sequence of dependency structures so as to approximate independent samples from

$$p(y|x, T, \theta) \propto \exp\left(s(x, y)/T\right) \tag{2}$$

The temperature parameter T controls how concentrated the samples are around the maximum of $s(x, y)$ (e.g., see Geman and Geman (1984)). Sampling from target distribution p is typically as hard as (or harder than) that maximizing $s(x, y)$.

Inputs: θ, x, T_0 (initial temperature), c (temperature update rate), proposal distribution q.
Outputs: y^*
$T \leftarrow T_0$
Set y^0 to some random tree
$y^* \leftarrow y^0$
repeat
  $y' \leftarrow q(\cdot|x, y^t, T, \theta)$
  if $s(x, y') > s(x, y^*)$ **then**
    $y^* \leftarrow y'$
  $\alpha = \min\left[1, \frac{p(y')q(y^t|y')}{p(y^t)q(y'|y^t)}\right]$
  Sample Bernouli variable Z with $P[Z = 1] = \alpha$.
  if $Z = 0$ **then**
    $y^{t+1} \leftarrow y^t$
  else
    $y^{t+1} \leftarrow y'$
  $t \leftarrow t + 1$
  $T \leftarrow c \cdot T$
until convergence
return y^*

Figure 1: Sampling-based algorithm for decoding (i.e., approximately maximizing $s(x, y)$).

We follow here a Metropolis-Hastings sampling algorithm (e.g., see Andrieu et al. (2003)) and explore different alternative proposal distributions $q(y'|x, y, \theta, T)$. The distribution q governs the small steps that are taken in generating a sequence of structures. The target distribution p folds into the procedure by defining the probability that we will accept the proposed move. The general structure of our sampling algorithm is given in Figure 1.

3.2.1 Gibbs Sampling

Perhaps the most natural choice of the proposal distribution q is a conditional distribution from p. This is feasible if we restrict the proposed moves to only small changes in the current tree. In our case, we choose a word j randomly, and then sample its head h_j according to p with the constraint that we obtain a valid tree (when projective trees are sought, this constraint is also incorporated). For this choice of q, the probability of accepting the new tree (α in Figure 1) is identically one. Thus new moves are always accepted.

3.2.2 Exact First-Order Sampling

One shortcoming of the Gibbs sampler is that it only changes one variable (arc) at a time. This usually leads to slow mixing, requiring more samples to get close to the parse with maximum score. Ideally, we would change multiple heads in the parse tree simultaneously, and sample those choices from the corresponding conditional distribution of p. While in general this is increasingly difficult with more heads, it is indeed tractable if

Inputs: x, y^t, θ, K (number of heads to change).
Outputs: y'
for $i = 1$ **to** $|x|$ **do**
  $inTree[i] \leftarrow false$
  $ChangeNode[i] \leftarrow false$
Set $ChangeNode$ to true for K random nodes.
$head[0] \leftarrow -1$
for $i = 1$ **to** $|x|$ **do**
  $u \leftarrow i$
  while not $inTree[u]$ **do**
    if $ChangeNode[u]$ **then**
      $head[u] \leftarrow$ randomHead(u, θ)
    else
      $head[u] \leftarrow y^t(u)$
    $u \leftarrow head[u]$
    if LoopExist$(head)$ **then**
      EraseLoop$(head)$
  $u \leftarrow i$
  while not $inTree[u]$ **do**
    $inTree[u] \leftarrow true$
    $u \leftarrow head[u]$
return Construct tree y' from the head array.

Figure 2: A proposal distribution $q(y'|y^t)$ based on the random walk sampler of Wilson (1996). The function randomHead samples a new head for node u according to the first-order weights given by θ.

the model corresponds to a first-order parser. One such sampling algorithm is the random walk sampler of Wilson (1996). It can be used to obtain i.i.d. samples from distributions of the form:

$$p(y) \propto \prod_{i \to j \in y} w_{ij}, \qquad (3)$$

where y corresponds to a tree with a spcified root and w_{ij} is the exponential of the first-order score. y is always a valid parse tree if we allow multiple children of the root and do not impose projective constraint. The algorithm in Wilson (1996) iterates over all the nodes, and for each node performs a random walk according to the weights w_{ij} until the walk creates a loop or hits a tree. In the first case the algorithm erases the loop and continues the walk. If the walk hits the current tree, the walk path is added to form a new tree with more nodes. This is repeated until all the nodes are included in the tree. It can be shown that this procedure generates i.i.d. trees from $p(y)$.

Since our features do not by design correspond to a first-order parser, we cannot use the Wilson algorithm as it is. Instead we use it as the proposal function and sample a subset of the dependencies from the first-order distribution of our model, while fixing the others. In each step we uniformly sample K nodes to update and sample their new

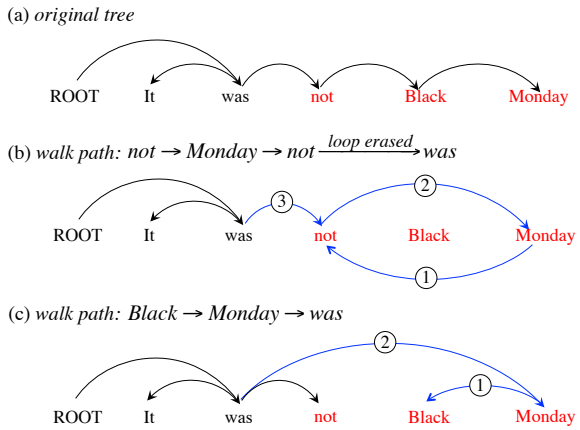

Figure 3: An illustration of random walk sampler. The index on each edge indicates its order on each walk path. The heads of the red words are sampled while others are fixed. The blue edges represent the current walk path and the black ones are already in the tree. Note that the walk direction is opposite to the dependency direction. (a) shows the original tree before sampling; (b) and (c) show the walk path and how the tree is generated in two steps. The loop *not*→ *Monday* → *not* in (b) is erased.

heads using the Wilson algorithm (in the experiments we use $K = 4$). Note that blocked Gibbs sampling would be exponential in K, and is thus very slow already at $K = 4$. The procedure is described in Figure 2 with a graphic illustration in Figure 3.

3.3 Training

In this section, we describe how to learn the adjustable parameters θ in the scoring function. The parameters are learned in an on-line fashion by successively imposing soft constraints between pairs of dependency structures. We introduce both margin constraints and constraints pertaining to successive samples generated along the search path. We demonstrate later that both types of constraints are essential.

We begin with the standard margin constraints. An ideal scoring function would always rank the gold parse higher than any alternative. Moreover, alternatives that are far from the gold parse should score even lower. As a result, we require that

$$s(x^{(i)}, y^{(i)}) - s(x^{(i)}, y) \geq \Delta(y^{(i)}, y) \quad \forall y \qquad (4)$$

where $\Delta(y^{(i)}, y)$ is the number of head mistakes in y relative to the gold parse $y^{(i)}$. We adopt here a shorthand $Err(y) = \Delta(y^{(i)}, y)$, where the de-

pendence on $y^{(i)}$ is implied from context. Note that Equation 4 contains exponentially many constraints and cannot be enforced jointly for general scoring functions. However, our sampling procedure generates a small number of structures along the search path. We enforce only constraints corresponding to those samples.

The second type of constraints are enforced between successive samples along the search path. To illustrate the idea, consider a parse y that differs from $y^{(i)}$ in only one arc, and a parse y' that differs from $y^{(i)}$ in ten arcs. We cannot necessarily assume that $s(x, y)$ is greater than $s(x, y')$ without additional encouragement. Thus, we can complement the constraints in Equation 4 with additional pairwise constraints (Wick et al., 2011):

$$s(x^{(i)}, y) - s(x^{(i)}, y') \geq Err(y') - Err(y) \quad (5)$$

where similarly to Equation 4, the difference in scores scales with the differences in errors with respect to the target $y^{(i)}$. We only enforce the above constraints for y, y' that are consecutive samples in the course of the sampling process. These constraints serve to guide the sampling process derived from the scoring function towards the gold parse.

We learn the parameters θ in an on-line fashion to satisfy the above constraints. This is done via the MIRA algorithm (Crammer and Singer, 2003). Specifically, if the current parameters are θ_t, and we enforce constraint Equation 5 for a particular pair y, y', then we will find θ_{t+1} that minimizes

$$\begin{array}{ll} \min & ||\theta - \theta_t||^2 + C\xi \\ \text{s.t.} & \theta \cdot (f(x, y) - f(x, y')) \geq Err(y') - Err(y) - \xi \end{array} \quad (6)$$

The updates can be calculated in closed form. Figure 4 summarizes the learning algorithm. We repeatedly generate parses based on the current parameters θ_t for each sentence $x^{(i)}$, and use successive samples to enforce constraints in Equation 4 and Equation 5 one at a time.

3.4 Joint Parsing and POS Correction

It is easy to extend our sampling-based parsing framework to joint prediction of parsing and other labels. Specifically, when sampling the new heads, we can also sample the values of other variables at the same time. For instance, we can sample the POS tag, the dependency relation or morphology information. In this work, we investigate a joint POS correction scenario in which only the predicted POS tags are provided in the testing phase, while both gold and predicted tags are available for the training set.

Inputs: $\mathcal{D} = \{(x^{(i)}, y^{(i)})\}_{i=1}^{N}$.
Outputs: Learned parameters θ.
$\theta_0 \leftarrow \mathbf{0}$
for $e = 1$ **to** #epochs **do**
  for $i = 1$ **to** N **do**
    $y' \leftarrow q(\cdot|x^{(i)}, y_i^{t_i}, \theta_t)$
    $y^+ = \arg\min_{y \in \left\{y_i^{t_i}, y'\right\}} Err(y)$
    $y^- = \arg\max_{y \in \left\{y_i^{t_i}, y'\right\}} Err(y)$
    $y_i^{t_i+1} \leftarrow$ acceptOrReject($y', y_i^{t_i}, \theta_t$)
    $t_i \leftarrow t_i + 1$
    $\nabla f = f(x^{(i)}, y^+) - f(x^{(i)}, y^-)$
    $\Delta Err = Err(y^+) - Err(y^-)$
    if $\Delta Err \neq 0$ and $\theta_t \cdot \nabla f < \Delta Err$ **then**
      $\theta_{t+1} \leftarrow$ updateMIRA($\nabla f, \Delta Err, \theta_t$)
      $t \leftarrow t + 1$
    $\nabla f_g = f(x^{(i)}, y^{(i)}) - f(x^{(i)}, y_i^{t_i})$
    if $\theta_t \cdot \nabla f_g < Err(y_i^{t_i})$ **then**
      $\theta_{t+1} \leftarrow$ updateMIRA($\nabla f_g, Err(y_i^{t_i}), \theta_t$)
      $t \leftarrow t + 1$
return Average of $\theta_0, \ldots, \theta_t$ parameters.

Figure 4: SampleRank algorithm for learning. The rejection strategy is as in Figure 1. $y_i^{t_i}$ is the t_ith tree sample of $x^{(i)}$. The first MIRA update (see Equation 6) enforces a ranking constraint between two sampled parses. The second MIRA update enforces constraints between a sampled parse and the gold parse. In practice several samples are drawn for each sentence in each epoch.

We extend our model such that it jointly learns how to predict a parse tree and also correct the predicted POS tags for a better parsing performance. We generate the POS candidate list for each word based on the confusion matrix on the training set. Let $c(t_g, t_p)$ be the count when the gold tag is t_g and the predicted one is t_p. For each word w, we first prune out its POS candidates by using the vocabulary from the training set. We don't prune anything if w is unseen. Assuming that the predicted tag for w is t_p, we further remove those tags t if their counts are smaller than some threshold $c(t, t_p) < \alpha \cdot c(t_p, t_p)$[2].

After generating the candidate lists for each word, the rest of the extension is rather straightforward. For each sampling, let $\mathcal{H}$ be the set of candidate heads and $\mathcal{T}$ be the set of candidate POS tags. The Gibbs sampler will generate a new sample from the space $\mathcal{H} \times \mathcal{T}$. The other parts of the algorithm remain the same.

[2]In our work we choose $\alpha = 0.003$, which gives a 98.9% oracle POS tagging accuracy on the CATiB development set.

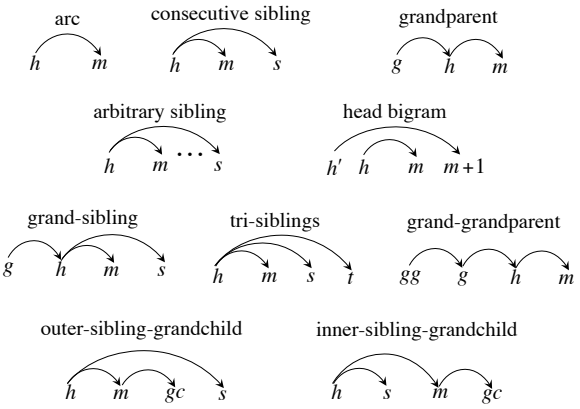

Figure 5: First- to third-order features.

4 Features

First- to Third-Order Features The feature templates of first- to third-order features are mainly drawn from previous work on graph-based parsing (McDonald and Pereira, 2006), transition-based parsing (Nivre et al., 2006) and dual decomposition-based parsing (Martins et al., 2011). As shown in Figure 5, the *arc* is the basic structure for first-order features. We also define features based on consecutive sibling, grandparent, arbitrary sibling, head bigram, grand-sibling and tri-siblings, which are also used in the Turbo parser (Martins et al., 2013). In addition to these first- to third-order structures, we also consider grand-grandparent and sibling-grandchild structures. There are two types of sibling-grandchild structures: (1) inner-sibling when the sibling is between the head and the modifier and (2) outer-sibling for the other cases.

Global Features We used feature shown promising in prior reranking work Charniak and Johnson (2005), Collins (2000) and Huang (2008).

- **Right Branch** This feature enables the model to prefer right or left-branching trees. It counts the number of words on the path from the root node to the right-most non-punctuation word, normalized by the length of the sentence.
- **Coordination** In a coordinate structure, the two adjacent conjuncts usually agree with each other on POS tags and their span lengths. For instance, in *cats and dogs*, the conjuncts are both short noun phrases. Therefore, we add different features to capture POS tag and span length consistency in a coordinate structure.
- **PP Attachment** We add features of lexical tuples involving the head, the argument and the preposition of prepositional phrases. Generally, this feature can be defined based on an instance of grandparent structure. However, we also handle the case of coordination. In this case, the arguments should be the conjuncts rather than the coordinator. Figure 6 shows an example.

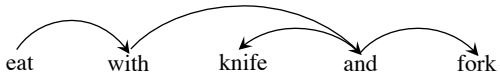

Figure 6: An example of PP attachment with coordination. The arguments should be *knife* and *fork*, not *and*.

- **Span Length** This feature captures the distribution of the binned span length of each POS tag. It also includes flags of whether the span reaches the end of the sentence and whether the span is followed by the punctuation.
- **Neighbors** The POS tags of the neighboring words to the left and right of each span, together with the binned span length and the POS tag at the span root.
- **Valency** We consider valency features for each POS tag. Specifically, we add two types of valency information: (1) the binned number of non-punctuation modifiers and (2) the concatenated POS string of all those modifiers.
- **Non-projective Arcs** A flag indicating if a dependency is projective or not (i.e. if it spans a word that does not descend from its head) (Martins et al., 2011). This flag is also combined with the POS tags or the lexical words of the head and the modifier.

POS Tag Features In the joint POS correction scenario, we also add additional features specifically for POS prediction. The feature templates are inspired by previous feature-rich POS tagging work (Toutanova et al., 2003). However, we are free to add higher order features because we do not rely on dynamic programming decoding. In our work we use feature templates up to 5-gram. Table 1 summarizes all POS tag feature templates.

5 Experimental Setup

Datasets We evaluate our model on standard benchmark corpora — CoNLL 2006 and CoNLL 2008 (Buchholz and Marsi, 2006; Surdeanu et al., 2008) — which include dependency treebanks for 14 different languages. Most of these data sets

1-gram	$\langle t_i \rangle, \langle t_i, w_{i-2} \rangle, \langle t_i, w_{i-1} \rangle, \langle t_i, w_i \rangle, \langle t_i, w_{i+1} \rangle, \langle t_i, w_{i+2} \rangle$
2-gram	$\langle t_{i-1}, t_i \rangle, \langle t_{i-2}, t_i \rangle, \langle t_{i-1}, t_i, w_{i-1} \rangle, \langle t_{i-1}, t_i, w_i \rangle$
3-gram	$\langle t_{i-1}, t_i, t_{i+1} \rangle, \langle t_{i-2}, t_i, t_{i+1}, \rangle, \langle t_{i-1}, t_i, t_{i+2} \rangle, \langle t_{i-2}, t_i, t_{i+2} \rangle$
4-gram	$\langle t_{i-2}, t_{i-1}, t_i, t_{i+1} \rangle, \langle t_{i-2}, t_{i-1}, t_i, t_{i+2} \rangle, \langle t_{i-2}, t_i, t_{i+1}, t_{i+2} \rangle$
5-gram	$\langle t_{i-2}, t_{i-1}, t_i, t_{i+1}, t_{i+2} \rangle$

Table 1: POS tag feature templates. t_i and w_i denotes the POS tag and the word at the current position. t_{i-x} and t_{i+x} denote the left and right context tags, and similarly for words.

contain non-projective dependency trees. We use all sentences in CoNLL datasets during training and testing. We also use the Columbia Arabic Treebank (CATiB) (Marton et al., 2013). CATiB mostly includes projective trees. The trees are annotated with both gold and predicted versions of POS tags and morphology information. Following Marton et al. (2013), for this dataset we use 12 core POS tags, word lemmas, determiner features, rationality features and functional genders and numbers.

Some CATiB sentences exceed 200 tokens. For efficiency, we limit the sentence length to 70 tokens in training and development sets. However, we do not impose this constraint during testing. We handle long sentences during testing by applying a simple split-merge strategy. We split the sentence based on the ending punctuation, predict the parse tree for each segment and group the roots of resulting trees into a single node.

Evaluation Measures Following standard practice, we use Unlabeled Attachment Score (UAS) as the evaluation metric in all our experiments. We report UAS excluding punctuation on CoNLL datasets, following Martins et al. (2013). For the CATiB dataset, we report UAS including punctuation in order to be consistent with the published results in the 2013 SPMRL shared task (Seddah et al., 2013).

Baselines We compare our model with the Turbo parser and the MST parser. For the Turbo parser, we directly compare with the recent published results in (Martins et al., 2013). For the MST parser, we train a second-order non-projective model using the most recent version of the code[3].

We also compare our model against a discriminative reranker. The reranker operates over the top-50 list obtained from the MST parser[4]. We use a 10-fold cross-validation to generate candidate lists for training. We then train the reranker by running 10 epochs of cost-augmented MIRA. The reranker uses the same features as our model, along with the tree scores obtained from the MST parser (which is a standard practice in reranking).

Experimental Details Following Koo and Collins (2010), we always first train a first-order pruner. For each word x_i, we prune away the incoming dependencies $\langle h_i, x_i \rangle$ with probability less than 0.005 times the probability of the most likely head, and limit the number of candidate heads up to 30. This gives a 99% pruning recall on the CATiB development set. The first-order model is also trained using the algorithm in Figure 4. After pruning, we tune the regularization parameter $C = \{0.1, 0.01, 0.001\}$ on development sets for different languages. Because the CoNLL datasets do not have a standard development set, we randomly select a held out of 200 sentences from the training set. We also pick the training epochs from $\{50, 100, 150\}$ which gives the best performance on the development set for each language. After tuning, the model is trained on the full training set with the selected parameters.

We apply the Random Walk-based sampling method (see Section 3.2.2) for the standard dependency parsing task. However, for the joint parsing and POS correction on the CATiB dataset we do not use the Random Walk method because the first-order features in normal parsing are no longer first-order when POS tags are also variables. Therefore, the first-order distribution is not well-defined and we only employ Gibbs sampling for simplicity. On the CATiB dataset, we restrict the sample trees to always be projective as described in Section 3.2.1. However, we do not impose this constraint for the CoNLL datasets.

6 Results

Comparison with State-of-the-art Parsers Table 2 summarizes the performance of our model and of the baselines. We first compare our model to the Turbo parser using the Turbo parser feature set. This is meant to test how our learning and inference methods compare to a dual decomposition approach. The first column in Table 2

[3] http://sourceforge.net/projects/mstparser/

[4] The MST parser is trained in projective mode for reranking because generating top-k list from second-order non-projective model is intractable.

Table 2: Results of our model, the Turbo parser, and the MST parser. "Best Published UAS" includes the most accurate parsers among Nivre et al. (2006), McDonald et al. (2006), Martins et al. (2010), Martins et al. (2011), Martins et al. (2013), Koo et al. (2010), Rush and Petrov (2012), Zhang and McDonald (2012) and Zhang et al. (2013). Martins et al. (2013) is the current Turbo parser. The last two columns shows UAS of the discriminative reranker.

shows the result for our model with an average of 88.87%, and the third column shows the results for the Turbo parser with an average of 88.72%. This suggests that our learning and inference procedures are as effective as the dual decomposition method in the Turbo parser.

Next, we add global features that are not used by the Turbo parser. The performance of our model is shown in the second column with an average of 89.23%. It outperforms the Turbo parser by 0.5% and achieves the best reported performance on four languages. Moreover, our model also outperforms the 88.80% average UAS reported in Martins et al. (2011), which is the top performing single parsing system (to the best of our knowledge).

Comparison with Reranking As column 6 of Table 2 shows, our model outperforms the reranker by 1.3%[5]. One possible explanation of this performance gap between the reranker and our model is the small number of candidates considered by the reranker. To test this hypothesis, we performed experiments with top-500 list for a subset of languages.[6] As column 7 shows, this increase in the list size does not change the relative performance of the reranker and our model.

Joint Parsing and POS Correction Table 3 shows the results of joint parsing and POS correction on the CATiB dataset, for our model and state-of-the-art systems. As the upper part of the table shows, the parser with corrected tags reaches 88.38% compared to the accuracy of 88.46% on the gold tags. This is a substantial increase from the parser that uses predicted tags (86.95%).

To put these numbers into perspective, the bottom part of Table 3 shows the accuracy of the best systems from the 2013 SPMRL shared task on Arabic parsing using predicted information (Seddah et al., 2013). Our system not only outperforms the best single system (Björkelund et al., 2013) by 1.4%, but it also tops the ensemble system that combines three powerful parsers: the Mate parser (Bohnet, 2010), the Easy-First parser (Goldberg and Elhadad, 2010) and the Turbo parser (Martins et al., 2013)

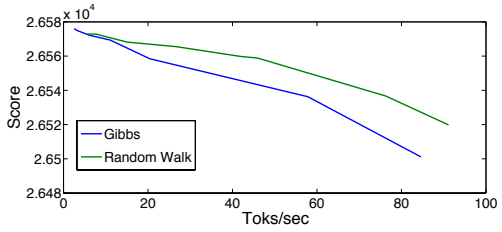
Impact of Sampling Methods We compare two sampling methods introduced in Section 3.2 with respect to their decoding efficiency. Specifically, we measure the score of the retrieved trees in testing as a function of the decoding speed, measured by the number of tokens per second. We change the temperature update rate c in order to decode with different speed. In Figure 7 we show the corresponding curves for two languages: Arabic and Chinese. We select these two languages as they correspond to two extremes in sentence length: Arabic has the longest sentences on average, while Chinese has the shortest ones. For both languages, the tree score improves over time. Given sufficient time, both sampling methods achieve the same score. However, the Random Walk-based sampler performs better when the quality is traded for speed. This result is to be expected given that each

[5]Note that the comparison is conservative because we can also add MST scores as features in our model as in reranker. With these features our model achieves an average UAS 89.28%.

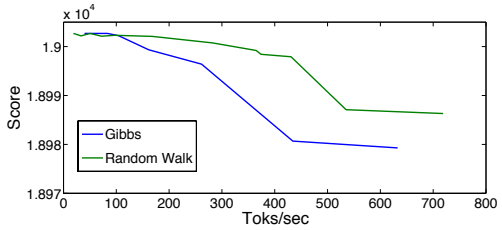
[6]We ran this experiment on 5 languages with small datasets due to the scalability issues associated with reranking top-500 list.

	Dev. Set ($\leq$ 70)		Testing Set	
	POS Acc.	UAS	POS Acc.	UAS
Gold	-	90.27	-	88.46
Predicted	96.87	88.81	96.82	86.95
POS Correction	97.72	90.08	97.49	**88.38**
CADIM	96.87	87.4-	96.82	85.78
IMS-Single	-	-	-	86.96
IMS-Ensemble	-	-	-	88.32

Table 3: Results for parsing and corrective tagging on the CATiB dataset. The upper part shows UAS of our model with gold/predicted information or POS correction. Bottom part shows UAS of the best systems in the SPMRL shared task. IMS-Single (Björkelund et al., 2013) is the best single parsing system, while IMS-Ensemble (Björkelund et al., 2013) is the best ensemble parsing system. We also show results for CADIM (Marton et al., 2013), the second best system, because we use their predicted features.



(a) Arabic



(b) Chinese

Figure 7: Total score of the predicted test trees as a function of the decoding speed, measured in the number of tokens per second.

iteration of this sampler makes multiple changes to the tree, in contrast to a single-edge change of Gibbs sampler.

The Effect of Constraints in Learning Our training method updates parameters to satisfy the pairwise constraints between (1) subsequent samples on the sampling path and (2) selected samples and the ground truth. Figure 8 shows that applying both types of constraints is consistently better than using either of them alone. Moreover, these results demonstrate that comparison between subsequent samples is more important than comparison against the gold tree.

Decoding Speed Our sampling-based parser is an anytime algorithm, and therefore its running time can be traded for performance. Figure 7 illustrates this trade-off. In the experiments reported above, we chose a conservative cooling rate and continued to sample until the score no longer changed. The parser still managed to process all the datasets in a reasonable time. For example, the time that it took to decode all the test sentences in Chinese and Arabic were 3min and 15min, respectively. Our current implementation is in Java and can be further optimized for speed.

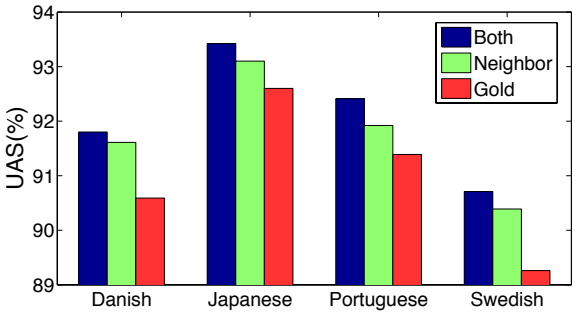


Figure 8: UAS on four languages when training with different constraints. "Neighbor" corresponds to pairwise constraints between subsequent samples, "Gold" represents constraints between a single sample and the ground truth, "Both" means applying both types of constraints.

7 Conclusions

This paper demonstrates the power of combining a simple inference procedure with a highly expressive scoring function. Our model achieves the best results on the standard dependency parsing benchmark, outperforming parsing methods with elaborate inference procedures. In addition, this framework provides simple and effective means for joint parsing and corrective tagging.

Abstract

Due to their origin in computer graphics, graphics processing units (GPUs) are highly optimized for dense problems, where the exact same operation is applied repeatedly to all data points. Natural language processing algorithms, on the other hand, are traditionally constructed in ways that exploit structural sparsity. Recently, Canny et al. (2013) presented an approach to GPU parsing that sacrifices traditional sparsity in exchange for raw computational power, obtaining a system that can compute Viterbi parses for a high-quality grammar at about 164 sentences per second on a mid-range GPU. In this work, we reintroduce sparsity to GPU parsing by adapting a coarse-to-fine pruning approach to the constraints of a GPU. The resulting system is capable of computing over 404 Viterbi parses per second—more than a 2x speedup—on the same hardware. Moreover, our approach allows us to efficiently implement less GPU-friendly minimum Bayes risk inference, improving throughput for this more accurate algorithm from only 32 sentences per second unpruned to over 190 sentences per second using pruning—nearly a 6x speedup.

1 Introduction

Because NLP models typically treat sentences independently, NLP problems have long been seen as "embarrassingly parallel" – large corpora can be processed arbitrarily fast by simply sending different sentences to different machines. However, recent trends in computer architecture, particularly the development of powerful "general purpose" GPUs, have changed the landscape even for problems that parallelize at the sentence level. First, classic single-core processors and main memory architectures are no longer getting substantially faster over time, so speed gains must now come from parallelism within a single machine. Second, compared to CPUs, GPUs devote a much larger fraction of their computational power to actual arithmetic. Since tasks like parsing boil down to repeated read-multiply-write loops, GPUs should be many times more efficient in time, power, or cost. The challenge is that GPUs are not a good fit for the kinds of sparse computations that most current CPU-based NLP algorithms rely on.

Recently, Canny et al. (2013) proposed a GPU implementation of a constituency parser that sacrifices all sparsity in exchange for the sheer horsepower that GPUs can provide. Their system uses a grammar based on the Berkeley parser (Petrov and Klein, 2007) (which is particularly amenable to GPU processing), "compiling" the grammar into a sequence of GPU kernels that are applied densely to every item in the parse chart. Together these kernels implement the Viterbi inside algorithm. On a mid-range GPU, their system can compute Viterbi derivations at 164 sentences per second on sentences of length 40 or less (see timing details below).

In this paper, we develop algorithms that can exploit sparsity on a GPU by adapting coarse-to-fine pruning to a GPU setting. On a CPU, pruning methods can give speedups of up to 100x. Such extreme speedups over a dense GPU baseline currently seem unlikely because fine-grained sparsity appears to be directly at odds with dense parallelism. However, in this paper, we present a system that finds a middle ground, where some level of sparsity can be maintained without losing the parallelism of the GPU. We use a coarse-to-fine approach as in Petrov and Klein (2007), but with only one coarse pass. Figure 1 shows an overview of the approach: we first parse densely with a coarse grammar and then parse sparsely with the

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 208–217,
Baltimore, Maryland, USA, June 23-25 2014.

fine grammar, skipping symbols that the coarse pass deemed sufficiently unlikely. Using this approach, we see a gain of more than 2x over the dense GPU implementation, resulting in overall speeds of up to 404 sentences per second. For comparison, the publicly available CPU implementation of Petrov and Klein (2007) parses approximately 7 sentences per second per core on a modern CPU.

A further drawback of the dense approach in Canny et al. (2013) is that it only computes Viterbi parses. As with other grammars with a parse/derivation distinction, the grammars of Petrov and Klein (2007) only achieve their full accuracy using minimum-Bayes-risk parsing, with improvements of over 1.5 F1 over best-derivation Viterbi parsing on the Penn Treebank (Marcus et al., 1993). To that end, we extend our coarse-to-fine GPU approach to computing marginals, along the way proposing a new way to exploit the coarse pass to avoid expensive log-domain computations in the fine pass. We then implement minimum-Bayes-risk parsing via the max recall algorithm of Goodman (1996). Without the coarse pass, the dense marginal computation is not efficient on a GPU, processing only 32 sentences per second. However, our approach allows us to process over 190 sentences per second, almost a 6x speedup.

2 A Note on Experiments

We build up our approach incrementally, with experiments interspersed throughout the paper, and summarized in Tables 1 and 2. In this paper, we focus our attention on current-generation NVIDIA GPUs. Many of the ideas described here apply to other GPUs (such as those from AMD), but some specifics will differ. All experiments are run with an NVIDIA GeForce GTX 680, a mid-range GPU that costs around $500 at time of writing. Unless otherwise noted, all experiments are conducted on sentences of length ≤ 40 words, and we estimate times based on batches of 20K sentences.[1] We should note that our experimental condition differs from that of Canny et al. (2013): they evaluate on sentences of length ≤ 30. Furthermore, they use two NVIDIA GeForce GTX *690*s—each of which is essentially a repackaging of two 680s—meaning that our system and experiments would run approximately four times faster on their hardware. (This expected 4x factor is empirically consistent with the result of running their system on our hardware.)

[1]The implementation of Canny et al. (2013) cannot handle batches so large, and so we tested it on batches of 1200 sentences. Our reimplementation is approximately the same speed for the same batch sizes. For batches of 20K sentences, we used sentences from the training set. We verified that there was no significant difference in speed for sentences from the training set and from the test set.

3 Sparsity and CPUs

One successful approach for speeding up constituency parsers has been to use coarse-to-fine inference (Charniak et al., 2006). In coarse-to-fine inference, we have a sequence of increasingly complex grammars G_ℓ. Typically, each successive grammar G_ℓ is a *refinement* of the preceding grammar $G_{\ell-1}$. That is, for each symbol A_x in the fine grammar, there is some symbol A in the coarse grammar. For instance, in a latent variable parser, the coarse grammar would have symbols like NP, VP, etc., and the fine pass would have refined symbols NP_0, NP_1, VP_4, and so on.

In coarse-to-fine inference, one applies the grammars in sequence, computing inside and outside scores. Next, one computes (max) marginals for every labeled span (A, i, j) in a sentence. These max marginals are used to compute a *pruning mask* for every span (i, j). This mask is the set of symbols allowed for that span. Then, in the next pass, one only processes rules that are licensed by the pruning mask computed at the previous level.

This approach works because a low quality coarse grammar can still reliably be used to prune many symbols from the fine chart without loss of accuracy. Petrov and Klein (2007) found that over 98% of symbols can be pruned from typical charts using a simple X-bar grammar without any loss of accuracy. Thus, the vast majority of rules can be skipped, and therefore most computation can be avoided. It is worth pointing out that although 98% of labeled spans can be skipped due to X-bar pruning, we found that only about 79% of binary rule applications can be skipped, because the unpruned symbols tend to be the ones with a larger grammar footprint.

4 GPU Architectures

Unfortunately, the standard coarse-to-fine approach does not naïvely translate to GPU architectures. GPUs work by executing thousands of threads at once, but impose the constraint that large blocks of threads must be executing the same

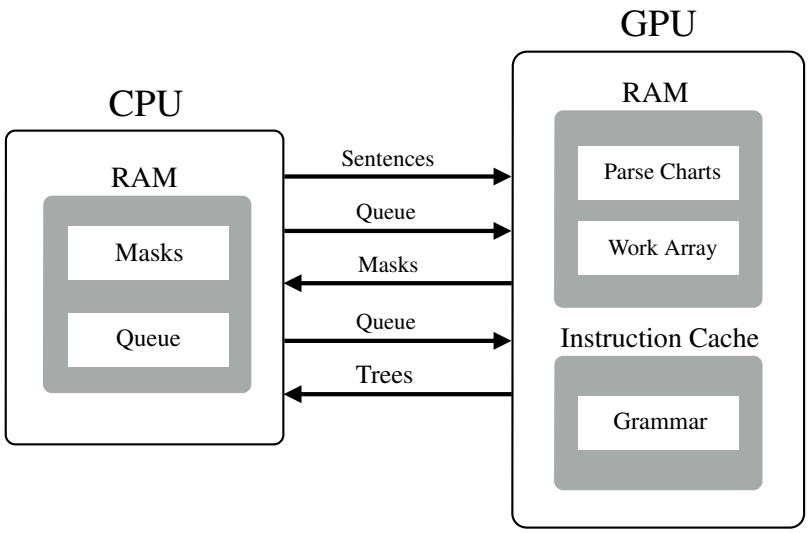

Figure 1: Overview of the architecture of our system, which is an extension of Canny et al. (2013)'s system. The GPU and CPU communicate via a work queue, which ferries parse items from the CPU to the GPU. Our system uses a coarse-to-fine approach, where the coarse pass computes a pruning mask that is used by the CPU when deciding which items to queue during the fine pass. The original system of Canny et al. (2013) only used the fine pass, with no pruning.

instructions in lockstep, differing only in their input data. Thus sparsely skipping rules and symbols will not save any work. Indeed, it may actually slow the system down. In this section, we provide an overview of GPU architectures, focusing on the details that are relevant to building an efficient parser.

The large number of threads that a GPU executes are packaged into blocks of 32 threads called *warps*. All threads in a warp must execute the same instruction at every clock cycle: if one thread takes a branch the others do not, then *all* threads in the warp must follow both code paths. This situation is called *warp divergence*. Because all threads execute all code paths that any thread takes, time can only be saved if an entire warp agrees to skip any particular branch.

NVIDIA GPUs have 8-15 processors called *streaming multi-processors* or SMs.[2] Each SM can process up to 48 different warps at a time: it interleaves the execution of each warp, so that when one warp is stalled another warp can execute. Unlike threads within a single warp, the 48 warps do not have to execute the same instructions. However, the memory architecture is such that they will be faster if they access related memory locations.

A further consideration is that the number of registers available to a thread in a warp is rather limited compared to a CPU. On the 600 series, maximum occupancy can only be achieved if each thread uses at most 63 registers (Nvidia, 2008).[3] Registers are many times faster than variables located in thread-local memory, which is actually the same speed as global memory.

5 Anatomy of a Dense GPU Parser

This architecture environment puts very different constraints on parsing algorithms from a CPU environment. Canny et al. (2013) proposed an implementation of a PCFG parser that sacrifices standard sparse methods like coarse-to-fine pruning, focusing instead on maximizing the instruction and memory throughput of the parser. They assume that they are parsing many sentences at once, with throughput being more important than latency. In this section, we describe their dense algorithm, which we take as the baseline for our work; we present it in a way that sets up the changes to follow.

At the top level, the CPU and GPU communicate via a *work queue* of parse items of the form (s, i, k, j), where s is an identifier of a sentence, i is the start of a span, k is the split point, and j

[2] Older hardware (600 series or older) has 8 SMs. Newer hardware has more.

[3] A thread can use more registers than this, but the full complement of 48 warps cannot execute if too many are used.

Clustering	Pruning	Sent/Sec	Speedup
Canny et al.	–	164.0	–
Reimpl	–	192.9	1.0x
Reimpl	Empty, Coarse	185.5	0.96x
Reimpl	Labeled, Coarse	187.5	0.97x
Parent	–	158.6	0.82x
Parent	Labeled, Coarse	278.9	1.4x
Parent	Labeled, 1-split	**404.7**	**2.1x**
Parent	Labeled, 2-split	343.6	1.8x

Table 1: Performance numbers for computing Viterbi inside charts on 20,000 sentences of length $\leq$40 from the Penn Treebank. All times are measured on an NVIDIA GeForce GTX 680. 'Reimpl' is our reimplementation of their approach. Speedups are measured in reference to this reimplementation. See Section 7 for discussion of the clustering algorithms and Section 6 for a description of the pruning methods. The Canny et al. (2013) system is benchmarked on a batch size of 1200 sentences, the others on 20,000.

is the end point. The GPU takes large numbers of parse items and applies the *entire* grammar to them in parallel. These parse items are enqueued in order of increasing span size, blocking until all items of a given length are complete. This approach is diagrammed in Figure 2.

Because all rules are applied to all parse items, all threads are executing the same sequence of instructions. Thus, there is no concern of warp divergence.

5.1 Grammar Compilation

One important feature of Canny et al. (2013)'s system is *grammar compilation*. Because registers are so much faster than thread-local memory, it is critical to keep as many variables in registers as possible. One way to accomplish this is to unroll loops at compilation time. Therefore, they inlined the iteration over the grammar directly into the GPU kernels (i.e. the code itself), which allows the compiler to more effectively use all of its registers.

However, register space is limited on GPUs. Because the Berkeley grammar is so large, the compiler is not able to efficiently schedule all of the operations in the grammar, resulting in register spills. Canny et al. (2013) found they had to partition the grammar into multiple different kernels. We discuss this partitioning in more detail in Section 7. However, in short, the entire grammar G is broken into multiple clusters G_i where each rule belongs to exactly one cluster.

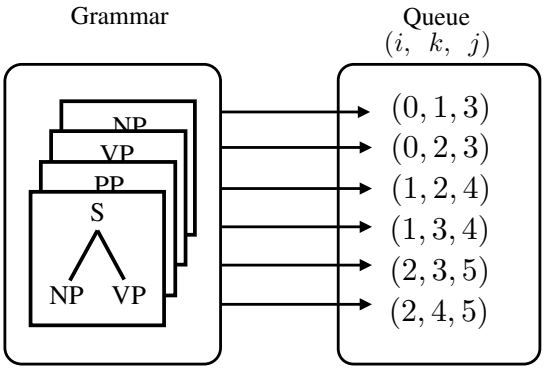

Figure 2: Schematic representation of the work queue used in Canny et al. (2013). The Viterbi inside loop for the grammar is inlined into a kernel. The kernel is applied to all items in the queue in a blockwise manner.

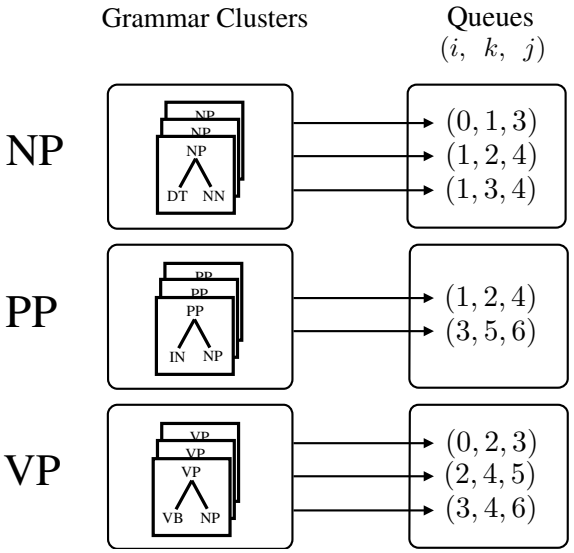

Figure 3: Schematic representation of the work queue and grammar clusters used in the fine pass of our work. Here, the rules of the grammar are clustered by their coarse parent symbol. We then have multiple work queues, with parse items only being enqueued if the span (i, j) allows that symbol in its pruning mask.

All in all, Canny et al. (2013)'s system is able to compute Viterbi charts at 164 sentences per second, for sentences up to length 40. On larger batch sizes, our reimplementation of their approach is able to achieve 193 sentences per second on the same hardware. (See Table 1.)

6 Pruning on a GPU

Now we turn to the algorithmic and architectural changes in our approach. First, consider trying to

directly apply the coarse-to-fine method sketched in Section 3 to the dense baseline described above. The natural implementation would be for each thread to check if each rule is licensed before applying it. However, we would only avoid the work of applying the rule if all threads in the warp agreed to skip it. Since each thread in the warp is processing a different span (perhaps even from a different sentence), consensus from all 32 threads on any skip would be unlikely.

Another approach would be to skip enqueuing any parse item (s, i, k, j) where the pruning mask for any of (i, j), (i, k), or (k, j) is entirely empty (i.e. all symbols are pruned in this cell by the coarse grammar). However, our experiments showed that only 40% of parse items are pruned in this manner. Because of the overhead associated with creating pruning masks and the further overhead of GPU communication, we found that this method did not actually produce any time savings at all. The result is a parsing speed of 185.5 sentences per second, as shown in Table 1 on the row labeled 'Reimpl' with 'Empty, Coarse' pruning.

Instead, we take advantage of the partitioned structure of the grammar and organize our computation around the coarse symbol set. Recall that the baseline already partitions the grammar G into rule clusters G_i to improve register sharing. (See Section 7 for more on the baseline clustering.) We create a separate work queue for each partition. We call each such queue a *labeled work queue*, and each one only queues items to which some rule in the corresponding partition applies. We call the set of coarse symbols for a partition (and therefore the corresponding labeled work queue) a *signature*.

During parsing, we only enqueue items (s, i, k, j) to a labeled queue if two conditions are met. First, the span (i, j)'s pruning mask must have a non-empty intersection with the signature of the queue. Second, the pruning mask for the children (i, k) and (k, j) must be non-empty.

Once on the GPU, parse items are processed using the same style of compiled kernel as in Canny et al. (2013). Because the entire partition (though not necessarily the entire grammar) is applied to each item in the queue, we still do not need to worry about warp divergence.

At the top level, our system first computes pruning masks with a coarse grammar. Then it processes the same sentences with the fine grammar. However, to the extent that the signatures are small, items can be selectively queued only to certain queues. This approach is diagrammed in Figure 3.

We tested our new pruning approach using an X-bar grammar as the coarse pass. The resulting speed is 187.5 sentences per second, labeled in Table 1 as row labeled 'Reimpl' with 'Labeled, Coarse' pruning. Unfortunately, this approach again does not produce a speedup relative to our reimplemented baseline. To improve upon this result, we need to consider how the grammar clustering interacts with the coarse pruning phase.

7 Grammar Clustering

Recall that the rules in the grammar are partitioned into a set of clusters, and that these clusters are further divided into subclusters. How can we best cluster and subcluster the grammar so as to maximize performance? A good clustering will group rules together that use the same symbols, since this means fewer memory accesses to read and write scores for symbols. Moreover, we would like the time spent processing each of the subclusters within a cluster to be about the same. We cannot move on to the next cluster until all threads from a cluster are finished, which means that the time a cluster takes is the amount of time taken by the longest-running subcluster. Finally, when pruning, it is best if symbols that have the same coarse projection are clustered together. That way, we are more likely to be able to skip a subcluster, since fewer distinct symbols need to be "off" for a parse item to be skipped in a given subcluster.

Canny et al. (2013) clustered *symbols* of the grammar using a sophisticated spectral clustering algorithm to obtain a permutation of the symbols. Then the rules of the grammar were laid out in a (sparse) three-dimensional tensor, with one dimension representing the parent of the rule, one representing the left child, and one representing the right child. They then split the cube into 6x2x2 contiguous "major cubes," giving a partition of the rules into 24 clusters. They then further subdivided these cubes into 2x2x2 minor cubes, giving 8 subclusters that executed in parallel. Note that the clusters induced by these major and minor cubes need not be of similar sizes; indeed, they often are not. Clustering using this method is labeled 'Reimplementation' in Table 1.

The addition of pruning introduces further considerations. First, we have a coarse grammar, with

many fewer rules and symbols. Second, we are able to skip a parse item for an entire cluster if that item's pruning mask does not intersect the cluster's signature. Spreading symbols across clusters may be inefficient: if a parse item licenses a given symbol, we will have to enqueue that item to any queue that has the symbol in its signature, no matter how many other symbols are in that cluster.

Thus, it makes sense to choose a clustering algorithm that exploits the structure introduced by the pruning masks. We use a very simple method: we cluster the rules in the grammar by coarse parent symbol. When coarse symbols are extremely unlikely (and therefore have few corresponding rules), we merge their clusters to avoid the overhead of beginning work on clusters where little work has to be done.[4] In order to subcluster, we divide up rules among subclusters so that each subcluster has the same number of active parent symbols. We found this approach to subclustering worked well in practice.

Clustering using this method is labeled 'Parent' in Table 1. Now, when we use a coarse pruning pass, we are able to parse nearly 280 sentences per second, a 70% increase in parsing performance relative to Canny et al. (2013)'s system, and nearly 50% over our reimplemented baseline.

It turns out that this simple clustering algorithm produces relatively efficient kernels even in the unpruned case. The unpruned Viterbi computations in a fine grammar using the clustering method of Canny et al. (2013) yields a speed of 193 sentences per second, whereas the same computation using coarse parent clustering has a speed of 159 sentences per second. (See Table 1.) This is not as efficient as Canny et al. (2013)'s highly tuned method, but it is still fairly fast, and much simpler to implement.

8 Pruning with Finer Grammars

The coarse to fine pruning approach of Petrov and Klein (2007) employs an X-bar grammar as its first pruning phase, but there is no reason why we cannot begin with a more complex grammar for our initial pass. As Petrov and Klein (2007) have shown, intermediate-sized Berkeley grammars prune many more symbols than the X-bar system. However, they are slower to parse with in a CPU context, and so they begin with an X-bar grammar.

Because of the overhead associated with transferring work items to GPU, using a very small grammar may not be an efficient use of the GPU's computational resources. To that end, we tried computing pruning masks with one-split and two-split Berkeley grammars. The X-bar grammar can compute pruning masks at just over 1000 sentences per second, the 1-split grammar parses 858 sentences per second, and the 2-split grammar parses 526 sentences per second.

Because parsing with these grammars is still quite fast, we tried using them as the coarse pass instead. As shown in Table 1, using a 1-split grammar as a coarse pass allows us to produce over 400 sentences per second, a full 2x improvement over our original system. Conducting a coarse pass with a 2-split grammar is somewhat slower, at a "mere" 343 sentences per second.

9 Minimum Bayes risk parsing

The Viterbi algorithm is a reasonably effective method for parsing. However, many authors have noted that parsers benefit substantially from minimum Bayes risk decoding (Goodman, 1996; Simaan, 2003; Matsuzaki et al., 2005; Titov and Henderson, 2006; Petrov and Klein, 2007). MBR algorithms for parsing do not compute the best derivation, as in Viterbi parsing, but instead the parse tree that maximizes the expected count of some figure of merit. For instance, one might want to maximize the expected number of correct constituents (Goodman, 1996), or the expected rule counts (Simaan, 2003; Petrov and Klein, 2007). MBR parsing has proven especially useful in latent variable grammars. Petrov and Klein (2007) showed that MBR trees substantially improved performance over Viterbi parses for latent variable grammars, earning up to 1.5F1.

Here, we implement the Max Recall algorithm of Goodman (1996). This algorithm maximizes the expected number of correct coarse symbols (A, i, j) with respect to the posterior distribution over parses for a sentence.

This particular MBR algorithm has the advantage that it is relatively straightforward to implement. In essence, we must compute the marginal probability of each fine-labeled span $\mu(A_x, i, j)$, and then marginalize to obtain $\mu(A, i, j)$. Then, for each span (i, j), we find the best possible split

[4] Specifically, after clustering based on the coarse parent symbol, we merge all clusters with less than 300 rules in them into one large cluster.

point k that maximizes $C(i,j) = \mu(A,i,j) + \max_k (C(i,k) + C(k,j))$. Parse extraction is then just a matter of following back pointers from the root, as in the Viterbi algorithm.

9.1 Computing marginal probabilities

The easiest way to compute marginal probabilities is to use the log space semiring rather than the Viterbi semiring, and then to run the inside and outside algorithms as before. We should expect this algorithm to be at least a factor of two slower: the outside pass performs at least as much work as the inside pass. Moreover, it typically has worse memory access patterns, leading to slower performance.

Without pruning, our approach does not handle these log domain computations well at all: we are only able to compute marginals for 32.1 sentences/second, more than a factor of 5 slower than our coarse pass. To begin, log space addition requires significantly more operations than max, which is a primitive operation on GPUs. Beyond the obvious consequence that executing more operations means more time taken, the sheer number of operations becomes too much for the compiler to handle. Because the grammars are compiled into code, the additional operations are all inlined into the kernels, producing much larger kernels. Indeed, in practice the compiler will often hang if we use the same size grammar clusters as we did for Viterbi. In practice, we found there is an effective maximum of 2000 rules per kernel using log sums, while we can use more than 10,000 rules rules in a single kernel with Viterbi.

With coarse pruning, however, we can avoid much of the increased cost associated with log domain computations. Because so many labeled spans are pruned, we are able to skip many of the grammar clusters and thus avoid many of the expensive operations. Using coarse pruning and log domain calculations, our system produces MBR trees at a rate of 130.4 sentences per second, a four-fold increase.

9.2 Scaling with the Coarse Pass

One way to avoid the expense of log domain computations is to use scaled probabilities rather than log probabilities. Scaling is one of the folk techniques that are commonly used in the NLP community, but not generally written about. Recall that floating point numbers are composed of a mantissa m and an exponent e, giving a number $f = m \cdot 2^e$. When a float underflows, the exponent becomes too low to represent the available number of bits. In scaling, floating point numbers are paired with an additional number that extends the exponent. That is, the number is represented as $f' = f \cdot \exp(s)$. Whenever f becomes either too big or too small, the number is rescaled back to a less "dangerous" range by shifting mass from the exponent e to the scaling factor s.

System	Sent/Sec	Speedup
Unpruned Log Sum MBR	32.1	–
Pruned Log Sum MBR	130.4	4.1x
Pruned Scaling MBR	**190.6**	**5.9x**
Pruned Viterbi	404.7	12.6x

Table 2: Performance numbers for computing max constituent (Goodman, 1996) trees on 20,000 sentences of length 40 or less from the Penn Treebank. For convenience, we have copied our pruned Viterbi system's result.

In practice, one scale s is used for an entire span (i,j), and all scores for that span are rescaled in concert. In our GPU system, multiple scores in any given span are being updated at the same time, which makes this dynamic rescaling tricky and expensive, especially since inter-warp communication is fairly limited.

We propose a much simpler static solution that exploits the coarse pass. In the coarse pass, we compute Viterbi inside and outside scores for every span. Because the grammar used in the coarse pass is a projection of the grammar used in the fine pass, these coarse scores correlate reasonably closely with the probabilities computed in the fine pass: If a span has a very high or very low score in the coarse pass, it typically has a similar score in the fine pass. Thus, we can use the coarse pass's inside and outside scores as the scaling values for the fine pass's scores. That is, in addition to computing a pruning mask, in the coarse pass we store the maximum inside and outside score in each span, giving two arrays of scores $s^I_{i,j}$ and $s^O_{i,j}$. Then, when applying rules in the fine pass, each fine inside score over a split span (i,k,j) is scaled to the appropriate $s^I_{i,j}$ by multiplying the score by $\exp\left(s^I_{i,k} + s^I_{k,j} - s^I_{i,j}\right)$, where $s^I_{i,k}, s^I_{k,j}, s^I_{i,j}$ are the scaling factors for the left child, right child, and parent, respectively. The outside scores are scaled analogously.

By itself, this approach works on nearly every sentence. However, scores for approximately

0.5% of sentences overflow (*sic*). Because we are summing instead of maxing scores in the fine pass, the scaling factors computed using max scores are not quite large enough, and so the rescaled inside probabilities grow too large when multiplied together. Most of this difference arises at the leaves, where the lexicon typically has more uncertainty than higher up in the tree. Therefore, in the fine pass, we normalize the inside scores at the leaves to sum to 1.0.[5] Using this slight modification, no sentences from the Treebank under- or overflow.

We know of no reason why this same trick cannot be employed in more traditional parsers, but it is especially useful here: with this static scaling, we can avoid the costly log sums without introducing any additional inter-thread communication, making the kernels much smaller and much faster. Using scaling, we are able to push our parser to 190.6 sentences/second for MBR extraction, just under half the speed of the Viterbi system.

9.3 Parsing Accuracies

It is of course important verify the correctness of our system; one easy way to do so is to examine parsing accuracy, as compared to the original Berkeley parser. We measured parsing accuracy on sentences of length ≤ 40 from section 22 of the Penn Treebank. Our Viterbi parser achieves 89.7 F1, while our MBR parser scores 91.0. These results are nearly identical to the Berkeley parsers most comparable numbers: 89.8 for Viterbi, and 90.9 for their "Max-Rule-Sum" MBR algorithm. These slight differences arise from the usual minor variation in implementation details. In particular, we use one coarse pass instead of several, and a different MBR algorithm. In addition, there are some differences in unary processing.

10 Analyzing System Performance

In this section we attempt to break down how exactly our system is spending its time. We do this in an effort to give a sense of how time is spent during computation on GPUs. These timing numbers are computed using the built-in profiling capabilities of the programming environment. As usual, profiles exhibit an observer effect, where the act of measuring the system changes the execution. Nevertheless, the general trends should more or less be preserved as compared to the unprofiled code.

System	Coarse Pass	Fine Pass
Unpruned Viterbi	–	6.4
Pruned Viterbi	1.2	1.5
Unpruned Logsum MBR	—	28.6
Pruned Scaling MBR	1.2	4.3

Table 3: Time spent in the passes of our different systems, in seconds per 1000 sentences. Pruning refers to using a 1-split grammar for the coarse pass.

To begin, we can compute the number of seconds needed to parse 1000 sentences. (We use seconds per sentence rather than sentences per second because the former measure is additive.) The results are in Table 3. In the case of pruned Viterbi, pruning reduces the amount of time spent in the fine pass by more than 4x, though half of those gains are lost to computing the pruning masks.

In Table 4, we break down the time taken by our system into individual components. As expected, binary rules account for the vast majority of the time in the unpruned Viterbi case, but much less time in the pruned case, with the total time taken for binary rules in the coarse and fine passes taking about 1/5 of the time taken by binaries in the unpruned version. Queueing, which involves copying memory around within the GPU to process the individual parse items, takes a fairly consistent amount of time in all systems. Overhead, which includes transport time between the CPU and GPU and other processing on the CPU, is relatively small for most system configurations. There is greater overhead in the scaling system, because scaling factors are copied to the CPU between the coarse and fine passes.

A final question is: how many sentences per second do we need to process to saturate the GPU's processing power? We computed Viterbi parses of successive powers of 10, from 1 to 100,000 sentences.[6] In Figure 4, we then plotted the throughput, in terms of number of sentences per second. Throughput increases through parsing 10,000 sentences, and then levels off by the time it reaches 100,000 sentences.

[5] One can instead interpret this approach as changing the scaling factors to $s^{I'}_{i,j} = s^{I}_{i,j} \cdot \prod_{i \leq k < j} \sum_A \text{inside}(A, k, k+1)$, where inside is the array of scores for the fine pass.

[6] We replicated the Treebank for the 100,000 sentences pass.

System	Coarse Pass					Fine Pass			
	Binary	Unary	Queueing	Masks	Overhead	Binary	Unary	Queueing	Overhead
Unpruned Viterbi	–	–	–	–	–	5.42	0.14	0.33	0.40
Pruned Viterbi	0.59	0.02	0.19	0.04	0.22	0.56	0.10	0.34	0.22
Pruned Scaling	0.59	0.02	0.19	0.04	0.20	1.74	0.24	0.46	0.84

Table 4: Breakdown of time spent in our different systems, in seconds per 1000 sentences. Binary and Unary refer to spent processing binary rules. Queueing refers to the amount of time used to move memory around within the GPU for processing. Overhead includes all other time, which includes communication between the GPU and the CPU.

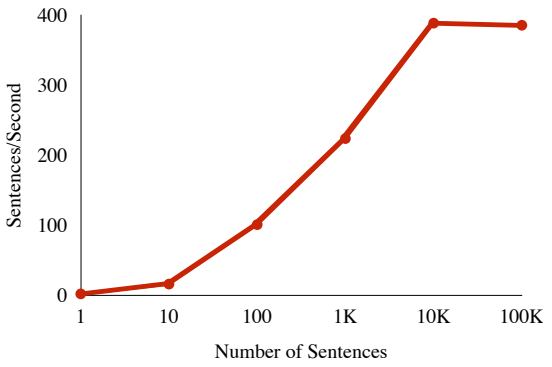

Figure 4: Plot of speeds (sentences / second) for various sizes of input corpora. The full power of the GPU parser is only reached when run on large numbers of sentences.

11 Related Work

Apart from the model of Canny et al. (2013), there have been a few attempts at using GPUs in NLP contexts before. Johnson (2011) and Yi et al. (2011) both had early attempts at porting parsing algorithms to the GPU. However, they did not demonstrate significantly increased speed over a CPU implementation. In machine translation, He et al. (2013) adapted algorithms designed for GPUs in the computational biology literature to speed up on-demand phrase table extraction.

12 Conclusion

GPUs represent a challenging opportunity for natural language processing. By carefully designing within the constraints imposed by the architecture, we have created a parser that can exploit the same kinds of sparsity that have been developed for more traditional architectures.

One of the key remaining challenges going forward is confronting the kind of lexicalized sparsity common in other NLP models. The Berkeley parser's grammars—by virtue of being unlexicalized—can be applied uniformly to all parse items. The bilexical features needed by dependency models and lexicalized constituency models are not directly amenable to acceleration using the techniques we described here. Determining how to efficiently implement these kinds of models is a promising area for new research.

Our system is available as open-source at `https://www.github.com/dlwh/puck`.

Abstract

This paper presents the first dependency model for a shift-reduce CCG parser. Modelling dependencies is desirable for a number of reasons, including handling the "spurious" ambiguity of CCG; fitting well with the theory of CCG; and optimizing for structures which are evaluated at test time. We develop a novel training technique using a dependency oracle, in which all derivations are hidden. A challenge arises from the fact that the oracle needs to keep track of exponentially many gold-standard derivations, which is solved by integrating a packed parse forest with the beam-search decoder. Standard CCGBank tests show the model achieves up to 1.05 labeled F-score improvements over three existing, competitive CCG parsing models.

1 Introduction

Combinatory Categorial Grammar (CCG; Steedman (2000)) is able to derive typed dependency structures (Hockenmaier, 2003; Clark and Curran, 2007), providing a useful approximation to the underlying predicate-argument relations of "who did what to whom". To date, CCG remains the most competitive formalism for recovering "deep" dependencies arising from many linguistic phenomena such as raising, control, extraction and coordination (Rimell et al., 2009; Nivre et al., 2010).

To achieve its expressiveness, CCG exhibits so-called "spurious" ambiguity, permitting many non-standard surface derivations which ease the recovery of certain dependencies, especially those arising from type-raising and composition. But this raises the question of what is the most suitable model for CCG: *should we model the derivations, the dependencies, or both?* The choice for some existing parsers (Hockenmaier, 2003; Clark and Curran, 2007) is to model derivations directly, restricting the gold-standard to be the normal-form derivations (Eisner, 1996) from CCGBank (Hockenmaier and Steedman, 2007).

Modelling dependencies, as a proxy for the semantic interpretation, fits well with the theory of CCG, in which Steedman (2000) argues that the derivation is merely a "trace" of the underlying syntactic process, and that the structure which is built, and predicated over when applying constraints on grammaticality, is the semantic interpretation. The early dependency model of Clark et al. (2002), in which model features were defined over *only* dependency structures, was partly motivated by these theoretical observations.

More generally, dependency models are desirable for a number of reasons. First, modelling dependencies provides an elegant solution to the spurious ambiguity problem (Clark and Curran, 2007). Second, obtaining training data for dependencies is likely to be easier than for syntactic derivations, especially for incomplete data (Schneider et al., 2013). Clark and Curran (2006) show how the dependency model from Clark and Curran (2007) extends naturally to the partial-training case, and also how to obtain dependency data cheaply from gold-standard lexical category sequences alone. And third, it has been argued that dependencies are an ideal representation for parser evaluation, especially for CCG (Briscoe and Carroll, 2006; Clark and Hockenmaier, 2002), and so optimizing for dependency recovery makes sense from an evaluation perspective.

In this paper, we fill a gap in the literature by developing the first dependency model for a shift-reduce CCG parser. Shift-reduce parsing applies naturally to CCG (Zhang and Clark, 2011), and the left-to-right, incremental nature of the decoding fits with CCG's cognitive claims. The discriminative model is global and trained with the structured perceptron. The decoder is based on beam-search

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 218–227,
Baltimore, Maryland, USA, June 23-25 2014.

(Zhang and Clark, 2008) with the advantage of linear-time decoding (Goldberg et al., 2013).

A main contribution of the paper is a novel technique for training the parser using a dependency oracle, in which all derivations are hidden. A challenge arises from the potentially exponential number of derivations leading to a gold-standard dependency structure, which the oracle needs to keep track of. Our solution is an integration of a packed parse *forest*, which efficiently stores all the derivations, with the beam-search decoder *at training time*. The derivations are not explicitly part of the data, since the forest is built from the gold-standard dependencies. We also show how perceptron learning with beam-search (Collins and Roark, 2004) can be extended to handle the additional ambiguity, by adapting the "violation-fixing" perceptron of Huang et al. (2012).

Results on the standard CCGBank tests show that our parser achieves absolute labeled F-score gains of up to 0.5 over the shift-reduce parser of Zhang and Clark (2011); and up to 1.05 and 0.64 over the normal-form and hybrid models of Clark and Curran (2007), respectively.

2 Shift-Reduce with Beam-Search

This section describes how shift-reduce techniques can be applied to CCG, following Zhang and Clark (2011). First we describe the deterministic process which a parser would follow when tracing out a single, correct derivation; then we describe how a model of normal-form derivations — or, more accurately, a sequence of shift-reduce actions leading to a normal-form derivation — can be used with beam-search to develop a non-deterministic parser which selects the highest scoring sequence of actions. Note this section only describes a normal-form derivation model for shift-reduce parsing. Section 3 explains how we extend the approach to dependency models.

The shift-reduce algorithm adapted to CCG is similar to that of shift-reduce dependency parsing (Yamada and Matsumoto, 2003; Nivre and McDonald, 2008; Zhang and Clark, 2008; Huang and Sagae, 2010). Following Zhang and Clark (2011), we define each item in the parser as a pair $\langle s, q \rangle$, where q is a queue of remaining input, consisting of words and a set of possible lexical categories for each word (with q_0 being the front word), and s is the stack that holds subtrees $s_0, s_1, ...$ (with s_0 at the top). Subtrees on the stack are partial derivations that have been built as part of the shift-reduce process. SHIFT, REDUCE and UNARY are the three types of actions that can be applied to an item. A SHIFT action shifts one of the lexical categories of q_0 onto the stack. A REDUCE action combines s_0 and s_1 according to a CCG combinatory rule, producing a new category on the top of the stack. A UNARY action applies either a type-raising or type-changing rule to the stack-top category s_0.[1]

step	stack $(s_n, ..., s_1, s_0)$	queue $(q_0, q_1, ..., q_m)$	action
0		Mr. President visited Paris	
1	N/N	President visited Paris	SHIFT
2	$N/N\ N$	visited Paris	SHIFT
3	N	visited Paris	REDUCE
4	NP	visited Paris	UNARY
5	$NP\ (S[dcl]\backslash NP)/NP$	Paris	SHIFT
6	$NP\ (S[dcl]\backslash NP)/NP\ N$		SHIFT
7	$NP\ (S[dcl]\backslash NP)/NP\ NP$		UNARY
8	$NP\ S[dcl]\backslash NP$		REDUCE
9	$S[dcl]$		REDUCE

Figure 1: Deterministic example of shift-reduce CCG parsing (lexical categories omitted on queue).

Figure 1 shows a deterministic example for the sentence *Mr. President visited Paris*, giving a single sequence of shift-reduce actions which produces a correct derivation (i.e. one producing the correct set of dependencies). Starting with the initial item $\langle s, q \rangle_0$ (row 0), which has an empty stack and a full queue, a total of nine actions are applied to produce the complete derivation.

Applying beam-search to a statistical shift-reduce parser is a straightforward extension to the deterministic example. At each step, a beam is used to store the top-k highest-scoring items, resulting from expanding all items in the previous beam. An item becomes a candidate output once it has an empty queue, and the parser keeps track of the highest scored candidate output and returns the best one as the final output. Compared with greedy local-search (Nivre and Scholz, 2004), the use of a beam allows the parser to explore a larger search space and delay difficult ambiguity-resolving decisions by considering multiple items in parallel.

We refer to the shift-reduce model of Zhang and Clark (2011) as the normal-form model, where the oracle for each sentence specifies a unique sequence of gold-standard actions which produces the corresponding normal-form derivation. No dependency structures are involved at training and test time, except for evaluation. In the next section, we describe a dependency oracle which considers all sequences of actions producing a gold-standard dependency structure to be correct.

[1] See Hockenmaier (2003) and Clark and Curran (2007) for a description of CCG rules.

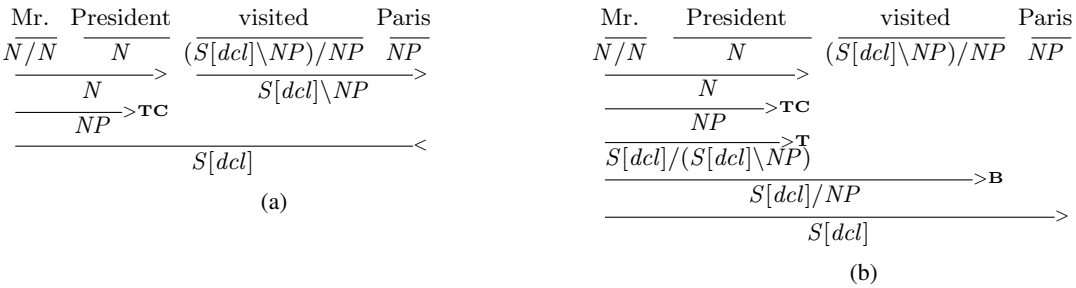

Figure 2: Two derivations leading to the same dependency structure. **TC** denotes type-changing.

3 The Dependency Model

Categories in CCG are either basic (such as NP and PP) or complex (such as $(S[dcl]\backslash NP)/NP$). Each complex category in the lexicon defines one or more predicate-argument relations, which can be realized as a predicate-argument dependency when the corresponding argument slot is consumed. For example, the transitive verb category above defines two relations: one for the subject NP and one for the object NP. In this paper a CCG predicate-argument dependency is a 4-tuple: $\langle h_f, f, s, h_a \rangle$ where h_f is the lexical item of the lexical category expressing the relation; f is the lexical category; s is the argument slot; and h_a is the head word of the argument. Since the lexical items in a dependency are indexed by their sentence positions, all dependencies for a sentence form a set, which is referred to as a CCG *dependency structure*. Clark and Curran (2007) contains a detailed description of dependency structures.

Fig. 2 shows an example demonstrating spurious ambiguity in relation to a CCG dependency structure. In both derivations, the first two lexical categories are combined using forward application ($>$) and the following dependency is realized: $\langle \textit{Mr.}, N/N_1, 1, \textit{President} \rangle$. In the normal-form derivation (a), the dependency $\langle \textit{visited}, (S\backslash NP_1)/NP_2, 2, \textit{Paris} \rangle$ is created by combining the transitive verb category with the object NP using forward application. One final dependency, $\langle \textit{visited}, (S\backslash NP_1)/NP_2, 1, \textit{President} \rangle$, is realized when the root node $S[dcl]$ is produced through backward application ($<$).

Fig. 2(b) shows a non-normal-form derivation which uses type-raising (**T**) and composition (**B**) (which are not required to derive the correct dependency structure). In this alternative derivation, the dependency $\langle \textit{visited}, (S\backslash NP_1)/NP_2, 1, \textit{President} \rangle$ is realized using forward composition (**B**), and $\langle \textit{visited}, (S\backslash NP_1)/NP_2, 2, \textit{Paris} \rangle$ is realized when the $S[dcl]$ root is produced.

The chart-based dependency model of Clark and Curran (2007) treats all derivations as hidden, and defines a probabilistic model for a dependency structure by summing probabilities of all derivations leading to a particular structure. Features are defined over both derivations and CCG predicate-argument dependencies. We follow a similar approach, but rather than define a probabilistic model (which requires summing), we define a linear model over sequences of shift-reduce actions, as for the normal-form shift-reduce model. However, the difference compared to the normal-form model is that we do not assume a single gold-standard sequence of actions.

Similar to Goldberg and Nivre (2012), we define an *oracle* which determines, for a gold-standard dependency structure, G, what the valid transition sequences are (i.e. those sequences corresponding to derivations leading to G). More specifically, the oracle can determine, given G and an item $\langle s, q \rangle$, what the valid actions are for that item (i.e. what actions can potentially lead to G, starting with $\langle s, q \rangle$ and the dependencies already built on s). However, there can be exponentially many valid action sequences for G, which we represent efficiently using a packed parse forest. We show how the forest can be used, during beam-search decoding, to determine the valid actions for a parse item (Section 3.2). We also show, in Section 3.3, how perceptron training with early-update (Collins and Roark, 2004) can be used in this setting.

3.1 The Oracle Forest

A CCG parse forest efficiently represents an exponential number of derivations. Following Clark and Curran (2007) (which builds on Miyao and Tsujii (2002)), and using the same notation, we define a CCG parse forest Φ as a tuple $\langle C, D, R, \gamma, \delta \rangle$, where C is a set of conjunctive

Algorithm 1 (Clark and Curran, 2007)

Input: A packed forest $\langle C, D, R, \gamma, \delta \rangle$, with $dmax(c)$ and $dmax(d)$ already computed

1: **function** MAIN
2: **for each** $d_r \in R$ s.t. $dmax(d_r) = |G|$ **do**
3: MARK(d_r)
4: **procedure** MARK(d)
5: mark d as a correct node
6: **for each** $c \in \gamma(d)$ **do**
7: **if** $dmax(c) == dmax(d)$ **then**
8: mark c as a correct node
9: **for each** $d' \in \delta(c)$ **do**
10: **if** d' has not been visited **then**
11: MARK(d')

nodes and D is a set of disjunctive nodes.[2] Conjunctive nodes are individual CCG categories in Φ, and are either obtained from the lexicon, or by combining two disjunctive nodes using a CCG rule, or by applying a unary rule to a disjunctive node. Disjunctive nodes are equivalence classes of conjunctive nodes. Two conjunctive nodes are equivalent iff they have the same category, head and unfilled dependencies (i.e. they will lead to the same derivation, and produce the same dependencies, in any future parsing). $R \subseteq D$ is a set of root disjunctive nodes. $\gamma : D \rightarrow 2^C$ is the conjunctive child function and $\delta : C \rightarrow 2^D$ is the disjunctive child function. The former returns the set of all conjunctive nodes of a disjunctive node, and the latter returns the disjunctive child nodes of a conjunctive node.

The dependency model requires all the conjunctive and disjunctive nodes of Φ that are part of the derivations leading to a gold-standard dependency structure G. We refer to such derivations as *correct* derivations and the packed forest containing all these derivations as the *oracle forest*, denoted as Φ_G, which is a subset of Φ. It is prohibitive to enumerate all correct derivations, but it is possible to identify, from Φ, all the conjunctive and disjunctive nodes that are part of Φ_G. Clark and Curran (2007) gives an algorithm for doing so, which we use here. The main intuition behind the algorithm is that a gold-standard dependency structure decomposes over derivations; thus gold-standard dependencies realized at conjunctive nodes can be counted when Φ is built, and all nodes that are part of Φ_G can then be marked out of Φ by traversing it top-down. A key idea in understanding the algorithm is that dependencies are created when disjunctive nodes are combined, and hence are associated with, or "live on", conjunctive nodes in the forest.

Following Clark and Curran (2007), we also define the following three values, where the first decomposes only over local rule productions, while the other two decompose over derivations:

$$cdeps(c) = \begin{cases} * & \text{if } \exists\, \tau \in deps(c), \tau \notin G \\ |deps(c)| & \text{otherwise} \end{cases}$$

$$dmax(c) = \begin{cases} * & \text{if } cdeps(c) == * \\ * & \text{if } dmax(d) == * \text{ for some } d \in \delta(c) \\ \sum_{d \in \delta(c)} dmax(d) + cdeps(c) & \text{otherwise} \end{cases}$$

$$dmax(d) = \max\{dmax(c) \mid c \in \gamma(d)\}$$

$deps(c)$ is the set of all dependencies on conjunctive node c, and $cdeps(c)$ counts the number of *correct* dependencies on c. $dmax(c)$ is the maximum number of correct dependencies over any sub-derivation headed by c and is calculated recursively; $dmax(d)$ returns the same value for a disjunctive node. In all cases, a special value $*$ indicates the presence of incorrect dependencies. To obtain the oracle forest, we first pre-compute $dmax(c)$ and $dmax(d)$ for all d and c in Φ when Φ is built using CKY, which are then used by Algorithm 1 to identify all the conjunctive and disjunctive nodes in Φ_G.

3.2 The Dependency Oracle Algorithm

We observe that the canonical shift-reduce algorithm (as demonstrated in Fig. 1) applied to a single parse tree exactly resembles bottom-up *post*-order traversal of that tree. As an example, consider the derivation in Fig. 2a, where the corresponding sequence of actions is: `sh` N/N, `sh` N, `re` N, `un` NP, `sh` $(S[dcl]\backslash NP)/NP$, `sh` NP, `re` $S[dcl]\backslash NP$, `re` $S[dcl]$.[3] The order of traversal is left-child, right-child and parent. For a single parse, the corresponding shift-reduce action sequence is unique, and for a given item this canonical order restricts the possible derivations that can be formed using further actions. We now extend this observation to the more general case of an oracle forest, where there may be more than one gold-standard action for a given item.

Definition 1. Given a gold-standard dependency

[2] Under the hypergraph framework (Gallo et al., 1993; Huang and Chiang, 2005), a conjunctive node corresponds to a hyperedge and a disjunctive node corresponds to the head of a hyperedge or hyperedge bundle.

[3] The derivation is "upside down", following the convention used for CCG, where the root is $S[dcl]$. We use `sh`, `re` and `un` to denote the three types of shift-reduce action.

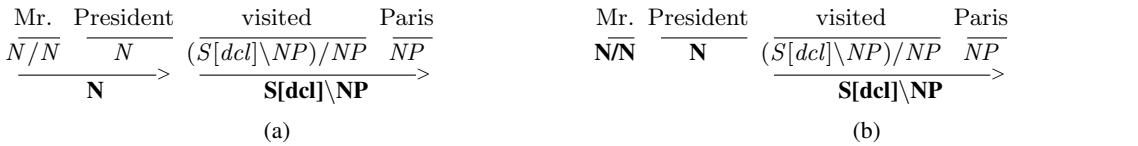

Figure 3: Example subtrees on two stacks, with two subtrees in (a) and three in (b); roots of subtrees are in bold.

structure G, an oracle forest Φ_G, and an item $\langle s, q\rangle$, we say s is a **realization** of G, denoted $s \simeq G$, if $|s| = 1$, q is empty and the single derivation on s is correct. If $|s| > 0$ and the subtrees on s can lead to a correct derivation in Φ_G using further actions, we say s is a **partial-realization** of G, denoted as $s \sim G$. And we define $s \sim G$ for $|s| = 0$.

As an example, assume that Φ_G contains only the derivation in Fig. 2a; then a stack containing the two subtrees in Fig. 3a is a partial-realization, while a stack containing the three subtrees in Fig. 3b is not. Note that each of the three subtrees in Fig. 3b is present in Φ_G; however, these subtrees cannot be combined into the single correct derivation, since the correct sequence of shift-reduce actions must first combine the lexical categories for *Mr.* and *President* before shifting the lexical category for *visited*.

We denote an action as a pair (x, c), where $x \in \{\text{SHIFT}, \text{REDUCE}, \text{UNARY}\}$ and c is the root of the subtree resulting from that action. For all three types of actions, c also corresponds to a unique conjunctive node in the *complete* forest Φ; and we use c_{s_i} to denote the conjunctive node in Φ corresponding to subtree s_i on the stack. Let $\langle s', q'\rangle = \langle s, q\rangle \circ (x, c)$ be the resulting item from applying the action (x, c) to $\langle s, q\rangle$; and let the set of all possible actions for $\langle s, q\rangle$ be $\mathcal{X}_{\langle s,q\rangle} = \{(x, c) \mid (x, c) \text{ is applicable to } \langle s, q\rangle\}$.

Definition 2. Given Φ_G and an item $\langle s, q\rangle$ s.t. $s \sim G$, we say an applicable action (x, c) for the item is **valid** iff $s' \sim G$ or $s' \simeq G$, where $\langle s', q'\rangle = \langle s, q\rangle \circ (x, c)$.

Definition 3. Given Φ_G, the dependency oracle function f_d is defined as:

$$f_d(\langle s, q\rangle, (x, c), \Phi_G) = \begin{cases} \textit{true} & \text{if } s' \sim G \text{ or } s' \simeq G \\ \textit{false} & \text{otherwise} \end{cases}$$

where $(x, c) \in \mathcal{X}_{\langle s,q\rangle}$ and $\langle s', q'\rangle = \langle s, q\rangle \circ (x, c)$.

The pseudocode in Algorithm 2 implements f_d. It determines, for a given item, whether an applicable action is valid in Φ_G.

It is trivial to determine the validity of a SHIFT action for the initial item, $\langle s, q\rangle_0$, since the SHIFT action is valid iff its category matches the gold-standard lexical category of the first word in the sentence. For any subsequent SHIFT action (SHIFT, c) to be valid, the *necessary* condition is $c \equiv c_{lex_0}$, where c_{lex_0} denotes the gold-standard lexical category of the front word in the queue, q_0 (line 3). However, this condition is not sufficient; a counterexample is the case where all the gold-standard lexical categories for the sentence in Figure 2 are shifted in succession. Hence, in general, the conditions under which an action is valid are more complex than the trivial case above.

First, suppose there is only one correct derivation in Φ_G. A SHIFT action $(\text{SHIFT}, c_{lex_0})$ is valid whenever c_{s_0} (the conjunctive node in Φ_G corresponding to the subtree s_0 on the stack) and c_{lex_0} (the conjunctive node in Φ_G corresponding to the next gold-standard lexical category from the queue) are both dominated by the conjunctive node parent p of c_{s_0} in Φ_G.[4] A REDUCE action (REDUCE, c) is valid if c matches the category of the conjunctive node parent of c_{s_0} and c_{s_1} in Φ_G. A UNARY action (UNARY, c) is valid if c matches the conjunctive node parent of c_{s_0} in Φ_G. We now generalize the case where Φ_G contains a single correct parse to the case of an oracle forest, where each parent p is replaced by a set of conjunctive nodes in Φ_G.

Definition 4. The **left parent set** $p_L(c)$ of conjunctive node $c \in \Phi_G$ is the set of all parent conjunctive nodes of c in Φ_G, which have the disjunctive node d containing c (i.e. $c \in \gamma(d)$) as a left child.

Definition 5. The **ancestor set** $\mathcal{A}(c)$ of conjunctive node $c \in \Phi_G$ is the set of all reachable ancestor conjunctive nodes of c in Φ_G.

Definition 6. Given an item $\langle s, q\rangle$, if $|s| = 1$ we say s is a **frontier stack**.

[4] Strictly speaking, the conjunctive node parent is a parent of the disjunctive node containing the conjunctive node c_{s_0}. We will continue to use this shorthand for parents of conjunctive nodes throughout the paper.

Algorithm 2 The Dependency Oracle Function f_d

Input: Φ_G, an item $\langle s, q\rangle$ s.t. $s \sim G$, $(x, c) \in \mathcal{X}_{\langle s,q\rangle}$
Let s' be the stack of $\langle s', q'\rangle = \langle s, q\rangle \circ (x, c)$

function MAIN($\langle s, q\rangle$, (x, c), Φ_G)
  if x is SHIFT **then**
    if $c \not\equiv c_{lex_0}$ **then** ▷ c not gold lexical category
      return false
    else if $c \equiv c_{lex_0}$ and $|s| = 0$ **then** ▷ the initial item
      return true
    else if $c \equiv c_{lex_0}$ and $|s| \neq 0$ **then**
      compute $\mathcal{R}(c_{s'_1}, \mathbf{c}_{s'_0})$
      return $\mathcal{R}(c_{s'_1}, \mathbf{c}_{s'_0}) \neq \emptyset$

  if x is REDUCE **then** ▷ s is non-frontier
    if $c \in \mathcal{R}(c_{s_1}, \mathbf{c}_{s_0})$ **then**
      compute $\mathcal{R}(c_{s'_1}, \mathbf{c}_{s'_0})$
      return true
    else return false

  if x is UNARY **then**
    if $|s| = 1$ **then** ▷ s is frontier
      return $c \in \Phi_G$
    if $|s| \neq 1$ **and** $c \in \Phi_G$ **then** ▷ s is non-frontier
      compute $\mathcal{R}(c_{s'_1}, \mathbf{c}_{s'_0})$
      return $\mathcal{R}(c_{s'_1}, \mathbf{c}_{s'_0}) \neq \emptyset$

A key to defining the dependency oracle function is the notion of a **shared ancestor set**. Intuitively, shared ancestor sets are built up through shift actions, and contain sets of nodes which can potentially become the results of reduce or unary actions. A further intuition is that shared ancestor sets define the space of possible correct derivations, and nodes in these sets are "ticked off" when reduce and unary actions are applied, as a single correct derivation is built through the shift-reduce process (corresponding to a bottom-up post-order traversal of the derivation). The following definition shows how the dependency oracle function builds shared ancestor sets for each action type.

Definition 7. Let $\langle s, q\rangle$ be an item and let $\langle s', q'\rangle = \langle s, q\rangle \circ (x, c)$. We define the **shared ancestor set** $\mathcal{R}(c_{s'_1}, \mathbf{c}_{s'_0})$ of $\mathbf{c}_{s'_0}$, after applying action (x, c), as:

- $\{c' \mid c' \in p_L(c_{s_0}) \cap \mathcal{A}(c)\}$, if s is frontier and $x =$ SHIFT
- $\{c' \mid c' \in p_L(c_{s_0}) \cap \mathcal{A}(c)$ and there is some $c'' \in \mathcal{R}(c_{s_1}, \mathbf{c}_{s_0})$ s.t. $c'' \in \mathcal{A}(c')\}$, if s is non-frontier and $x =$ SHIFT
- $\{c' \mid c' \in \mathcal{R}(c_{s_2}, \mathbf{c}_{s_1}) \cap \mathcal{A}(c)\}$, if $x =$ REDUCE
- $\{c' \mid c' \in \mathcal{R}(c_{s_1}, \mathbf{c}_{s_0}) \cap \mathcal{A}(c)\}$, if s is non-frontier and $x =$ UNARY
- $\mathcal{R}(\epsilon, \mathbf{c}^0_{s_0}) = \emptyset$ where $\mathbf{c}^0_{s_0}$ is the conjunctive node corresponding to the gold-standard lexical category of the first word in the sentence (ϵ is a dummy symbol indicating the bottom of stack).

The base case for Definition 7 is when the gold-standard lexical category of the first word in the sentence has been shifted, which creates an empty shared ancestor set. Furthermore, the shared ancestor set is always empty when the stack is a frontier stack.

The dependency oracle algorithm checks the validity of applicable actions. A SHIFT action is valid if $\mathcal{R}(c_{s'_1}, \mathbf{c}_{s'_0}) \neq \emptyset$ for the resulting stack s'. A valid REDUCE action consumes s_1 and s_0. For the new node, its shared ancestor set is the subset of the conjunctive nodes in $\mathcal{R}(c_{s_2}, \mathbf{c}_{s_1})$ which dominate the resulting conjunctive node of a valid REDUCE action. The UNARY case for a frontier stack is trivial: any UNARY action applicable to s in Φ_G is valid. For a non-frontier stack, the UNARY case is similar to REDUCE except the resulting shared ancestor set is a subset of $\mathcal{R}(c_{s_1}, \mathbf{c}_{s_0})$.

We now turn to the problem of finding the shared ancestor sets. In practice, we do not do this by traversing Φ_G top-down from the conjunctive nodes in $p_L(c_{s_0})$ on-the-fly to find each member of $\mathcal{R}$. Instead, when we build Φ_G in bottom-up topological order, we pre-compute the set of reachable disjunctive nodes of each conjunctive node c in Φ_G as:

$$\mathcal{D}(c) = \delta(c) \cup (\cup_{c' \in \gamma(d), d \in \delta(c)}(\mathcal{D}(c')))$$

Each $\mathcal{D}$ is implemented as a hash map, which allows us to test the membership of one potential conjunctive node in $\mathcal{O}(1)$ time. For example, a conjunctive node $c \in p_L(c_{s_0})$ is reachable from c_{lex_0} if there is a *disjunctive node* $d \in \mathcal{D}(c)$ s.t. $c_{lex_0} \in \gamma(d)$. With this implementation, the complexity of checking each valid SHIFT action is then $\mathcal{O}(|p_L(c_{s_0})|)$.

3.3 Training

We use the averaged perceptron (Collins, 2002) to train a global linear model and score each action. The normal-form model of Zhang and Clark (2011) uses an early update mechanism (Collins and Roark, 2004), where decoding is stopped to update model weights whenever the single gold action falls outside the beam. In our parser, there can be multiple gold items in a beam. One option would be to apply early update whenever at least

Algorithm 3 Dependency Model Training

Input: (y, G) and beam size k
1: $\mathbf{w} \leftarrow \mathbf{0}$; $\mathcal{B}_0 \leftarrow \emptyset$; $i \leftarrow 0$
2: $\mathcal{B}_0$.push($\langle s, q \rangle_0$) ▷ the initial item
3: $cand \leftarrow \emptyset$ ▷ candidate output priority queue
4: $gold \leftarrow \emptyset$ ▷ gold output priority queue
5: **while** $\mathcal{B}_i \neq \emptyset$ **do**
6: **for each** $\langle s, q \rangle \in \mathcal{B}_i$ **do**
7: **if** $|q| = 0$ **then** ▷ candidate output
8: $cand$.push($\langle s, q \rangle$)
9: **if** $s \simeq G$ **then** ▷ s is a realization of G
10: $gold$.push($\langle s, q \rangle$)
11: expand $\langle s, q \rangle$ into $\mathcal{B}_{i+1}$
12: $\mathcal{B}_{i+1} \leftarrow \mathcal{B}_{i+1}[1:k]$ ▷ apply beam
13: **if** $\Pi_G \neq \emptyset, \Pi_G \cap \mathcal{B}_{i+1} = \emptyset$ **and** $cand[0] \not\simeq G$ **then**
14: $\mathbf{w} \leftarrow \mathbf{w} + \phi(\Pi_G[0]) - \phi(\mathcal{B}_{i+1}[0])$ ▷ early update
15: **return**
16: $i \leftarrow i + 1$ ▷ continue to next step
17: **if** $cand[0] \not\simeq G$ **then** ▷ final update
18: $\mathbf{w} \leftarrow \mathbf{w} + \phi(gold[0]) - \phi(cand[0])$

one of these gold items falls outside the beam. However, this may not be a true violation of the gold-standard (Huang et al., 2012). Thus, we use a relaxed version of early update, in which *all* gold-standard actions must fall outside the beam before an update is performed. This update mechanism is provably correct under the violation-fixing framework of Huang et al. (2012).

Let (y, G) be a training sentence paired with its gold-standard dependency structure and let $\Pi_{\langle s,q \rangle}$ be the following set for an item $\langle s, q \rangle$:

$$\{\langle s, q \rangle \circ (x, c) \mid f_d(\langle s, q \rangle, (x, c), \Phi_G) = true\}$$

$\Pi_{\langle s,q \rangle}$ contains all *correct* items at step $i + 1$ obtained by expanding $\langle s, q \rangle$. Let the set of *all* correct items at a step $i + 1$ be:[5]

$$\Pi_G = \bigcup_{\langle s,q \rangle \in \mathcal{B}_i} \Pi_{\langle s,q \rangle}$$

Algorithm 3 shows the pseudocode for training the dependency model with early update for one input (y, G). The score of an item $\langle s, q \rangle$ is calculated as $\mathbf{w} \cdot \phi(\langle s, q \rangle)$ with respect to the current model $\mathbf{w}$, where $\phi(\langle s, q \rangle)$ is the feature vector for the item. At step i, all items are expanded and added onto the next beam $\mathcal{B}_{i+1}$, and the top-k retained. Early update is applied when all gold items first fall outside the beam, and any candidate output is incorrect (line 14). Since there are potentially many gold items, and one gold item is required for the perceptron update, a decision needs to be made regarding which gold item to update against. We choose to reward the highest scoring gold item, in line with the violation-fixing framework; and penalize the highest scoring incorrect item, using the standard perceptron update. A final update is performed if no more expansions are possible but the final output is incorrect.

[5] In Algorithm 3 we abuse notation by using $\Pi_G[0]$ to denote the highest scoring gold item in the set.

4 Experiments

We implement our shift-reduce parser on top of the core C&C code base (Clark and Curran, 2007) and evaluate it against the shift-reduce parser of Zhang and Clark (2011) (henceforth Z&C) and the chart-based normal-form and hybrid models of Clark and Curran (2007). For all experiments, we use CCGBank with the standard split: sections 2-21 for training (39,604 sentences), section 00 for development (1,913 sentences) and section 23 (2,407 sentences) for testing.

The way that the CCG grammar is implemented in C&C has some implications for our parser. First, unlike Z&C, which uses a context-free cover (Fowler and Penn, 2010) and hence is able to use all sentences in the training data, we are only able to use 36,036 sentences. The reason is that the grammar in C&C does not have complete coverage of CCGBank, due to the fact that e.g. not all rules in CCGBank conform to the combinatory rules of CCG. Second, our parser uses the unification mechanism from C&C to output dependencies directly, and hence does not need a separate post-processing step to convert derivations into CCG dependencies, as required by Z&C.

The feature templates of our model consist of all of those in Z&C, except the ones which require lexical heads to come from either the left or right child, as such features are incompatible with the head passing mechanism used by C&C. Each Z&C template is defined over a parse item, and captures various aspects of the stack and queue context. For example, one template returns the top category on the stack plus its head word, together with the first word and its POS tag on the queue. Another template returns the second category on the stack, together with the POS tag of its head word. Every Z&C feature is defined as a pair, consisting of an instantiated context template and a parse action. In addition, we use all the CCG predicate-argument dependency features from Clark and Curran (2007), which contribute to the score of a REDUCE action when dependencies

are realized. Detailed descriptions of all the templates in our model can be found in the respective papers. We run 20 training iterations and the resulting model contains 16.5M features with a non-zero weight.

We use 10-fold cross validation for POS tagging and supertagging the training data, and automatically assigned POS tags for all experiments. A probability cut-off value of 0.0001 for the β parameter in the supertagger is used for both training and testing. The β parameter determines how many lexical categories are assigned to each word; $\beta = 0.0001$ is a relatively small value which allows in a large number of categories, compared to the default value used in Clark and Curran (2007). For training only, if the gold-standard lexical category is not supplied by the supertagger for a particular word, it is added to the list of categories.

4.1 Results and Analysis

The beam size was tuned on the development set, and a value of 128 was found to achieve a reasonable balance of accuracy and speed; hence this value was used for all experiments. Since C&C always enforces non-fragmentary output (i.e. it can only produce spanning analyses), it fails on some sentences in the development and test sets, and thus we also evaluate on the reduced sets, following Clark and Curran (2007). Our parser does not fail on any sentences because it permits fragmentary output (those cases where there is more than one subtree left on the final stack). The results for Z&C, and the C&C normal-form and hybrid models, are taken from Zhang and Clark (2011).

Table 1 shows the accuracies of all parsers on the development set, in terms of labeled precision and recall over the predicate-argument dependencies in CCGBank. On both the full and reduced sets, our parser achieves the highest F-score. In comparison with C&C, our parser shows significant increases across all metrics, with 0.57% and 1.06% absolute F-score improvements over the hybrid and normal-form models, respectively. Another major improvement over the other two parsers is in sentence level accuracy, LSent, which measures the number of sentences for which the dependency structure is completely correct.

Table 1 also shows that our parser has improved recall over Z&C at some expense of precision. To probe this further we compare labeled precision and recall relative to dependency length, as measured by the distance between the two words in a dependency, grouped into bins of 5 values. Fig. 4 shows clearly that Z&C favors precision over recall, giving higher precision scores for almost all dependency lengths compared to our parser. In

Table 3: Accuracy comparison on section 23 (auto POS).

terms of recall (Fig. 4b), our parser outperforms Z&C over all dependency lengths, especially for longer dependencies ($x \geq 20$). When compared with C&C, the recall of the Z&C parser drops quickly for dependency lengths over 10. While our parser also suffers from this problem, it is less severe and is able to achieve higher recall at $x \geq 30$.

Table 2 compares our parser with Z&C and the C&C hybrid model, for the most frequent dependency relations. While our parser achieved lower precision than Z&C, it is more balanced and gives higher recall for all of the dependency relations except the last one, and higher F-score for over half of them.

Table 3 presents the final test results on Section 23. Again, our parser achieves the highest scores across all metrics (for both the full and reduced test sets), except for precision and lexical category assignment, where Z&C performed better.

5 Conclusion

We have presented a dependency model for a shift-reduce CCG parser, which fully aligns CCG parsing with the left-to-right, incremental nature of a shift-reduce parser. Our work is in part inspired by the dependency models of Clark and Curran (2007) and, in the use of a dependency oracle, is close in spirit to that of Goldberg and Nivre (2012). The difference is that the Goldberg and Nivre parser builds, and scores, dependency structures directly, whereas our parser uses a unification mechanism to create dependencies, and scores the CCG derivations, allowing great flexibility in terms of what dependencies can be realized. Another related work is Yu et al. (2013), which introduced a similar technique to deal with spurious ambiguity in MT. Finally, there may be potential to integrate the techniques of Auli and Lopez (2011), which currently represents the state-of-the-art in CCGBank parsing, into our parser.

Less Grammar, More Features

Abstract

We present a parser that relies primarily on extracting information directly from surface spans rather than on propagating information through enriched grammar structure. For example, instead of creating separate grammar symbols to mark the definiteness of an NP, our parser might instead capture the same information from the first word of the NP. Moving context out of the grammar and onto surface features can greatly simplify the structural component of the parser: because so many deep syntactic cues have surface reflexes, our system can still parse accurately with context-free backbones as minimal as X-bar grammars. Keeping the structural backbone simple and moving features to the surface also allows easy adaptation to new languages and even to new tasks. On the SPMRL 2013 multilingual constituency parsing shared task (Seddah et al., 2013), our system outperforms the top single parser system of Björkelund et al. (2013) on a range of languages. In addition, despite being designed for syntactic analysis, our system also achieves state-of-the-art numbers on the structural sentiment task of Socher et al. (2013). Finally, we show that, in both syntactic parsing and sentiment analysis, many broad linguistic trends can be captured via surface features.

1 Introduction

Naïve context-free grammars, such as those embodied by standard treebank annotations, do not parse well because their symbols have too little context to constrain their syntactic behavior. For example, *to* PPs usually attach to verbs and *of* PPs usually attach to nouns, but a context-free PP symbol can equally well attach to either. Much of the last few decades of parsing research has therefore focused on propagating contextual information from the leaves of the tree to internal nodes. For example, head lexicalization (Eisner, 1996; Collins, 1997; Charniak, 1997), structural annotation (Johnson, 1998; Klein and Manning, 2003), and state-splitting (Matsuzaki et al., 2005; Petrov et al., 2006) are all designed to take coarse symbols like PP and decorate them with additional context. The underlying reason that such propagation is even needed is that PCFG parsers score trees based on local configurations only, and any information that is not threaded through the tree becomes inaccessible to the scoring function. There have been non-local approaches as well, such as tree-substitution parsers (Bod, 1993; Sima'an, 2000), neural net parsers (Henderson, 2003), and rerankers (Collins and Koo, 2005; Charniak and Johnson, 2005; Huang, 2008). These non-local approaches can actually go even further in enriching the grammar's structural complexity by coupling larger domains in various ways, though their non-locality generally complicates inference.

In this work, we instead try to *minimize* the structural complexity of the grammar by moving as much context as possible onto local surface features. We examine the position that grammars should not propagate any information that is available from surface strings, since a discriminative parser can access that information directly. We therefore begin with a minimal grammar and iteratively augment it with rich input features that do not enrich the context-free backbone. Previous work has also used surface features in their parsers, but the focus has been on machine learning methods (Taskar et al., 2004), latent annotations (Petrov and Klein, 2008a; Petrov and Klein, 2008b), or implementation (Finkel et al., 2008).

By contrast, we investigate the extent to which

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 228–237,
Baltimore, Maryland, USA, June 23-25 2014.

we need a grammar at all. As a thought experiment, consider a parser with no grammar, which functions by independently classifying each span (i, j) of a sentence as an NP, VP, and so on, or *null* if that span is a non-constituent. For example, spans that begin with *the* might tend to be NPs, while spans that end with *of* might tend to be non-constituents. An independent classification approach is actually very viable for part-of-speech tagging (Toutanova et al., 2003), but is problematic for parsing – if nothing else, parsing comes with a structural requirement that the output be a well-formed, nested tree. Our parser uses a minimal PCFG backbone grammar to ensure a basic level of structural well-formedness, but relies mostly on features of surface spans to drive accuracy. Formally, our model is a CRF where the features factor over anchored rules of a small backbone grammar, as shown in Figure 1.

Some aspects of the parsing problem, such as the tree constraint, are clearly best captured by a PCFG. Others, such as heaviness effects, are naturally captured using surface information. The open question is whether surface features are adequate for key effects like subcategorization, which have deep definitions but regular surface reflexes (e.g. the preposition selected by a verb will often linearly follow it). Empirically, the answer seems to be yes, and our system produces strong results, e.g. up to 90.5 F1 on English parsing. Our parser is also able to generalize well across languages with little tuning: it achieves state-of-the-art results on multilingual parsing, scoring higher than the best single-parser system from the SPMRL 2013 Shared Task on a range of languages, as well as on the competition's average F1 metric.

One advantage of a system that relies on surface features and a simple grammar is that it is portable not only across languages but also across tasks to an extent. For example, Socher et al. (2013) demonstrates that sentiment analysis, which is usually approached as a flat classification task, can be viewed as tree-structured. In their work, they propagate real-valued vectors up a tree using neural tensor nets and see gains from their recursive approach. Our parser can be easily adapted to this task by replacing the X-bar grammar over treebank symbols with a grammar over the sentiment values to encode the output variables and then adding n-gram indicators to our feature set to capture the bulk of the lexical effects. When applied to this task, our system generally matches their accuracy overall and is able to outperform it on the overall sentence-level subtask.

2 Parsing Model

In order to exploit non-independent surface features of the input, we use a discriminative formulation. Our model is a conditional random field (Lafferty et al., 2001) over trees, in the same vein as Finkel et al. (2008) and Petrov and Klein (2008a). Formally, we define the probability of a tree T conditioned on a sentence $\mathbf{w}$ as

$$p(T|\mathbf{w}) \propto \exp\left(\theta^\intercal \sum_{r \in T} f(r, \mathbf{w})\right) \qquad (1)$$

where the feature domains r range over the (anchored) rules used in the tree. An anchored rule r is the conjunction of an unanchored grammar rule $\mathrm{rule}(r)$ and the start, stop, and split indexes where that rule is anchored, which we refer to as $\mathrm{span}(r)$. It is important to note that the richness of the backbone grammar is reflected in the structure of the trees T, while the features that condition directly on the input enter the equation through the anchoring $\mathrm{span}(r)$. To optimize model parameters, we use the Adagrad algorithm of Duchi et al. (2010) with L2 regularization.

We start with a simple X-bar grammar whose only symbols are NP, NP-bar, VP, and so on. Our base model has no surface features: formally, on each anchored rule r we have only an indicator of the (unanchored) rule identity, $\mathrm{rule}(r)$. Because the X-bar grammar is so minimal, this grammar does not parse very accurately, scoring just 73 F1 on the standard English Penn Treebank task.

In past work that has used tree-structured CRFs in this way, increased accuracy partially came from decorating trees T with additional annotations, giving a tree T' over a more complex symbol set. These annotations introduce additional context into the model, usually capturing linguistic intuition about the factors that influence grammaticality. For instance, we might annotate every constituent X in the tree with its parent Y, giving a tree with symbols $X[\hat{}Y]$. Finkel et al. (2008) used parent annotation, head tag annotation, and horizontal sibling annotation together in a single large grammar. In Petrov and Klein (2008a) and Petrov and Klein (2008b), these annotations were latent; they were inferred automatically during training.

Hall and Klein (2012) employed both kinds of annotations, along with lexicalized head word annotation. All of these past CRF parsers do also exploit span features, as did the structured margin parser of Taskar et al. (2004); the current work primarily differs in shifting the work from the grammar to the surface features.

The problem with rich annotations is that they increase the state space of the grammar substantially. For example, adding parent annotation can square the number of symbols, and each subsequent annotation causes a multiplicative increase in the size of the state space. Hall and Klein (2012) attempted to reduce this state space by factoring these annotations into individual components. Their approach changed the multiplicative penalty of annotation into an additive penalty, but even so their individual grammar projections are much larger than the base X-bar grammar.

In this work, we want to see how much of the expressive capability of annotations can be captured using surface evidence, with little or no annotation of the underlying grammar. To that end, we avoid annotating our trees at all, opting instead to see how far simple surface features will go in achieving a high-performance parser. We will return to the question of annotation in Section 5.

3 Surface Feature Framework

To improve the performance of our X-bar grammar, we will add a number of surface feature templates derived only from the words in the sentence. We say that an indicator is a surface property if it can be extracted without reference to the parse tree. These features can be implemented without reference to structured linguistic notions like headedness; however, we will argue that they still capture a wide range of linguistic phenomena in a data-driven way.

Throughout this and the following section, we will draw on motivating examples from the English Penn Treebank, though similar examples could be equally argued for other languages. For performance on other languages, see Section 6.

Recall that our CRF factors over anchored rules r, where each r has identity $\text{rule}(r)$ and anchoring $\text{span}(r)$. The X-bar grammar has only indicators of $\text{rule}(r)$, ignoring the anchoring. Let a *surface property* of r be an indicator function of $\text{span}(r)$ and the sentence itself. For example, the first word in a constituent is a surface property, as

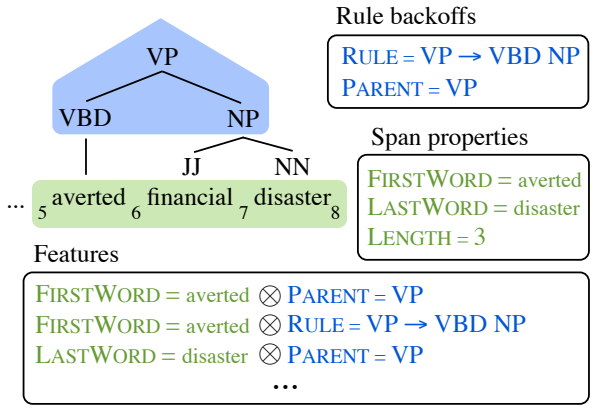

Figure 1: Features computed over the application of the rule VP → VBD NP over the anchored span *averted financial disaster* with the shown indices. Span properties are generated as described throughout Section 4; they are then conjoined with the rule and just the parent nonterminal to give the features fired over the anchored production.

is the word directly preceding the constituent. As illustrated in Figure 1, the actual features of the model are obtained by conjoining surface properties with various abstractions of the rule identity. For rule abstractions, we use two templates: the parent of the rule and the identity of the rule. The surface features are somewhat more involved, and so we introduce them incrementally.

One immediate computational and statistical issue arises from the sheer number of possible surface features. There are a great number of spans in a typical treebank; extracting features for every possible combination of span and rule is prohibitive. One simple solution is to only extract features for rule/span pairs that are actually observed in gold annotated examples during training. Because these "positive" features correspond to observed constituents, they are far less numerous than the set of all possible features extracted from all spans. As far as we can tell, all past CRF parsers have used "positive" features only.

However, negative features—features that are not observed in any tree—are still powerful indicators of (un)grammaticality: if we have never seen a PRN that starts with "has," or a span that begins with a quotation mark and ends with a close bracket, then we would like the model to be able to place negative weights on these features. Thus, we use a simple feature hashing scheme where positive features are indexed individually, while nega-

Features	Section	F1
RULE	4	73.0
+ SPAN FIRST WORD + SPAN LAST WORD + LENGTH	4.1	85.0
+ WORD BEFORE SPAN + WORD AFTER SPAN	4.2	89.0
+ WORD BEFORE SPLIT + WORD AFTER SPLIT	4.3	89.7
+ SPAN SHAPE	4.4	89.9

Table 1: Results for the Penn Treebank development set, reported in F1 on sentences of length ≤ 40 on Section 22, for a number of incrementally growing feature sets. We show that each feature type presented in Section 4 adds benefit over the previous, and in combination they produce a reasonably good yet simple parser.

tive features are bucketed together. During training there are no collisions between positive features, which generally receive positive weight, and negative features, which generally receive negative weight; only negative features can collide. Early experiments indicated that using a number of negative buckets equal to the number of positive features was effective.

4 Features

Our goal is to use surface features to replicate the functionality of other annotations, without increasing the state space of our grammar, meaning that the rules $\mathrm{rule}(r)$ remain simple, as does the state space used during inference.

Before we present our main features, we briefly discuss the issue of feature sparsity. While lexical features are a powerful driver of our parser, firing features on rare words would allow it to overfit the training data quite heavily. To that end, for the purposes of computing our features, a word is represented by its longest suffix that occurs 100 or more times in the training data (which will be the entire word, for common words).[1]

Table 1 shows the results of incrementally building up our feature set on the Penn Treebank development set. RULE specifies that we use only indicators on rule identity for binary production and nonterminal unaries. For this experiment and all others, we include a basic set of lexicon features, i.e. features on preterminal part-of-speech tags. A given preterminal unary at position i in the sentence includes features on the words (suffixes) at position $i-1$, i, and $i+1$. Because the lexicon is especially sensitive to morphological effects, we also fire features on all prefixes and suffixes of the current word up to length 5, regardless of frequency.

Subsequent lines in Table 1 indicate additional surface feature templates computed over the span, which are then conjoined with the rule identity as shown in Figure 1 to give additional features. In the rest of the section, we describe the features of this type that we use. Note that many of these features have been used before (Taskar et al., 2004; Finkel et al., 2008; Petrov and Klein, 2008b); our goal here is not to amass as many feature templates as possible, but rather to examine the extent to which a simple set of features can replace a complicated state space.

4.1 Basic Span Features

We start with some of the most obvious properties available to us, namely, the identity of the first and last words of a span. Because heads of constituents are often at the beginning or the end of a span, these feature templates can (noisily) capture monolexical properties of heads without having to incur the inferential cost of lexicalized annotations. For example, in English, the syntactic head of a verb phrase is typically at the beginning of the span, while the head of a simple noun phrase is the last word. Other languages, like Korean or Japanese, are more consistently head final.

Structural contexts like those captured by parent annotation (Johnson, 1998) are more subtle. Parent annotation can capture, for instance, the difference in distribution in NPs that have S as a parent (that is, subjects) and NPs under VPs (objects). We try to capture some of this same intuition by introducing a feature on the length of a span. For instance, VPs embedded in NPs tend to be short, usually as embedded gerund phrases. Because constituents in the treebank can be quite long, we bin our length features into 8 buckets, of

[1] Experiments with the Brown clusters (Brown et al., 1992) provided by Turian et al. (2010) in lieu of suffixes were not promising. Moreover, lowering this threshold did not improve performance.

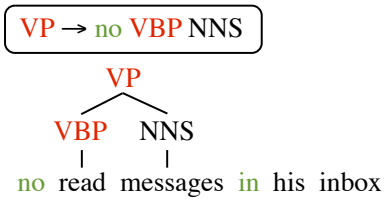

Figure 2: An example showing the utility of span context. The ambiguity about whether *read* is an adjective or a verb is resolved when we construct a VP and notice that the word proceeding it is unlikely.

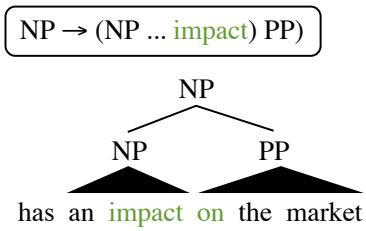

Figure 3: An example showing split point features disambiguating a PP attachment. Because *impact* is likely to take a PP, the monolexical indicator feature that conjoins *impact* with the appropriate rule will help us parse this example correctly.

lengths 1, 2, 3, 4, 5, 10, 20, and ≥21 words.

Adding these simple features (first word, last word, and lengths) as span features of the X-bar grammar already gives us a substantial improvement over our baseline system, improving the parser's performance from 73.0 F1 to 85.0 F1 (see Table 1).

4.2 Span Context Features

Of course, there is no reason why we should confine ourselves to just the words within the span: words outside the span also provide a rich source of context. As an example, consider disambiguating the POS tag of the word *read* in Figure 2. A VP is most frequently preceded by a subject NP, whose rightmost word is often its head. Therefore, we fire features that (separately) look at the words immediately preceding and immediately following the span.

4.3 Split Point Features

Another important source of features are the words at and around the split point of a binary rule application. Figure 3 shows an example of one instance of this feature template. *impact* is a noun that is more likely to take a PP than other nouns, and so we expect this feature to have high weight and encourage the attachment; this feature proves generally useful in resolving such cases of right-attachments to noun phrases, since the last word of the noun phrase is often the head. As another example, coordination can be represented by an indicator of the conjunction, which comes immediately after the split point. Finally, control structures with infinitival complements can be captured with a rule S → NP VP with the word "to" at the split point.

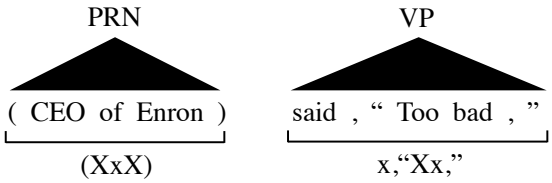

Figure 4: Computation of span shape features on two examples. Parentheticals, quotes, and other punctuation-heavy, short constituents benefit from being explicitly modeled by a descriptor like this.

4.4 Span Shape Features

We add one final feature characterizing the span, which we call span shape. Figure 4 shows how this feature is computed. For each word in the span,[2] we indicate whether that word begins with a capital letter, lowercase letter, digit, or punctuation mark. If it begins with punctuation, we indicate the punctuation mark explicitly. Figure 4 shows that this is especially useful in characterizing constructions such as parentheticals and quoted expressions. Because this feature indicates capitalization, it can also capture properties of NP internal structure relevant to named entities, and its sensitivity to capitalization and punctuation makes it useful for recognizing appositive constructions.

5 Annotations

We have built up a strong set of features by this point, but have not yet answered the question of whether or not grammar annotation is useful on top of them. In this section, we examine two of the most commonly used types of additional annotation, structural annotation, and lexical annotation.

[2]For longer spans, we only use words sufficiently close to the span's beginning and end.

Annotation	Dev, len ≤ 40
$v = 0, h = 0$	90.1
$v = 1, h = 0$	90.5
$v = 0, h = 1$	90.2
$v = 1, h = 1$	90.9
Lexicalized	90.3

Table 2: Results for the Penn Treebank development set, sentences of length ≤ 40, for different annotation schemes implemented on top of the X-bar grammar.

Recall from Section 3 that every span feature is conjoined with indicators over rules and rule parents to produce features over anchored rule productions; when we consider adding an annotation layer to the grammar, what that does is refine the rule indicators that are conjoined with every span feature. While this is a powerful way of refining features, we show that common successful annotation schemes provide at best modest benefit on top of the base parser.

5.1 Structural Annotation

The most basic, well-understood kind of annotation on top of an X-bar grammar is structural annotation, which annotates each nonterminal with properties of its environment (Johnson, 1998; Klein and Manning, 2003). This includes vertical annotation (parent, grandparent, etc.) as well as horizontal annotation (only partially Markovizing rules as opposed to using an X-bar grammar).

Table 2 shows the performance of our feature set in grammars with several different levels of structural annotation.[3] Klein and Manning (2003) find large gains (6% absolute improvement, 20% relative improvement) going from $v = 0, h = 0$ to $v = 1, h = 1$; however, we do not find the same level of benefit. To the extent that our parser needs to make use of extra information in order to apply a rule correctly, simply inspecting the input to determine this information appears to be almost as effective as relying on information threaded through the parser.

In Section 6 and Section 7, we use $v = 1$ and $h = 0$; we find that $v = 1$ provides a small, reliable improvement across a range of languages and tasks, whereas other annotations are less clearly beneficial.

[3]We use $v = 0$ to indicate no annotation, diverging from the notation in Klein and Manning (2003).

	Test ≤ 40	Test all
Berkeley	90.6	90.1
This work	89.9	89.2

Table 3: Final Parseval results for the $v = 1, h = 0$ parser on Section 23 of the Penn Treebank.

5.2 Lexical Annotation

Another commonly-used kind of structural annotation is lexicalization (Eisner, 1996; Collins, 1997; Charniak, 1997). By annotating grammar nonterminals with their headwords, the idea is to better model phenomena that depend heavily on the semantics of the words involved, such as coordination and PP attachment.

Table 2 shows results from lexicalizing the X-bar grammar; it provides meager improvements. One probable reason for this is that our parser already includes monolexical features that inspect the first and last words of each span, which captures the syntactic or the semantic head in many cases or can otherwise provide information about what the constituent's type may be and how it is likely to combine. Lexicalization allows us to capture bilexical relationships along dependency arcs, but it has been previously shown that these add only marginal benefit to Collins's model anyway (Gildea, 2001).

5.3 English Evaluation

Finally, Table 3 shows our final evaluation on Section 23 of the Penn Treebank. We use the $v = 1, h = 0$ grammar. While we do not do as well as the Berkeley parser, we will see in Section 6 that our parser does a substantially better job of generalizing to other languages.

6 Other Languages

Historically, many annotation schemes for parsers have required language-specific engineering: for example, lexicalized parsers require a set of head rules and manually-annotated grammars require detailed analysis of the treebank itself (Klein and Manning, 2003). A key strength of a parser that does not rely heavily on an annotated grammar is that it may be more portable to other languages. We show that this is indeed the case: on nine languages, our system is competitive with or better than the Berkeley parser, which is the best single

	Arabic	Basque	French	German	Hebrew	Hungarian	Korean	Polish	Swedish	Avg

Table 4: Results for the nine treebanks in the SPMRL 2013 Shared Task; all values are F-scores for sentences of all lengths using the version of `evalb` distributed with the shared task. Berkeley-Rep is the best single parser from (Björkelund et al., 2013); we only compare to this parser on the development set because neither the system nor test set values are publicly available. Berkeley-Tags is a version of the Berkeley parser run by the task organizers where tags are provided to the model, and is the best single parser submitted to the official task. In both cases, we match or outperform the baseline parsers in aggregate and on the majority of individual languages.

parser[4] for the majority of cases we consider.

We evaluate on the constituency treebanks from the Statistical Parsing of Morphologically Rich Languages Shared Task (Seddah et al., 2013). We compare to the Berkeley parser (Petrov and Klein, 2007) as well as two variants. First, we use the "Replaced" system of Björkelund et al. (2013) (Berkeley-Rep), which is their best single parser.[5] The "Replaced" system modifies the Berkeley parser by replacing rare words with morphological descriptors of those words computed using language-specific modules, which have been hand-crafted for individual languages or are trained with additional annotation layers in the treebanks that we do not exploit. Unfortunately, Björkelund et al. (2013) only report results on the development set for the Berkeley-Rep model; however, the task organizers also use a version of the Berkeley parser provided with parts of speech from high-quality POS taggers for each language (Berkeley-Tags). These part-of-speech taggers often incorporate substantial knowledge of each language's morphology. Both Berkeley-Rep and Berkeley-Tags make up for some shortcomings of the Berkeley parser's unknown word model, which is tuned to English.

In Table 4, we see that our performance is overall substantially higher than that of the Berkeley parser. On the development set, we outperform the Berkeley parser and match the performance of the Berkeley-Rep parser. On the test set, we outperform both the Berkeley parser and the Berkeley-Tags parser on seven of nine languages, losing only on Arabic and French.

These results suggest that the Berkeley parser may be heavily fit to English, particularly in its lexicon. However, even when language-specific unknown word handling is added to the parser, our model still outperforms the Berkeley parser overall, showing that our model generalizes even better across languages than a parser for which this is touted as a strength (Petrov and Klein, 2007). Our span features appear to work well on both head-initial and head-final languages (see Basque and Korean in the table), and the fact that our parser performs well on such morphologically-rich languages as Hungarian indicates that our suffix model is sufficient to capture most of the morphological effects relevant to parsing. Of course, a language that was heavily prefixing would likely require this feature to be modified. Likewise, our parser does not perform as well on Arabic and Hebrew. These closely related languages use templatic morphology, for which suffixing is not appropriate; however, using additional surface features based on the output of a morphological analyzer did not lead to increased performance.

Finally, our high performance on languages such as Polish and Swedish, whose training treebanks consist of 6578 and 5000 sentences, respectively, show that our feature-rich model performs robustly even on treebanks much smaller than the Penn Treebank.[6]

[4] I.e. it does not use a reranking step or post-hoc combination of parser results.

[5] Their best parser, and the best overall parser from the shared task, is a reranked product of "Replaced" Berkeley parsers.

[6] The especially strong performance on Polish relative to other systems is partially a result of our model being able to produce unary chains of length two, which occur frequently in the Polish treebank (Björkelund et al., 2013).

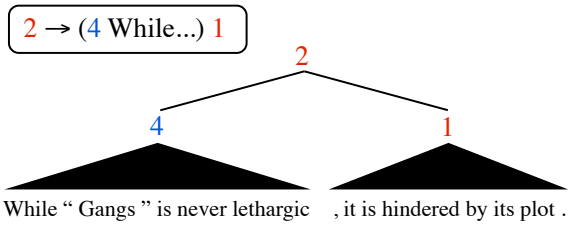

Figure 5: An example of a sentence from the Stanford Sentiment Treebank which shows the utility of our span features for this task. The presence of "While" under this kind of rule tells us that the sentiment of the constituent to the right dominates the sentiment to the left.

7 Sentiment Analysis

Finally, because the system is, at its core, a classifier of spans, it can be used equally well for tasks that do not normally use parsing algorithms. One example is sentiment analysis. While approaches to sentiment analysis often simply classify the sentence monolithically, treating it as a bag of n-grams (Pang et al., 2002; Pang and Lee, 2005; Wang and Manning, 2012), the recent dataset of Socher et al. (2013) imposes a layer of structure on the problem that we can exploit. They annotate every constituent in a number of training trees with an integer sentiment value from 1 (very negative) to 5 (very positive), opening the door for models such as ours to learn how syntax can structurally affect sentiment.[7]

Figure 5 shows an example that requires some analysis of sentence structure to correctly understand. The first constituent conveys positive sentiment with *never lethargic* and the second conveys negative sentiment with *hindered*, but to determine the overall sentiment of the sentence, we need to exploit the fact that *while* signals a discounting of the information that follows it. The grammar rule $2 \rightarrow 4\ 1$ already encodes the notion of the sentiment of the right child being dominant, so when this is conjoined with our span feature on the first word (*While*), we end up with a feature that captures this effect. Our features can also lexicalize on other discourse connectives such as *but* or *however*, which often occur at the split point between two spans.

[7]Note that the tree structure is assumed to be given; the problem is one of labeling a fixed parse backbone.

7.1 Adapting to Sentiment

Our parser is almost entirely unchanged from the parser that we used for syntactic analysis. Though the treebank grammar is substantially different, with the nonterminals consisting of five integers with very different semantics from syntactic nonterminals, we still find that parent annotation is effective and otherwise additional annotation layers are not useful.

One structural difference between sentiment analysis and syntactic parsing lies in where the relevant information is present in a span. Syntax is often driven by heads of constituents, which tend to be located at the beginning or the end, whereas sentiment is more likely to depend on modifiers such as adjectives, which are typically present in the middle of spans. Therefore, we augment our existing model with standard sentiment analysis features that look at unigrams and bigrams in the span (Wang and Manning, 2012). Moreover, the Stanford Sentiment Treebank is unique in that each constituent was annotated in isolation, meaning that context never affects sentiment and that every word always has the same tag. We exploit this by adding an additional feature template similar to our span shape feature from Section 4.4 which uses the (deterministic) tag for each word as its descriptor.

7.2 Results

We evaluated our model on the fine-grained sentiment analysis task presented in Socher et al. (2013) and compare to their released system. The task is to predict the root sentiment label of each parse tree; however, because the data is annotated with sentiment at each span of each parse tree, we can also evaluate how well our model does at these intermediate computations. Following their experimental conditions, we filter the test set so that it only contains trees with non-neutral sentiment labels at the root.

Table 5 shows that our model outperforms the model of Socher et al. (2013)—both the published numbers and latest released version—on the task of root classification, even though the system was not explicitly designed for this task. Their model has high capacity to model complex interactions of words through a combinatory tensor, but it appears that our simpler, feature-driven model is just as effective at capturing the key effects of compositionality for sentiment analysis.

	Root	All Spans
Non-neutral Dev (872 trees)		
Stanford CoreNLP current	50.7	80.8
This work	53.1	80.5
Non-neutral Test (1821 trees)		
Stanford CoreNLP current	49.1	80.2
Stanford EMNLP 2013	45.7	80.7
This work	49.6	80.4

Table 5: Fine-grained sentiment analysis results on the Stanford Sentiment Treebank of Socher et al. (2013). We compare against the printed numbers in Socher et al. (2013) as well as the performance of the corresponding release, namely the sentiment component in the latest version of the Stanford CoreNLP at the time of this writing. Our model handily outperforms the results from Socher et al. (2013) at root classification and edges out the performance of the latest version of the Stanford system. On all spans of the tree, our model has comparable accuracy to the others.

8 Conclusion

To date, the most successful constituency parsers have largely been generative, and operate by refining the grammar either manually or automatically so that relevant information is available locally to each parsing decision. Our main contribution is to show that there is an alternative to such annotation schemes: namely, conditioning on the input and firing features based on anchored spans. We build up a small set of feature templates as part of a discriminative constituency parser and outperform the Berkeley parser on a wide range of languages. Moreover, we show that our parser is adaptable to other tree-structured tasks such as sentiment analysis; we outperform the recent system of Socher et al. (2013) and obtain state of the art performance on their dataset.

Our system is available as open-source at `https://www.github.com/dlwh/epic`.

Don't count, predict! A systematic comparison of context-counting vs. context-predicting semantic vectors

Marco Baroni and **Georgiana Dinu** and **Germán Kruszewski**
Center for Mind/Brain Sciences (University of Trento, Italy)
(marco.baroni|georgiana.dinu|german.kruszewski)@unitn.it

Abstract

Context-predicting models (more commonly known as embeddings or neural language models) are the new kids on the distributional semantics block. Despite the buzz surrounding these models, the literature is still lacking a systematic comparison of the predictive models with classic, count-vector-based distributional semantic approaches. In this paper, we perform such an extensive evaluation, on a wide range of lexical semantics tasks and across many parameter settings. The results, to our own surprise, show that the buzz is fully justified, as the context-predicting models obtain a thorough and resounding victory against their count-based counterparts.

1 Introduction

A long tradition in computational linguistics has shown that contextual information provides a good approximation to word meaning, since semantically similar words tend to have similar contextual distributions (Miller and Charles, 1991). In concrete, *distributional semantic models* (DSMs) use vectors that keep track of the contexts (e.g., co-occurring words) in which target terms appear in a large corpus as proxies for meaning representations, and apply geometric techniques to these vectors to measure the similarity in meaning of the corresponding words (Clark, 2013; Erk, 2012; Turney and Pantel, 2010).

It has been clear for decades now that raw co-occurrence counts don't work that well, and DSMs achieve much higher performance when various transformations are applied to the raw vectors, for example by reweighting the counts for context informativeness and smoothing them with dimensionality reduction techniques. This vector optimization process is generally unsupervised, and based on independent considerations (for example, context reweighting is often justified by information-theoretic considerations, dimensionality reduction optimizes the amount of preserved variance, etc.). Occasionally, some kind of indirect supervision is used: Several parameter settings are tried, and the best setting is chosen based on performance on a semantic task that has been selected for tuning.

The last few years have seen the development of a new generation of DSMs that frame the vector estimation problem directly as a supervised task, where the weights in a word vector are set to maximize the probability of the contexts in which the word is observed in the corpus (Bengio et al., 2003; Collobert and Weston, 2008; Collobert et al., 2011; Huang et al., 2012; Mikolov et al., 2013a; Turian et al., 2010). The traditional construction of context vectors is turned on its head: Instead of first collecting context vectors and then reweighting these vectors based on various criteria, the vector weights are directly set to optimally predict the contexts in which the corresponding words tend to appear. Since similar words occur in similar contexts, the system naturally learns to assign similar vectors to similar words.

This new way to train DSMs is attractive because it replaces the essentially heuristic stacking of vector transforms in earlier models with a single, well-defined supervised learning step. At the same time, supervision comes at no manual annotation cost, given that the context windows used for training can be automatically extracted from an unannotated corpus (indeed, they are the very same data used to build traditional DSMs). Moreover, at least some of the relevant methods can efficiently scale up to process very large amounts of input data.[1]

[1]The idea to directly learn a parameter vector based on an objective optimum function is shared by Latent Dirichlet

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 238–247,
Baltimore, Maryland, USA, June 23-25 2014.

We will refer to DSMs built in the traditional way as *count* models (since they initialize vectors with co-occurrence counts), and to their training-based alternative as *predict(ive)* models.[2] Now, the most natural question to ask, of course, is which of the two approaches is best in empirical terms. Surprisingly, despite the long tradition of extensive evaluations of alternative count DSMs on standard benchmarks (Agirre et al., 2009; Baroni and Lenci, 2010; Bullinaria and Levy, 2007; Bullinaria and Levy, 2012; Sahlgren, 2006; Padó and Lapata, 2007), the existing literature contains very little in terms of direct comparison of count vs. predictive DSMs. This is in part due to the fact that context-predicting vectors were first developed as an approach to language modeling and/or as a way to initialize feature vectors in neural-network-based "deep learning" NLP architectures, so their effectiveness as semantic representations was initially seen as little more than an interesting side effect. Sociological reasons might also be partly responsible for the lack of systematic comparisons: Context-predictive models were developed within the neural-network community, with little or no awareness of recent DSM work in computational linguistics.

Whatever the reasons, we know of just three works reporting direct comparisons, all limited in their scope. Huang et al. (2012) compare, in passing, one count model and several predict DSMs on the standard WordSim353 benchmark (Table 3 of their paper). In this experiment, the count model actually outperforms the best predictive approach. Instead, in a word-similarity-in-context task (Table 5), the best predict model outperforms the count model, albeit not by a large margin.

Blacoe and Lapata (2012) compare count and predict representations as input to composition functions. Count vectors make for better inputs in a phrase similarity task, whereas the two representations are comparable in a paraphrase classification experiment.[3]

Finally, Mikolov et al. (2013d) compare their predict models to "Latent Semantic Analysis" (LSA) count vectors on syntactic and semantic analogy tasks, finding that the predict models are highly superior. However, they provide very little details about the LSA count vectors they use.[4]

In this paper, we overcome the comparison scarcity problem by providing a direct evaluation of count and predict DSMs across many parameter settings and on a large variety of mostly standard lexical semantics benchmarks. Our title already gave away what we discovered.

2 Distributional semantic models

Both count and predict models are extracted from a corpus of about 2.8 billion tokens constructed by concatenating ukWaC,[5] the English Wikipedia[6] and the British National Corpus.[7] For both model types, we consider the top 300K most frequent words in the corpus both as target and context elements.

2.1 Count models

We prepared the count models using the DISSECT toolkit.[8] We extracted count vectors from symmetric context windows of two and five words to either side of target. We considered two weighting schemes: positive Pointwise Mutual Information and Local Mutual Information (akin to the widely used Log-Likelihood Ratio scheme) (Evert, 2005). We used both full and compressed vectors. The latter were obtained by applying the Singular Value Decomposition (Golub and Van Loan, 1996) or Non-negative Matrix Factorization (Lee and Seung, 2000), Lin (2007) algorithm, with reduced sizes ranging from 200 to 500 in steps of 100. In total, 36 count models were evaluated.

Count models have such a long and rich history that we can only explore a small subset of the counting, weighting and compressing methods proposed in the literature. However, it is worth pointing out that the evaluated parameter subset encompasses settings (narrow context window, positive PMI, SVD reduction) that have been

Allocation (LDA) models (Blei et al., 2003; Griffiths et al., 2007), where parameters are set to optimize the joint probability distribution of words and documents. However, the fully probabilistic LDA models have problems scaling up to large data sets.

[2] We owe the first term to Hinrich Schütze (p.c.). Predictive DSMs are also called neural language models, because their supervised context prediction training is performed with neural networks, or, more cryptically, "embeddings".

[3] We refer here to the updated results reported in the erratum at `http://homepages.inf.ed.ac.uk/s1066731/pdf/emnlp2012erratum.pdf`

[4] Chen et al. (2013) present an extended empirical evaluation, that is however limited to alternative context-predictive models, and does not include the word2vec variant we use here.

found to be most effective in the systematic explorations of the parameter space conducted by Bullinaria and Levy (2007; 2012).

2.2 Predict models

We trained our predict models with the word2vec toolkit.[9] The toolkit implements both the skip-gram and CBOW approaches of Mikolov et al. (2013a; 2013c). We experimented only with the latter, which is also the more computationally-efficient model of the two, following Mikolov et al. (2013b) which recommends CBOW as more suitable for larger datasets.

The CBOW model learns to predict the word in the middle of a symmetric window based on the sum of the vector representations of the words in the window. We considered context windows of 2 and 5 words to either side of the central element. We vary vector dimensionality within the 200 to 500 range in steps of 100. The word2vec toolkit implements two efficient alternatives to the standard computation of the output word probability distributions by a softmax classifier. Hierarchical softmax is a computationally efficient way to estimate the overall probability distribution using an output layer that is proportional to $log(unigram.perplexity(W))$ instead of W (for W the vocabulary size). As an alternative, negative sampling estimates the probability of an output word by learning to distinguish it from draws from a noise distribution. The number of these draws (number of *negative samples*) is given by a parameter k. We test both hierarchical softmax and negative sampling with k values of 5 and 10. Very frequent words such as *the* or *a* are not very informative as context features. The word2vec toolkit implements a method to downsize their effect (and simultaneously improve speed performance). More precisely, words in the training data are discarded with a probability that is proportional to their frequency (capturing the same intuition that motivates traditional count vector weighting measures such as PMI). This is controlled by a parameter t and words that occur with higher frequency than t are aggressively subsampled. We train models without subsampling and with subsampling at $t = 1e^{-5}$ (the toolkit page suggests $1e^{-3} - 1e^{-5}$ as a useful range based on empirical observations).

In total, we evaluate 48 predict models, a number comparable to that of the count models we consider.

2.3 Out-of-the-box models

Baroni and Lenci (2010) make the vectors of their best-performing *Distributional Memory* (dm) model available.[10] This model, based on the same input corpus we use, exemplifies a "linguistically rich" count-based DSM, that relies on lemmas instead or raw word forms, and has dimensions that encode the syntactic relations and/or lexico-syntactic patterns linking targets and contexts. Baroni and Lenci showed, in a large scale evaluation, that dm reaches near-state-of-the-art performance in a variety of semantic tasks.

We also experiment with the popular predict vectors made available by Ronan Collobert.[11] Following the earlier literature, with refer to them as *Collobert and Weston* (cw) vectors. These are 100-dimensional vectors trained for two months (!) on the Wikipedia. In particular, the vectors were trained to optimize the task of choosing the right word over a random alternative in the middle of an 11-word context window (Collobert et al., 2011).

3 Evaluation materials

We test our models on a variety of benchmarks, most of them already widely used to test and compare DSMs. The following benchmark descriptions also explain the figures of merit and state-of-the-art results reported in Table 2.

Semantic relatedness A first set of semantic benchmarks was constructed by asking human subjects to rate the degree of semantic similarity or relatedness between two words on a numerical scale. The performance of a computational model is assessed in terms of correlation between the average scores that subjects assigned to the pairs and the cosines between the corresponding vectors in the model space (following the previous art, we use Pearson correlation for rg, Spearman in all other cases). The classic data set of Rubenstein and Goodenough (1965) (rg) consists of 65 noun pairs. State of the art performance on this set has been reported by Hassan and Mihalcea (2011) using a technique that exploits the Wikipedia linking structure and word sense disambiguation techniques. Finkelstein et al. (2002)

[9] https://code.google.com/p/word2vec/

[10] http://clic.cimec.unitn.it/dm/

[11] http://ronan.collobert.com/senna/

introduced the widely used WordSim353 set (ws) that, as the name suggests, consists of 353 pairs. The current state of the art is reached by Halawi et al. (2012) with a method that is in the spirit of the predict models, but lets synonymy information from WordNet constrain the learning process (by favoring solutions in which WordNet synonyms are near in semantic space). Agirre et al. (2009) split the ws set into similarity (wss) and relatedness (wsr) subsets. The first contains tighter taxonomic relations, such as synonymy and cohyponymy (*king/queen*) whereas the second encompasses broader, possibly topical or syntagmatic relations (*family/planning*). We report state-of-the-art performance on the two subsets from the work of Agirre and colleagues, who used different kinds of count vectors extracted from a very large corpus (orders of magnitude larger than ours). Finally, we use (the test section of) MEN (men), that comprises 1,000 word pairs. Bruni et al. (2013), the developers of this benchmark, achieve state-of-the-art performance by extensive tuning on *ad-hoc* training data, and by using both textual and image-extracted features to represent word meaning.

Synonym detection The classic TOEFL (toefl) set was introduced by Landauer and Dumais (1997). It contains 80 multiple-choice questions that pair a target term with 4 synonym candidates. For example, for the target *levied* one must choose between *imposed* (correct), *believed*, *requested* and *correlated*. The DSMs compute cosines of each candidate vector with the target, and pick the candidate with largest cosine as their answer. Performance is evaluated in terms of correct-answer accuracy. Bullinaria and Levy (2012) achieved 100% accuracy by a very thorough exploration of the count model parameter space.

Concept categorization Given a set of nominal concepts, the task is to group them into natural categories (e.g., *helicopters* and *motorcycles* should go to the *vehicle* class, *dogs* and *elephants* into the *mammal* class). Following previous art, we tackle categorization as an unsupervised clustering task. The vectors produced by a model are clustered into n groups (with n determined by the gold standard partition) using the CLUTO toolkit (Karypis, 2003), with the repeated bisections with global optimization method and CLUTO's default settings otherwise (these are standard choices in the literature). Performance is evaluated in terms of *purity*, a measure of the extent to which each cluster contains concepts from a single gold category. If the gold partition is reproduced perfectly, purity reaches 100%; it approaches 0 as cluster quality deteriorates. The Almuhareb-Poesio (ap) benchmark contains 402 concepts organized into 21 categories (Almuhareb, 2006). State-of-the-art purity was reached by Rothenhäusler and Schütze (2009) with a count model based on carefully crafted syntactic links. The ESSLLI 2008 Distributional Semantic Workshop shared-task set (esslli) contains 44 concepts to be clustered into 6 categories (Baroni et al., 2008) (we ignore here the 3- and 2-way higher-level partitions coming with this set). Katrenko and Adriaans (2008) reached top performance on this set using the full Web as a corpus and manually crafted, linguistically motivated patterns. Finally, the Battig (battig) test set introduced by Baroni et al. (2010) includes 83 concepts from 10 categories. Current state of the art was reached by the window-based count model of Baroni and Lenci (2010).

Selectional preferences We experiment with two data sets that contain verb-noun pairs that were rated by subjects for the typicality of the noun as a subject or object of the verb (e.g., *people* received a high average score as subject of *to eat*, and a low score as object of the same verb). We follow the procedure proposed by Baroni and Lenci (2010) to tackle this challenge: For each verb, we use the corpus-based tuples they make available to select the 20 nouns that are most strongly associated to the verb as subjects or objects, and we average the vectors of these nouns to obtain a "prototype" vector for the relevant argument slot. We then measure the cosine of the vector for a target noun with the relevant prototype vector (e.g., the cosine of *people* with the *eating* subject prototype vector). Systems are evaluated by Spearman correlation of these cosines with the averaged human typicality ratings. Our first data set was introduced by Ulrike Padó (2007) and includes 211 pairs (up). Top-performance was reached by the supervised count vector system of Herdağdelen and Baroni (2009) (supervised in the sense that they directly trained a classifier on gold data, as opposed to the 0-cost supervision of the context-learning methods). The mcrae set (McRae et al., 1998) consists of 100 noun–verb pairs, with top performance reached by the DepDM system of Baroni and Lenci (2010), a count DSM relying on

syntactic information.

Analogy While all the previous data sets are relatively standard in the DSM field to test traditional count models, our last benchmark was introduced in Mikolov et al. (2013a) specifically to test predict models. The data-set contains about 9K semantic and 10.5K syntactic analogy questions. A semantic question gives an example pair (*brother-sister*), a test word (*grandson*) and asks to find another word that instantiates the relation illustrated by the example with respect to the test word (*granddaughter*). A syntactic question is similar, but in this case the relationship is of a grammatical nature (*work–works*, *speak… speaks*). Mikolov and colleagues tackle the challenge by subtracting the second example term vector from the first, adding the test term, and looking for the nearest neighbour of the resulting vector (what is the nearest neighbour of $\vec{brother} - \vec{sister} + \vec{grandson}$?). Systems are evaluated in terms of proportion of questions where the nearest neighbour from the whole semantic space is the correct answer (the given example and test vector triples are excluded from the nearest neighbour search). Mikolov et al. (2013a) reach top accuracy on the syntactic subset (ansyn) with a CBOW predict model akin to ours (but trained on a corpus twice as large). Top accuracy on the entire data set (an) and on the semantic subset (ansem) was reached by Mikolov et al. (2013c) using a skip-gram predict model. Note however that, because of the way the task is framed, performance also depends on the size of the vocabulary to be searched: Mikolov et al. (2013a) pick the nearest neighbour among vectors for 1M words, Mikolov et al. (2013c) among 700K words, and we among 300K words.

Some characteristics of the benchmarks we use are summarized in Table 1.

4 Results

Table 2 summarizes the evaluation results. The first block of the table reports the maximum per-task performance (across all considered parameter settings) for count and predict vectors. The latter emerge as clear winners, with a large margin over count vectors in most tasks. Indeed, the predictive models achieve an impressive overall performance, beating the current state of the art in several cases, and approaching it in many more. It is worth stressing that, as reviewed in Section 3, the state-of-the-art results were obtained in almost all cases using specialized approaches that rely on external knowledge, manually-crafted rules, parsing, larger corpora and/or task-specific tuning. Our predict results were instead achieved by simply downloading the word2vec toolkit and running it with a range of parameter choices recommended by the toolkit developers.

The success of the predict models cannot be blamed on poor performance of the count models. Besides the fact that this would not explain the near-state-of-the-art performance of the predict vectors, the count model results are actually quite good in absolute terms. Indeed, in several cases they are close, or even better than those attained by dm, a linguistically-sophisticated count-based approach that was shown to reach top performance across a variety of tasks by Baroni and Lenci (2010).

Interestingly, count vectors achieve performance comparable to that of predict vectors only on the selectional preference tasks. The up task in particular is also the only benchmark on which predict models are seriously lagging behind state-of-the-art and dm performance. Recall from Section 3 that we tackle selectional preference by creating average vectors representing typical verb arguments. We conjecture that this averaging approach, that worked well for dm vectors, might be problematic for prediction-trained vectors, and we plan to explore alternative methods to build the prototypes in future research.

Are our results robust to parameter choices, or are they due to very specific and brittle settings? The next few blocks of Table 2 address this question. The second block reports results obtained with single count and predict models that are best in terms of average performance rank across tasks (these are the models on the top rows of tables 3 and 4, respectively). We see that, for both approaches, performance is not seriously affected by using the single best setup rather than task-specific settings, except for a considerable drop in performance for the best predict model on esslli (due to the small size of this data set?), and an even more dramatic drop of the count model on ansem. A more cogent and interesting evaluation is reported in the third block of Table 2, where we see what happens if we use the single models with *worst* performance across tasks (recall from Section 2 above that, in any case, we are exploring a space of reasonable parameter settings, of the sort that an

Table 2: Performance of count (cnt), predict (pre), dm and cw models on all tasks. See Section 3 and Table 1 for figures of merit and state-of-the-art results (soa). Since dm has very low coverage of the an* data sets, we do not report its performance there.

experimenter might be tempted to choose without tuning). The count model performance is severely affected by this unlucky choice (2-word window, Local Mutual Information, NMF, 400 dimensions, mean performance rank: 83), whereas the predict approach is much more robust: To put its worst instantiation (2-word window, hierarchical softmax, no subsampling, 200 dimensions, mean rank: 51) into perspective, its performance is more than 10% below the *best* count model only for the an and ansem tasks, and actually higher than it in 3 cases (note how on esslli the worst predict models performs much better than the best one, confirming our suspicion about the brittleness of this small data set). The fourth block reports performance in what might be the most realistic scenario, namely by tuning the parameters on a development task. Specifically, we pick the models that work best on the small rg set, and report their performance on all tasks (we obtained similar results by picking other tuning sets). The selected count model is the third best overall model of its class as reported in Table 3. The selected predict model is the fourth best model in Table 4. The overall count performance is not greatly affected by this choice. Again, predict models confirm their robustness, in that their rg-tuned performance is always close (and in 3 cases better) than the one achieved by the best overall setup.

Tables 3 and 4 let us take a closer look at the most important count and predict parameters, by reporting the characteristics of the best models (in terms of average performance-based ranking across tasks) from both classes. For the count models, PMI is clearly the better weighting scheme, and SVD outperforms NMF as a dimensionality reduction technique. However, no compression at all (using all 300K original dimensions) works best. Compare this to the best overall predict vectors, that have 400 dimensions only, making them much more practical to use. For the predict models, we observe in Table 4 that negative sampling, where the task is to distinguish the target output word from samples drawn from the noise distribution, outperforms the more costly hierarchical softmax method. Subsampling frequent words, which downsizes the importance of these words similarly to PMI weighting in count models, is also bringing significant improvements.

Finally, we go back to Table 2 to point out the poor performance of the out-of-the-box cw model.

window	weight	compress	dim.	mean rank
2	PMI	no	300K	35
5	PMI	no	300K	38
2	PMI	SVD	500	42
2	PMI	SVD	400	46
5	PMI	SVD	500	47
2	PMI	SVD	300	50
5	PMI	SVD	400	51
2	PMI	NMF	300	52
2	PMI	NMF	400	53
5	PMI	SVD	300	53

Table 3: Top count models in terms of mean performance-based model ranking across all tasks. The first row states that the window-2, PMI, 300K count model was the best count model, and, across all tasks, its average rank, when ALL models are decreasingly ordered by performance, was 35. See Section 2.1 for explanation of the parameters.

We must leave the investigation of the parameters that make our predict vectors so much better than cw (more varied training corpus? window size? objective function being used? subsampling? ...) to further work. Still, our results show that it's not just training by context prediction that ensures good performance. The cw approach is very popular (for example both Huang et al. (2012) and Blacoe and Lapata (2012) used it in the studies we discussed in Section 1). Had we also based our systematic comparison of count and predict vectors on the cw model, we would have reached opposite conclusions from the ones we can draw from our word2vec-trained vectors!

5 Conclusion

This paper has presented the first systematic comparative evaluation of count and predict vectors. As seasoned distributional semanticists with thorough experience in developing and using count vectors, we set out to conduct this study because we were annoyed by the triumphalist overtones often surrounding predict models, despite the almost complete lack of a proper comparison to count vectors.[12] Our secret wish was to discover that it is all hype, and count vectors are far superior to their predictive counterparts. A more realistic expec-

[12]Here is an example, where word2vec is called the crown jewel of natural language processing: `http://bit.ly/1ipv72M`

win.	hier. softm.	neg. samp.	subsamp.	dim	mean rank

2	no	5	yes	300	16

Table 4: Top predict models in terms of mean performance-based model ranking across all tasks. See Section 2.2 for explanation of the parameters.

tation was that a complex picture would emerge, with predict and count vectors beating each other on different tasks. Instead, we found that the predict models are so good that, while the triumphalist overtones still sound excessive, there are very good reasons to switch to the new architecture. However, due to space limitations we have only focused here on quantitative measures: It remains to be seen whether the two types of models are complementary in the errors they make, in which case combined models could be an interesting avenue for further work.

The space of possible parameters of count DSMs is very large, and it's entirely possible that some options we did not consider would have improved count vector performance somewhat. Still, given that the predict vectors also outperformed the syntax-based dm model, and often approximated state-of-the-art performance, a more proficuous way forward might be to focus on parameters and extensions of the predict models instead: After all, we obtained our already excellent results by just trying a few variations of the word2vec defaults. Add to this that, beyond the standard lexical semantics challenges we tested here, predict models are currently been successfully applied in cutting-edge domains such as representing phrases (Mikolov et al., 2013c; Socher et al., 2012) or fusing language and vision in a common semantic space (Frome et al., 2013; Socher et al., 2013).

Based on the results reported here and the considerations we just made, we would certainly recommend anybody interested in using DSMs for theoretical or practical applications to go for the predict models, with the important caveat that they are not all created equal (cf. the big difference between word2vec and cw models). At the same time, given the large amount of work that has been carried out on count DSMs, we would like to explore, in the near future, how certain questions and methods that have been considered with respect to traditional DSMs will transfer to predict models. For example, the developers of Latent Semantic Analysis (Landauer and Dumais, 1997), Topic Models (Griffiths et al., 2007) and related DSMs have shown that the dimensions of these models can be interpreted as general "latent" semantic domains, which gives the corresponding models some *a priori* cognitive plausibility while paving the way for interesting applications. Another important line of DSM research concerns "context engineering": There has been for example much work on how to encode syntactic information into context features (Padó and Lapata, 2007), and more recent studies construct and combine feature spaces expressing topical vs. functional information (Turney, 2012). To give just one last example, distributional semanticists have looked at whether certain properties of vectors reflect semantic relations in the expected way: e.g., whether the vectors of hypernyms "distributionally include" the vectors of hyponyms in some mathematical precise sense.

Do the dimensions of predict models also encode latent semantic domains? Do these models afford the same flexibility of count vectors in capturing linguistically rich contexts? Does the structure of predict vectors mimic meaningful semantic relations? Does all of this even matter, or are we on the cusp of discovering radically new ways to tackle the same problems that have been approached as we just sketched in traditional distributional semantics?

Either way, the results of the present investigation indicate that these are important directions for future research in computational semantics.

Abstract

We show that it is possible to reliably discriminate whether a syntactic construction is meant literally or metaphorically using lexical semantic features of the words that participate in the construction. Our model is constructed using English resources, and we obtain state-of-the-art performance relative to previous work in this language. Using a model transfer approach by pivoting through a bilingual dictionary, we show our model can identify metaphoric expressions in other languages. We provide results on three new test sets in Spanish, Farsi, and Russian. The results support the hypothesis that metaphors are conceptual, rather than lexical, in nature.

1 Introduction

Lakoff and Johnson (1980) characterize metaphor as reasoning about one thing in terms of another, i.e., a metaphor is a type of *conceptual mapping*, where words or phrases are applied to objects and actions in ways that do not permit a literal interpretation. They argue that metaphors play a fundamental communicative role in verbal and written interactions, claiming that much of our everyday language is delivered in metaphorical terms. There is empirical evidence supporting the claim: recent corpus studies have estimated that the proportion of words used metaphorically ranges from 5% to 20% (Steen et al., 2010), and Thibodeau and Boroditsky (2011) provide evidence that a choice of metaphors affects decision making.

Given the prevalence and importance of metaphoric language, effective automatic detection of metaphors would have a number of benefits, both practical and scientific. Language processing applications that need to understand language or preserve meaning (information extraction, machine translation, dialog systems, sentiment analysis, and text analytics, etc.) would have access to a potentially useful high-level bit of information about whether something is to be understood literally or not. Second, scientific hypotheses about metaphoric language could be tested more easily at a larger scale with automation.

However, metaphor detection is a hard problem. On one hand, there is a subjective component: humans may disagree whether a particular expression is used metaphorically or not, as there is no clear-cut semantic distinction between figurative and metaphorical language (Shutova, 2010). On the other, metaphors can be domain- and context-dependent.[1]

Previous work has focused on metaphor identification in English, using both extensive manually-created linguistic resources (Mason, 2004; Gedigian et al., 2006; Krishnakumaran and Zhu, 2007; Turney et al., 2011; Broadwell et al., 2013) and corpus-based approaches (Birke and Sarkar, 2007; Shutova et al., 2013; Neuman et al., 2013; Shutova and Sun, 2013; Hovy et al., 2013). We build on this foundation and also extend metaphor detection into other languages in which few resources may exist. Our work makes the following contributions: (1) we develop a new state-of-the-art English metaphor detection system that uses *conceptual* semantic features, such as a degree of abstractness and semantic supersenses;[2] (2) we create new metaphor-annotated corpora for Russian and English;[3] (3) using a paradigm of model transfer (McDonald et al., 2011; Täckström et al., 2013; Kozhenikov and Titov, 2013), we provide support for the hypothesis that metaphors are concep-

[1] For example, *drowning students* could be used metaphorically to describe the situation where students are overwhelmed with work, but in the sentence *a lifeguard saved drowning students*, this phrase is used literally.

tual (rather than lexical) in nature by showing that our English-trained model can detect metaphors in Spanish, Farsi, and Russian.

2 Methodology

Our task in this work is to define features that distinguish between metaphoric and literal uses of two syntactic constructions: subject-verb-object (SVO) and adjective-noun (AN) tuples.[4] We give examples of a prototypical metaphoric usage of each type:

- **SVO metaphors.** A sentence containing a metaphoric SVO relation is *my car drinks gasoline*. According to Wilks (1978), this metaphor represents a violation of selectional preferences for the verb *drink*, which is normally associated with animate subjects (the car is inanimate and, hence, cannot drink in the literal sense of the verb).

- **AN metaphors.** The phrase *broken promise* is an AN metaphor, where attributes from a concrete domain (associated with the concrete word *broken*) are transferred to a more abstract domain, which is represented by the relatively abstract word *promise*. That is, we map an abstract concept *promise* to a concrete domain of physical things, where things can be literally broken to pieces.

Motivated by Lakoff's (1980) argument that metaphors are systematic conceptual mappings, we will use coarse-grained *conceptual*, rather than fine-grained *lexical* features, in our classifier. Conceptual features pertain to concepts and ideas as opposed to individual words or phrases expressed in a particular language. In this sense, as long as two words in two different languages refer to the same concepts, their conceptual features should be the same. Furthermore, we hypothesize that our coarse semantic features give us a language-invariant representation suitable for metaphor detection. To test this hypothesis, we use a cross-lingual model transfer approach: we use bilingual dictionaries to project words from other syntactic constructions found in other languages into English and then apply the English model on the derived conceptual representations.

[4]Our decision to focus on SVO and AN metaphors is justified by corpus studies that estimate that verb- and adjective-based metaphors account for a substantial proportion of all metaphoric expressions, approximately 60% and 24%, respectively (Shutova and Teufel, 2010; Gandy et al., 2013).

Each SVO (or AN) instance will be represented by a triple (duple) from which a feature vector will be extracted.[5] The vector will consist of the concatenation of the conceptual features (which we discuss below) for all participating words, and conjunction features for word pairs.[6] For example, to generate the feature vector for the SVO triple $(car, drink, gasoline)$, we compute all the features for the individual words *car*, *drink*, *gasoline* and combine them with the conjunction features for the pairs *car drink* and *drink gasoline*.

We define three main feature categories (1) abstractness and imageability, (2) supersenses, (3) unsupervised vector-space word representations; each category corresponds to a group of features with a common theme and representation.

- **Abstractness and imageability.** Abstractness and imageability were shown to be useful in detection of metaphors (it is easier to invoke mental pictures of concrete and imageable words) (Turney et al., 2011; Broadwell et al., 2013). We expect that abstractness, used in conjunction features (e.g., a feature denoting that the subject is abstract and the verb is concrete), is especially useful: semantically, an abstract agent performing a concrete action is a strong signal of metaphorical usage.

  Although often correlated with abstractness, imageability is not a redundant property. While most abstract things are hard to visualize, some call up images, e.g., *vengeance* calls up an emotional image, *torture* calls up emotions and even visual images. There are concrete things that are hard to visualize too, for example, *abbey* is harder to visualize than *banana* (B. MacWhinney, personal communication).

- **Supersenses.** Supersenses[7] are coarse semantic categories originating in WordNet. For nouns and verbs there are 45 classes: 26 for nouns and 15 for verbs, for example,

[5]Looking at components of the syntactic constructions independent of their context has its limitations, as discussed above with the *drowning students* example; however, it simplifies the representation challenges considerably.

[6]If word one is represented by features $\mathbf{u} \in \mathbb{R}^n$ and word two by features $\mathbf{v} \in \mathbb{R}^m$ then the conjunction feature vector is the vectorization of the outer product $\mathbf{u}\mathbf{v}^\top$.

[7]Supersenses are called "lexicographer classes" in WordNet documentation (Fellbaum, 1998), `http://wordnet.princeton.edu/man/lexnames.5WN.html`

noun.body, *noun.animal*, *verb.consumption*, or *verb.motion* (Ciaramita and Altun, 2006). English adjectives do not, as yet, have a similar high-level semantic partitioning in WordNet, thus we use a 13-class taxonomy of adjective supersenses constructed by Tsvetkov et al. (2014) (discussed in §3.2).

Supersenses are particularly attractive features for metaphor detection: coarse sense taxonomies can be viewed as semantic concepts, and since concept mapping is a process in which metaphors are born, we expect different supersense co-occurrences in metaphoric and literal combinations. In "drinks gasoline", for example, mapping to supersenses would yield a pair <*verb.consumption, noun.substance*>, contrasted with <*verb.consumption, noun.food*> for "drinks juice". In addition, this coarse semantic categorization is preserved in translation (Schneider et al., 2013), which makes supersense features suitable for cross-lingual approaches such as ours.

- **Vector space word representations.** Vector space word representations learned using unsupervised algorithms are often effective features in supervised learning methods (Turian et al., 2010). In particular, many such representations are designed to capture lexical semantic properties and are quite effective features in semantic processing, including named entity recognition (Turian et al., 2009), word sense disambiguation (Huang et al., 2012), and lexical entailment (Baroni et al., 2012). In a recent study, Mikolov et al. (2013) reveal an interesting cross-lingual property of distributed word representations: there is a strong similarity between the vector spaces across languages that can be easily captured by linear mapping. Thus, vector space models can also be seen as vectors of (latent) semantic concepts, that preserve their "meaning" across languages.

3 Model and Feature Extraction

In this section we describe a classification model, and provide details on mono- and cross-lingual implementation of features.

3.1 Classification using Random Forests

To make classification decisions, we use a random forest classifier (Breiman, 2001), an ensemble of decision tree classifiers learned from many independent subsamples of the training data. Given an input, each tree classifier assigns a probability to each label; those probabilities are averaged to compute the probability distribution across the ensemble. Random forest ensembles are particularly suitable for our resource-scarce scenario: rather than overfitting, they produce a limiting value of the generalization error as the number of trees increases,[8] and no hyperparameter tuning is required. In addition, decision-tree classifiers learn non-linear responses to inputs and often outperform logistic regression (Perlich et al., 2003).[9] Our random forest classifier models the probability that the input syntactic relation is metaphorical. If this probability is above a threshold, the relation is classified as metaphoric, otherwise it is literal. We used the `scikit-learn` toolkit to train our classifiers (Pedregosa et al., 2011).

3.2 Feature extraction

Abstractness and imageability. The MRC psycholinguistic database is a large dictionary listing linguistic and psycholinguistic attributes obtained experimentally (Wilson, 1988).[10] It includes, among other data, 4,295 words rated by the degrees of abstractness and 1,156 words rated by the imageability. Similarly to Tsvetkov et al. (2013), we use a logistic regression classifier to propagate abstractness and imageability scores from MRC ratings to all words for which we have vector space representations. More specifically, we calculate the degree of abstractness and imageability of all English items that have a vector space representation, using vector elements as features. We train two separate classifiers for abstractness and imageability on a seed set of words from the MRC database. Degrees of abstractness and imageability are posterior probabilities of classifier predictions. We binarize these posteriors into abstract-concrete (or imageable-unimageable) boolean indicators using pre-defined thresholds.[11] Perfor-

[8] See Theorem 1.2 in (Breiman, 2001) for details.

[9] In our experiments, random forests model slightly outperformed logistic regression and SVM classifiers.

[10] `http://ota.oucs.ox.ac.uk/headers/1054.xml`

[11] Thresholds are equal to 0.8 for abstractness and to 0.9 for imageability. They were chosen empirically based on ac-

mance of these classifiers, tested on a sampled held-out data, is 0.94 and 0.85 for the abstractness and imageability classifiers, respectively.

Supersenses. In the case of SVO relations, we incorporate supersense features for nouns and verbs; noun and adjective supersenses are used in the case of AN relations.

Supersenses of nouns and verbs. A lexical item can belong to several synsets, which are associated with different supersenses. Degrees of membership in different supersenses are represented by feature vectors, where each element corresponds to one supersense. For example, the word *head* (when used as a noun) participates in 33 synsets, three of which are related to the supersense *noun.body*. The value of the feature corresponding to this supersense is $3/33 \approx 0.09$.

Supersenses of adjectives. WordNet lacks coarse-grained semantic categories for adjectives. To divide adjectives into groups, Tsvetkov et al. (2014) use 13 top-level classes from the adapted taxonomy of Hundsnurscher and Splett (1982), which is incorporated in GermaNet (Hamp and Feldweg, 1997). For example, the top-level classes in GermaNet include: *adj.feeling* (e.g., willing, pleasant, cheerful); *adj.substance* (e.g., dry, ripe, creamy); *adj.spatial* (e.g., adjacent, gigantic).[12] For each adjective type in WordNet, they produce a vector with a classifier posterior probabilities corresponding to degrees of membership of this word in one of the 13 semantic classes,[13] similar to the feature vectors we build for nouns and verbs. For example, for a word *calm* the top-2 categories (with the first and second highest degrees of membership) are *adj.behavior* and *adj.feeling*.

Vector space word representations. We employ 64-dimensional vector-space word representations constructed by Faruqui and Dyer (2014).[14] Vector construction algorithm is a variation on traditional latent semantic analysis (Deerwester et al., 1990) that uses multilingual information to produce representations in which synonymous words have similar vectors. The vectors were trained on the news commentary corpus released by WMT-2011,[15] comprising 180,834 types.

3.3 Cross-lingual feature projection

For languages other than English, feature vectors are projected to English features using translation dictionaries. We used the Babylon dictionary,[16] which is a proprietary resource, but any bilingual dictionary can in principle be used. For a non-English word in a source language, we first obtain all translations into English. Then, we average all feature vectors related to these translations. Consider an example related to projection of WordNet supersenses. A Russian word голова is translated as *head* and *brain*. Hence, we select all the synsets of the nouns *head* and *brain*. There are 38 such synsets (33 for *head* and 5 for *brain*). Four of these synsets are associated with the supersense *noun.body*. Therefore, the value of the feature *noun.body* is $4/38 \approx 0.11$.

4 Datasets

In this section we describe a training and testing dataset as well a data collection procedure.

4.1 English training sets

To train an SVO metaphor classifier, we employ the TroFi (Trope Finder) dataset.[17] TroFi includes 3,737 manually annotated English sentences from the *Wall Street Journal* (Birke and Sarkar, 2007). Each sentence contains either literal or metaphorical use for one of 50 English verbs. First, we use a dependency parser (Martins et al., 2010) to extract subject-verb-object (SVO) relations. Then, we filter extracted relations to eliminate parsing-related errors, and relations with verbs which are not in the TroFi verb list. After filtering, there are 953 metaphorical and 656 literal SVO relations which we use as a training set.

In the case of AN relations, we construct and make publicly available a training set containing 884 metaphorical AN pairs and 884 pairs with literal meaning. It was collected by two annotators using public resources (collections of metaphors on the web). At least one additional person carefully examined and culled the collected metaphors, by removing duplicates, weak metaphors, and metaphorical phrases (such as

curacy during cross-validation.

[12] For the full taxonomy see http://www.sfs.uni-tuebingen.de/lsd/adjectives.shtml

[15] http://www.statmt.org/wmt11/

[16] http://www.babylon.com

[17] http://www.cs.sfu.ca/~anoop/students/jbirke/

drowning students) whose interpretation depends on the context.

4.2 Multilingual test sets

We collect and annotate metaphoric and literal test sentences in four languages. Thus, we compile eight test datasets, four for SVO relations, and four for AN relations. Each dataset has an equal number of metaphors and non-metaphors, i.e., the datasets are balanced. English (EN) and Russian (RU) datasets have been compiled by our team and are publicly available. Spanish (ES) and Farsi (FA) datasets are published elsewhere (Levin et al., 2014). Table 1 lists test set sizes.

	SVO	AN
EN	222	200
RU	240	200
ES	220	120
FA	44	320

Table 1: Sizes of the eight test sets. Each dataset is balanced, i.e., it has an equal number of metaphors and non-metaphors. For example, English SVO dataset has 222 relations: 111 metaphoric and 111 literal.

We used the following procedure to compile the EN and RU test sets. A moderator started with seed lists of 1000 most common verbs and adjectives.[18]

Then she used the SketchEngine, which provides searching capability for the TenTen Web corpus,[19] to extract sentences with words that frequently co-occurred with words from the seed lists. From these sentences, she removed sentences that contained more than one metaphor, and sentences with non-SVO and non-AN metaphors. Remaining sentences were annotated by several native speakers (five for English and six for Russian), who judged AN and SVO phrases in context. The annotation instructions were general: *"Please, mark in bold all words that, in your opinion, are used non-literally in the following sentences. In many sentences, all the words may be used literally."* The Fleiss' Kappas for 5 English and 6 Russian annotators are: EN-AN = .76, RU-AN = .85, EN-SVO = .75, RU-SVO = .78. For the final selection, we filtered out low-agreement ($<.8$) sentences.

The test candidate sentences were selected by a person who did not participate in the selection of the training samples. No English annotators of the test set, and only one Russian annotator out of 6 participated in the selection of the training samples. Thus, we trust that annotator judgments were not biased towards the cases that the system is trained to process.

5 Experiments

5.1 English experiments

Our task, as defined in Section 2, is to classify SVO and AN relations as either metaphoric or literal. We first conduct a 10-fold cross-validation experiment on the training set defined in Section 4.1. We represent each candidate relation using the features described in Section 3.2, and evaluate performance of the three feature categories and their combinations. This is done by computing an accuracy in the 10-fold cross validation. Experimental results are given in Table 2, where we also provide the number of features in each feature set.

	SVO		AN	
	# FEAT	ACC	# FEAT	ACC
AbsImg	20	0.73*	16	0.76*
Supersense	67	0.77*	116	0.79*
AbsImg+Sup.	87	0.78*	132	0.80*
VSM	192	0.81	228	0.84*
All	279	**0.82**	360	**0.86**

Table 2: 10-fold cross validation results for three feature categories and their combination, for classifiers trained on English SVO and AN training sets. # FEAT column shows a number of features. ACC column reports an accuracy score in the 10-fold cross validation. Statistically significant differences ($p < 0.01$) from the all-feature combination are marked with a star.

These results show superior performance over previous state-of-the-art results, confirming our hypothesis that conceptual features are effective in metaphor classification. For the SVO task, the cross-validation accuracy is about 10% better than that of Tsvetkov et al. (2013). For the AN task, the cross validation accuracy is better by 8% than the result of Turney et al. (2011) (two baseline

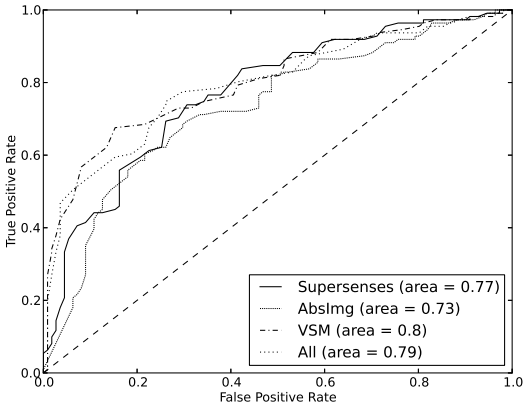
[18] Selection of 1000 most common verbs and adjectives achieves much broader lexical and domain coverage than what can be realistically obtained from continuous text. Our test sentence domains are, therefore, diverse: economic, political, sports, etc.

[19] http://trac.sketchengine.co.uk/wiki/Corpora/enTenTen

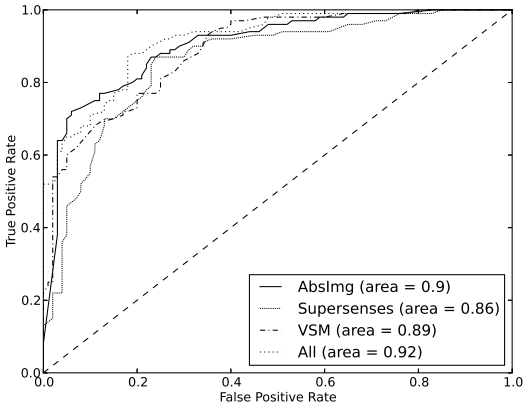
methods are described in Section 5.2). We can see that all types of features have good performance on their own (VSM is the strongest feature type). Noun supersense features alone allows us to achieve an accuracy of 75%, i.e., adjective supersense features contribute 4% to adjective-noun supersense feature combination. Experiments with the pairs of features yield better results than individual features, implying that the feature categories are not redundant. Yet, combining all features leads to even higher accuracy during cross-validation. In the case of the AN task, a difference between the All feature combination and any other combination of features listed in Table 2 is statistically significant ($p < 0.01$ for both the sign and the permutation test).

Although the first experiment shows very high scores, the 10-fold cross-validation cannot fully reflect the generality of the model, because all folds are parts of the same corpus. They are collected by the same human judges and belong to the same domain. Therefore, experiments on out-of-domain data are crucial. We carry out such experiments using held-out SVO and AN EN test sets, described in Section 4.2 and Table 1. In this experiment, we measure the f-score. We classify SVO and AN relations using a classifier trained on the All feature combination and balanced thresholds. The values of the f-score are 0.76, both for SVO and AN tasks. This out-of-domain experiment suggests that our classifier is portable across domains and genres.

However, (1) different application may have different requirements for recall/precision, and (2) classification results may be skewed towards having high precision and low recall (or vice versa). It is possible to trade precision for recall by choosing a different threshold. Thus, in addition to giving a single f-score value for balanced thresholds, we present a Receiver Operator Characteristic (ROC) curve, where we plot a fraction of true positives against the fraction of false positives for 100 threshold values in the range from zero to one. The area under the ROC curve (AUC) can be interpreted as the probability that a classifier will assign a higher score to a randomly chosen positive example than to a randomly chosen negative example.[20] For a randomly guessing classifier, the ROC curve is a dashed diagonal line. A bad classifier has an ROC curve that goes close to the dashed diagonal or even below it.



(a) **SVO**



(b) **AN**

Figure 1: ROC curves for classifiers trained using different feature sets (English SVO and AN test sets).

According to ROC plots in Figure 1, all three feature sets are effective, both for SVO and for AN tasks. Abstractness and Imageability features work better for adjectives and nouns, which is in line with previous findings (Turney et al., 2011; Broadwell et al., 2013). It can be also seen that VSM features are very effective. This is in line with results of Hovy et al. (2013), who found that it is hard to improve over the classifier that uses only VSM features.

5.2 Comparison to baselines

In this section, we compare our method to state-of-the-art methods of Tsvetkov et al. (2013) and of Turney et al. (2011), who focused on classifying SVO and AN relations, respectively.

In the case of SVO relations, we use software

[20] Assuming that positive examples are labeled by ones, and negative examples are labeled by zeros.

and datasets from Tsvetkov et al. (2013). These datasets, denoted as an SVO-baseline, consist of 98 English and 149 Russian sentences. We train SVO metaphor detection tools on SVO relations extracted from TroFi sentences and evaluate them on the SVO-baseline dataset. We also use the same thresholds for classifier posterior probabilities as Tsvetkov et al. (2013). Our approach is different from that of Tsvetkov et al. (2013) in that it uses additional features (vector space word representations) and a different classification method (we use random forests while Tsvetkov et al. (2013) use logistic regression). According to Table 3, we obtain higher performance scores for both Russian and English.

	EN	**RU**
SVO-baseline	0.78	0.76
This work	0.86	0.85

Table 3: Comparing f-scores of our SVO metaphor detection method to the baselines.

In the case of AN relations, we use the dataset (denoted as an AN-baseline) created by Turney et al. (2011) (see Section 4.1 in the referred paper for details). Turney et al. (2011) manually annotated 100 pairs where an adjective was one of the following: *dark*, *deep*, *hard*, *sweet*, and *worm*. The pairs were presented to five human judges who rated each pair on a scale from 1 (very literal/denotative) to 4 (very non-literal/connotative). Turney et al. (2011) train logistic-regression employing only abstractness ratings as features. Performance of the method was evaluated using the 10-fold cross-validation separately for each judge.

We replicate the above described evaluation procedure of Turney et al. (2011) using their model and features. In our classifier, we use the All feature combination and the balanced threshold as described in Section 5.1.

According to results in Table 4, almost all of the judge-specific f-scores are slightly higher for our system, as well as the overall average f-score.

In both baseline comparisons, we obtain performance at least as good as in previously published studies.

5.3 Cross-lingual experiments

In the next experiment we corroborate the main hypothesis of this paper: a model trained on English data can be successfully applied to other languages. Namely, we use a trained English model discussed in Section 5.1 to classify literal and metaphoric SVO and AN relations in English, Spanish, Farsi and Russian test sets, listed in Section 4.2. This time we used all available features.

	AN-baseline	**This work**
Judge 1	0.73	0.75
Judge 2	0.81	0.84
Judge 3	0.84	0.88
Judge 4	0.79	0.81
Judge 5	0.78	0.77
average	0.79	0.81

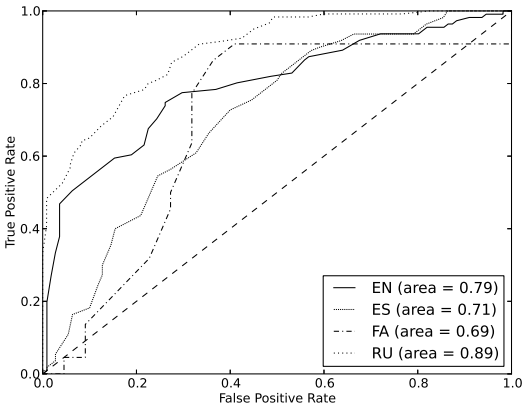
Table 4: Comparing AN metaphor detection method to the baselines: accuracy of the 10-fold cross validation on annotations of five human judges.

Experimental results for all four languages, are given in Figure 2. The ROC curves for SVO and AN tasks are plotted in Figure 2a and Figure 2b, respectively. Each curve corresponds to a test set described in Table 1. In addition, we perform an oracle experiment, to obtain actual f-score values for best thresholds. Detailed results are shown in Table 5.

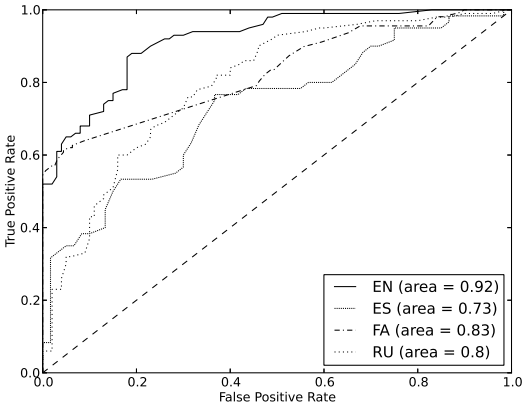
Consistent results with high f-scores are obtained across all four languages. Note that higher scores are obtained for the Russian test set. We hypothesize that this happens due to a higher-quality translation dictionary (which allows a more accurate model transfer). Relatively lower (yet reasonable) results for Farsi can be explained by a smaller size of the bilingual dictionary (thus, fewer feature projections can be obtained). Also note that, in our experience, most of Farsi metaphors are adjective-noun constructions. This is why the AN FA dataset in Table 1 is significantly larger than SVO FA. In that, for the AN Farsi task we observe high performance scores.

Figure 2 and Table 5 confirm, that *we obtain similar, robust results on four very different languages, using the same English classifiers*. We view this result as a strong evidence of language-independent nature of our metaphor detection method. In particular, this shows that proposed conceptual features can be used to detect selectional preferences violation across languages.

To summarize the experimental section, our metaphor detection approach obtains state-of-the-



(a) **SVO**



(b) **AN**

Figure 2: Cross-lingual experiment: ROC curves for classifiers trained on the English data using a combination of all features, and applied to SVO and AN metaphoric and literal relations in four test languages: English, Russian, Spanish, and Farsi.

art performance in English, is effective when applied to out-of-domain English data, and works cross-lingually.

5.4 Examples

Manual data analysis on adjective-noun pairs supports an abstractness-concreteness hypothesis formulated by several independent research studies. For example, in English we classify as metaphoric *dirty word* and *cloudy future*. Word pairs *dirty diaper* and *cloudy weather* have same adjectives. Yet they are classified as literal. Indeed, *diaper* is a more concrete term than *word* and *weather* is more concrete than *future*. Same pattern is observed in non-English datasets. In Russian, больное общество "sick society" and пустой звук "empty sound" are classified as metaphoric, while

	SVO	AN
EN	0.79	0.85
RU	0.84	0.77
ES	0.76	0.72
FA	0.75	0.74

Table 5: Cross-lingual experiment: f-scores for classifiers trained on the English data using a combination of all features, and applied, with optimal thresholds, to SVO and AN metaphoric and literal relations in four test languages: English, Russian, Spanish, and Farsi.

больная бабушка "sick grandmother" and пустая чашка "empty cup" are classified as literal. Spanish example of an adjective-noun metaphor is a well-known *músculo económico* "economic muscle". We also observe that non-metaphoric adjective noun pairs tend to have more imageable adjectives, such as literal *derecho humano* "human right". In Spanish, *human* is more imageable than *economic*.

Verb-based examples that are correctly classified by our model are: *blunder escaped notice* (metaphoric) and *prisoner escaped jail* (literal). We hypothesize that supersense features are instrumental in the correct classification of these examples: <*noun.person,verb.motion*> is usually used literally, while <*noun.act,verb.motion*> is used metaphorically.

6 Related Work

For a historic overview and a survey of common approaches to metaphor detection, we refer the reader to recent reviews by Shutova et al. (Shutova, 2010; Shutova et al., 2013). Here we focus only on recent approaches.

Shutova et al. (2010) proposed a bottom-up method: one starts from a set of seed metaphors and seeks phrases where verbs and/or nouns belong to the same cluster as verbs or nouns in seed examples.

Turney et al. (2011) show how abstractness scores could be used to detect metaphorical AN phrases. Neuman et al. (2013) describe a Concrete Category Overlap algorithm, where co-occurrence statistics and Turney's abstractness scores are used to determine WordNet supersenses that correspond to literal usage of a given adjective or verb. For example, given an adjective, we can learn that it modifies concrete nouns that usually have the

supersense *noun.body*. If this adjective modifies a noun with the supersense *noun.feeling*, we conclude that a metaphor is found.

Broadwell et al. (2013) argue that metaphors are highly imageable words that do not belong to a discussion topic. To implement this idea, they extend MRC imageability scores to all dictionary words using links among WordNet supersenses (mostly hypernym and hyponym relations). Strzalkowski et al. (2013) carry out experiments in a specific (government-related) domain for four languages: English, Spanish, Farsi, and Russian. Strzalkowski et al. (2013) explain the algorithm only for English and say that is the same for Spanish, Farsi, and Russian. Because they heavily rely on WordNet and availability of imageability scores, their approach may not be applicable to low-resource languages.

Hovy et al. (2013) applied tree kernels to metaphor detection. Their method also employs WordNet supersenses, but it is not clear from the description whether WordNet is essential or can be replaced with some other lexical resource. We cannot compare directly our model with this work because our classifier is restricted to detection of only SVO and AN metaphors.

Tsvetkov et al. (2013) propose a cross-lingual detection method that uses only English lexical resources and a dependency parser. Their study focuses only on the verb-based metaphors. Tsvetkov et al. (2013) employ only English and Russian data. Current work builds on this study, and incorporates new syntactic relations as metaphor candidates, adds several new feature sets and different, more reliable datasets for evaluating results. We demonstrate results on two new languages, Spanish and Farsi, to emphasize the generality of the method.

A words sense disambiguation (WSD) is a related problem, where one identifies meanings of polysemous words. The difference is that in the WSD task, we need to select an already existing sense, while for the metaphor detection, the goal is to identify cases of sense borrowing. Studies showed that cross-lingual evidence allows one to achieve a state-of-the-art performance in the WSD task, yet, most cross-lingual WSD methods employ parallel corpora (Navigli, 2009).

7 Conclusion

The key contribution of our work is that we show how to identify metaphors across languages by building a model in English and applying it—without adaptation—to other languages: Spanish, Farsi, and Russian. This model uses language-independent (rather than lexical or language specific) conceptual features. Not only do we establish benchmarks for Spanish, Farsi, and Russian, but we also achieve state-of-the-art performance in English. In addition, we present a comparison of relative contributions of several types of features. We concentrate on metaphors in the context of two kinds of syntactic relations: subject-verb-object (SVO) relations and adjective-noun (AN) relations, which account for a majority of all metaphorical phrases.

Future work will expand the scope of metaphor identification by including nominal metaphoric relations as well as explore techniques for incorporating contextual features, which can play a key role in identifying certain kinds of metaphors. Second, cross-lingual model transfer can be improved with more careful cross-lingual feature projection.

Acknowledgments

We are extremely grateful to Shuly Wintner for a thorough review that helped us improve this draft; we also thank people who helped in creating the datasets and/or provided valuable feedback on this work: Ed Hovy, Vlad Niculae, Davida Fromm, Brian MacWhinney, Carlos Ramírez, and other members of the CMU METAL team. Abstract

Unsupervised word sense disambiguation (WSD) methods are an attractive approach to all-words WSD due to their non-reliance on expensive annotated data. Unsupervised estimates of sense frequency have been shown to be very useful for WSD due to the skewed nature of word sense distributions. This paper presents a fully unsupervised topic modelling-based approach to sense frequency estimation, which is highly portable to different corpora and sense inventories, in being applicable to any part of speech, and not requiring a hierarchical sense inventory, parsing or parallel text. We demonstrate the effectiveness of the method over the tasks of predominant sense learning and sense distribution acquisition, and also the novel tasks of detecting senses which aren't attested in the corpus, and identifying novel senses in the corpus which aren't captured in the sense inventory.

1 Introduction

The automatic determination of word sense information has been a long-term pursuit of the NLP community (Agirre and Edmonds, 2006; Navigli, 2009). Word sense distributions tend to be Zipfian, and as such, a simple but surprisingly high-accuracy back-off heuristic for word sense disambiguation (WSD) is to tag each instance of a given word with its predominant sense (McCarthy et al., 2007). Such an approach requires knowledge of predominant senses; however, word sense distributions — and predominant senses too — vary from corpus to corpus. Therefore, methods for automatically learning predominant senses and sense distributions for specific corpora are required (Koeling et al., 2005; Lapata and Brew, 2004).

In this paper, we propose a method which uses topic models to estimate word sense distributions. This method is in principle applicable to all parts of speech, and moreover does not require a parser, a hierarchical sense representation or parallel text. Topic models have been used for WSD in a number of studies (Boyd-Graber et al., 2007; Li et al., 2010; Lau et al., 2012; Preiss and Stevenson, 2013; Cai et al., 2007; Knopp et al., 2013), but our work extends significantly on this earlier work in focusing on the acquisition of prior word sense distributions (and predominant senses).

Because of domain differences and the skewed nature of word sense distributions, it is often the case that some senses in a sense inventory will not be attested in a given corpus. A system capable of automatically finding such senses could reduce ambiguity, particularly in domain adaptation settings, while retaining rare but nevertheless viable senses. We further propose a method for applying our sense distribution acquisition system to the task of finding unattested senses — i.e., senses that are in the sense inventory but not attested in a given corpus. In contrast to the previous work of McCarthy et al. (2004a) on this topic which uses the sense ranking score from McCarthy et al. (2004b) to remove low-frequency senses from WordNet, we focus on finding senses that are unattested in the corpus on the premise that, given accurate disambiguation, rare senses in a corpus contribute to correct interpretation.

Corpus instances of a word can also correspond to senses that are not present in a given sense inventory. This can be due to, for example, words taking on new meanings over time (e.g. the rela-

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 259–270,
Baltimore, Maryland, USA, June 23-25 2014.

tively recent senses of *tablet* and *swipe* related to touchscreen computers) or domain-specific terms not being included in a more general-purpose sense inventory. A system for automatically identifying such novel senses — i.e. senses that are attested in the corpus but not in the sense inventory — would be a very valuable lexicographical tool for keeping sense inventories up-to-date (Cook et al., 2013). We further propose an application of our proposed method to the identification of such novel senses. In contrast to McCarthy et al. (2004b), the use of topic models makes this possible, using topics as a proxy for sense (Brody and Lapata, 2009; Yao and Durme, 2011; Lau et al., 2012). Earlier work on identifying novel senses focused on individual tokens (Erk, 2006), whereas our approach goes further in identifying groups of tokens exhibiting the same novel sense.

2 Background and Related Work

There has been a considerable amount of research on representing word senses and disambiguating usages of words in context (WSD) as, in order to produce computational systems that understand and produce natural language, it is essential to have a means of representing and disambiguating word sense. WSD algorithms require word sense information to disambiguate token instances of a given ambiguous word, e.g. in the form of sense definitions (Lesk, 1986), semantic relationships (Navigli and Velardi, 2005) or annotated data (Zhong and Ng, 2010). One extremely useful piece of information is the word sense prior or expected word sense frequency distribution. This is important because word sense distributions are typically skewed (Kilgarriff, 2004), and systems do far better when they take bias into account (Agirre and Martinez, 2004).

Typically, word frequency distributions are estimated with respect to a sense-tagged corpus such as SemCor (Miller et al., 1993), a 220,000 word corpus tagged with WordNet (Fellbaum, 1998) senses. Due to the expense of hand tagging, and sense distributions being sensitive to domain and genre, there has been some work on trying to estimate sense frequency information automatically (McCarthy et al., 2004b; Chan and Ng, 2005; Mohammad and Hirst, 2006; Chan and Ng, 2006). Much of this work has been focused on ranking word senses to find the predominant sense in a given corpus (McCarthy et al., 2004b; Mohammad and Hirst, 2006), which is a very powerful heuristic approach to WSD. Most WSD systems rely upon this heuristic for back-off in the absence of strong contextual evidence (McCarthy et al., 2007). McCarthy et al. (2004b) proposed a method which relies on distributionally similar words (nearest neighbours) associated with the target word in an automatically acquired thesaurus (Lin, 1998). The distributional similarity scores of the nearest neighbours are associated with the respective target word senses using a WordNet similarity measure, such as those proposed by Jiang and Conrath (1997) and Banerjee and Pedersen (2002). The word senses are ranked based on these similarity scores, and the most frequent sense is selected for the corpus that the distributional similarity thesaurus was trained over.

As well as sense ranking for predominant sense acquisition, automatic estimates of sense frequency distribution can be very useful for WSD for training data sampling purposes (Agirre and Martinez, 2004), entropy estimation (Jin et al., 2009), and prior probability estimates, all of which can be integrated within a WSD system (Chan and Ng, 2005; Chan and Ng, 2006; Lapata and Brew, 2004). Various approaches have been adopted, such as normalizing sense ranking scores to obtain a probability distribution (Jin et al., 2009), using subcategorisation information as an indication of verb sense (Lapata and Brew, 2004) or alternatively using parallel text (Chan and Ng, 2005; Chan and Ng, 2006; Agirre and Martinez, 2004).

The work of Boyd-Graber and Blei (2007) is highly related in that it extends the method of McCarthy et al. (2004b) to provide a generative model which assumes the words in a given document are generated according to the topic distribution appropriate for that document. They then predict the most likely sense for each word in the document based on the topic distribution and the words in context ("corroborators"), each of which, in turn, depends on the document's topic distribution. Using this approach, they get comparable results to McCarthy et al. when context is ignored (i.e. using a model with one topic), and at most a 1% improvement on SemCor when they use more topics in order to take context into account. Since the results do not improve on McCarthy et al. as regards sense distribution acquisition irrespective of context, we will compare our model with that proposed by McCarthy et al.

Recent work on finding novel senses has tended to focus on comparing diachronic corpora (Sagi et al., 2009; Cook and Stevenson, 2010; Gulordava and Baroni, 2011) and has also considered topic models (Lau et al., 2012). In a similar vein, Peirsman et al. (2010) considered the identification of words having a sense particular to one language variety with respect to another (specifically Belgian and Netherlandic Dutch). In contrast to these studies, we propose a model for comparing a corpus with a sense inventory. Carpuat et al. (2013) exploit parallel corpora to identify words in domain-specific monolingual corpora with previously-unseen translations; the method we propose does not require parallel data.

3 Methodology

Our methodology is based on the WSI system described in Lau et al. (2012),[1] which has been shown (Lau et al., 2012; Lau et al., 2013a; Lau et al., 2013b) to achieve state-of-the-art results over the WSI tasks from SemEval-2007 (Agirre and Soroa, 2007), SemEval-2010 (Manandhar et al., 2010) and SemEval-2013 (Navigli and Vannella, 2013; Jurgens and Klapaftis, 2013). The system is built around a Hierarchical Dirichlet Process (HDP: Teh et al. (2006)), a non-parametric variant of a Latent Dirichlet Allocation topic model (Blei et al., 2003) where the model automatically optimises the number of topics in a fully-unsupervised fashion over the training data.

To learn the senses of a target lemma, we train a single topic model per target lemma. The system reads in a collection of usages of that lemma, and automatically induces topics (= senses) in the form of a multinomial distribution over words, and per-usage topic assignments (= probabilistic sense assignments) in the form of a multinomial distribution over topics. Following Lau et al. (2012), we assign one topic to each usage by selecting the topic that has the highest cumulative probability density, based on the topic allocations of all words in the context window for that usage.[2] Note that in their original work, Lau et al. (2012) experimented with the use of features extracted from a dependency parser. Due to the computational overhead associated with these features, and the fact that the empirical impact of the features was found to be marginal, we make no use of parser-based features in this paper.[3]

The induced topics take the form of word multinomials, and are often represented by the top-N words in descending order of conditional probability. We interpret each topic as a sense of the target lemma.[4] To illustrate this, we give the example of topics induced by the HDP model for *network* in Table 1.

We refer to this method as HDP-WSI henceforth.[5]

In predominant sense acquisition, the task is to learn, for each target lemma, the most frequently occurring word sense in a particular domain or corpus, relative to a predefined sense inventory. The WSI system provides us with a topic allocation per usage of a given word, from which we can derive a distribution of topics over usages and a **predominant topic**. In order to map this onto the **predominant sense**, we need to have some way of aligning a topic with a sense. We design our topic–sense alignment methodology with portability in mind — it should be applicable to any sense inventory. As such, our alignment methodology assumes only that we have access to a conventional sense gloss or definition for each sense, and does not rely on ontological/structural knowledge (e.g. the WordNet hierarchy).

To compute the similarity between a sense and a topic, we first convert the words in the gloss/definition into a multinomial distribution over words, based on simple maximum likelihood estimation.[6] We then calculate the Jensen–Shannon divergence between the multinomial distribution (over words) of the gloss and that of the topic, and convert the divergence value into a similarity score by subtracting it from 1. Formally, the similarity sense s_i and topic t_j is:

$$\text{sim}(s_i, t_j) = 1 - \text{JS}(S \| T) \quad (1)$$

where S and T are the multinomial distributions

[1] Based on the implementation available at: `https://github.com/jhlau/hdp-wsi`

[2] This includes all words in the usage sentence except stopwords, which were filtered in the preprocessing step.

[3] For hyper-parameters α and γ, we used 0.1 for both. We did not tune the parameters, and opted to use the default parameters introduced in Teh et al. (2006).

[4] To avoid confusion, we will refer to the HDP-induced topics as *topics*, and reserve the term *sense* to denote senses in a sense inventory.

[5] The code used to learn predominant sense and run all experiments described in this paper is available at: `https://github.com/jhlau/predom_sense`.

[6] Words are tokenised using OpenNLP and lemmatised with Morpha (Minnen et al., 2001). We additionally remove the target lemma, stopwords and words that are less than 3 characters in length.

over words for sense s_i and topic t_j, respectively, and $\text{JS}(X\|Y)$ is the Jensen–Shannon divergence for distribution X and Y.

To learn the predominant sense, we compute the **prevalence score** of each sense and take the sense with the highest prevalence score as the predominant sense. The prevalence score for a sense is computed by summing the product of its similarity scores with each topic (i.e. $\text{sim}(s_i, t_j)$) and the prior probability of the topic in question (based on maximum likelihood estimation). Formally, the prevalence score of sense s_i is given as follows:

$$\text{prevalence}(s_i) = \sum_{j}^{T} (\text{sim}(s_i, t_j) \times P(t_j)) \quad (2)$$
$$= \sum_{j}^{T} \left(\text{sim}(s_i, t_j) \times \frac{f(t_j)}{\sum_{k}^{T} f(t_k)} \right)$$

where $f(t_j)$ is the frequency of topic t_j (i.e. the number of usages assigned to topic t_j), and T is the number of topics.

The intuition behind the approach is that the predominant sense should be the sense that has relatively high similarity (in terms of lexical overlap) with high-probability topic(s).

4 WordNet Experiments

We first test the proposed method over the tasks of predominant sense learning and sense distribution induction, using the WordNet-tagged dataset of Koeling et al. (2005), which is made up of 3 collections of documents: a domain-neutral corpus (BNC), and two domain-specific corpora (SPORTS and FINANCE). For each domain, annotators were asked to sense-annotate a random selection of sentences for each of 40 target nouns, based on WordNet v1.7. The predominant sense and distribution across senses for each target lemma was obtained by aggregating over the sense annotations. The authors evaluated their method in terms of WSD accuracy over a given corpus, based on assigning all instances of a target word with the predominant sense learned from that corpus. For the remainder of the paper, we denote their system as MKWC.

To compare our system (HDP-WSI) with MKWC, we apply it to the three datasets of Koeling et al. (2005). For each dataset, we use HDP to induce topics for each target lemma, compute the similarity between the topics and the WordNet senses (Equation (1)), and rank the senses based on the prevalence scores (Equation (2)). In addition to the WSD accuracy based on the predominant sense inferred from a particular corpus, we additionally compute: (1) Acc_{UB}, the upper bound for the first sense-based WSD accuracy (using the gold standard predominant sense for disambiguation);[7] and (2) ERR, the error rate reduction between the accuracy for a given system (Acc) and the upper bound (Acc_{UB}), calculated as follows:

$$\text{ERR} = 1 - \frac{\text{Acc}_{\text{UB}} - \text{Acc}}{\text{Acc}_{\text{UB}}}$$

Looking at the results in Table 2, we see little difference in the results for the two methods, with MKWC performing better over two of the datasets (BNC and SPORTS) and HDP-WSI performing better over the third (FINANCE), but all differences are small. Based on the McNemar's Test with Yates correction for continuity, MKWC is significantly better over BNC and HDP-WSI is significantly better over FINANCE ($p < 0.0001$ in both cases), but the difference over SPORTS is not statistically significance ($p > 0.1$). Note that there is still much room for improvement with

[7] The upper bound for a WSD approach which tags all token occurrences of a given word with the same sense, as a first step towards context-sensitive unsupervised WSD.

Dataset	FS_{CORPUS} Acc_{UB}	MKWC Acc	MKWC ERR	HDP-WSI Acc	HDP-WSI ERR
BNC	0.524	**0.407**	(0.777)	0.376	(0.718)
FINANCE	0.801	0.499	(0.623)	**0.555**	(0.693)
SPORTS	0.774	**0.437**	(0.565)	0.422	(0.545)

Table 2: WSD accuracy for MKWC and HDP-WSI on the WordNet-annotated datasets, as compared to the upper-bound based on actual first sense in the corpus (higher values indicate better performance; the **best** system in each row [other than the FS_{CORPUS} upper bound] is indicated in boldface).

Dataset	MKWC	HDP-WSI
BNC	0.226	**0.214**
FINANCE	0.426	**0.375**
SPORTS	0.420	**0.363**

Table 3: Sense distribution evaluation of MKWC and HDP-WSI on the WordNet-annotated datasets, evaluated using JS divergence (lower values indicate better performance; the **best** system in each row is indicated in boldface).

both systems, as we see in the gap between the upper bound (based on perfect determination of the first sense) and the respective system accuracies.

Given that both systems compute a continuous-valued prevalence score for each sense of a target lemma, a distribution of senses can be obtained by normalising the prevalence scores across all senses. The predominant sense learning task of McCarthy et al. (2007) evaluates the ability of a method to identify only the head of this distribution, but it is also important to evaluate the full sense distribution (Jin et al., 2009). To this end, we introduce a second evaluation metric: the Jensen–Shannon (JS) divergence between the inferred sense distribution and the gold-standard sense distribution, noting that smaller values are better in this case, and that it is now theoretically possible to obtain a JS divergence of 0 in the case of a perfect estimate of the sense distribution. Results are presented in Table 3.

HDP-WSI consistently achieves lower JS divergence, indicating that the distribution of senses that it finds is closer to the gold standard distribution. Testing for statistical significance over the paired JS divergence values for each lemma using the Wilcoxon signed-rank test, the result for FINANCE is significant ($p < 0.05$) but the results for the other two datasets are not ($p > 0.1$ in each case).

Dataset	FS_{CORPUS} Acc_{UB}	FS_{DICT} Acc	FS_{DICT} ERR	HDP-WSI Acc	HDP-WSI ERR
UKWAC	0.574	0.387	(0.674)	**0.514**	(0.895)

Table 5: Sense distribution evaluation of HDP-WSI on the Macmillan-annotated datasets as compared to corpus- and dictionary-based first sense methods, evaluated using JS divergence (lower values indicate better performance; the **best** system in each row is indicated in boldface).

To summarise, the results for MKWC and HDP-WSI are fairly even for predominant sense learning (each outperforms the other at a level of statistical significance over one dataset), but HDP-WSI is better at inducing the overall sense distribution.

It is important to bear in mind that MKWC in these experiments makes use of full-text parsing in calculating the distributional similarity thesaurus, and the WordNet graph structure in calculating the similarity between associated words and different senses. Our method, on the other hand, uses no parsing, and only the synset definitions (and not the graph structure) of WordNet.[8] The non-reliance on parsing is significant in terms of portability to text sources which are less amenable to parsing (such as Twitter: (Baldwin et al., 2013)), and the non-reliance on the graph structure of WordNet is significant in terms of portability to conventional "flat" sense inventories. While comparable results on a different dataset have been achieved with a proximity thesaurus (McCarthy et al., 2007) compared to a dependency one,[9] it is not stated how

[8] McCarthy et al. (2004b) obtained good results with definition overlap, but their implementation uses the relation structure alongside the definitions (Banerjee and Pedersen, 2002). Iida et al. (2008) demonstrate that further extensions using distributional data are required when applying the method to resources without hierarchical relations.

[9] The thesauri used in the reimplementation of MKWC in this paper were obtained from `http://webdocs.cs.ualberta.ca/~lindek/downloads.htm`.

wide a window is needed for the proximity thesaurus. This could be a significant issue with Twitter data, where context tends to be limited. In the next section, we demonstrate the robustness of the method in experimenting with two new datasets, based on Twitter and a web corpus, and the Macmillan English Dictionary.

5 Macmillan Experiments

In our second set of experiments, we move to a new dataset (Gella et al., to appear) based on text from ukWaC (Ferraresi et al., 2008) and Twitter, and annotated using the Macmillan English Dictionary[10] (henceforth "Macmillan"). For the purposes of this research, the choice of Macmillan is significant in that it is a conventional dictionary with sense definitions and examples, but no linking between senses.[11] In terms of the original research which gave rise to the sense-tagged dataset, Macmillan was chosen over WordNet for reasons including: (1) the well-documented difficulties of sense tagging with fine-grained WordNet senses (Palmer et al., 2004; Navigli et al., 2007); (2) the regular update cycle of Macmillan (meaning it contains many recently-emerged senses); and (3) the finding in a preliminary sense-tagging task that it better captured Twitter usages than WordNet (and also OntoNotes: Hovy et al. (2006)).

The dataset is made up of 20 target nouns which were selected to span the high- to mid-frequency range in both Twitter and the ukWaC corpus, and have at least 3 Macmillan senses. The average sense ambiguity of the 20 target nouns in Macmillan is 5.6 (but 12.3 in WordNet). 100 usages of each target noun were sampled from each of Twitter (from a crawl over the time period Jan 3–Feb 28, 2013 using the Twitter Streaming API) and ukWaC, after language identification using `langid.py` (Lui and Baldwin, 2012) and POS tagging (based on the CMU ARK Twitter POS tagger v2.0 (Owoputi et al., 2012) for Twitter, and the POS tags provided with the corpus for ukWaC). Amazon Mechanical Turk (AMT) was then used to 5-way sense-tag each usage relative to Macmillan, including allowing the annotators the option to label a usage as "Other" in instances where the usage was not captured by any of the Macmillan senses. After quality control over the annotators/annotations (see Gella et al. (to appear) for details), and aggregation of the annotations into a single sense per usage (possibly "Other"), there were 2000 sense-tagged ukWaC sentences and Twitter messages over the 20 target nouns. We refer to these two datasets as UKWAC and TWITTER henceforth.

To apply our method to the two datasets, we use HDP-WSI to train a model for each target noun, based on the combined set of usages of that lemma in each of the two background corpora, namely the original Twitter crawl that gave rise to the TWITTER dataset, and all of ukWaC.

5.1 Learning Sense Distributions

As in Section 4, we evaluate in terms of WSD accuracy (Table 4) and JS divergence over the gold-standard sense distribution (Table 5). We also present the results for: (a) a supervised baseline ("FS_{CORPUS}"), based on the most frequent sense in the corpus; and (b) an unsupervised baseline ("FS_{DICT}"), based on the first-listed sense in Macmillan. In each case, the sense distribution is based on allocating all probability mass for a given word to the single sense identified by the respective method.

We first notice that, despite the coarser-grained senses of Macmillan as compared to WordNet, the upper bound WSD accuracy using Macmillan is comparable to that of the WordNet-based datasets over the balanced BNC, and quite a bit lower than that of the two domain corpora of Koeling et al. (2005). This suggests that both datasets are diverse in domain and content.

In terms of WSD accuracy, the results over UKWAC (ERR = 0.895) are substantially higher than those for BNC, while those over TWITTER (ERR = 0.716) are comparable. The accuracy is significantly higher than the dictionary-based first sense baseline (FS_{DICT}) over both datasets (McNemar's test; $p < 0.0001$), and the ERR is also considerably higher than for the two domain datasets in Section 4 (FINANCE and SPORTS). One cause of difficulty in sense-modelling TWITTER is large numbers of missing senses, with 12.3% of usages in TWITTER and 6.6% in UKWAC having no corresponding Macmillan sense.[12] This challenges the assumption built into the sense prevalence calculation that all topics will align to a pre-existing sense, a point we return to in Section 5.2.

[10] `http://www.macmillandictionary.com/`

[11] Strictly speaking, there is limited linking in the form of sets of synonyms in Macmillan, but we choose to not use this information in our research.

[12] The relative occurrence of unlisted/unclear senses in the datasets of Koeling et al. (2005) is comparable to UKWAC.

Dataset	P	R	F
UKWAC	0.73	0.85	0.74
TWITTER	0.56	0.88	0.65

Table 6: Evaluation of our method for identifying unattested senses, averaged over 10 runs of 10-fold cross validation

The JS divergence results for both datasets are well below (= better than) the results for all three WordNet-based datasets, and also superior to both the supervised and unsupervised first-sense baselines. Part of the reason for this improvement is simply that the average polysemy in Macmillan (5.6 senses per target lemma) is slightly less than in WordNet (6.7 senses per target lemma),[13] making the task slightly easier in the Macmillan case.

5.2 Identification of Unattested Senses

We observed in Section 5.1 that there are relatively frequent occurrences of usages (e.g. 12.3% for TWITTER) which aren't captured by Macmillan. Conversely, there are also senses in Macmillan which aren't attested in the annotated sample of usages. Specifically, of the 112 senses defined for the 20 target lemmas, 25 (= 22.3%) of the senses are not attested in the 2000 usages in either corpora. Given that our methodology computes a prevalence score for each sense, it can equally be applied to the detection of these unattested senses, and it is this task that we address in this section: the identification of senses that are defined in the sense inventory but not attested in a given corpus.

Intuitively, an unused sense should have low similarity with the HDP induced topics. As such, we introduce sense-to-topic affinity, a measure that estimates how likely a sense is not attested in the corpus:

$$\text{st-affinity}(s_i) = \frac{\sum_j^T \text{sim}(s_i, t_j)}{\sum_k^S \sum_l^T \text{sim}(s_k, t_l)} \quad (3)$$

where $\text{sim}(s_i, t_j)$ is carried over from Equation (1), and T and S represent the number of topics and senses, respectively.

We treat the task of identification of unused senses as a binary classification problem, where the goal is to find a sense-to-topic affinity threshold below which a sense will be considered to be unused. We pool together all the senses and run 10-fold cross validation to learn the threshold for identifying unused senses,[14] evaluated using sense-level precision (P), recall (R) and F-score (F) at detecting unattested senses. We repeat the experiment 10 times (partitioning the items randomly into folds) and collect the mean precision, recall and F-scores across the 10 runs. We found encouraging results for the task, as detailed in Table 6. For the threshold, the average value with standard deviation is 0.092 ± 0.044 over UKWAC and 0.125 ± 0.052 over TWITTER, indicating relative stability in the value of the threshold both internally within a dataset, and also across datasets.

5.3 Identification of Novel Senses

In both TWITTER and UKWAC, we observed frequent occurrences of usages of our target nouns which didn't map onto a pre-existing Macmillan sense. A natural question to ask is whether our method can be used to predict word senses that are missing from our sense inventory, and identify usages associated with each such missing sense. We will term these "novel senses", and define "novel sense identification" to be the task of identifying new senses that are not recorded in the inventory but are seen in the corpus.

An immediate complication in evaluating novel sense identification is that we are attempting to identify senses which explicitly aren't in our sense inventory. This contrasts with the identification of unattested senses, e.g., where we were attempting to identify which of the *known* senses wasn't observed in the corpus. Also, while we have annotations of "Other" usages in TWITTER and UKWAC, there is no real expectation that all such usages will correspond to the same sense: in practice, they are attributable to a myriad of effects such as incorporation in a non-compositional multiword expression, and errors in POS tagging (i.e. the usage not being nominal). As such, we can't use the "Other" annotations to evaluate novel sense identification. The evaluation of systems for this task is a known challenge, which we address similarly to Erk (2006) by artificially synthesising novel senses through removal of senses from the sense inventory. In this way, even if we remove multiple senses for a given word, we still have access to information about which usages correspond to

[13] Note that the set of lemmas differs between the respective datasets, so this isn't an accurate reflection of the relative granularity of the two dictionaries.

[14] We used a fixed step and increment at steps of 0.001, up to the max value of st-affinity when optimising the threshold.

No. Lemmas with a Removed Sense	Relative Freq of Removed Sense	Threshold Mean±stdev	P	R	F
20	0.0–0.2	0.052±0.009	0.35	0.42	0.36
9	0.2–0.4	0.089±0.024	0.24	0.59	0.29
6	0.4–0.6	0.061±0.004	0.63	0.64	0.63

Table 7: Classification of usages with novel sense for all target lemmas.

No. Lemmas with a Removed Sense	Relative Freq of Removed Sense	Threshold Mean±stdev	P	R	F
9	0.2–0.4	0.093±0.023	0.50	0.66	0.52
6	0.4–0.6	0.099±0.018	0.73	0.90	0.80

Table 8: Classification of usages with novel sense for target lemmas with a removed sense.

which novel sense. An additional advantage of this procedure is that it allows us to control an important property of novel senses: their frequency of occurrence.

In the experiments that follow, we randomly select senses for removal from three frequency bands: low, medium and high frequency senses. Frequency is defined by relative occurrence in the annotated usages: low = 0.0–0.2; medium = 0.2–0.4; and high = 0.4–0.6. Note that we do not consider high-frequency senses with frequency higher than 0.6, as it is rare for a medium- to high-frequency word to take on a novel sense which is then the predominant sense in a given corpus. Note also that not all target lemmas will have a novel sense through synthesis, as they may have no senses that fall within the indicated bounds of relative occurrence (e.g. if $> 60\%$ of usages are a single sense). For example, only 6 of our 20 target nouns have senses which are candidates for high-frequency novel senses.

As before, we treat the novel sense identification task as a classification problem, although with a significantly different formulation: we are no longer attempting to identify pre-existing senses, as novel senses are by definition not included in the sense inventory. Instead, we are seeking to identify clusters of usages which are instances of a novel sense, e.g. for presentation to a lexicographer as part of a dictionary update process (Rundell and Kilgarriff, 2011; Cook et al., 2013). That is, for each usage, we want to classify whether it is an instance of a given novel sense.

A usage that corresponds to a novel sense should have a topic that does not align well with any of the pre-existing senses in the sense inventory. Based on this intuition, we introduce topic-to-sense affinity to estimate the similarity of a topic to the set of senses, as follows:

$$\text{ts-affinity}(t_j) = \frac{\sum_i^S \text{sim}(s_i, t_j)}{\sum_l^T \sum_k^S \text{sim}(s_k, t_l)} \quad (4)$$

where, once again, $\text{sim}(s_i, t_j)$ is defined as in Equation (1), and T and S represent the number of topics and senses, respectively.

Using topic-to-sense affinity as the sole feature, we pool together all instances and optimise the affinity feature to classify instances that have novel senses. Evaluation is done by computing the mean precision, recall and F-score across 10 separate runs; results are summarised in Table 7. Note that we evaluate only over UKWAC in this section, for ease of presentation.

The results show that instances with high-frequency novel senses are more easily identifiable than instances with medium/low-frequency novel senses. This is unsurprising given that high-frequency senses have a higher probability of generating related topics (sense-related words are observed more frequently in the corpus), and as such are more easily identifiable.

We are interested in understanding whether pooling all instances — instances from target lemmas that have a sense artificially removed and those that do not — impacted the results (recall that not all target lemmas have a removed sense). To that end, we chose to include only instances from lemmas with a removed sense, and repeated the experiment for the medium- and high-frequency novel sense condition (for the low-frequency condition, all target lemmas have a novel sense). In other words, we are assuming knowledge of which words have novel sense, and the task is to identify specifically what the novel sense is, as represented by novel usages. Results are presented in Table 8.

No. of Lemmas with a Removed Sense	No. of Lemmas without a Removed Sense	Relative Freq of Removed Sense	Wilcoxon Rank Sum p-value
10	0	0.0–0.2	0.4543
9	11	0.2–0.4	0.0391
6	14	0.4–0.6	0.0247

Table 9: Wilcoxon Rank Sum p-value results for testing target lemmas with removed sense vs. target lemmas without removed sense using novelty.

From the results, we see that the F-scores improved notably. This reveals that an additional step is necessary to determine whether a target lemma has a potential novel sense before feeding its instances to learn which of them contains the usage of the novel sense.

In the last experiment, we propose a new measure to tackle this: the identification of target lemmas that have a novel sense. We introduce novelty, a measure of the likelihood of a target lemma w having a novel sense:

$$\text{novelty}(w) = \min_{t_j} \left(\max_{s_i} \frac{\text{sim}(s_i, t_j)}{f(t_j)} \right) \quad (5)$$

where $f(t_j)$ is the frequency of topic t_j in the corpus. The intuition behind novelty is that a target lemma with a novel sense should have a (somewhat-)frequent topic that has low association with any sense. That we use the frequency rather than the probability of the topic here is deliberate, as topics with a higher raw number of occurrences (whether as a low-probability topic for a high-frequency word, or a high-probability topic for a low-frequency word) are indicative of a novel word sense.

For each of our three datasets (with low-, medium- and high-frequency novel senses, respectively), we compute the novelty of the target lemmas and the p-value of a one-tailed Wilcoxon rank sum test to test if the two groups of lemmas (i.e. lemmas with a novel sense vs. lemmas without a novel sense) are statistically different.[15] Results are presented in Table 9. We see that the novelty measure can readily identify target lemmas with high- and medium-frequency novel senses ($p < 0.05$), but the results are less promising for the low-frequency novel senses.

6 Discussion

Our methodologies for the two proposed tasks of identifying unused and novel senses are simple extensions to demonstrate the flexibility and robustness of our methodology. Future work could pursue a more sophisticated methodology, using non-linear combinations of $\text{sim}(s_i, t_j)$ for computing the affinity measures or multiple features in a supervised context. We contend, however, that these extensions are ultimately a preliminary demonstration to the flexibility and robustness of our methodology.

A natural next step for this research would be to couple sense distribution estimation and the detection of unattested senses with evidence from the context, using topics or other information about the local context (e.g. Agirre and Soroa (2009)) to carry out unsupervised WSD of individual token occurrences of a given word.

In summary, we have proposed a topic modelling-based method for estimating word sense distributions, based on Hierarchical Dirichlet Processes and the earlier work of Lau et al. (2012) on word sense induction, in probabilistically mapping the automatically-learned topics to senses in a sense inventory. We evaluated the ability of the method to learn predominant senses and induce word sense distributions, based on a broad range of datasets and two separate sense inventories. In doing so, we established that our method is comparable to the approach of McCarthy et al. (2007) at predominant sense learning, and superior at inducing word sense distributions. We further demonstrated the applicability of the method to the novel tasks of detecting word senses which are unattested in a corpus, and identifying novel senses which are found in a corpus but not captured in a word sense inventory.

Acknowledgements

We wish to thank the anonymous reviewers for their valuable comments. This research was supported in part by funding from the Australian Research Council.

[15] Note that the number of words with low-frequency novel senses here is restricted to 10 (cf. 20 in Table 7) to ensure we have both positive and negative lemmas in the dataset.

Abstract

We present an approach for automatically learning to solve algebra word problems. Our algorithm reasons across sentence boundaries to construct and solve a system of linear equations, while simultaneously recovering an alignment of the variables and numbers in these equations to the problem text. The learning algorithm uses varied supervision, including either full equations or just the final answers. We evaluate performance on a newly gathered corpus of algebra word problems, demonstrating that the system can correctly answer almost 70% of the questions in the dataset. This is, to our knowledge, the first learning result for this task.

1 Introduction

Algebra word problems concisely describe a world state and pose questions about it. The described state can be modeled with a system of equations whose solution specifies the questions' answers. For example, Figure 1 shows one such problem. The reader is asked to infer how many children and adults were admitted to an amusement park, based on constraints provided by ticket prices and overall sales. This paper studies the task of learning to automatically solve such problems given only the natural language.[1]

Solving these problems requires reasoning across sentence boundaries to find a system of equations that concisely models the described semantic relationships. For example, in Figure 1, the total ticket revenue computation in the second equation summarizes facts about ticket prices and total sales described in the second, third, and fifth sentences. Furthermore, the first equation models an implicit semantic relationship, namely that the children and adults admitted are non-intersecting subsets of the set of people who entered the park.

Word problem
An amusement park sells 2 kinds of tickets. Tickets for children cost $1.50. Adult tickets cost $4. On a certain day, 278 people entered the park. On that same day the admission fees collected totaled $792. How many children were admitted on that day? How many adults were admitted?
Equations
$x + y = 278$ $1.5x + 4y = 792$
Solution
$x = 128 \quad y = 150$

Figure 1: An example algebra word problem. Our goal is to map a given problem to a set of equations representing its algebraic meaning, which are then solved to get the problem's answer.

Our model defines a joint log-linear distribution over full systems of equations and alignments between these equations and the text. The space of possible equations is defined by a set of equation templates, which we induce from the training examples, where each template has a set of slots. Number slots are filled by numbers from the text, and unknown slots are aligned to nouns. For example, the system in Figure 1 is generated by filling one such template with four specific numbers (1.5, 4, 278, and 792) and aligning two nouns ("Tickets" in "Tickets for children", and "tickets" in "Adult tickets"). These inferred correspondences are used to define cross-sentence features that provide global cues to the model. For instance, in our running example, the string

[1] The code and data for this work are available at http://groups.csail.mit.edu/rbg/code/wordprobs/.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 271–281,
Baltimore, Maryland, USA, June 23-25 2014.

pairs ("$1.50", "children") and ("$4","adults") both surround the word "cost," suggesting an output equation with a sum of two constant-variable products.

We consider learning with two different levels of supervision. In the first scenario, we assume access to each problem's numeric solution (see Figure 1) for most of the data, along with a small set of seed examples labeled with full equations. During learning, a solver evaluates competing hypotheses to drive the learning process. In the second scenario, we are provided with a full system of equations for each problem. In both cases, the available labeled equations (either the seed set, or the full set) are abstracted to provide the model's equation templates, while the slot filling and alignment decisions are latent variables whose settings are estimated by directly optimizing the marginal data log-likelihood.

The approach is evaluated on a new corpus of 514 algebra word problems and associated equation systems gathered from Algebra.com. Provided with full equations during training, our algorithm successfully solves over 69% of the word problems from our test set. Furthermore, we find the algorithm can robustly handle weak supervision, achieving more than 70% of the above performance when trained exclusively on answers.

2 Related Work

Our work is related to three main areas of research: situated semantic interpretation, information extraction, and automatic word problem solvers.

Situated Semantic Interpretation There is a large body of research on learning to map natural language to formal meaning representations, given varied forms of supervision. Reinforcement learning can be used to learn to read instructions and perform actions in an external world (Branavan et al., 2009; Branavan et al., 2010; Vogel and Jurafsky, 2010). Other approaches have relied on access to more costly annotated logical forms (Zelle and Mooney, 1996; Thompson and Mooney, 2003; Wong and Mooney, 2006; Zettlemoyer and Collins, 2005; Kwiatkowski et al., 2010). These techniques have been generalized more recently to learn from sentences paired with indirect feedback from a controlled application. Examples include question answering (Clarke et al., 2010; Cai and Yates, 2013a; Cai and Yates, 2013b; Berant et al., 2013; Kwiatkowski et al., 2013), dialog systems (Artzi and Zettlemoyer, 2011), robot instruction (Chen and Mooney, 2011; Chen, 2012; Kim and Mooney, 2012; Matuszek et al., 2012; Artzi and Zettlemoyer, 2013), and program executions (Kushman and Barzilay, 2013; Lei et al., 2013). We focus on learning from varied supervision, including question answers and equation systems, both can be obtained reliably from annotators with no linguistic training and only basic math knowledge.

Nearly all of the above work processed single sentences in isolation. Techniques that consider multiple sentences typically do so in a serial fashion, processing each in turn with limited cross-sentence reasoning (Branavan et al., 2009; Zettlemoyer and Collins, 2009; Chen and Mooney, 2011; Artzi and Zettlemoyer, 2013). We focus on analyzing multiple sentences simultaneously, as is necessary to generate the global semantic representations common in domains such as algebra word problems.

Information Extraction Our approach is related to work on template-based information extraction, where the goal is to identify instances of event templates in text and extract their slot fillers. Most work has focused on the supervised case, where the templates are manually defined and data is labeled with alignment information, e.g. (Grishman et al., 2005; Maslennikov and Chua, 2007; Ji and Grishman, 2008; Reichart and Barzilay, 2012). However, some recent work has studied the automatic induction of the set of possible templates from data (Chambers and Jurafsky, 2011; Ritter et al., 2012). In our approach, systems of equations are relatively easy to specify, providing a type of template structure, and the alignment of the slots in these templates to the text is modeled primarily with latent variables during learning. Additionally, mapping to a semantic representation that can be executed allows us to leverage weaker supervision during learning.

Automatic Word Problem Solvers Finally, there has been research on automatically solving various types of mathematical word problems. The dominant existing approach is to hand engineer rule-based systems to solve math problem in specific domains (Mukherjee and Garain, 2008; Lev et al., 2004). Our focus is on learning a model for the end-to-end task of solving word problems given only a training corpus of questions paired with equations or answers.

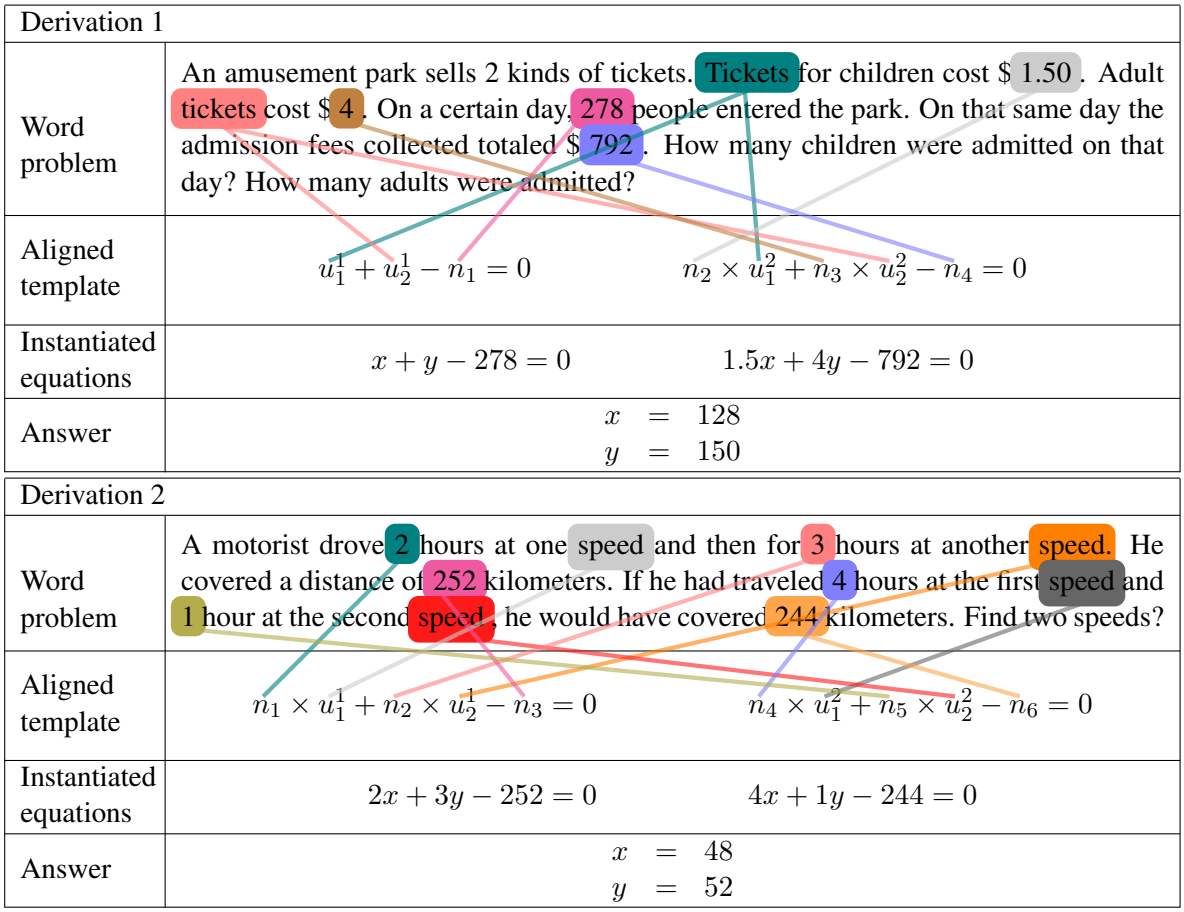

Figure 2: Two complete derivations for two different word problems. Derivation 1 shows an alignment where two instances of the same slot are aligned to the same word (e.g., u_1^1 and u_1^2 both are aligned to "Tickets"). Derivation 2 includes an alignment where four identical nouns are each aligned to different slot instances in the template (e.g., the first "speed" in the problem is aligned to u_1^1).

3 Mapping Word Problems to Equations

We define a two step process to map word problems to equations. First, a template is selected to define the overall structure of the equation system. Next, the template is instantiated with numbers and nouns from the text. During inference we consider these two steps jointly.

Figure 2 shows both steps for two derivations. The template dictates the form of the equations in the system and the type of slots in each: u slots represent unknowns and n slots are for numbers that must be filled from the text. In Derivation 1, the selected template has two unknown slots, u_1 and u_2, and four number slots, n_1 to n_4. Slots can be shared between equations, for example, the unknown slots u_1 and u_2 in the example appear in both equations. A slot may have different instances, for example u_1^1 and u_1^2 are the two instances of u_1 in the example.

We align each slot instance to a word in the problem. Each number slot n is aligned to a number, and each unknown slot u is aligned to a noun. For example, Derivation 1 aligns the number 278 to n_1, 1.50 to n_2, 4 to n_3, and 792 to n_4. It also aligns both instances of u_1 (e.g., u_1^1 and u_1^2) to "Tickets", and both instances of u_2 to "tickets". In contrast, in Derivation 2, instances of the same unknown slot (e.g. u_1^1 and u_1^2) are aligned to two different words in the problem (different occurrences of the word "speed"). This allows for a tighter mapping between the natural language and the system template, where the words aligned to the first equation in the template come from the first two sentences, and the words aligned to the second equation come from the third.

Given an alignment, the template can then be instantiated: each number slot n is replaced with the aligned number, and each unknown slot u with a variable. This output system of equations is then automatically solved to generate the final answer.

3.1 Derivations

Definitions Let $\mathcal{X}$ be the set of all word problems. A word problem $x \in \mathcal{X}$ is a sequence of k words $\langle w_1, \ldots w_k \rangle$. Also, define an *equation template* t to be a formula $A = B$, where A and B are expressions. An expression A is one of the following:

- A number constant f.
- A number slot n.
- An unknown slot u.
- An application of a mathematical relation R to two expressions (e.g., $n_1 \times u_1$).

We define a *system template* T to be a set of l equation templates $\{t_0, \ldots, t_l\}$. $\mathcal{T}$ is the set of all system templates. A slot may occur more than once in a system template, to allow variables to be reused in different equations. We denote a specific instance i of a slot, u for example, as u^i. For brevity, we omit the instance index when a slot appears only once. To capture a correspondence between the text of x and a template T, we define an alignment p to be a set of pairs (w, s), where w is a token in x and s is a slot instance in T.

Given the above definitions, an equation e can be constructed from a template t where each number slot n is replaced with a real number, each unknown slot u is replaced with a variable, and each number constant f is kept as is. We call the process of turning a template into an equation *template instantiation*. Similarly, an equation system E is a set of l equations $\{e_0, \ldots, e_l\}$, which can be constructed by instantiating each of the equation templates in a system template T. Finally, an answer a is a tuple of real numbers.

We define a derivation y from a word problem to an answer as a tuple (T, p, a), where T is the selected system template, p is an alignment between T and x, and a is the answer generated by instantiating T using x through p and solving the generated equations. Let $\mathcal{Y}$ be the set of all derivations.

The Space of Possible Derivations We aim to map each word problem x to an equation system E. The space of equation systems considered is defined by the set of possible system templates $\mathcal{T}$ and the words in the original problem x, that are available for filling slots. In practice, we generate $\mathcal{T}$ from the training data, as described in Section 4.1. Given a system template $T \in \mathcal{T}$, we create an alignment p between T and x. The set of possible alignment pairs is constrained as follows: each number slot $n \in T$ can be aligned to any number in the text, a number word can only be aligned to a single slot n, and must be aligned to all instances of that slot. Additionally, an unknown slot instance $u \in T$ can only be aligned to a noun word. A complete derivation's alignment pairs all slots in T with words in x.

An **amusement park** sells 2 **kinds** of **tickets**. **Tickets** for **children** cost **$** 1.50. Adult **tickets** cost **$** 4. On a certain **day**, 278 **people** entered the **park**. On that same **day** the **admission fees** collected totaled **$** 792. How many **children** were admitted on that **day**? How many **adults** were admitted?

$$\begin{aligned} u_1^1 + u_2^1 - n_1 &= 0 \\ n_2 \times u_1^2 + n_3 \times u_2^2 - n_4 &= 0 \end{aligned}$$

Figure 3: The first example problem and selected system template from Figure 2 with all potential aligned words marked. Nouns (boldfaced) may be aligned to unknown slot instances u_i^j, and number words (highlighted) may be aligned to number slots n_i.

Figure 3 illustrates the space of possible alignments for the first problem and system template from Figure 2. Nouns (shown in boldface) can be aligned to any of the unknown slot instances in the selected template (u_1^1, u_1^2, u_2^1, and u_2^2 for the template selected). Numbers (highlighted) can be aligned to any of the number slots (n_1, n_2, n_3, and n_4 in the template).

3.2 Probabilistic Model

Due to the ambiguity in selecting the system template and alignment, there will be many possible derivations $y \in \mathcal{Y}$ for each word problem $x \in \mathcal{X}$. We discriminate between competing analyses using a log-linear model, which has a feature function $\phi : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}^d$ and a parameter vector $\theta \in \mathbb{R}^d$. The probability of a derivation y given a problem x is defined as:

$$p(y|x;\theta) = \frac{e^{\theta \cdot \phi(x,y)}}{\sum_{y' \in \mathcal{Y}} e^{\theta \cdot \phi(x,y')}}$$

Section 6 defines the full set of features used.

The inference problem at test time requires us to find the most likely answer a given a problem

x, assuming the parameters θ are known:

$$f(x) = \arg\max_a p(a|x;\theta)$$

Here, the probability of the answer is marginalized over template selection and alignment:

$$p(a|x;\theta) = \sum_{\substack{y \in \mathcal{Y} \\ \text{s.t. } \text{AN}(y)=a}} p(y|x;\theta) \quad (1)$$

where $\text{AN}(y)$ extracts the answer a out of derivation y. In this way, the distribution over derivations y is modeled as a latent variable. We use a beam search inference procedure to approximately compute Equation 1, as described in Section 5.

4 Learning

To learn our model, we need to induce the structure of system templates in $\mathcal{T}$ and estimate the model parameters θ.

4.1 Template Induction

It is possible to generate system templates $\mathcal{T}$ when provided access to a set of n training examples $\{(x_i, E_i) : i = 1, \ldots, n\}$, where x_i is a word problem and E_i is a set of equations. We generalize each E to a system template T by (a) replacing each variable with an unknown slot, and (b) replacing each number mentioned in the text with a number slot. Numbers not mentioned in the problem text remain in the template as constants. This allows us to solve problems that require numbers that are implied by the problem semantics rather than appearing directly in the text, such as the percent problem in Figure 4.

4.2 Parameter Estimation

For parameter estimation, we assume access to n training examples $\{(x_i, \mathcal{V}_i) : i = 1, \ldots, n\}$, each containing a word problem x_i and a validation function $\mathcal{V}_i$. The validation function $\mathcal{V} : \mathcal{Y} \rightarrow \{0, 1\}$ maps a derivation $y \in \mathcal{Y}$ to 1 if it is correct, or 0 otherwise.

We can vary the validation function to learn from different types of supervision. In Section 8, we will use validation functions that check whether the derivation y has either (1) the correct system of equations E, or (2) the correct answer a. Also, using different types of validation functions on different subsets of the data enables semi-supervised learning. This approach is related to Artzi and Zettlemoyer (2013).

Word problem
A chemist has a solution that is 18 % alcohol and one that is 50 % alcohol. He wants to make 80 liters of a 30 % solution. How many liters of the 18 % solution should he add? How many liters of the 30 % solution should he add?
Labeled equations
$18 \times 0.01 \times x + 50 \times 0.01 \times y = 30 \times 0.01 \times 80$ $x + y = 80$
Induced template system
$n_1 \times 0.01 \times u_1^1 + n_2 \times 0.01 \times u_2^1 = n_3 \times 0.01 \times n_4$ $u_1^2 + u_2^2 = n_5$

Figure 4: During template induction, we automatically detect the numbers in the problem (highlighted above) to generalize the labeled equations to templates. Numbers not present in the text are considered part of the induced template.

We estimate θ by maximizing the conditional log-likelihood of the data, marginalizing over all valid derivations:

$$O = \sum_i \sum_{\substack{y \in \mathcal{Y} \\ \text{s.t. } \mathcal{V}_i(y)=1}} \log p(y|x_i;\theta)$$

We use L-BFGS (Nocedal and Wright, 2006) to optimize the parameters. The gradient of the individual parameter θ_j is given by:

$$\frac{\partial O}{\partial \theta_j} = \sum_i E_{p(y|x_i,\mathcal{V}_i(y)=1;\theta)}\left[\phi_j(x_i, y)\right] - E_{p(y|x_i;\theta)}\left[\phi_j(x_i, y)\right] \quad (2)$$

Section 5 describes how we approximate the two terms of the gradient using beam search.

5 Inference

Computing the normalization constant for Equation 1 requires summing over all templates and all possible ways to instantiate them. This results in a search space exponential in the number of slots in the largest template in $\mathcal{T}$, the set of available system templates. Therefore, we approximate this computation using beam search. We initialize the beam with all templates in $\mathcal{T}$ and iteratively align slots from the templates in the beam to words in the problem text. For each template, the next slot

to be considered is selected according to a predefined canonicalized ordering for that template. After each iteration we prune the beam to keep the top-k partial derivations according to the model score. When pruning the beam, we allow at most l partial derivations for each template, to ensure that a small number of templates don't monopolize the beam. We continue this process until all templates in the beam are fully instantiated.

During learning we compute the second term in the gradient (Equation 2) using our beam search approximation. Depending on the available validation function $\mathcal{V}$ (as defined in Section 4.2), we can also accurately prune the beam for the computation of the first half of the gradient. Specifically, when assuming access to labeled equations, we can constrain the search to consider only partial hypotheses that could possibly be completed to produce the labeled equations.

6 Model Details

Template Canonicalization There are many syntactically different but semantically equivalent ways to express a given system of equations. For example, the phrase "John is 3 years older than Bill" can be written as $j = b + 3$ or $j - 3 = b$. To avoid such ambiguity, we canonicalize templates into a normal form representation. We perform this canonicalization by obtaining the symbolic solution for the unknown slots in terms of the number slots and constants using the mathematical solver Maxima (Maxima, 2014).

Slot Signature In a template like $s_1 + s_2 = s_3$, the slot s_1 is distinct from the slot s_2, but we would like them to share many of the features used in deciding their alignment. To facilitate this, we generate signatures for each slot and slot pair. The signature for a slot indicates the system of equations it appears in, the specific equation it is in, and the terms of the equation it is a part of. Pairwise slot signatures concatenate the signatures for the two slots as well as indicating which terms are shared. This allows, for example, n_2 and n_3 in Derivation 1 in Figure 2 to have the same signature, while the pairs $\langle n_2, u_1 \rangle$ and $\langle n_3, u_1 \rangle$ have different ones. To share features across templates, slot and slot-pair signatures are generated for both the full template, as well as for each of the constituent equations.

Features The features $\phi(x, y)$ are computed for a derivation y and problem x and cover all derivation decisions, including template and alignment selection. When required, we use standard tools to generate part-of-speech tags, lematizations, and dependency parses to compute features.[2] For each number word in y we also identify the closest noun in the dependency parse. For example, the noun for 278 in Derivation 1, Figure 2 would be "people." The features are calculated based on these nouns, rather than the number words.

Document level
Unigrams
Bigrams
Single slot
Has the same lemma as a question object
Is a question object
Is in a question sentence
Is equal to one or two (for numbers)
Word lemma X nearby constant
Slot pair
Dep. path contains: Word
Dep. path contains: Dep. Type
Dep. path contains: Word X Dep. Type
Are the same word instance
Have the same lemma
In the same sentence
In the same phrase
Connected by a preposition
Numbers are equal
One number is larger than the other
Equivalent relationship
Solution Features
Is solution all positive
Is solution all integer

Table 1: The features divided into categories.

We use four types of features: document level features, features that look at a single slot entry, features that look at pairs of slot entries, and features that look at the numeric solutions. Table 1 lists all the features used. Unless otherwise noted, when computing slot and slot pair features, a separate feature is generated for each of the signature types discussed earlier.

Document level features Oftentimes the natural language in x will contain words or phrases which are indicative of a certain template, but are not associated with any of the words aligned to slots in the template. For example, the word "chemist"

[2] In our experiments these are generated using the Stanford parser (de Marneffe et al., 2006)

might indicate a template like the one seen in Figure 4. We include features that connect each template with the unigrams and bigrams in the word problem. We also include an indicator feature for each system template, providing a bias for its use.

Single Slot Features The natural language x always contains one or more questions or commands indicating the queried quantities. For example, the first problem in Figure 2 asks "How many children were admitted on that day?" The queried quantities, the number of children in this case, must be represented by an unknown in the system of equations. We generate a set of features which look at both the word overlap and the noun phrase overlap between slot words and the objects of a question or command sentence. We also compute a feature indicating whether a slot is filled from a word in a question sentence. Additionally, algebra problems frequently use phrases such as "2 kinds of tickets" (e.g., Figure 2). These numbers do not typically appear in the equations. To account for this, we add a single feature indicating whether a number is one or two. Lastly, many templates contain constants which are identifiable from words used in nearby slots. For example, in Figure 4 the constant 0.01 is related to the use of "%" in the text. To capture such usage, we include a set of lexicalized features which concatenate the word lemma with nearby constants in the equation. These features do not include the slot signature.

Slot Pair Features The majority of features we compute account for relationships between slot words. This includes features that trigger for various equivalence relations between the words themselves, as well as features of the dependency path between them. We also include features that look at the numerical relationship of two numbers, where the numeric values of the unknowns are generated by solving the system of equations. This helps recognize that, for example, the total of a sum is typically larger than each of the (typically positive) summands.

Additionally, we also have a single feature looking at shared relationships between pairs of slots. For example, in Figure 2 the relationship between "tickets for children" and "$1.50" is "cost". Similarly the relationship between "Adult tickets" and "$4" is also "cost". Since the actual nature of this relationship is not important, this feature is not lexicalized, instead it is only triggered for the presence of equality. We consider two cases: subject-object relationships where the intervening verb is equal, and noun-to-preposition object relationships where the intervening preposition is equal.

# problems	514

Mean slots per system	7
Mean derivations per problem	4M

Table 2: Dataset statistics.

Solution Features By grounding our semantics in math, we are able to include features which look at the final answer, a, to learn which answers are reasonable for the algebra problems we typically see. For example, the solution to many, but not all, of the problems involves the size of some set of objects which must be both positive and integer.

7 Experimental Setup

Dataset We collected a new dataset of algebra word problems from Algebra.com, a crowdsourced tutoring website. The questions were posted by students for members of the community to respond with solutions. Therefore, the problems are highly varied, and are taken from real problems given to students. We heuristically filtered the data to get only linear algebra questions which did not require any explicit background knowledge. From these we randomly chose a set of 1024 questions. As the questions are posted to a web forum, the posts often contained additional comments which were not part of the word problems and the solutions are embedded in long free-form natural language descriptions. To clean the data we asked Amazon Mechanical Turk workers to extract from the text: the algebra word problem itself, the solution equations, and the numeric answer. We manually verified both the equations and the numbers to ensure they were correct. To ensure each problem type is seen at least a few times in the training data, we removed the infrequent problem types. Specifically, we induced the system template from each equation system, as described in Section 4.1, and removed all problems for which the associated system template appeared

less than 6 times in the dataset. This left us with 514 problems. Table 2 provides the data statistics.

Forms of Supervision We consider both semi-supervised and supervised learning. In the semi-supervised scenario, we assume access to the numerical answers of all problems in the training corpus and to a small number of problems paired with full equation systems. To select which problems to annotate with equations, we identified the five most common types of questions in the data and annotated a randomly sampled question of each type. 5EQ+ANS uses this form of weak supervision. To show the benefit of using the weakly supervised data, we also provide results for a baseline scenario 5EQ, where the training data includes *only* the five seed questions annotated with equation systems. In the fully supervised scenario ALLEQ, we assume access to full equation systems for the entire training set.

Evaluation Protocol We run all our experiments using 5-fold cross-validation. Since our model generates a solution for every problem, we report only accuracy. We report two metrics: equation accuracy to measure how often the system generates the correct equation system, and answer accuracy to evaluate how often the generated numerical answer is correct. When comparing equations, we avoid spurious differences by canonicalizing the equation system, as described in Section 6. To compare answer tuples we disregard the ordering and require each number appearing in the reference answer to appear in the generated answer.

Parameters and Solver In our experiments we set k in our beam search algorithm (Section 5) to 200, and l to 20. We run the L-BFGS computation for 50 iterations. We regularize our learning objective using the L^2-norm and a λ value of 0.1. The set of mathematical relations supported by our implementation is $\{+, -, \times, /\}$.Our implementation uses the Gaussian Elimination function in the Efficient Java Matrix Library (EJML) (Abeles, 2014) to generate answers given a set of equations.

8 Results

8.1 Impact of Supervision

Table 3 summarizes the results. As expected, having access to the full system of equations (ALLEQ) at training time results in the best learned model, with nearly 69% accuracy. However, training from primarily answer annotations (5EQ+ANS) results in performance which is almost 70% of ALLEQ, demonstrating the value of weakly supervised data. In contrast, 5EQ, which cannot use this weak supervision, performs much worse.

	Equation accuracy	Answer accuracy
5EQ	20.4	20.8
5EQ+ANS	45.7	46.1
ALLEQ	66.1	68.7

Table 3: Cross-validation accuracy results for various forms of supervision.

	Equation accuracy	Answer accuracy	% of data
≤ 10	43.6	50.8	25.5
$11 - 15$	46.6	45.1	10.5
$16 - 20$	44.2	52.0	11.3
> 20	85.7	86.1	52.7

Table 4: Performance on different template frequencies for ALLEQ.

8.2 Performance and Template Frequency

To better understand the results, we also measured equation accuracy as a function of the frequency of each equation template in the data set. Table 4 reports results for ALLEQ after grouping the problems into four different frequency bins. We can see that the system correctly answers more than 85% of the question types which occur frequently while still achieving more than 50% accuracy on those that occur relatively infrequently. We do not include template frequency results for 5EQ+ANS since in this setup our system is given only the top five most common templates. This limited set of templates covers only those questions in the > 20 bin, or about 52% of the data. However, on this subset 5EQ+ANS performs very well, answering 88% of them correctly, which is approximately the same as the 86% achieved by ALLEQ. Thus while the weak supervision is not helpful in generating the space of possible equations, it is very helpful in learning to generate the correct answer when given an appropriate space of equations.

8.3 Ablation Analysis

Table 5 shows ablation results for each group of features. The results along the diagonal show the performance when a single group of features is ablated, while the off-diagonal numbers show the

	w/o pair	w/o document	w/o solution	w/o single
w/o pair	42.8	25.7	19.0	39.6
w/o document	–	63.8	50.4	57.6
w/o solution	–	–	63.6	62.0
w/o single	–	–	–	65.9

Table 5: Cross-validation accuracy results with different feature groups ablated for ALLEQ. Results are for answer accuracy which is 68.7% without any features ablated.

performance when two groups of features are ablated together. We can see that all of the features contribute to the overall performance, and that the pair features are the most important followed by the document and solution features. We also see that the pair features can compensate for the absence of other features. For example, the performance drops only slightly when either the document or solution features are removed in isolation. However, the drop is much more dramatic when they are removed along with the pair features.

8.4 Qualitative Error Analysis

We examined our system output on one fold of ALLEQ and identified two main classes of errors.

The first, accounting for approximately one-quarter of the cases, includes mistakes where more background or world knowledge might have helped. For example, Problem 1 in Figure 5 requires understanding the relation between the dimensions of a painting, and how this relation is maintained when the painting is printed, and Problem 2 relies on understanding concepts of commerce, including cost, sale price, and profit. While these relationships could be learned in our model with enough data, as it does for percentage problems (e.g., Figure 4), various outside resources, such as knowledge bases (e.g. Freebase) or distributional statistics from a large text corpus, might help us learn them with less training data.

The second category, which accounts for about half of the errors, includes mistakes that stem from compositional language. For example, the second sentence in Problem 3 in Figure 5 could generate the equation $2x - y = 5$, with the phrase "twice of one of them" generating the expression $2x$. Given the typical shallow nesting, it's possible to learn templates for these cases given enough data, and in the future it might also be possible to develop new, cross-sentence semantic parsers to enable better generalization from smaller datasets.

(1)	A painting is 10 inches tall and 15 inches wide. A print of the painting is 25 inches tall, how wide is the print in inches?
(2)	A textbook costs a bookstore 44 dollars, and the store sells it for 55 dollars. Find the amount of profit based on the selling price.
(3)	The sum of two numbers is 85. The difference of twice of one of them and the other one is 5. Find both numbers.
(4)	The difference between two numbers is 6. If you double both numbers, the sum is 36. Find the two numbers.

Figure 5: Examples of problems our system does not solve correctly.

9 Conclusion

We presented an approach for automatically learning to solve algebra word problems. Our algorithm constructs systems of equations, while aligning their variables and numbers to the problem text. Using a newly gathered corpus we measured the effects of various forms of weak supervision on performance. To the best of our knowledge, we present the first learning result for this task.

There are still many opportunities to improve the reported results, and extend the approach to related domains. We would like to develop techniques to learn compositional models of meaning for generating new equations. Furthermore, the general representation of mathematics lends itself to many different domains including geometry, physics, and chemistry. Eventually, we hope to extend the techniques to synthesize even more complex structures, such as computer programs, from natural language.

Abstract

Inspired by experimental psychological findings suggesting that function words play a special role in word learning, we make a simple modification to an Adaptor Grammar based Bayesian word segmentation model to allow it to learn sequences of monosyllabic "function words" at the beginnings and endings of collocations of (possibly multi-syllabic) words. This modification improves unsupervised word segmentation on the standard Bernstein-Ratner (1987) corpus of child-directed English by more than 4% token f-score compared to a model identical except that it does not special-case "function words", setting a new state-of-the-art of 92.4% token f-score. Our function word model assumes that function words appear at the left periphery, and while this is true of languages such as English, it is not true universally. We show that a learner can use Bayesian model selection to determine the location of function words in their language, even though the input to the model only consists of unsegmented sequences of phones. Thus our computational models support the hypothesis that function words play a special role in word learning.

1 Introduction

Over the past two decades psychologists have investigated the role that function words might play in human language acquisition. Their experiments suggest that function words play a special role in the acquisition process: children learn function words before they learn the vast bulk of the associated content words, and they use function words to help identify context words.

The goal of this paper is to determine whether computational models of human language acquisition can provide support for the hypothesis that function words are treated specially in human language acquisition. We do this by comparing two computational models of word segmentation which differ solely in the way that they model function words. Following Elman et al. (1996) and Brent (1999) our word segmentation models identify word boundaries from unsegmented sequences of phonemes corresponding to utterances, effectively performing unsupervised learning of a lexicon. For example, given input consisting of unsegmented utterances such as the following:

j u w a n t t u s i ð ə b ʊ k

a word segmentation model should segment this as *ju want tu si ðə bʊk*, which is the IPA representation of "you want to see the book".

We show that a model equipped with the ability to learn some rudimentary properties of the target language's function words is able to learn the vocabulary of that language more accurately than a model that is identical except that it is incapable of learning these generalisations about function words. This suggests that there are acquisition advantages to treating function words specially that human learners could take advantage of (at least to the extent that they are learning similar generalisations as our models), and thus supports the hypothesis that function words are treated specially in human lexical acquisition. As a reviewer points out, we present no evidence that children use function words in the way that our model does, and we want to emphasise we make no such claim. While absolute accuracy is not directly relevant to the main point of the paper, we note that the models that learn generalisations about function words perform unsupervised word segmentation at 92.5% token f-score on the standard Bernstein-Ratner (1987) corpus, which improves the previous state-of-the-art by more than 4%.

As a reviewer points out, the changes we make to our models to incorporate function words can be viewed as "building in" substantive information about possible human languages. The model

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 282–292,
Baltimore, Maryland, USA, June 23-25 2014.

that achieves the best token f-score expects function words to appear at the left edge of phrases. While this is true for languages such as English, it is not true universally. By comparing the posterior probability of two models — one in which function words appear at the left edges of phrases, and another in which function words appear at the right edges of phrases — we show that a learner could use Bayesian posterior probabilities to determine that function words appear at the left edges of phrases in English, even though they are not told the locations of word boundaries or which words are function words.

This paper is structured as follows. Section 2 describes the specific word segmentation models studied in this paper, and the way we extended them to capture certain properties of function words. The word segmentation experiments are presented in section 3, and section 4 discusses how a learner could determine whether function words occur on the left-periphery or the right-periphery in the language they are learning. Section 5 concludes and describes possible future work. The rest of this introduction provides background on function words, the Adaptor Grammar models we use to describe lexical acquisition and the Bayesian inference procedures we use to infer these models.

1.1 Psychological evidence for the role of function words in word learning

Traditional descriptive linguistics distinguishes *function words*, such as determiners and prepositions, from *content words*, such as nouns and verbs, corresponding roughly to the distinction between functional categories and lexical categories of modern generative linguistics (Fromkin, 2001).

Function words differ from content words in at least the following ways:

1. there are usually far fewer function word types than content word types in a language
2. function word types typically have much higher token frequency than content word types
3. function words are typically morphologically and phonologically simple (e.g., they are typically monosyllabic)
4. function words typically appear in peripheral positions of phrases (e.g., prepositions typically appear at the beginning of prepositional phrases)
5. each function word class is associated with specific content word classes (e.g., determiners and prepositions are associated with nouns, auxiliary verbs and complementisers are associated with main verbs)
6. semantically, content words denote sets of objects or events, while function words denote more complex relationships over the entities denoted by content words
7. historically, the rate of innovation of function words is much lower than the rate of innovation of content words (i.e., function words are typically "closed class", while content words are "open class")

Properties 1–4 suggest that function words might play a special role in language acquisition because they are especially easy to identify, while property 5 suggests that they might be useful for identifying lexical categories. The models we study here focus on properties 3 and 4, in that they are capable of learning specific sequences of monosyllabic words in peripheral (i.e., initial or final) positions of phrase-like units.

A number of psychological experiments have shown that infants are sensitive to the function words of their language within their first year of life (Shi et al., 2006; Hallé et al., 2008; Shafer et al., 1998), often before they have experienced the "word learning spurt". Crucially for our purpose, infants of this age were shown to exploit frequent function words to segment neighboring content words (Shi and Lepage, 2008; Hallé et al., 2008). In addition, 14 to 18-month-old children were shown to exploit function words to constrain lexical access to known words - for instance, they expect a noun after a determiner (Cauvet et al., 2014; Kedar et al., 2006; Zangl and Fernald, 2007). In addition, it is plausible that function words play a crucial role in children's acquisition of more complex syntactic phenomena (Christophe et al., 2008; Demuth and McCullough, 2009), so it is interesting to investigate the roles they might play in computational models of language acquisition.

1.2 Adaptor grammars

Adaptor grammars are a framework for Bayesian inference of a certain class of hierarchical non-parametric models (Johnson et al., 2007b). They define distributions over the trees specified by a context-free grammar, but unlike probabilistic context-free grammars, they "learn" distributions over the possible subtrees of a user-specified set of "adapted" nonterminals. (Adaptor grammars are non-parametric, i.e., not characterisable by a finite

set of parameters, if the set of possible subtrees of the adapted nonterminals is infinite). Adaptor grammars are useful when the goal is to learn a potentially unbounded set of entities that need to satisfy hierarchical constraints. As section 2 explains in more detail, word segmentation is such a case: words are composed of syllables and belong to phrases or collocations, and modelling this structure improves word segmentation accuracy.

Adaptor Grammars are formally defined in Johnson et al. (2007b), which should be consulted for technical details. Adaptor Grammars (AGs) are an extension of Probabilistic Context-Free Grammars (PCFGs), which we describe first. A *Context-Free Grammar* (CFG) $G = (N, W, R, S)$ consists of disjoint finite sets of *nonterminal symbols* N and *terminal symbols* W, a finite set of *rules* R of the form $A \rightarrow \alpha$ where $A \in N$ and $\alpha \in (N \cup W)^\star$, and a *start symbol* $S \in N$. (We assume there are no "ϵ-rules" in R, i.e., we require that $|\alpha| \geq 1$ for each $A \rightarrow \alpha \in R$).

A *Probabilistic Context-Free Grammar* (PCFG) is a quintuple $(N, W, R, S, \boldsymbol{\theta})$ where N, W, R and S are the nonterminals, terminals, rules and start symbol of a CFG respectively, and $\boldsymbol{\theta}$ is a vector of non-negative reals indexed by R that satisfy $\sum_{\alpha \in R_A} \theta_{A \rightarrow \alpha} = 1$ for each $A \in N$, where $R_A = \{A \rightarrow \alpha : A \rightarrow \alpha \in R\}$ is the set of rules expanding A.

Informally, $\theta_{A \rightarrow \alpha}$ is the probability of a node labelled A expanding to a sequence of nodes labelled α, and the probability of a tree is the product of the probabilities of the rules used to construct each non-leaf node in it. More precisely, for each $X \in N \cup W$ a PCFG associates distributions G_X over the set of trees $\mathcal{T}_X$ generated by X as follows:

If $X \in W$ (i.e., if X is a terminal) then G_X is the distribution that puts probability 1 on the single-node tree labelled X.

If $X \in N$ (i.e., if X is a nonterminal) then:

$$G_X = \sum_{X \rightarrow B_1 \ldots B_n \in R_X} \theta_{X \rightarrow B_1 \ldots B_n} \mathrm{TD}_X(G_{B_1}, \ldots, G_{B_n}) \quad (1)$$

where R_X is the subset of rules in R expanding nonterminal $X \in N$, and:

$$\mathrm{TD}_X(G_1, \ldots, G_n) \left(\begin{array}{c} X \\ \wedge \\ t_1 \ldots t_n \end{array} \right) = \prod_{i=1}^{n} G_i(t_i).$$

That is, $\mathrm{TD}_X(G_1, \ldots, G_n)$ is a distribution over the set of trees $\mathcal{T}_X$ generated by nonterminal X, where each subtree t_i is generated independently from G_i. The PCFG generates the distribution G_S over the set of trees $\mathcal{T}_S$ generated by the start symbol S; the distribution over the strings it generates is obtained by marginalising over the trees.

In a Bayesian PCFG one puts Dirichlet priors $\mathrm{Dir}(\boldsymbol{\alpha})$ on the rule probability vector $\boldsymbol{\theta}$, such that there is one Dirichlet parameter $\alpha_{A \rightarrow \alpha}$ for each rule $A \rightarrow \alpha \in R$. There are Markov Chain Monte Carlo (MCMC) and Variational Bayes procedures for estimating the posterior distribution over rule probabilities $\boldsymbol{\theta}$ and parse trees given data consisting of terminal strings alone (Kurihara and Sato, 2006; Johnson et al., 2007a).

PCFGs can be viewed as recursive mixture models over trees. While PCFGs are expressive enough to describe a range of linguistically-interesting phenomena, PCFGs are *parametric models*, which limits their ability to describe phenomena where the set of basic units, as well as their properties, are the target of learning. Lexical acqusition is an example of a phenomenon that is naturally viewed as *non-parametric inference*, where the number of lexical entries (i.e., words) as well as their properties must be learnt from the data.

It turns out there is a straight-forward modification to the PCFG distribution (1) that makes it suitably non-parametric. As Johnson et al. (2007b) explain, by inserting a Dirichlet Process (DP) or Pitman-Yor Process (PYP) into the generative mechanism (1) the model "concentrates" mass on a subset of trees (Teh et al., 2006). Specifically, an Adaptor Grammar identifies a subset $A \subseteq N$ of *adapted nonterminals*. In an Adaptor Grammar the unadapted nonterminals $N \setminus A$ expand via (1), just as in a PCFG, but the distributions of the adapted nonterminals A are "concentrated" by passing them through a DP or PYP:

$$\begin{aligned} H_X &= \sum_{X \rightarrow B_1 \ldots B_n \in R_X} \theta_{X \rightarrow B_1 \ldots B_n} \mathrm{TD}_X(G_{B_1}, \ldots, G_{B_n}) \\ G_X &= \mathrm{PYP}(H_X, a_X, b_X) \end{aligned}$$

Here a_X and b_X are parameters of the PYP associated with the adapted nonterminal X. As Goldwater et al. (2011) explain, such Pitman-Yor Processes naturally generate power-law distributed data.

Informally, Adaptor Grammars can be viewed as caching entire subtrees of the adapted nonterminals. Roughly speaking, the probability of generating a particular subtree of an adapted nonterminal is proportional to the number of times that subtree has been generated before. This "rich get

richer" behaviour causes the distribution of subtrees to follow a power-law (the power is specified by the a_X parameter of the PYP). The PCFG rules expanding an adapted nonterminal X define the "base distribution" of the associated DP or PYP, and the a_X and b_X parameters determine how much mass is reserved for "new" trees.

There are several different procedures for inferring the parse trees and the rule probabilities given a corpus of strings: Johnson et al. (2007b) describe a MCMC sampler and Cohen et al. (2010) describe a Variational Bayes procedure. We use the MCMC procedure here since this has been successfully applied to word segmentation problems in previous work (Johnson, 2008).

2 Word segmentation with Adaptor Grammars

Perhaps the simplest word segmentation model is the *unigram model*, where utterances are modeled as sequences of words, and where each word is a sequence of segments (Brent, 1999; Goldwater et al., 2009). A unigram model can be expressed as an Adaptor Grammar with one adapted nonterminal Word (we indicate adapted nonterminals by underlining them in grammars here; regular expressions are expanded into right-branching productions).

$$\mathsf{Sentence} \rightarrow \mathsf{Word}^{+} \quad (2)$$

$$\underline{\mathsf{Word}} \rightarrow \mathsf{Phone}^{+} \quad (3)$$

The first rule (2) says that a sentence consists of one or more Words, while the second rule (3) states that a Word consists of a sequence of one or more Phones; we assume that there are rules expanding Phone into all possible phones. Because Word is an adapted nonterminal, the adaptor grammar memoises Word subtrees, which corresponds to learning the phone sequences for the words of the language.

The more sophisticated Adaptor Grammars discussed below can be understood as specialising either the first or the second of the rules in (2–3). The next two subsections review the Adaptor Grammar word segmentation models presented in Johnson (2008) and Johnson and Goldwater (2009): section 2.1 reviews how phonotactic syllable-structure constraints can be expressed with Adaptor Grammars, while section 2.2 reviews how phrase-like units called "collocations" capture inter-word dependencies. Section 2.3 presents the major novel contribution of this paper by explaining how we modify these adaptor grammars to capture some of the special properties of function words.

2.1 Syllable structure and phonotactics

The rule (3) models words as sequences of independently generated phones: this is what Goldwater et al. (2009) called the "monkey model" of word generation (it instantiates the metaphor that word types are generated by a monkey randomly banging on the keys of a typewriter). However, the words of a language are typically composed of one or more syllables, and explicitly modelling the internal structure of words typically improves word segmentation considerably.

Johnson (2008) suggested replacing (3) with the following model of word structure:

$$\underline{\mathsf{Word}} \rightarrow \mathsf{Syllable}^{1:4} \quad (4)$$

$$\mathsf{Syllable} \rightarrow (\mathsf{Onset})\ \mathsf{Rhyme} \quad (5)$$

$$\underline{\mathsf{Onset}} \rightarrow \mathsf{Consonant}^{+} \quad (6)$$

$$\mathsf{Rhyme} \rightarrow \mathsf{Nucleus}\ (\mathsf{Coda}) \quad (7)$$

$$\underline{\mathsf{Nucleus}} \rightarrow \mathsf{Vowel}^{+} \quad (8)$$

$$\underline{\mathsf{Coda}} \rightarrow \mathsf{Consonant}^{+} \quad (9)$$

Here and below superscripts indicate iteration (e.g., a Word consists of 1 to 4 Syllables), while an Onset consists of an unbounded number of Consonants), while parentheses indicate optionality (e.g., a Rhyme consists of an obligatory Nucleus followed by an optional Coda). We assume that there are rules expanding Consonant and Vowel to the set of all consonants and vowels respectively (this amounts to assuming that the learner can distinguish consonants from vowels). Because Onset, Nucleus and Coda are adapted, this model learns the possible syllable onsets, nucleii and coda of the language, even though neither syllable structure nor word boundaries are explicitly indicated in the input to the model.

The model just described assumes that word-internal syllables have the same structure as word-peripheral syllables, but in languages such as English word-peripheral onsets and codas can be more complex than the corresponding word-internal onsets and codas. For example, the word "string" begins with the onset cluster *str*, which is relatively rare word-internally. Johnson (2008) showed that word segmentation accuracy improves if the model can learn different consonant sequences for word-inital onsets and word-final codas. It is easy to express this as an Adaptor

Grammar: (4) is replaced with (10–11) and (12–17) are added to the grammar.

$$\text{Word} \rightarrow \text{SyllableIF} \quad (10)$$
$$\text{Word} \rightarrow \text{SyllableI Syllable}^{0:2}\ \text{SyllableF} \quad (11)$$
$$\text{SyllableIF} \rightarrow (\text{OnsetI})\ \text{RhymeF} \quad (12)$$
$$\text{SyllableI} \rightarrow (\text{OnsetI})\ \text{Rhyme} \quad (13)$$
$$\text{SyllableF} \rightarrow (\text{Onset})\ \text{RhymeF} \quad (14)$$
$$\text{OnsetI} \rightarrow \text{Consonant}^{+} \quad (15)$$
$$\text{RhymeF} \rightarrow \text{Nucleus}\ (\text{CodaF}) \quad (16)$$
$$\text{CodaF} \rightarrow \text{Consonant}^{+} \quad (17)$$

In this grammar the suffix "I" indicates a word-initial element, and "F" indicates a word-final element. Note that the model simply has the ability to learn that different clusters can occur word-peripherally and word-internally; it is not given any information about the relative complexity of these clusters.

2.2 Collocation models of inter-word dependencies

Goldwater et al. (2009) point out the detrimental effect that inter-word dependencies can have on word segmentation models that assume that the words of an utterance are independently generated. Informally, a model that generates words independently is likely to incorrectly segment multi-word expressions such as "the doggie" as single words because the model has no way to capture word-to-word dependencies, e.g., that "doggie" is typically preceded by "the". Goldwater et al show that word segmentation accuracy improves when the model is extended to capture bigram dependencies.

Adaptor grammar models cannot express bigram dependencies, but they can capture similiar inter-word dependencies using phrase-like units that Johnson (2008) calls collocations. Johnson and Goldwater (2009) showed that word segmentation accuracy improves further if the model learns a nested hierarchy of collocations. This can be achieved by replacing (2) with (18–21).

$$\text{Sentence} \rightarrow \text{Colloc3}^{+} \quad (18)$$
$$\text{Colloc3} \rightarrow \text{Colloc2}^{+} \quad (19)$$
$$\text{Colloc2} \rightarrow \text{Colloc1}^{+} \quad (20)$$
$$\text{Colloc1} \rightarrow \text{Word}^{+} \quad (21)$$

Informally, Colloc1, Colloc2 and Colloc3 define a nested hierarchy of phrase-like units. While not designed to correspond to syntactic phrases, by examining the sample parses induced by the Adaptor Grammar we noticed that the collocations often correspond to noun phrases, prepositional phrases or verb phrases. This motivates the extension to the Adaptor Grammar discussed below.

2.3 Incorporating "function words" into collocation models

The starting point and baseline for our extension is the adaptor grammar with syllable structure phonotactic constraints and three levels of collocational structure (5-21), as prior work has found that this yields the highest word segmentation token f-score (Johnson and Goldwater, 2009).

Our extension assumes that the Colloc1 – Colloc3 constituents are in fact phrase-like, so we extend the rules (19–21) to permit an optional sequence of monosyllabic words at the left edge of each of these constituents. Our model thus captures two of the properties of function words discussed in section 1.1: they are monosyllabic (and thus phonologically simple), and they appear on the periphery of phrases. (We put "function words" in scare quotes below because our model only approximately captures the linguistic properties of function words).

Specifically, we replace rules (19–21) with the following sequence of rules:

$$\text{Colloc3} \rightarrow (\text{FuncWords3})\ \text{Colloc2}^{+} \quad (22)$$
$$\text{Colloc2} \rightarrow (\text{FuncWords2})\ \text{Colloc1}^{+} \quad (23)$$
$$\text{Colloc1} \rightarrow (\text{FuncWords1})\ \text{Word}^{+} \quad (24)$$
$$\text{FuncWords3} \rightarrow \text{FuncWord3}^{+} \quad (25)$$
$$\text{FuncWord3} \rightarrow \text{SyllableIF} \quad (26)$$
$$\text{FuncWords2} \rightarrow \text{FuncWord2}^{+} \quad (27)$$
$$\text{FuncWord2} \rightarrow \text{SyllableIF} \quad (28)$$
$$\text{FuncWords1} \rightarrow \text{FuncWord1}^{+} \quad (29)$$
$$\text{FuncWord1} \rightarrow \text{SyllableIF} \quad (30)$$

This model memoises (i.e., learns) both the individual "function words" and the sequences of "function words" that modify the Colloc1 – Colloc3 constituents. Note also that "function words" expand directly to SyllableIF, which in turn expands to a monosyllable with a word-initial onset and word-final coda. This means that "function words" are memoised independently of the "content words" that Word expands to; i.e., the model learns distinct "function word" and "content word" vocabularies. Figure 1 depicts a sample parse generated by this grammar.

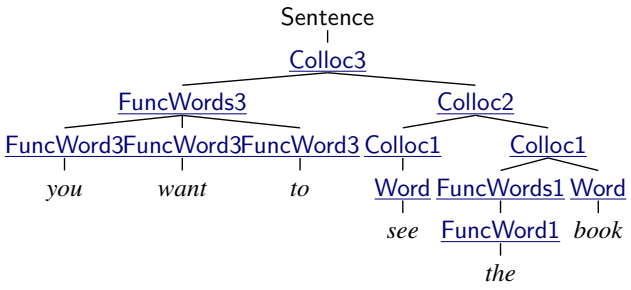

Figure 1: A sample parse generated by the "function word" Adaptor Grammar with rules (10–18) and (22–30). To simplify the parse we only show the root node and the adapted nonterminals, and replace word-internal structure by the word's orthographic form.

This grammar builds in the fact that function words appear on the left periphery of phrases. This is true of languages such as English, but is not true cross-linguistically. For comparison purposes we also include results for a mirror-image model that permits "function words" on the right periphery, a model which permits "function words" on both the left and right periphery (achieved by changing rules 22–24), as well as a model that analyses all words as monosyllabic.

Section 4 explains how a learner could use Bayesian model selection to determine that function words appear on the left periphery in English by comparing the posterior probability of the data under our "function word" Adaptor Grammar to that obtained using a grammar which is identical except that rules (22–24) are replaced with the mirror-image rules in which "function words" are attached to the right periphery.

3 Word segmentation results

This section presents results of running our Adaptor Grammar models on subsets of the Bernstein-Ratner (1987) corpus of child-directed English. We use the Adaptor Grammar software available from http://web.science.mq.edu.au/~mjohnson/ with the same settings as described in Johnson and Goldwater (2009), i.e., we perform Bayesian inference with "vague" priors for all hyperparameters (so there are no adjustable parameters in our models), and perform 8 different MCMC runs of each condition with table-label resampling for 2,000 sweeps of the training data. At every 10th sweep of the last 1,000 sweeps we use the model to segment the entire corpus (even if it is only trained on a subset of it), so we collect 800 sample segmentations of each utterance. The most frequent segmentation in these 800 sample segmentations is the one we score in the evaluations below.

Model	Token f-score	Boundary precision	Boundary recall
Baseline	0.872	0.918	0.956
+ left FWs	**0.924**	0.935	**0.990**
+ left + right FWs	0.912	**0.957**	0.953

Table 1: Mean token f-scores and boundary precision and recall results averaged over 8 trials, each consisting of 8 MCMC runs of models trained and tested on the full Bernstein-Ratner (1987) corpus (the standard deviations of all values are less than 0.006; Wilcox sign tests show the means of all token f-scores differ $p < 2\text{e-}4$).

3.1 Word segmentation with "function word" models

Here we evaluate the word segmentations found by the "function word" Adaptor Grammar model described in section 2.3 and compare it to the baseline grammar with collocations and phonotactics from Johnson and Goldwater (2009). Figure 2 presents the standard token and lexicon (i.e., type) f-score evaluations for word segmentations proposed by these models (Brent, 1999), and Table 1 summarises the token and lexicon f-scores for the major models discussed in this paper. It is interesting to note that adding "function words" improves token f-score by more than 4%, corresponding to a 40% reduction in overall error rate.

When the training data is very small the Monosyllabic grammar produces the highest accuracy results, presumably because a large proportion of the words in child-directed speech are monosyllabic. However, at around 25 sentences the more complex models that are capable of finding multi-syllabic words start to become more accurate.

It's interesting that after about 1,000 sentences the model that allows "function words" only on the right periphery is considerably less accurate than the baseline model. Presumably this is because it tends to misanalyse multi-syllabic words on the right periphery as sequences of monosyllabic words.

The model that allows "function words" only on the left periphery is more accurate than the model that allows them on both the left and right periphery when the input data ranges from about 100 to about 1,000 sentences, but when the training data

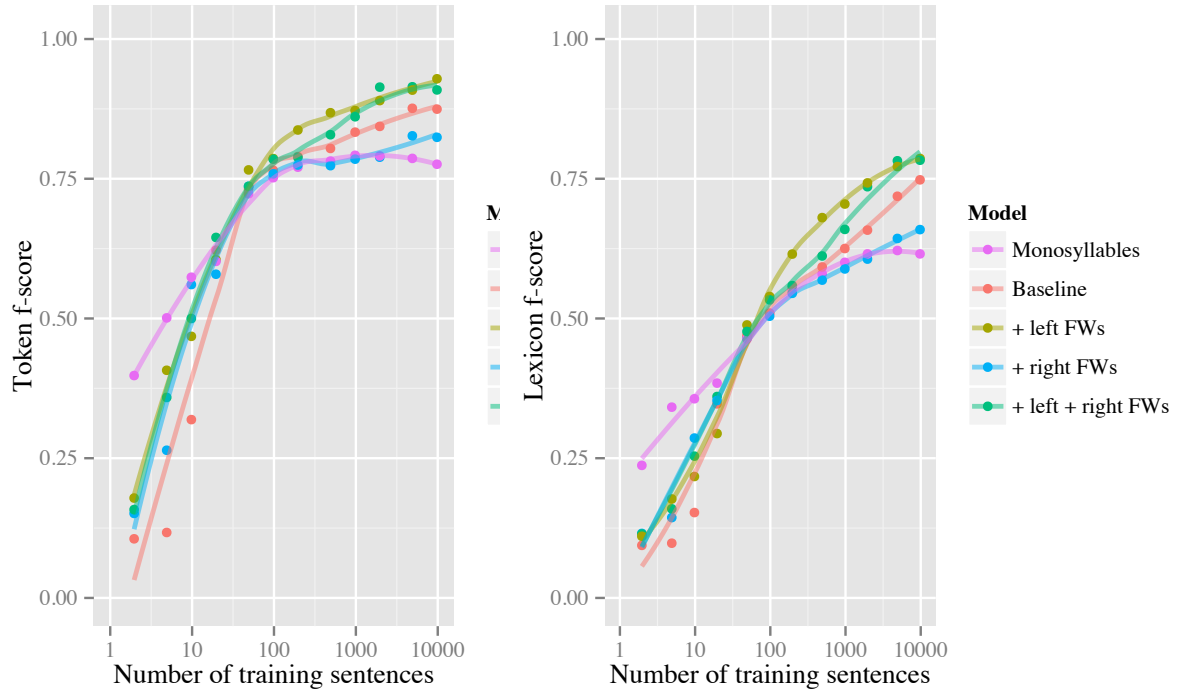

Figure 2: Token and lexicon (i.e., type) f-score on the Bernstein-Ratner (1987) corpus as a function of training data size for the baseline model, the model where "function words" can appear on the left periphery, a model where "function words" can appear on the right periphery, and a model where "function words" can appear on both the left and the right periphery. For comparison purposes we also include results for a model that assumes that all words are monosyllabic.

is larger than about 1,000 sentences both models are equally accurate.

3.2 Content and function words found by "function word" model

As noted earlier, the "function word" model generates function words via adapted nonterminals other than the Word category. In order to better understand just how the model works, we give the 5 most frequent words in each word category found during 8 MCMC runs of the left-peripheral "function word" grammar above:

Word : *book, doggy, house, want, I*
FuncWord1 : *a, the, your, little*[1], *in*
FuncWord2 : *to, in, you, what, put*
FuncWord3 : *you, a, what, no, can*

Interestingly, these categories seem fairly reasonable. The Word category includes open-class nouns and verbs, the FuncWord1 category includes noun modifiers such as determiners, while the FuncWord2 and FuncWord3 categories include prepositions, pronouns and auxiliary verbs.

[1]The phone 'l' is generated by both Consonant and Vowel, so "little" can be (incorrectly) analysed as one syllable.

Thus, the present model, initially aimed at segmenting words from continuous speech, shows three interesting characteristics that are also exhibited by human infants: it distinguishes between function words and content words (Shi and Werker, 2001), it allows learners to acquire at least some of the function words of their language (e.g. (Shi et al., 2006)); and furthermore, it may also allow them to start grouping together function words according to their category (Cauvet et al., 2014; Shi and Melançon, 2010).

4 Are "function words" on the left or right periphery?

We have shown that a model that expects function words on the left periphery performs more accurate word segmentation on English, where function words do indeed typically occur on the left periphery, leaving open the question: how could a learner determine whether function words generally appear on the left or the right periphery of phrases in the language they are learning? This question is important because knowing the side where function words preferentially occur is re-

lated to the question of the direction of syntactic headedness in the language, and an accurate method for identifying the location of function words might be useful for initialising a syntactic learner. Experimental evidence suggests that infants as young as 8 months of age already expect function words on the correct side for their language — left-periphery for Italian infants and right-periphery for Japanese infants (Gervain et al., 2008) — so it is interesting to see whether purely distributional learners such as the ones studied here can identify the correct location of function words in phrases.

We experimented with a variety of approaches that use a single adaptor grammar inference process, but none of these were successful. For example, we hoped that given an Adaptor Grammar that permits "function words" on both the left and right periphery, the inference procedure would decide that the right-periphery rules simply are not used in a language like English. Unfortunately we did not find this in our experiments; the right-periphery rules were used almost as often as the left-periphery rules (recall that a large fraction of the words in English child-directed speech are monosyllabic).

In this section, we show that learners could use Bayesian model selection to determine that function words appear on the left periphery in English by comparing the marginal probability of the data for the left-periphery and the right-periphery models.

Instead, we used Bayesian model selection techniques to determine whether left-peripheral or a right-peripheral model better fits the unsegmented utterances that constitute the training data.[2] While Bayesian model selection is in principle straight-forward, it turns out to require the ratio of two integrals (for the "evidence" or marginal likelihood) that are often intractable to compute.

Specifically, given a training corpus D of unsegmented sentences and model families G_1 and G_2 (here the "function word" adaptor grammars with left-peripheral and right-peripheral attachment respectively), the Bayes factor K is the ratio of the marginal likelihoods of the data:

$$K = \frac{\mathrm{P}(D \mid G_1)}{\mathrm{P}(D \mid G_2)}$$

[2]Note that neither the left-peripheral nor the right-peripheral model is correct: even strongly left-headed languages like English typically contain a few right-headed constructions. For example, "ago" is arguably the head of the phrase "ten years ago".

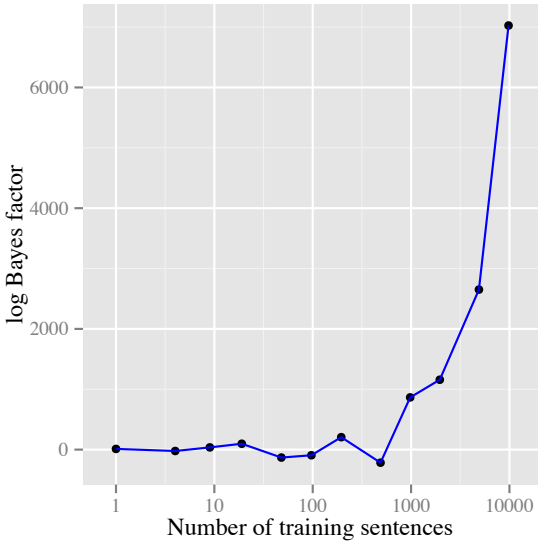

Figure 3: Bayes factor in favour of left-peripheral "function word" attachment as a function of the number of sentences in the training corpus, calculated using the Harmonic Mean estimator (see warning in text).

where the marginal likelihood or "evidence" for a model G is obtained by integrating over all of the hidden or latent structure and parameters $\boldsymbol{\theta}$:

$$\mathrm{P}(D \mid G) = \int_{\Delta} \mathrm{P}(D, \boldsymbol{\theta} \mid G)\, d\boldsymbol{\theta} \quad (31)$$

Here the variable $\boldsymbol{\theta}$ ranges over the space Δ of all possible parses for the utterances in D and all possible configurations of the Pitman-Yor processes and their parameters that constitute the "state" of the Adaptor Grammar G. While the probability of any specific Adaptor Grammar configuration $\boldsymbol{\theta}$ is not too hard to calculate (the MCMC sampler for Adaptor Grammars can print this after each sweep through D), the integral in (31) is in general intractable.

Textbooks such as Murphy (2012) describe a number of methods for calculating $\mathrm{P}(D \mid G)$, but most of them assume that the parameter space Δ is continuous and so cannot be directly applied here. The Harmonic Mean estimator (32) for (31), which we used here, is a popular estimator for (31) because it only requires the ability to calculate $\mathrm{P}(D, \boldsymbol{\theta} \mid G)$ for samples from $\mathrm{P}(\boldsymbol{\theta} \mid D, G)$:

$$\mathrm{P}(D \mid G) \approx \left(\frac{1}{n} \sum_{i=1}^{n} \frac{1}{\mathrm{P}(D, \boldsymbol{\theta}_i \mid G)} \right)^{-1}$$

where $\boldsymbol{\theta}_i, \ldots, \boldsymbol{\theta}_n$ are n samples from $\mathrm{P}(\boldsymbol{\theta} \mid$

D, G), which can be generated by the MCMC procedure.

Figure 3 depicts how the Bayes factor in favour of left-peripheral attachment of "function words" varies as a function of the number of utterances in the training data D (calculated from the last 1000 sweeps of 8 MCMC runs of the corresponding adaptor grammars). As that figure shows, once the training data contains more than about 1,000 sentences the evidence for the left-peripheral grammar becomes very strong. On the full training data the estimated log Bayes factor is over 6,000, which would constitute overwhelming evidence in favour of left-peripheral attachment.

Unfortunately, as Murphy and others warn, the Harmonic Mean estimator is extremely unstable (Radford Neal calls it "the worst MCMC method ever" in his blog), so we think it is important to confirm these results using a more stable estimator. However, given the magnitude of the differences and the fact that the two models being compared are of similar complexity, we believe that these results suggest that Bayesian model selection can be used to determine properties of the language being learned.

5 Conclusions and future work

This paper showed that the word segmentation accuracy of a state-of-the-art Adaptor Grammar model is significantly improved by extending it so that it explicitly models some properties of function words. We also showed how Bayesian model selection can be used to identify that function words appear on the left periphery of phrases in English, even though the input to the model only consists of an unsegmented sequence of phones.

Of course this work only scratches the surface in terms of investigating the role of function words in language acquisition. It would clearly be very interesting to examine the performance of these models on other corpora of child-directed English, as well as on corpora of child-directed speech in other languages. Our evaluation focused on word-segmentation, but we could also evaluate the effect that modelling "function words" has on other aspects of the model, such as its ability to learn syllable structure.

The models of "function words" we investigated here only capture two of the 7 linguistic properties of function words identified in section 1 (i.e., that function words tend to be monosyllabic, and that they tend to appear phrase-peripherally), so it would be interesting to develop and explore models that capture other linguistic properties of function words. For example, following the suggestion by Hochmann et al. (2010) that human learners use frequency cues to identify function words, it might be interesting to develop computational models that do the same thing. In an Adaptor Grammar the frequency distribution of function words might be modelled by specifying the prior for the Pitman-Yor Process parameters associated with the function words' adapted nonterminals so that it prefers to generate a small number of high-frequency items.

It should also be possible to develop models which capture the fact that function words tend not to be topic-specific. Johnson et al. (2010) and Johnson et al. (2012) show how Adaptor Grammars can model the association between words and non-linguistic "topics"; perhaps these models could be extended to capture some of the semantic properties of function words.

It would also be interesting to further explore the extent to which Bayesian model selection is a useful approach to linguistic "parameter setting". In order to do this it is imperative to develop better methods than the problematic "Harmonic Mean" estimator used here for calculating the evidence (i.e., the marginal probability of the data) that can handle the combination of discrete and continuous hidden structure that occur in computational linguistic models.

As well as substantially improving the accuracy of unsupervised word segmentation, this work is interesting because it suggests a connection between unsupervised word segmentation and the induction of syntactic structure. It is reasonable to expect that hierarchical non-parametric Bayesian models such as Adaptor Grammars may be useful tools for exploring such a connection.

Abstract

Recently, neural network models for natural language processing tasks have been increasingly focused on for their ability to alleviate the burden of manual feature engineering. In this paper, we propose a novel neural network model for Chinese word segmentation called Max-Margin Tensor Neural Network (**MMTNN**). By exploiting tag embeddings and tensor-based transformation, **MMTNN** has the ability to model complicated interactions between tags and context characters. Furthermore, a new tensor factorization approach is proposed to speed up the model and avoid overfitting. Experiments on the benchmark dataset show that our model achieves better performances than previous neural network models and that our model can achieve a competitive performance with minimal feature engineering. Despite Chinese word segmentation being a specific case, **MMTNN** can be easily generalized and applied to other sequence labeling tasks.

1 Introduction

Unlike English and other western languages, Chinese do not delimit words by white-space. Therefore, word segmentation is a preliminary and important pre-process for Chinese language processing. Most previous systems address this problem by treating this task as a sequence labeling problem where each character is assigned a tag indicating its position in the word. These systems are effective because researchers can incorporate a large body of handcrafted features into the models. However, the ability of these models is restricted by the design of features and the number of features could be so large that the result models are too large for practical use and prone to overfit on training corpus.

Recently, neural network models have been increasingly focused on for their ability to minimize the effort in feature engineering. Collobert et al. (2011) developed the SENNA system that approaches or surpasses the state-of-the-art systems on a variety of sequence labeling tasks for English. Zheng et al. (2013) applied the architecture of Collobert et al. (2011) to Chinese word segmentation and POS tagging and proposed a perceptron-style algorithm to speed up the training process with negligible loss in performance.

Workable as previous neural network models seem, a limitation of them to be pointed out is that the tag-tag interaction, tag-character interaction and character-character interaction are not well modeled. In conventional feature-based linear (log-linear) models, these interactions are explicitly modeled as features. Take phrase "打篮球(play basketball)" as an example, assuming we are labeling character C_0="篮", possible features could be:

$$f_1 = \begin{cases} 1 & C_{-1}\text{="打" and } C_1\text{="球" and } y_0\text{="B"} \\ 0 & \text{else} \end{cases}$$

$$f_2 = \begin{cases} 1 & C_0\text{="篮" and } y_0\text{="B" and } y_{-1}\text{="S"} \\ 0 & \text{else} \end{cases}$$

To capture more interactions, researchers have designed a large number of features based on linguistic intuition and statistical information. In previous neural network models, however, hardly can such interactional effects be fully captured relying only on the simple transition score and the single non-linear transformation (See section 2). In order to address this problem, we propose a new model called Max-Margin Tensor Neural Network (**MMTNN**) that explicitly models the interactions

Baltimore, Maryland, USA, June 23-25 2014.

between tags and context characters by exploiting tag embeddings and tensor-based transformation. Moreover, we propose a tensor factorization approach that effectively improves the model efficiency and prevents from overfitting. We evaluate the performance of Chinese word segmentation on the PKU and MSRA benchmark datasets in the second International Chinese Word Segmentation Bakeoff (Emerson, 2005) which are commonly used for evaluation of Chinese word segmentation. Experiment results show that our model outperforms other neural network models.

Although we focus on the question that how far we can go without using feature engineering in this paper, the study of deep learning for NLP tasks is still a new area in which it is currently challenging to surpass the state-of-the-art without additional features. Following Mansur et al. (2013), we wonder how well our model can perform with minimal feature engineering. Therefore, we integrate additional simple character bigram features into our model and the result shows that our model can achieve a competitive performance that other systems hardly achieve unless they use more complex task-specific features.

The main contributions of our work are as follows:

- We propose a Max-Margin Tensor Neural Network for Chinese word segmentation without feature engineering. The test results on the benchmark dataset show that our model outperforms previous neural network models.
- We propose a new tensor factorization approach that models each tensor slice as the product of two low-rank matrices. Not only does this approach improve the efficiency of our model but also it avoids the risk of overfitting.
- Compared with previous works that use a large number of handcrafted features, our model can achieve a competitive performance with minimal feature engineering.
- Despite Chinese word segmentation being a specific case, our approach can be easily generalized to other sequence labeling tasks.

The remaining part of this paper is organized as follows. Section 2 describes the details of conventional neural network architecture. Section 3 describes the details of our model. Experiment results are reported in Section 4. Section 5 reviews the related work. The conclusions are given in Section 6.

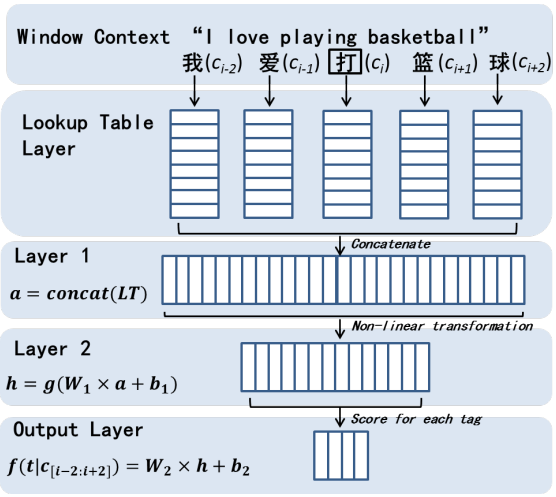

Figure 1: Conventional Neural Network

2 Conventional Neural Network

2.1 Lookup Table

The idea of distributed representation for symbolic data is one of the most important reasons why the neural network works. It was proposed by Hinton (1986) and has been a research hot spot for more than twenty years (Bengio et al., 2003; Collobert et al., 2011; Schwenk et al., 2012; Mikolov et al., 2013a). Formally, in the Chinese word segmentation task, we have a character dictionary D of size $|D|$. Unless otherwise specified, the character dictionary is extracted from the training set and unknown characters are mapped to a special symbol that is not used elsewhere. Each character $c \in D$ is represented as a real-valued vector (character embedding) $Embed(c) \in \mathbb{R}^d$ where d is the dimensionality of the vector space. The character embeddings are then stacked into a embedding matrix $M \in \mathbb{R}^{d \times |D|}$. For a character $c \in D$ that has an associated index k, the corresponding character embedding $Embed(c) \in \mathbb{R}^d$ is retrieved by the Lookup Table layer as shown in Figure 1:

$$Embed(c) = Me_k \tag{1}$$

Here $e_k \in \mathbb{R}^{|D|}$ is a binary vector which is zero in all positions except at k-th index. The Lookup Table layer can be seen as a simple projection layer where the character embedding for each context

character is achieved by table lookup operation according to their indices. The embedding matrix M is initialized with small random numbers and trained by back-propagation. We will analyze in more detail about the effect of character embeddings in Section 4.

2.2 Tag Scoring

The most common tagging approach is the window approach. The window approach assumes that the tag of a character largely depends on its neighboring characters. Given an input sentence $c_{[1:n]}$, a window of size w slides over the sentence from character c_1 to c_n. We set $w = 5$ in all experiments. As shown in Figure 1, at position $c_i, 1 \leq i \leq n$, the context characters are fed into the Lookup Table layer. The characters exceeding the sentence boundaries are mapped to one of two special symbols, namely "start" and "end" symbols. The character embeddings extracted by the Lookup Table layer are then concatenated into a single vector $a \in \mathbb{R}^{H_1}$, where $H_1 = w \cdot d$ is the size of Layer 1. Then a is fed into the next layer which performs linear transformation followed by an element-wise activation function g such as *tanh*, which is used in our experiments:

$$h = g(W_1 a + b_1) \tag{2}$$

where $W_1 \in \mathbb{R}^{H_2 \times H_1}$, $b_1 \in \mathbb{R}^{H_2 \times 1}$, $h \in \mathbb{R}^{H_2}$. H_2 is a hyper-parameter which is the number of hidden units in Layer 2. Given a set of tags T of size $|T|$, a similar linear transformation is performed except that no non-linear function is followed:

$$f(\boldsymbol{t}|c_{[i-2:i+2]}) = W_2 h + b_2 \tag{3}$$

where $W_2 \in \mathbb{R}^{|T| \times H_2}$, $b_2 \in \mathbb{R}^{|T| \times 1}$. $f(\boldsymbol{t}|c_{[i-2:i+2]}) \in \mathbb{R}^{|T|}$ is the score vector for each possible tag. In Chinese word segmentation, the most prevalent tag set T is BMES tag set, which uses 4 tags to carry word boundary information. It uses B, M, E and S to denote the Beginning, the Middle, the End of a word and a Single character forming a word respectively. We use this tag set in our method.

2.3 Model Training and Inference

Despite sharing commonalities mentioned above, previous work models the segmentation task differently and therefore uses different training and inference procedure. Mansur et al. (2013) modeled Chinese word segmentation as a series of classification task at each position of the sentence in which the tag score is transformed into probability using softmax function:

$$p(t_i|c_{[i-2:i+2]}) = \frac{exp(f(t_i|c_{[i-2:i+2]}))}{\sum_{t'} exp(f(t'|c_{[i-2:i+2]}))}$$

The model is then trained in MLE-style which maximizes the log-likelihood of the tagged data. Obviously, it is a local model which cannot capture the dependency between tags and does not support to infer the tag sequence globally.

To model the tag dependency, previous neural network models (Collobert et al., 2011; Zheng et al., 2013) introduce a transition score A_{ij} for jumping from tag $i \in T$ to tag $j \in T$. For a input sentence $c_{[1:n]}$ with a tag sequence $t_{[1:n]}$, a sentence-level score is then given by the sum of transition and network scores:

$$s(c_{[1:n]}, t_{[1:n]}, \theta) = \sum_{i=1}^{n} (A_{t_{i-1}t_i} + f_\theta(t_i|c_{[i-2:i+2]})) \tag{4}$$

where $f_\theta(t_i|c_{[i-2:i+2]})$ indicates the score output for tag t_i at the i-th character by the network with parameters $\theta = (M, A, W_1, b_1, W_2, b_2)$. Given the sentence-level score, Zheng et al. (2013) proposed a perceptron-style training algorithm inspired by the work of Collins (2002). Compared with Mansur et al. (2013), their model is a global one where the training and inference is performed at sentence-level.

Workable as these methods seem, one of the limitations of them is that the tag-tag interaction and the neural network are modeled seperately. The simple tag-tag transition neglects the impact of context characters and thus limits the ability to capture flexible interactions between tags and context characters. Moreover, the simple non-linear transformation in equation (2) is also poor to model the complex interactional effects in Chinese word segmentation.

3 Max-Margin Tensor Neural Network

3.1 Tag Embedding

To better model the tag-tag interaction given the context characters, distributed representation for tags instead of traditional discrete symbolic representation is used in our model. Similar to character embeddings, given a fixed-sized tag set T, the tag embeddings for tags are stored in a tag embedding matrix $L \in \mathbb{R}^{d \times |T|}$, where d is the dimensionality

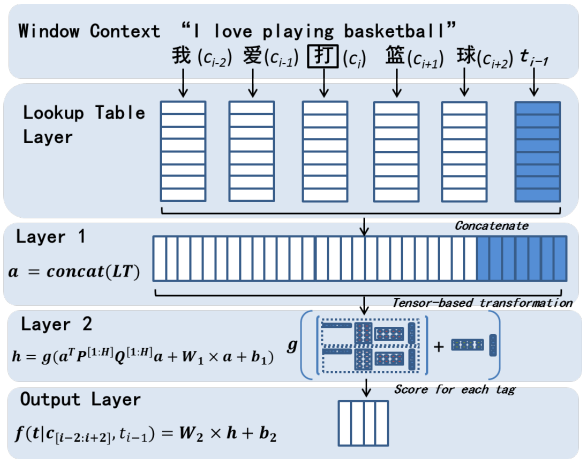

Figure 2: Max-Margin Tensor Neural Network

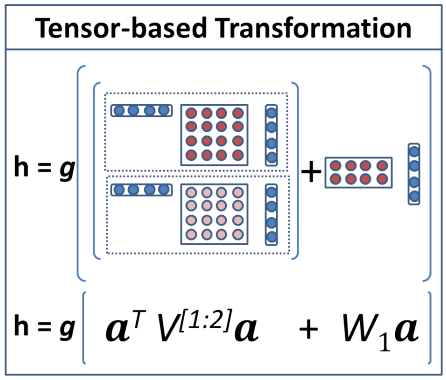

Figure 3: The tensor-based transformation in Layer 2. a is the input from Layer 1. V is the tensor parameter. Each dashed box represents one of the H_2-many tensor slices, which defines the bilinear form on vector a.

of the vector space (same with character embeddings). Then the tag embedding $Embed(t) \in \mathbb{R}^d$ for tag $t \in T$ with index k can be retrieved by the lookup operation:

$$Embed(t) = Le_k \tag{5}$$

where $e_k \in \mathbb{R}^{|T|\times 1}$ is a binary vector which is zero in all positions except at k-th index. The tag embeddings start from a random initialization and can be automatically trained by back-propagation. Figure 2 shows the new Lookup Table layer with tag embeddings. Assuming we are at the i-th character of a sentence, besides the character embeddings, the tag embeddings of the previous tags are also considered[1]. For a fast tag inference, only the previous tag t_{i-1} is used in our model even though a longer history of tags can be considered. The concatenation operation in Layer 1 then concatenates the character embeddings and tag embedding together into a long vector a. In this way, the tag representation can be directly incorporated in the neural network so that the tag-tag interaction and tag-character interaction can be explicitly modeled in deeper layers (See Section 3.2). Moreover, the transition score in equation (4) is not necessary in our model, because, by incorporating tag embedding into the neural network, the effect of tag-tag interaction and tag-character interaction are covered uniformly in one same model. Now equation (4) can be rewritten as follows:

$$s(c_{[1:n]}, t_{[1:n]}, \theta) = \sum_{i=1}^{n} f_\theta(t_i|c_{[i-2:i+2]}, t_{i-1}) \tag{6}$$

where $f_\theta(t_i|c_{[i-2:i+2]}, t_{i-1})$ is the score output for tag t_i at the i-th character by the network with parameters θ. Like Collobert et al. (2011) and Zheng et al. (2013), our model is also trained at sentence-level and carries out inference globally.

3.2 Tensor Neural Network

A tensor is a geometric object that describes relations between vectors, scalars, and other tensors. It can be represented as a multi-dimensional array of numerical values. An advantage of the tensor is that it can explicitly model multiple interactions in data. As a result, tensor-based model have been widely used in a variety of tasks (Salakhutdinov et al., 2007; Krizhevsky et al., 2010; Socher et al., 2013b).

In Chinese word segmentation, a proper modeling of the tag-tag interaction, tag-character interaction and character-character interaction is very important. In linear models, these kinds of interactions are usually modeled as features. In conventional neural network models, however, the input embeddings only implicitly interact through the non-linear function which can hardly model the complexity of the interactions. Given the advantage of tensors, we apply a tensor-based transformation to the input vector. Formally, we use a 3-way tensor $V^{[1:H_2]} \in \mathbb{R}^{H_2\times H_1\times H_1}$ to directly model the interactions, where H_2 is the size of

[1]We also tried the architecture in which the tag embedding of current tag is also considered, but this did not bring much improvement and runs slower

Layer 2 and $H_1 = (w+1) \cdot d$ is the size of concatenated vector a in Layer 1 as shown in Figure 2. Figure 3 gives an example of the tensor-based transformation[2]. The output of a tensor product is a vector $z \in \mathbb{R}^{H_2}$ where each dimension z_i is the result of the bilinear form defined by each tensor slice $V^{[i]} \in \mathbb{R}^{H_1 \times H_1}$:

$$z = a^T V^{[1:H_2]} a; z_i = a^T V^{[i]} a = \sum_{j,k} V^{[i]}_{jk} a_j a_k \tag{7}$$

Since vector a is the concatenation of character embeddings and the tag embedding, equation (7) can be written in the following form:

$$z_i = \sum_{p,q} \sum_{j,k} V^{[i]}_{(p,q,j,k)} E^{[p]}_j E^{[q]}_k$$

where $E^{[p]}_j$ is the j-th element of the p-th embedding in Lookup Table layer and $V^{[i]}_{(p,q,j,k)}$ is the corresponding coefficient for $E^{[p]}_j$ and $E^{[q]}_k$ in $V^{[i]}$. As we can see, in each tensor slice i, the embeddings are explicitly related in a bilinear form which captures the interactions between characters and tags. The multiplicative operations between tag embeddings and character embeddings can somehow be seen as "feature combination", which are hand-designed in feature-based models. Our model learns the information automatically and encodes them in tensor parameters and embeddings. Intuitively, we can interpret each slice of the tensor as capturing a specific type of tag-character interaction and character-character interaction.

Combining the tensor product with linear transformation, the tensor-based transformation in Layer 2 is defined as:

$$h = g(a^T V^{[1:H_2]} a + W_1 a + b_1) \tag{8}$$

where $W_1 \in \mathbb{R}^{H_2 \times H_1}$, $b_1 \in \mathbb{R}^{H_2 \times 1}$, $h \in \mathbb{R}^{H_2}$. In fact, equation (2) used in previous work is a special case of equation (8) when V is set to 0.

3.3 Tensor Factorization

Despite tensor-based transformation being effective for capturing the interactions, introducing tensor-based transformation into neural network models to solve sequence labeling task is time prohibitive since the tensor product operation drastically slows down the model. Without considering matrix optimization algorithms, the complexity of the non-linear transformation in equation (2) is $O(H_1 H_2)$ while the tensor operation complexity in equation (8) is $O(H_1^2 H_2)$. The tensor-based transformation is H_1 times slower. Moreover, the additional tensor could bring millions of parameters to the model which makes the model suffer from the risk of overfitting. To remedy this, we propose a tensor factorization approach that factorizes each tensor slice as the product of two low-rank matrices. Formally, each tensor slice $V^{[i]} \in \mathbb{R}^{H_1 \times H_1}$ is factorized into two low rank matrix $P^{[i]} \in \mathbb{R}^{H_1 \times r}$ and $Q^{[i]} \in \mathbb{R}^{r \times H_1}$:

$$V^{[i]} = P^{[i]} Q^{[i]}, 1 \leq i \leq H_2 \tag{9}$$

where $r \ll H_1$ is the number of factors. Substituting equation (9) into equation (8), we get the factorized tensor function:

$$h = g(a^T P^{[1:H_2]} Q^{[1:H_2]} a + W_1 a + b_1) \tag{10}$$

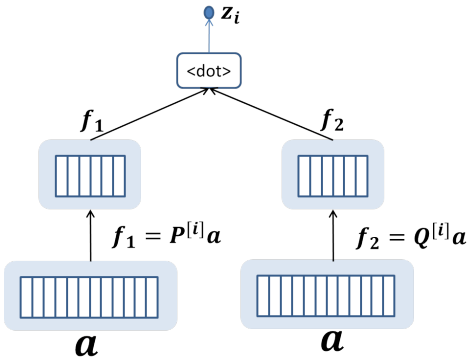

Figure 4: Tensor product with tensor factorization

Figure 4 illustrates the operation in each slice of the factorized tensor. First, vector a is projected into two r-dimension vectors f_1 and f_2. Then the output z_i for each tensor slice i is the dot-product of f_1 and f_2. The complexity of the tensor operation is now $O(rH_1H_2)$. As long as r is small enough, the factorized tensor operation would be much faster than the un-factorized one and the number of free parameters would also be much smaller, which prevent the model from overfitting.

3.4 Max-Margin Training

We use the Max-Margin criterion to train our model. Intuitively, the Max-Margin criterion provides an alternative to probabilistic, likelihood-based estimation methods by concentrating directly on the robustness of the decision boundary of a model (Taskar et al., 2005). We use $Y(x_i)$ to denote the set of all possible tag sequences for

[2]The bias term is omitted in Figure 3 for simplicity

a given sentence x_i and the correct tag sequence for x_i is y_i. The parameters of our model are $\theta = \{W_1, b_1, W_2, b_2, M, L, P^{[1:H_2]}, Q^{[1:H_2]}\}$. We first define a structured margin loss $\triangle(y_i, \hat{y})$ for predicting a tag sequence $\hat{y}$ for a given correct tag sequence y_i:

$$\triangle(y_i, \hat{y}) = \sum_{j}^{n} \kappa \mathbf{1}\{y_{i,j} \neq \hat{y}_j\} \qquad (11)$$

where n is the length of sentence x_i and κ is a discount parameter. The loss is proportional to the number of characters with an incorrect tag in the proposed tag sequence, which increases the more incorrect the proposed tag sequence is. For a given training instance (x_i, y_i), we search for the tag sequence with the highest score:

$$y^* = \arg\max_{\hat{y} \in Y(x)} s(x_i, \hat{y}, \theta) \qquad (12)$$

where the tag sequence is found and scored by the Tensor Neural Network via the function s in equation (6). The object of Max-Margin training is that the highest scoring tag sequence is the correct one: $y^* = y_i$ and its score will be larger up to a margin to other possible tag sequences $\hat{y} \in Y(x_i)$:

$$s(x, y_i, \theta) \geq s(x, \hat{y}, \theta) + \triangle(y_i, \hat{y})$$

This leads to the regularized objective function for m training examples:

$$\begin{aligned} J(\theta) &= \frac{1}{m}\sum_{i=1}^{m} l_i(\theta) + \frac{\lambda}{2}||\theta||^2 \\ l_i(\theta) &= \max_{\hat{y} \in Y(x_i)} (s(x_i, \hat{y}, \theta) + \triangle(y_i, \hat{y})) \\ &\quad -s(x_i, y_i, \theta)) \end{aligned} \qquad (13)$$

By minimizing this object, the score of the correct tag sequence y_i is increased and score of the highest scoring incorrect tag sequence $\hat{y}$ is decreased.

The objective function is not differentiable due to the hinge loss. We use a generalization of gradient descent called subgradient method (Ratliff et al., 2007) which computes a gradient-like direction. The subgradient of equation (13) is:

$$\frac{\partial J}{\partial \theta} = \frac{1}{m}\sum_{i}(\frac{\partial s(x_i, \hat{y}_{max}, \theta)}{\partial \theta} - \frac{\partial s(x_i, y_i, \theta)}{\partial \theta}) + \lambda\theta$$

where $\hat{y}_{max}$ is the tag sequence with the highest score in equation (13). Following Socher et al. (2013a), we use the diagonal variant of AdaGrad (Duchi et al., 2011) with minibatchs to minimize the objective. The parameter update for the i-th parameter $\theta_{t,i}$ at time step t is as follows:

$$\theta_{t,i} = \theta_{t-1,i} - \frac{\alpha}{\sqrt{\sum_{\tau=1}^{t} g_{\tau,i}^2}} g_{t,i} \qquad (14)$$

where α is the initial learning rate and $g_\tau \in \mathbb{R}^{|\theta_i|}$ is the subgradient at time step τ for parameter θ_i.

4 Experiment

4.1 Data and Model Selection

We use the PKU and MSRA data provided by the second International Chinese Word Segmentation Bakeoff (Emerson, 2005) to test our model. They are commonly used by previous state-of-the-art models and neural network models. Details of the data are listed in Table 1. For evaluation, we use the standard bake-off scoring program to calculate precision, recall, F1-score and out-of-vocabulary (OOV) word recall.

For model selection, we use the first 90% sentences in the training data for training and the rest 10% sentences as development data. The minibatch size is set to 20. Generally, the number of hidden units has a limited impact on the performance as long as it is large enough. We found that 50 is a good trade-off between speed and model performance. The dimensionality of character (tag) embedding is set to 25 which achieved the best performance and faster than 50- or 100-dimensional ones. We also validated on the number of factors for tensor factorization. The performance is not boosted and the training time in-

creases drastically when the number of factors is larger than 10. We hypothesize that larger factor size results in too many parameters to train and hence perform worse. The final hyperparameters of our model are set as in Table 2.

4.2 Experiment Results

We first perform a close test[3] on the PKU dataset to show the effect of different model configurations. We also compare our model with the CRF model (Lafferty et al., 2001), which is a widely used log-linear model for Chinese word segmentation. The input feature to the CRF model is simply the context characters (unigram feature) without any additional feature engineering. We use an open source toolkit *CRF++*[4] to train the CRF model. All the neural networks are trained using the Max-Margin approach described in Section 3.4. Table 3 summarizes the test results. As we can see, by using Tag embedding, the F-score is improved by +0.6% and OOV recall is improved by +1.0%, which shows that tag embeddings succeed in modeling the tag-tag interaction and tag-character interaction. Model performance is further boosted after using tensor-based transformation. The F-score is improved by +0.6% while OOV recall is improved by +3.2%, which denotes that tensor-based transformation captures more interactional information than simple non-linear transformation.

Another important result in Table 3 is that our neural network models perform much better than CRF-based model when only unigram features are used. Compared with CRF, there are two differences in neural network models. First, the discrete feature vector is replaced with dense character embeddings. Second, the non-linear transformation is used to discover higher level representation. In fact, CRF can be regarded as a special neural network without non-linear function (Wang and Manning, 2013). Wang and Manning (2013) conduct an empirical study on the effect of non-linearity and the results suggest that non-linear models are highly effective only when distributed representation is used. To explain why distributed representation captures more information than discrete features, we show in Table 4 the effect of character embeddings which are obtained from the lookup table of MMTNN after training. The first row lists three characters we are interested in. In each column, we list the top 5 characters that are nearest (measured by Euclidean distance) to the corresponding character in the first row according to their embeddings. As we can see, characters in the first column are all Chinese number characters and characters in the second column and the third column are all Chinese family names and Chinese punctuations respectively. Therefore, compared with discrete feature representations, distributed representation can capture the syntactic and semantic similarity between characters. As a result, the model can still perform well even if some words do not appear in the training cases.

Table 4: Examples of character embeddings

We further compare our model with previous neural network models on both PKU and MSRA datasets. Since Zheng et al. (2013) did not report the results on the these datasets, we re-implemented their model and tested it on the test data. The results are listed in the first three rows of Table 5, which shows that our model achieved higher F-score than the previous neural network models.

4.3 Unsupervised Pre-training

Previous work found that the performance can be improved by pre-training the character embeddings on large unlabeled data and using the obtained embeddings to initialize the character lookup table instead of random initialization

Table 5: Comparison with previous neural network models

(Mansur et al., 2013; Zheng et al., 2013). Mikolov et al. (2013b) show that pre-trained embeddings can capture interesting semantic and syntactic information such as $king-man+woman \approx queen$ on English data. There are several ways to learn the embeddings on unlabeled data. Mansur et al. (2013) used the model proposed by Bengio et al. (2003) which learns the embeddings based on neural language model. Zheng et al. (2013) followed the model proposed by Collobert et al. (2008). They constructed a neural network that outputs high scores for windows that occur in the corpus and low scores for windows where one character is replaced by a random one. Mikolov et al. (2013a) proposed a faster skip-gram model *word2vec*[5] which tries to maximize classification of a word based on another word in the same sentence. In this paper, we use *word2vec* because preliminary experiments did not show differences between performances of these models but *word2vec* is much faster to train. We pre-train the embeddings on the Chinese Giga-word corpus (Graff and Chen, 2005). As shown in Table 5 (last three rows), both the F-score and OOV recall of our model boost by using pre-training. Our model still outperforms other models after pre-training.

4.4 Minimal Feature Engineering

Although we focus on the question that how far we can go without using feature engineering in this paper, the study of deep learning for NLP tasks is still a new area in which it is currently challenging to surpass the state-of-the-art without additional features. To incorporate features into the neural network, Mansur et al. (2013) proposed the feature-based neural network where each context feature is represented as feature embeddings. The idea of feature embeddings is similar to that of character embeddings described in section 2.1.

MMTNN	94.0	94.9
MMTNN + bigram	95.2	97.2

Table 6: Comparison with state-of-the-art systems

Formally, we assume the extracted features form a feature dictionary D_f. Then each feature $f \in D_f$ is represented by a d-dimensional vector which is called feature embedding. Following their idea, we try to find out how well our model can perform with minimal feature engineering.

A very common feature in Chinese word segmentation is the character bigram feature. Formally, at the i-th character of a sentence $c_{[1:n]}$, the bigram features are $c_k c_{k+1}(i-3 < k < i+2)$. In our model, the bigram features are extracted in the window context and then the corresponding bigram embeddings are concatenated with character embeddings in Layer 1 and fed into Layer 2. In Mansur et al. (2013), the bigram embeddings are pre-trained on unlabeled data with character embeddings, which significantly improves the model performance. Given the long time for pre-training bigram embeddings, we only pre-train the character embeddings and the bigram embeddings are initialized as the average of character embeddings of c_k and c_{k+1}. Further improvement could be obtained if the bigram embeddings are also pre-trained. Table 6 lists the segmentation performances of our model as well as previous state-of-the-art systems. When bigram features are added, the F-score of our model improves

from 94.0% to 95.2% on PKU dataset and from 94.9% to 97.2% on MSRA dataset. It is a competitive result given that our model only use simple bigram features while other models use more complex features. For example, Sun et al. (2012) uses additional word-based features. Zhang et al. (2013) uses eight types of features such as Mutual Information and Accessor Variety and they extract dynamic statistical features from both an in-domain corpus and an out-of-domain corpus using co-training. Since feature engineering is not the main focus of this paper, we did not experiment with more features.

5 Related Work

Chinese word segmentation has been studied with considerable efforts in the NLP community. The most popular approach treats word segmentation as a sequence labeling problem which was first proposed in Xue (2003). Most previous systems address this task by using linear statistical models with carefully designed features such as bigram features, punctuation information (Li and Sun, 2009) and statistical information (Sun and Xu, 2011). Recently, researchers have tended to explore new approaches for word segmentation which circumvent the feature engineering by automatically learning features with neural network models (Mansur et al., 2013; Zheng et al., 2013). Our study is consistent with this line of research, however, our model explicitly models the interactions between tags and context characters and accordingly captures more semantic information.

Tensor-based transformation was also used in other neural network models for its ability to capture multiple interactions in data. For example, Socher et al. (2013b) exploited tensor-based function in the task of Sentiment Analysis to capture more semantic information from constituents. However, given the small size of their tensor matrix, they do not have the problem of high time cost and overfitting problem as we faced in modeling a sequence labeling task like Chinese word segmentation. That's why we propose to decrease computational cost and avoid overfitting with tensor factorization.

Various tensor factorization (decomposition) methods have been proposed recently for tensor-based dimension reduction (Cohen et al., 2013; Van de Cruys et al., 2013; Chang et al., 2013). For example, Chang et al. (2013) proposed the Multi-Relational Latent Semantic Analysis. Similar to LSA, a low rank approximation of the tensor is derived using a tensor decomposition approch. Similar ideas were also used for collaborative filtering (Salakhutdinov et al., 2007) and object recognition (Ranzato et al., 2010). Our tensor factorization is related to these work but uses a different tensor factorization approach. By introducing tensor factorization into the neural network model for sequence labeling tasks, the model training and inference are speeded up and overfitting is prevented.

6 Conclusion

In this paper, we propose a new model called Max-Margin Tensor Neural Network that explicitly models the interactions between tags and context characters. Moreover, we propose a tensor factorization approach that effectively improves the model efficiency and avoids the risk of overfitting. Experiments on the benchmark datasets show that our model achieve better results than previous neural network models and that our model can achieve a competitive result with minimal feature engineering. In the future, we plan to further extend our model and apply it to other structure prediction problems.

Abstract

Negation words, such as *no* and *not*, play a fundamental role in modifying sentiment of textual expressions. We will refer to a negation word as the *negator* and the text span within the scope of the negator as the *argument*. Commonly used heuristics to estimate the sentiment of negated expressions rely simply on the sentiment of argument (and not on the negator or the argument itself). We use a sentiment treebank to show that these existing heuristics are poor estimators of sentiment. We then modify these heuristics to be dependent on the negators and show that this improves prediction. Next, we evaluate a recently proposed composition model (Socher et al., 2013) that relies on both the negator and the argument. This model learns the syntax and semantics of the negator's argument with a recursive neural network. We show that this approach performs better than those mentioned above. In addition, we explicitly incorporate the prior sentiment of the argument and observe that this information can help reduce fitting errors.

1 Introduction

Morante and Sporleder (2012) define negation to be "a grammatical category that allows the changing of the truth value of a proposition". Negation is often expressed through the use of negative signals or negators–words like *isn't* and *never*, and it can significantly affect the sentiment of its scope. Understanding the impact of negation on sentiment is essential in automatic analysis of sentiment. The literature contains interesting research attempting to model and understand the behavior (reviewed in Section 2). For example,

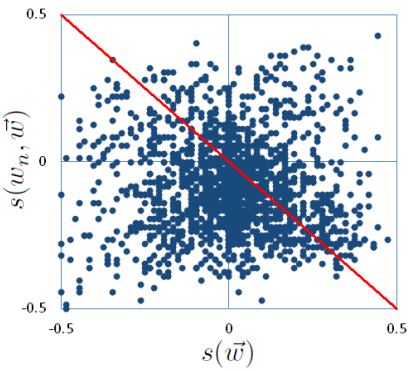

Figure 1: Effect of a list of common negators in modifying sentiment values in Stanford Sentiment Treebank. The x-axis is $s(\vec{w})$, and y-axis is $s(w_n, \vec{w})$. Each dot in the figure corresponds to a text span being modified by (composed with) a negator in the treebank. The red diagonal line corresponds to the sentiment-reversing hypothesis that simply reverses the sign of sentiment values.

a simple yet influential hypothesis posits that a negator reverses the sign of the sentiment value of the modified text (Polanyi and Zaenen, 2004; Kennedy and Inkpen, 2006). The *shifting* hypothesis (Taboada et al., 2011), however, assumes that negators change sentiment values by a constant amount. In this paper, we refer to a negation word as the *negator* (e.g., *isn't*), a text span being modified by and composed with a negator as the *argument* (e.g., *very good*), and entire phrase (e.g., *isn't very good*) as the *negated phrase*.

The recently available Stanford Sentiment Treebank (Socher et al., 2013) renders manually annotated, real-valued sentiment scores for all phrases in parse trees. This corpus provides us with the data to further understand the quantitative behavior of negators, as the effect of negators can now be studied with *arguments* of rich syntactic and semantic variety. Figure 1 illustrates the effect of a common list of negators on sentiment as observed

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 304–313,
Baltimore, Maryland, USA, June 23-25 2014.

on the Stanford Sentiment Treebank.[1] Each dot in the figure corresponds to a *negated phrase* in the treebank. The x-axis is the sentiment score of its *argument* $s(\vec{w})$ and y-axis the sentiment score of the entire negated phrase $s(w_n, \vec{w})$.

We can see that the *reversing* assumption (the red diagonal line) does capture some regularity of human perception, but rather roughly. Moreover, the figure shows that same or similar $s(\vec{w})$ scores (x-axis) can correspond to very different $s(w_n, \vec{w})$ scores (y-axis), which, to some degree, suggests the potentially complicated behavior of negators.[2]

This paper describes a quantitative study of the effect of a list of frequent negators on sentiment. We regard the negators' behavior as an underlying function embedded in annotated data; we aim to model this function from different aspects. By examining sentiment compositions of negators and arguments, we model the quantitative behavior of negators in changing sentiment. That is, given a negated phrase (e.g., *isn't very good*) and the sentiment score of its argument (e.g., $s(\text{“}very\ good'') = 0.5$), we focus on understanding the negator's quantitative behavior in yielding the sentiment score of the negated phrase $s(\text{“}isn't\ very\ good'')$.

We first evaluate the modeling capabilities of two influential heuristics and show that they capture only very limited regularity of negators' effect. We then extend the models to be dependent on the negators and demonstrate that such a simple extension can significantly improve the performance of fitting to the human annotated data. Next, we evaluate a recently proposed composition model (Socher, 2013) that relies on both the negator and the argument. This model learns the syntax and semantics of the negator's argument with a recursive neural network. This approach performs significantly better than those mentioned above. In addition, we explicitly incorporate the prior sentiment of the argument and observe that this information helps reduce fitting errors.

[1]The sentiment values have been linearly rescaled from the original range [0, 1] to [-0.5, 0.5]; in the figure a negative or positive value corresponds to a negative or a positive sentiment respectively; zero means neutral. The negator list will be discussed later in the paper.

[2]Similar distribution is observed in other data such as Tweets (Kiritchenko et al., 2014).

2 Related work

Automatic sentiment analysis The expression of sentiment is an integral component of human language. In written text, sentiment is conveyed with word senses and their composition, and in speech also via prosody such as pitch (Mairesse et al., 2012). Early work on automatic sentiment analysis includes the widely cited work of (Hatzivassiloglou and McKeown, 1997; Pang et al., 2002; Turney, 2002), among others. Since then, there has been an explosion of research addressing various aspects of the problem, including detecting subjectivity, rating and classifying sentiment, labeling sentiment-related semantic roles (e.g., target of sentiment), and visualizing sentiment (see surveys by Pang and Lee (2008) and Liu and Zhang (2012)).

Negation modeling Negation is a general grammatical category pertaining to the changing of the truth values of propositions; negation modeling is not limited to sentiment. For example, paraphrase and contradiction detection systems rely on detecting negated expressions and opposites (Harabagiu et al., 2006). In general, a negated expression and the opposite of the expression may or may not convey the same meaning. For example, *not alive* has the same meaning as *dead*, however, *not tall* does not always mean *short*. Some automatic methods to detect opposites were proposed by Hatzivassiloglou and McKeown (1997) and Mohammad et al. (2013).

Negation modeling for sentiment An early yet influential *reversing* assumption conjectures that a negator reverses the sign of the sentiment value of the modified text (Polanyi and Zaenen, 2004; Kennedy and Inkpen, 2006), e.g., from +0.5 to -0.5, or vice versa. A different hypothesis, called the *shifting* hypothesis in this paper, assumes that negators change the sentiment values by a constant amount (Taboada et al., 2011; Liu and Seneff, 2009). Other approaches to negation modeling have been discussed in (Jia et al., 2009; Wiegand et al., 2010; Lapponi et al., 2012; Benamara et al., 2012).

In the process of semantic composition, the effect of negators could depend on the syntax and semantics of the text spans they modify. The approaches of modeling this include bag-of-word-based models. For example, in the work of (Kennedy and Inkpen, 2006), a feature *not_good* will be created if the word *good* is encountered

within a predefined range after a negator.

There exist different ways of incorporating more complicated syntactic and semantic information. Much recent work considers sentiment analysis from a semantic-composition perspective (Moilanen and Pulman, 2007; Choi and Cardie, 2008; Socher et al., 2012; Socher et al., 2013), which achieved the state-of-the-art performance. Moilanen and Pulman (2007) used a collection of hand-written compositional rules to assign sentiment values to different granularities of text spans. Choi and Cardie (2008) proposed a learning-based framework. The more recent work of (Socher et al., 2012; Socher et al., 2013) proposed models based on recursive neural networks that do not rely on any heuristic rules. Such models work in a bottom-up fashion over the parse tree of a sentence to infer the sentiment label of the sentence as a composition of the sentiment expressed by its constituting parts. The approach leverages a principled method, the forward and backward propagation, to learn a vector representation to optimize the system performance. In principle neural network is able to fit very complicated functions (Mitchell, 1997), and in this paper, we adapt the state-of-the-art approach described in (Socher et al., 2013) to help understand the behavior of negators specifically.

3 Negation models based on heuristics

We begin with previously proposed methods that leverage heuristics to model the behavior of negators. We then propose to extend them to consider lexical information of the negators themselves.

3.1 Non-lexicalized assumptions and modeling

In previous research, some influential, widely adopted assumptions posit the effect of negators to be independent of both the specific negators and the semantics and syntax of the arguments. In this paper, we call a model based on such assumptions a non-lexicalized model. In general, we can simply define this category of models in Equation 1. That is, the model parameters are only based on the sentiment value of the arguments.

$$s(w_n, \vec{w}) \stackrel{\text{def}}{=} f(s(\vec{w})) \quad (1)$$

3.1.1 Reversing hypothesis

A typical model falling into this category is the *reversing* hypothesis discussed in Section 2, where a negator simply reverses the sentiment score $s(\vec{w})$ to be $-s(\vec{w})$; i.e., $f(s(\vec{w})) = -s(\vec{w})$.

3.1.2 Shifting hypothesis

Basic shifting Similarly, a *shifting* based model depends on $s(\vec{w})$ only, which can be written as:

$$f(s(\vec{w})) = s(\vec{w}) - sign(s(\vec{w})) * C \quad (2)$$

where $sign(.)$ is the standard *sign* function which determines if the constant C should be added to or deducted from $s(w_n)$: the constant is added to a negative $s(\vec{w})$ but deducted from a positive one.

Polarity-based shifting As will be shown in our experiments, negators can have different shifting power when modifying a positive or a negative phrase. Thus, we explore the use of two different constants for these two situations, i.e., $f(s(\vec{w})) = s(\vec{w}) - sign(s(\vec{w})) * C(sign(s(\vec{w})))$. The constant C now can take one of two possible values. We will show that this simple modification improves the fitting performance statistically significantly. Note also that instead of determining these constants by human intuition, we use the training data to find the constants in all shifting-based models as well as for the parameters in other models.

3.2 Simple lexicalized assumptions

The above negation hypotheses rely on $s(\vec{w})$. As intuitively shown in Figure 1, the capability of the non-lexicalized heuristics might be limited. Further semantic or syntactic information from either the negators or the phrases they modify could be helpful. The most straightforward way of expanding the non-lexicalized heuristics is probably to make the models to be dependent on the negators.

$$s(w_n, \vec{w}) \stackrel{\text{def}}{=} f(w_n, s(\vec{w})) \quad (3)$$

Negator-based shifting We can simply extend the basic shifting model above to consider the lexical information of negators: $f(s(\vec{w})) = s(\vec{w}) - sign(s(\vec{w})) * C(w_n)$. That is, each negator has its own C. We call this model *negator-based shifting*. We will show that this model also statistically significantly outperforms the basic shifting without overfitting, although the number of parameters have increased.

Combined shifting We further combine the *negator-based shifting* and *polarity-based shifting* above: $f(s(\vec{w})) = s(\vec{w}) - sign(s(\vec{w})) * C(w_n, sign(s(\vec{w})))$. This shifting model is based on negators and the polarity of the text they modify: constants can be different for each negator-polarity pair. The number of parameters in this model is the multiplication of number of negators by two (the number of sentiment polarities). This model further improves the fitting performance on the test data.

4 Semantics-enriched modeling

Negators can interact with arguments in complex ways. Figure 1 shows the distribution of the effect of negators on sentiment without considering further semantics of the arguments. The question then is that whether and how much incorporating further syntax and semantic information can help better fit or predict the negation effect. Above, we have considered the semantics of the negators. Below, we further make the models to be dependent on the arguments. This can be written as:

$$s(w_n, \vec{w}) \stackrel{\text{def}}{=} f(w_n, s(\vec{w}), r(\vec{w})) \quad (4)$$

In the formula, $r(\vec{w})$ is a certain type of representation for the argument $\vec{w}$ and it models the semantics or/and syntax of the argument. There exist different ways of implementing $r(\vec{w})$. We consider two models in this study: one drops $s(\vec{w})$ in Equation 4 and directly models $f(w_n, r(\vec{w}))$. That is, the non-uniform information shown in Figure 1 is not directly modeled. The other takes into account $s(\vec{w})$ too.

For the former, we adopt the recursive neural tensor network (RNTN) proposed recently by Socher et al. (2013), which has showed to achieve the state-of-the-art performance in sentiment analysis. For the latter, we propose a prior sentiment-enriched tensor network (PSTN) to take into account the prior sentiment of the argument $s(\vec{w})$.

4.1 RNTN: Recursive neural tensor network

A recursive neural tensor network (RNTN) is a specific form of feed-forward neural network based on syntactic (phrasal-structure) parse tree to conduct compositional sentiment analysis. For completeness, we briefly review it here. More details can be found in (Socher et al., 2013).

As shown in the *black* portion of Figure 2, each instance of RNTN corresponds to a binary parse tree of a given sentence. Each node of the parse tree is a fixed-length vector that encodes compositional semantics and syntax, which can be used to predict the sentiment of this node. The vector of a node, say p_2 in Figure 2, is computed from the d-dimensional vectors of its two children, namely a and p_1 ($a, p_1 \in \mathbb{R}^{d\times 1}$), with a non-linear function:

$$p_2 = tanh(\begin{bmatrix} a \\ p_1 \end{bmatrix}^T V^{[1:d]} \begin{bmatrix} a \\ p_1 \end{bmatrix} + W \begin{bmatrix} a \\ p_1 \end{bmatrix}) \quad (5)$$

where, $W \in \mathbb{R}^{d\times(d+d)}$ and $V \in \mathbb{R}^{(d+d)\times(d+d)\times d}$ are the matrix and tensor for the composition function. A major difference of RNTN from the conventional recursive neural network (RRN) (Socher et al., 2012) is the use of the tensor V in order to directly capture the multiplicative interaction of two input vectors, although the matrix W *implicitly* captures the nonlinear interaction between the input vectors. The training of RNTN uses conventional forward-backward propagation.

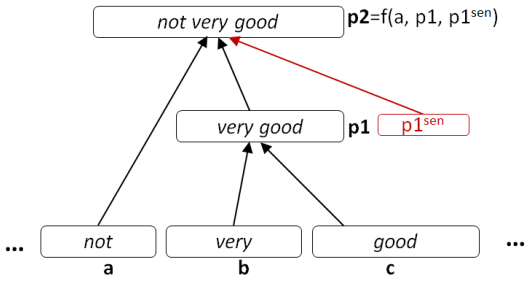

Figure 2: Prior sentiment-enriched tensor network (PSTN) model for sentiment analysis.

4.2 PSTN: Prior sentiment-enriched tensor network

The non-uniform distribution in Figure 1 has showed certain correlations between the sentiment values of $s(w_n, \vec{w})$ and $s(\vec{w})$, and such information has been leveraged in the models discussed in Section 3. We intend to devise a model that implements Equation 4. It bridges between the models we have discussed above that use either $s(\vec{w})$ or $r(\vec{w})$.

We extend RNTN to directly consider the sentiment information of arguments. Consider the node p_2 in Figure 2. When calculating its vector, we aim to directly engage the sentiment information of its right child, i.e., the argument. To this end, we make use of the sentiment class information of

p_1, noted as p_1^{sen}. As a result, the vector of p_2 is calculated as follows:

$$p_2 = tanh(\begin{bmatrix} a \\ p_1 \end{bmatrix}^T V^{[1:d]} \begin{bmatrix} a \\ p_1 \end{bmatrix} + W \begin{bmatrix} a \\ p_1 \end{bmatrix} + \begin{bmatrix} a \\ p_1^{sen} \end{bmatrix}^T V^{sen^{[1:d]}} \begin{bmatrix} a \\ p_1^{sen} \end{bmatrix} + W^{sen} \begin{bmatrix} a \\ p_1^{sen} \end{bmatrix}) \quad (6)$$

As shown in Equation 6, for the node vector $p_1 \in \mathbb{R}^{d\times 1}$, we employ a matrix, namely $W^{sen} \in \mathbb{R}^{d\times(d+m)}$ and a tensor, $V^{sen} \in \mathbb{R}^{(d+m)\times(d+m)\times d}$, aiming at explicitly capturing the interplays between the sentiment class of p_1, denoted as $p_1^{sen}(\in \mathbb{R}^{m\times 1})$, and the negator a. Here, we assume the sentiment task has m classes. Following the idea of Wilson et al. (2005), we regard the sentiment of p_1 as a *prior* sentiment as it has not been affected by the specific context (negators), so we denote our method as prior sentiment-enriched tensor network (PSTN). In Figure 2, the *red* portion shows the added components of PSTN.

Note that depending on different purposes, p_1^{sen} can take the value of the automatically predicted sentiment distribution obtained in forward propagation, the gold sentiment annotation of node p_1, or even other normalized prior sentiment value or confidence score from external sources (e.g., sentiment lexicons or external training data). This is actually an interesting place to extend the current recursive neural network to consider extrinsic knowledge. However, in our current study, we focus on exploring the behavior of negators. As we have discussed above, we will use the human annotated sentiment for the arguments, same as in the models discussed in Section 3.

With the new matrix and tensor, we then have $\theta = (V, V^{sen}, W, W^{sen}, W^{label}, L)$ as the PSTN model's parameters. Here, L denotes the vector representations of the word dictionary.

4.2.1 Inference and Learning

Inference and learning in PSTN follow a forward-backward propagation process similar to that in (Socher et al., 2013), and for completeness, we depict the details as follows. To train the model, one first needs to calculate the predicted sentiment distribution for each node:

$$p_i^{sen} = W^{label} p_i, \quad p_i^{sen} \in \mathbb{R}^{m\times 1}$$

and then compute the posterior probability over the m labels:

$$y^i = \text{softmax}(p_i^{sen})$$

During learning, following the method used by the RNTN model in (Socher et al., 2013), PSTN also aims to minimize the cross-entropy error between the predicted distribution $y^i \in \mathbb{R}^{m\times 1}$ at node i and the target distribution $t^i \in \mathbb{R}^{m\times 1}$ at that node. That is, the error for a sentence is calculated as:

$$E(\theta) = \sum_i \sum_j t_j^i \log y_j^i + \lambda \|\theta\|^2 \quad (7)$$

where, λ represents the regularization hyperparameters, and $j \in m$ denotes the j-th element of the multinomial target distribution.

To minimize $E(\theta)$, the gradient of the objective function with respect to each of the parameters in θ is calculated efficiently via backpropagation through structure, as proposed by Goller and Kchler (1996). Specifically, we first compute the prediction errors in all tree nodes bottom-up. After this forward process, we then calculate the derivatives of the softmax classifiers at each node in the tree in a top-down fashion. We will discuss the gradient computation for the V^{sen} and W^{sen} in detail next. Note that the gradient calculations for the V, W, W^{label}, L are the same as that of presented in (Socher et al., 2013).

In the backpropogation process of the training, each node (except the root node) in the tree carries two kinds of errors: the local softmax error and the error passing down from its parent node. During the derivative computation, the two errors will be summed up as the complement incoming error for the node. We denote the complete incoming error and the softmax error vector for node i as $\delta^{i,com} \in \mathbb{R}^{d\times 1}$ and $\delta^{i,s} \in \mathbb{R}^{d\times 1}$, respectively. With this notation, the error for the root node p_2 can be formulated as follows.

$$\begin{aligned} \delta^{p_2,com} &= \delta^{p_2,s} \\ &= (W^T(y^{p_2} - t^{p_2})) \otimes f'([a; p_1]) \end{aligned} \quad (8)$$

where $\otimes$ is the Hadamard product between the two vectors and f' is the element-wise derivative of $f = tanh$. With the results from Equation 8, we then can calculate the derivatives for the W^{sen} at node p_2 using the following equation:

$$\frac{\partial E^{p_2}}{W^{sen}} = \delta^{p_2,com}([a; p_1^{sen}])^T$$

Similarly, for the derivative of each slice $k(k =$

$1, \ldots, d)$ of the V^{sen} tensor, we have the following:

$$\frac{\partial E^{p_2}}{V^{sen}_{[k]}} = \delta^{p_2,com}_k \begin{bmatrix} a \\ p_1^{sen} \end{bmatrix} \begin{bmatrix} a \\ p_1^{sen} \end{bmatrix}^T$$

Now, let's form the equations for computing the error for the two children of the p_2 node. The difference for the error at p_2 and its two children is that the error for the latter will need to compute the error message passing down from p_2. We denote the error passing down as $\delta^{p_2,down}$, where the left child and the right child of p_2 take the 1^{st} and 2^{nd} half of the error $\delta^{p_2,down}$, namely $\delta^{p_2,down}[1:d]$ and $\delta^{p_2,down}[d+1:2d]$, respectively. Following this notation, we have the error message for the two children of p_2, provided that we have the $\delta^{p_2,down}$:

$$\begin{aligned}\delta^{p_1,com} &= \delta^{p_1,s} + \delta^{p_2,down}[d+1:2d] \\ &= (W^T(y^{p_1} - t^{p_1})) \otimes f^{'}([b;c]) \\ &+ \delta^{p_2,down}[d+1:2d]\end{aligned}$$

The incoming error message of node a can be calculated similarly. Finally, we can finish the above equations with the following formula for computing $\delta^{p_2,down}$:

$$\delta^{p_2,down} = (W^T\delta^{p_2,com}) \otimes f^{'}([a;p_1]) + \delta^{tensor}$$

where

$$\begin{aligned}&\delta^{tensor} = [\delta^V[1:d] + \delta^{V^{sen}}[1:d], \delta^V[d+1:2d]] \\ &= \sum_{k=1}^{d} \delta^{p_2,com}_k (V_{[k]} + (V_{[k]})^T) \otimes f^{'}([a;p_1])[1:d] \\ &+ \sum_{k=1}^{d} \delta^{p_2,com}_k (V^{sen}_{[k]} + (V^{sen}_{[k]})^T) \otimes f^{'}([a;p_1^{sen}])[1:d] \\ &+ \sum_{k=1}^{d} \delta^{p_2,com}_k (V_{[k]} + (V_{[k]})^T) \otimes f^{'}([a;p_1])[d+1:2d]\end{aligned}$$

After the models are trained, they are applied to predict the sentiment of the test data. The original RNTN and the PSTN predict 5-class sentiment for each negated phrase; we map the output to real-valued scores based on the scale that Socher et al. (2013) used to map real-valued sentiment scores to sentiment categories. Specifically, we conduct the mapping with the formula: $p_i^{real} = y^i \cdot [0.1\ 0.3\ 0.5\ 0.7\ 0.9]$; i.e., we calculate the dot product of the posterior probability y^i and the scaling vector. For example, if $y^i = [0.5\ 0.5\ 0\ 0\ 0]$, meaning this phrase has a 0.5 probability to be in the first category (strong negative) and 0.5 for the second category (weak negative), the resulting p_i^{real} will be 0.2 (0.5*0.1+0.5*0.3).

5 Experiment set-up

Data As described earlier, the Stanford Sentiment Treebank (Socher et al., 2013) has manually annotated, real-valued sentiment values for all phrases in parse trees. This provides us with the training and evaluation data to study the effect of negators with syntax and semantics of different complexity in a natural setting. The data contain around 11,800 sentences from movie reviews that were originally collected by Pang and Lee (2005). The sentences were parsed with the Stanford parser (Klein and Manning, 2003). The phrases at all tree nodes were manually annotated with one of 25 sentiment values that uniformly span between the positive and negative poles. The values are normalized to the range of [0, 1].

In this paper, we use a list of most frequent negators that include the words *not*, *no*, *never*, and their combinations with auxiliaries (e.g., *didn't*). We search these negators in the Stanford Sentiment Treebank and normalize the same negators to a single form; e.g., "*is n't*", "*isn't*", and "*is not*" are all normalized to "is_not". Each occurrence of a negator and the phrase it is directly composed with in the treebank, i.e., $\langle w_n, \vec{w} \rangle$, is considered a data point in our study. In total, we collected 2,261 pairs, including 1,845 training and 416 test cases. The split of training and test data is same as specified in (Socher et al., 2013).

Evaluation metrics We use the mean absolute error (MAE) to evaluate the models, which measures the averaged absolute offsets between the predicted sentiment values and the gold standard. More specifically, MAE is calculated as: $MAE = \frac{1}{N}\sum_{\langle w_n,\vec{w}\rangle} |(\hat{s}(w_n,\vec{w}) - s(w_n,\vec{w}))|$, where $\hat{s}(w_n,\vec{w})$ denotes the gold sentiment value and $s(w_n,\vec{w})$ the predicted one for the pair $\langle w_n,\vec{w}\rangle$, and N is the total number of test instances. Note that mean square error (MSE) is another widely used measure for regression, but it is less intuitive for out task here.

6 Experimental results

Overall regression performance Table 1 shows the overall fitting performance of all models. The first row of the table is a random baseline, which

simply guesses the sentiment value for each test case randomly in the range [0,1]. The table shows that the basic *reversing* and *shifting* heuristics do capture negators' behavior to some degree, as their MAE scores are higher than that of the baseline. Making the basic shifting model to be dependent on the negators (model 4) reduces the prediction error significantly as compared with the error of the basic shifting (model 3). The same is true for the polarity-based shifting (model 5), reflecting that the roles of negators are different when modifying positive and negative phrases. Merging these two models yields additional improvement (model 6).

Assumptions	MAE
Baseline	
(1) Random	0.2796
Non-lexicalized	
(2) Reversing	0.1480*
(3) Basic shifting	0.1452*
Simple-lexicalized	
(4) Negator-based shifting	0.1415†
(5) Polarity-based shifting	0.1417†
(6) Combined shifting	0.1387†
Semantics-enriched	
(7) RNTN	0.1097**
(8) PSTN	0.1062††

Table 1: Mean absolute errors (MAE) of fitting different models to Stanford Sentiment Treebank. Models marked with an asterisk (*) are statistically significantly better than the random baseline. Models with a dagger sign (†) significantly outperform model (3). Double asterisks ** indicates a statistically significantly different from model (6), and the model with the double dagger ††is significantly better than model (7). One-tailed paired t-test with a 95% significance level is used here.

Furthermore, modeling the syntax and semantics with the state-of-the-art recursive neural network (model 7 and 8) can dramatically improve the performance over model 6. The PSTN model, which takes into account the human-annotated *prior* sentiment of arguments, performs the best. This could suggest that additional external knowledge, e.g., that from human-built resources or automatically learned from other data (e.g., as in (Kiritchenko et al., 2014)), including sentiment that cannot be inferred from its constituent expressions, might be incorporated to benefit the current neural-network-based models as *prior* knowledge.

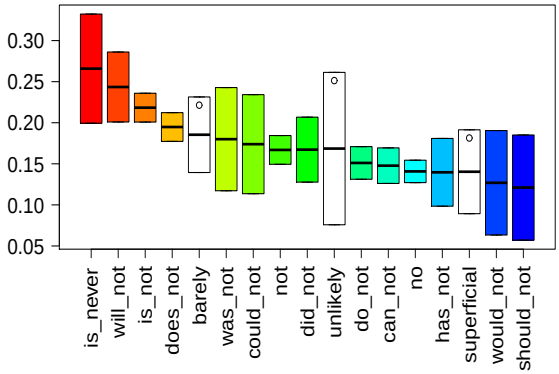

Figure 3: Effect of different negators in shifting sentiment values.

Note that the two neural network based models incorporate the syntax and semantics by representing each node with a vector. One may consider that a straightforward way of considering the semantics of the modified phrases is simply memorizing them. For example, if a phrase *very good* modified by a negator *not* appears in the training and test data, the system can simply memorize the sentiment score of *not very good* in training and use this score at testing. When incorporating this memorizing strategy into model (6), we observed a MAE score of 0.1222. It's not surprising that memorizing the phrases has some benefit, but such matching relies on the exact reoccurrences of phrases. Note that this is a special case of what the neural network based models can model.

Discriminating negators The results in Table 1 has demonstrated the benefit of discriminating negators. To understand this further, we plot in Figure 3 the behavior of different negators: the x-axis is a subset of our negators and the y-axis denotes absolute shifting in sentiment values. For example, we can see that the negator "is_never" on average shifts the sentiment of the arguments by 0.26, which is a significant change considering the range of sentiment value is [0, 1]. For each negator, a 95% confidence interval is shown by the boxes in the figure, which is calculated with the bootstrapping resampling method. We can observe statistically significant differences of shifting abilities between many negator pairs such as that between "*is_never*" and "*do_not*" as well as between "*does_not*" and "*can_not*".

Figure 3 also includes three diminishers (the

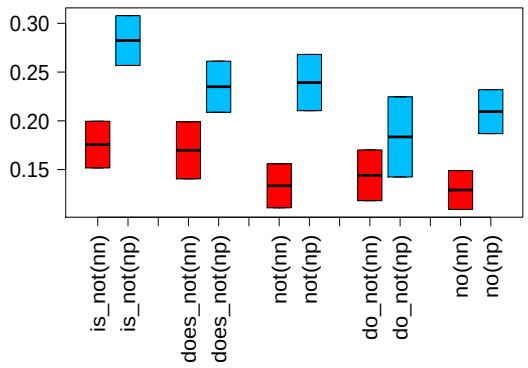

Figure 4: The behavior of individual negators in negated negative (nn) and negated positive (np) context.

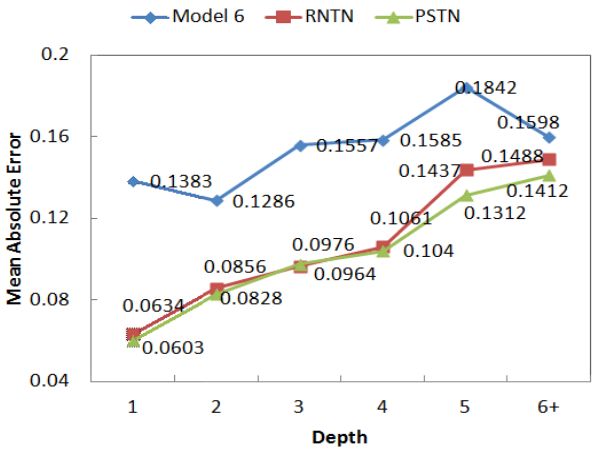

Figure 5: Errors made at different depths in the sentiment tree bank.

white bars), i.e., *barely*, *unlikely*, and *superficial*. By following (Kennedy and Inkpen, 2006), we extracted 319 diminishers (also called *understatement* or *downtoners*) from *General Inquirer*[3]. We calculated their shifting power in the same manner as for the negators and found three diminishers having shifting capability in the shifting range of these negators. This shows that the boundary between negators and diminishers can by fuzzy. In general, we argue that one should always consider modeling negators individually in a sentiment analysis system. Alternatively, if the modeling has to be done in groups, one should consider clustering valence shifters by their shifting abilities in training or external data.

Figure 4 shows the shifting capacity of negators when they modify positive (blue boxes) or negative phrases (red boxes). The figure includes five most frequently used negators found in the sentiment treebank. Four of them have significantly different shifting power when composed with positive or negative phrases, which can explain why the polarity-based shifting model achieves improvement over the basic shifting model.

Modeling syntax and semantics We have seen above that modeling syntax and semantics through the-state-of-the-art neural networks help improve the fitting performance. Below, we take a closer look at the fitting errors made at different depths of the sentiment treebank. The *depth* here is defined as the longest distance between the root of a negator-phrase pair $\langle w_n, \vec{w} \rangle$ and their descendant leafs. Negators appearing at deeper levels of the tree tend to have more complicated syntax and semantics. In Figure 5, the x-axis corresponds to different depths and y-axis is the mean absolute errors (MAE).

The figure shows that both RNTN and PSTN perform much better at all depths than the model 6 in Table 1. When the depths are within 4, the RNTN performs very well and the (human annotated) *prior* sentiment of arguments used in PSTN does not bring additional improvement over RNTN. PSTN outperforms RNTN at greater depths, where the syntax and semantics are more complicated and harder to model. The errors made by model 6 is bumpy, as the model considers no semantics and hence its errors are not dependent on the depths. On the other hand, the errors of RNTN and PSTN monotonically increase with depths, indicating the increase in the task difficulty.

7 Conclusions

Negation plays a fundamental role in modifying sentiment. In the process of semantic composition, the impact of negators is complicated by the syntax and semantics of the text spans they modify. This paper provides a comprehensive and quantitative study of the behavior of negators through a unified view of fitting human annotation. We first measure the modeling capabilities of two influential heuristics on a sentiment treebank and find that they capture some effect of negation; however, extending these non-lexicalized models to be dependent on the negators improves the per-

[3]http://www.wjh.harvard.edu/ inquirer/

formance statistically significantly. The detailed analysis reveals the differences in the behavior among negators, and we argue that they should always be modeled separately. We further make the models to be dependent on the text being modified by negators, through adaptation of a state-of-the-art recursive neural network to incorporate the syntax and semantics of the arguments; we discover this further reduces fitting errors.

Extracting Opinion Targets and Opinion Words from Online Reviews with Graph Co-ranking

Kang Liu, Liheng Xu and Jun Zhao

{kliu, lhxu, jzhao}@nlpr.ia.ac.cn

Abstract

Extracting opinion targets and opinion words from online reviews are two fundamental tasks in opinion mining. This paper proposes a novel approach to collectively extract them with graph co-ranking. First, compared to previous methods which solely employed opinion relations among words, our method constructs a heterogeneous graph to model two types of relations, including semantic relations and opinion relations. Next, a co-ranking algorithm is proposed to estimate the confidence of each candidate, and the candidates with higher confidence will be extracted as opinion targets/words. In this way, different relations make cooperative effects on candidates' confidence estimation. Moreover, word preference is captured and incorporated into our co-ranking algorithm. In this way, our co-ranking is personalized and each candidate's confidence is only determined by its preferred collocations. It helps to improve the extraction precision. The experimental results on three data sets with different sizes and languages show that our approach achieves better performance than state-of-the-art methods.

1 Introduction

In opinion mining, extracting opinion targets and opinion words are two fundamental subtasks. Opinion targets are objects about which users' opinions are expressed, and opinion words are words which indicate opinions' polarities. Extracting them can provide essential information for obtaining fine-grained analysis on customers' opinions. Thus, it has attracted a lot of attentions (Hu and Liu, 2004b; Liu et al., 2012; Moghaddam and Ester, 2011; Mukherjee and Liu, 2012).

To this end, previous work usually employed a collective extraction strategy (Qiu et al., 2009; Hu and Liu, 2004b; Liu et al., 2013b). Their intuition is: opinion words usually co-occur with opinion targets in sentences, and there are strong modification relationship between them (called *opinion relation* in (Liu et al., 2012)). If a word is an opinion word, other words with which that word having opinion relations will have highly probability to be opinion targets, and vice versa. In this way, extraction is alternatively performed and mutual reinforced between opinion targets and opinion words. Although this strategy has been widely employed by previous approaches, it still has several limitations.

1) **Only considering opinion relations is insufficient**. Previous methods mainly focused on employing opinion relations among words for opinion target/word co-extraction. They have investigated a series of techniques to enhance opinion relations identification performance, such as nearest neighbor rules (Liu et al., 2005), syntactic patterns (Zhang et al., 2010; Popescu and Etzioni, 2005), word alignment models (Liu et al., 2012; Liu et al., 2013b; Liu et al., 2013a), etc. However, we are curious that whether merely employing opinion relations among words is enough for opinion target/word extraction? We note that there are additional types of relations among words. For example, "*LCD*" and "*LED*" both denote the same aspect "*screen*" in TV set domain, and they are topical related. We call such relations between homogeneous words as semantic relations. If we have known "*LCD*" to be an opinion target, "*LED*" is naturally to be an opinion target. Intuitively, besides opinion relations, semantic relations may provide additional rich clues for indicating opinion targets/words. Which kind of relations is more effective for opinion targets/words extraction? Is it beneficial to consider these two types of relations together for the extraction? To our best knowl-

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 314–324,
Baltimore, Maryland, USA, June 23-25 2014.

edge, these problems have seldom been studied before (see Section 2).

2) **Ignoring word preference**. When employing opinion relations to perform mutual reinforcing extraction between opinion targets and opinion words, previous methods depended on opinion associations among words, but seldom considered *word preference*. Word preference denotes a word's preferred collocations. Intuitively, the confidence of a candidate being an opinion target (opinion word) should mostly be determined by its word preferences rather than all words having opinion relations with it. For example

"*This camera's price is expensive for me.*"

"*It's price is good.*"

"*Canon 40D has a good price.*"

In these three sentences, "*price*" is modified by "*good*" more times than "*expensive*". In traditional extraction strategy, opinion associations are usually computed based on the co-occurrence frequency. Thus, "*good*" has more strong opinion association with "*price*" than "*expensive*", and it would have more contributions on determining "*price*" to be an opinion target or not. It's unreasonable. "*Expensive*" actually has more relatedness with "*price*" than "*good*", and "*expensive*" is likely to be a word preference for "*price*". The confidence of "*price*" being an opinion target should be influenced by "*expensive*" in greater extent than "*good*". In this way, we argue that the extraction will be more precise.

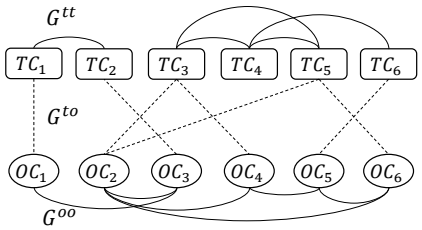

Figure 1: Heterogeneous Graph: OC means opinion word candidates. TC means opinion target candidates. Solid curves and dotted lines respectively mean semantic relations and opinion relations between two candidates.

Thus, to resolve these two problems, we present a novel approach with graph co-ranking. The collective extraction of opinion targets/words is performed in a co-ranking process. First, we operate over a heterogeneous graph to model semantic relations and opinion relations into a unified model. Specifically, our heterogeneous graph is composed of three subgraphs which model different relation types and candidates, as shown in Figure 1. The first subgraph G^{tt} represents semantic relations among opinion target candidates, and the second subgraph G^{oo} models semantic relations among opinion word candidates. The third part is a bipartite subgraph G^{to}, which models opinion relations among different candidate types and connects the above two subgraphs together. Then we perform a random walk algorithm on G^{tt}, G^{oo} and G^{to} separately, to estimate all candidates' confidence, and the entries with higher confidence than a threshold are correspondingly extracted as opinion targets/words. The results could reflect which type of relation is more useful for the extraction.

Second, a co-ranking algorithm, which incorporates three separate random walks on G^{tt}, G^{oo} and G^{to} into a unified process, is proposed to perform candidate confidence estimation. Different relations may cooperatively affect candidate confidence estimation and generate more global ranking results. Moreover, we discover each candidate's preferences through topics. Such word preference will be different for different candidates. We add word preference information into our algorithm and make our co-ranking algorithm be personalized. A candidate's confidence would mainly absorb the contributions from its word preferences rather than its all neighbors with opinion relations, which may be beneficial for improving extraction precision.

We perform experiments on real-world datasets from different languages and different domains. Results show that our approach effectively improves extraction performance compared to the state-of-the-art approaches.

2 Related Work

There are many significant research efforts on opinion targets/words extraction (sentence level and corpus level). In sentence level extraction, previous methods (Wu et al., 2009; Ma and Wan, 2010; Li et al., 2010; Yang and Cardie, 2013) mainly aimed to identify all opinion target/word mentions in sentences. They regarded it as a sequence labeling task, where several classical models were used, such as CRFs (Li et al., 2010) and SVM (Wu et al., 2009).

This paper belongs to corpus level extraction, and aims to generate a sentiment lexicon and a target list rather than to identify mentions in sen-

tences. Most of previous corpus-level methods adopted a co-extraction framework, where opinion targets and opinion words reinforce each other according to their opinion relations. Thus, how to improve opinion relations identification performance was their main focus. (Hu and Liu, 2004a) exploited nearest neighbor rules to mine opinion relations among words. (Popescu and Etzioni, 2005) and (Qiu et al., 2011) designed syntactic patterns to perform this task. (Zhang et al., 2010) promoted Qiu's method. They adopted some special designed patterns to increase recall. (Liu et al., 2012; Liu et al., 2013a; Liu et al., 2013b) employed word alignment model to capture opinion relations rather than syntactic parsing. The experimental results showed that these alignment-based methods are more effective than syntax-based approaches for online informal texts. However, all aforementioned methods only employed opinion relations for the extraction, but ignore considering semantic relations among homogeneous candidates. Moreover, they all ignored word preference in the extraction process.

In terms of considering semantic relations among words, our method is related with several approaches based on topic model (Zhao et al., 2010; Moghaddam and Ester, 2011; Moghaddam and Ester, 2012a; Moghaddam and Ester, 2012b; Mukherjee and Liu, 2012). The main goals of these methods weren't to extract opinion targets/words, but to categorize all given aspect terms and sentiment words. Although these models could be used for our task according to the associations between candidates and topics, solely employing semantic relations is still one-sided and insufficient to obtain expected performance.

Furthermore, there is little work which considered these two types of relations globally (Su et al., 2008; Hai et al., 2012; Bross and Ehrig, 2013). They usually captured different relations using co-occurrence information. That was too coarse to obtain expected results (Liu et al., 2012). In addition, (Hai et al., 2012) extracted opinion targets/words in a bootstrapping process, which had an error propagation problem. In contrast, we perform extraction with a global graph co-ranking process, where error propagation can be effectively alleviated. (Su et al., 2008) used heterogeneous relations to find implicit sentiment associations among words. Their aim was only to perform aspect terms categorization but not to extract opinion targets/words. They extracted opinion targets/words in advanced through simple phrase detection. Thus, the extraction performance is far from expectation.

3 The Proposed Method

In this section, we propose our method in detail. We formulate opinion targets/words extraction as a co-ranking task. All nouns/noun phrases are regarded as opinion target candidates, and all adjectives/verbs are regarded as opinion word candidates, which are widely adopted by pervious methods (Hu and Liu, 2004a; Qiu et al., 2011; Wang and Wang, 2008; Liu et al., 2012). Then each candidate will be assigned a confidence and ranked, and the candidates with higher confidence than a threshold will be extracted as the results.

Different from traditional methods, besides opinion relations among words, we additionally capture semantic relations among homogeneous candidates. To this end, a heterogeneous undirected graph $G = (V, E)$ is constructed. $V = V^t \cup V^o$ denotes the vertex set, which includes opinion target candidates $v^t \in V^t$ and opinion word candidates $v^o \in V^o$. E denotes the edge set, where $e_{ij} \in E$ means that there is a relation between two vertices. $E^{tt} \subset E$ represents the semantic relations between two opinion target candidates. $E^{oo} \subset E$ represents the semantic relations between two opinion word candidates. $E^{to} \subset E$ represents the opinion relations between opinion target candidates and opinion word candidates. Based on different relation types, we used three matrices $M_{tt} \in \mathbb{R}^{|V^t|\times|V^t|}$, $M_{oo} \in \mathbb{R}^{|V^o|\times|V^o|}$ and $M_{to} \in \mathbb{R}^{|V^t|\times|V^o|}$ to record the association weights between any two vertices, respectively. Section 3.4 will illustrate how to construct them.

3.1 Only Considering Opinion Relations

To estimate the confidence of each candidate, we use a random walk algorithm on our graph to perform co-ranking. Most previous methods (Hu and Liu, 2004a; Qiu et al., 2011; Wang and Wang, 2008; Liu et al., 2012) only considered opinion relations among words. Their basic assumption is as follows.

> **Assumption 1:** If a word is likely to be an opinion word, the words which it has opinion relation with will have higher confidence to be opinion targets, and vice versa.

In this way, candidates' confidences (v^t or v^o) are collectively determined by each other iteratively. It equals to making random walk on subgraph $G^{to} = (V, E^{to})$ of G. Thus we have

$$\begin{aligned} C_t &= (1-\mu) \times M_{to} \times C_o + \mu \times I_t \\ C_o &= (1-\mu) \times M_{to}^T \times C_t + \mu \times I_o \end{aligned} \tag{1}$$

where C_t and C_o respectively represent confidences of opinion targets and opinion words. $m_{i,j}^{to} \in M_{to}$ means the association weight between the ith opinion target and the jth opinion word according to their opinion relations.

It's worthy noting that I_t and I_o respectively denote prior confidences of opinion target candidates and opinion word candidates. We argue that opinion targets are usually domain-specific, and there are remarkably distribution difference of them on different domains (in-domain D_{in} vs. out-domain D_{out}). If a candidate is salient in D_{in} but common in D_{out}, it's likely to be an opinion target in D_{in}. Thus, we use a domain relevance measure (DR) (Hai et al., 2013) to compute I_t.

$$DR(t) = \frac{R(t, D_{in})}{R(t, D_{out})} \tag{2}$$

where $R(t, D) = \frac{\bar{w}_t}{s_t} \times \sum_{j=1}^{N}(w_{tj} - \frac{1}{W_j} \times \sum_{k=1}^{W_j} w_{kj})$ represents candidate relevance with domain D. $w_{tj} = (1 + logTF_{tj}) \times log\frac{N}{DF_t}$ is a TF-IDF-like weight of candidate t in document j. TF_{tj} is the frequency of the candidate t in the jth document, and DF_t is document frequency. N means the document number in domain D. $R(t, D)$ includes two measures to reflect the salient of a candidate in D. 1) $w_{tj} - \frac{1}{W_j} \times \sum_{k=1}^{W_j} w_{kj}$ reflects how frequently a term is mentioned in a particular document. W_j denotes the word number in document j. 2) $\frac{\bar{w}_t}{s_t}$ quantifies how significantly a term is mentioned across all documents in D. $\bar{w}_t = \frac{1}{N} \times \sum_{k=1}^{N} w_{tk}$ denotes average weight across all documents for t. $s_t = \sqrt{\frac{1}{N} \times \sum_{j=1}^{N} (w_{tj} - \bar{w}_j)^2}$ denotes the standard variance of term t. We use the given reviews as in-domain collection D_{in} and Google n-gram corpus[1] as out-domain collection D_{out}. Finally, each entry in I_t is a normalized $DR(t)$ score. In contrast, opinion words are usually domain-independent. Users may use same words to express theirs opinions, like "good", "bad", etc. But there are still some domain-dependent opinion words, like "delicious" in the restaurant domain, "powerful" in the car domain. It's difficult to discriminate them from other words by using statistical information. So we simply set all entries in I_o to be 1. $\mu \in [0, 1]$ in Eq.1 determines the impact of the prior confidence on results.

[1] http://books.google.com/ngrams/datasets

3.2 Only Considering Semantic Relations

To estimate candidates' confidences by only considering semantic relations among words, we make two separately random walks on the subgraphs of G, $G^{tt} = (V, E^{tt})$ and $G^{oo} = (V, E^{oo})$. The basic assumption is as follows:

> **Assumption 2:** If a word is likely to be an opinion target (opinion word), the words which it has strong semantic relation with will have higher confidence to be opinion targets (opinion words).

In this way, the confidence of the candidate is determined only by its homogeneous neighbours. There is no mutual reinforcement between opinion targets and opinion words. Thus we have

$$\begin{aligned} C_t &= (1-\nu) \times M_{tt} \times C_t + \nu \times I_t \\ C_o &= (1-\nu) \times M_{oo} \times C_o + \nu \times I_o \end{aligned} \tag{3}$$

where ν has the same role as μ in Eq.1.

3.3 Considering Semantic Relations and Opinion Relations Together

To jointly model semantic relations and opinion relations for opinion targets/words extraction, we couple two random walking algorithms mentioned above together. Here, **Assumption 1** and **Assumption 2** are both satisfied. Thus, an opinion target/word candidate's confidence is collectively determined by its neighbours according to different relation types. Meanwhile, each item may make influence on it's neighbours. It's an iterative reinforcement process. Thus, we have

$$\begin{aligned} C_t &= (1-\lambda-\mu) \times M_{to} \times C_o \\ &\quad + \lambda \times M_{tt} \times C_t + \mu \times I_t \\ C_o &= (1-\lambda-\mu) \times M_{to}^T \times C_t \\ &\quad + \lambda \times M_{oo} \times C_o + \mu \times I_o \end{aligned} \tag{4}$$

where $\lambda \in [0, 1]$ determines which type of relations dominates candidate confidence estimation. $\lambda = 0$ means that each candidate's confidence is estimated by only considering opinion relations among words, which equals to Eq.1. Otherwise, when $\lambda = 1$, candidate confidence estimation only

considers semantic relations among words, which equals to Eq.3. μ, I_o and I_t have the same meaning in Eq.1. Our algorithm will run iteratively until it converges or in a fixed iteration number $Iter$. In experiments, we set $Iter = 200$.

Obtaining Word Preference. The co-ranking algorithm in Eq.4 is based on a standard random walking algorithm, which randomly selects a link according to the association matrix M_{to}, M_{tt} and M_{oo}, or jumps to a random node with prior confidence value. However, it generates a global ranking over all candidates without taking the node preference (word preference) into account. As mentioned in the first section, each opinion target/word has its preferred collocations, it's reasonable that the confidence of an opinion target (opinion word) candidate should be preferentially determined by its preferences, rather than all of its neighbors with opinion relations.

To obtain the word preference, we resort to topics. We believe that if an opinion word ${v_i}^o$ is topical related with a target word ${v_j}^t$, ${v_i}^o$ can be regarded as a word preference for ${v_j}^t$, and vice versa. For example, "*price*" and "*expensive*" are topically related in phone's domain, so they are a word preference for each other.

Specifically, we use a vector $P^{T_i} = [P_1^{T_i}, ..., P_k^{T_i}, ..., P_{|V^o|}^{T_i}]_{1\times|V^o|}$ to represent word preference of the ith opinion target candidate. $P_k^{T_i}$ means the preferred probability of the ith potential opinion target for the kth potential opinion words. To compute $P_k^{T_i}$, we first use *Kullback-Leibler* divergence to measure the semantic distance between any two candidates on the bridge of topics. Thus, we have

$$D(v_i, v_j) = \frac{1}{2}\Sigma_z(KL_z(v_i||v_j) + KL_z(v_j||v_i))$$

where $KL_z(v_i||v_j) = p(z|v_i)log\frac{p(z|v_i)}{p(z|v_j)}$ means the KL-divergence from candidate v_i to v_j based on topic z. $p(z|v) = p(v|z)\frac{p(z)}{p(v)}$, where $p(v|z)$ is the probability of the candidate v to topic z (see Section 3.4). $p(z)$ is the probability that topic z in reviews. $p(v)$ is the probability that a candidate occurs in reviews. Then, a logistic function is used to map $D(v_i, v_j)$ into $[0, 1]$.

$$SA(v_i, v_j) = \frac{1}{1 + e^{D(v_i,v_j)}} \quad (5)$$

Then, we calculate $P_k^{T_i}$ by normalize $SA(v_i, v_j)$ score, i.e. $P_k^{T_i} = \frac{SA(v_i^t, v_k^o)}{\sum_{p=1}^{|V^o|} SA(v_i^t, v_p^o)}$. For demonstration, we give some examples in Table 1, where each entry denotes a $SA(v_i, v_j)$ score between two candidates. We can see that using topics can successfully capture the preference information for each opinion target/word.

	expensive	good	long	colorful
price	0.265	0.043	0.003	0.000
LED	0.002	0.035	0.007	0.098
battery	0.000	0.015	0.159	0.001

Table 1: Examples of Calculated Word Preference

And we use a vector $P^{O_j} = [P_1^{O_j}, ..., P_q^{O_j}, ..., P_{|V^t|}^{O_j}]_{1\times|V^t|}$ to represent the preference information of the jth opinion word candidate. Similarly, we have $P_q^{O_j} = \frac{SA(v_q^t, v_j^o)}{\sum_{k=1}^{|V^t|} SA(v_k^t, v_j^o)}$.

Incorporating Word Preference into Co-ranking. To consider such word preference in our co-ranking algorithm, we incorporate it into the random walking on G^{to}. Intuitively, preference vectors will be different for different candidates. Thus, the co-ranking algorithm would be personalized. It allows that the candidate confidence propagates to other candidates only in its preference cluster. Specifically, we make modification on original transition matrix $M_{to} = (M_1^{to}, M_2^{to}, ..., M_{|V^t|}^{to})$ and add each candidate's preference in it. Let $\hat{M}_{to} = (\hat{M}_1^{to}, \hat{M}_2^{to}, ..., \hat{M}_{|V^t|}^{to})$ be the modified transition matrix, which records the associations between opinion target candidates and opinion word candidates. Here $M_k^{to} \in \mathbb{R}^{1\times|V^o|}$ and $\hat{M}_k^{to} \in \mathbb{R}^{1\times|V^o|}$ denotes the kth column vector in M_{to} and $\hat{M}_{to}$, respectively. And let $Diag(P^{T_k})$ denote a diagonal matrix whose eigenvalue is vector P^{T_k}, we have

$$\hat{M}_k^{to} = M_k^{to} Diag(P^{T_k})$$

Similarly, let $U_k^{to} \in \mathbb{R}^{1\times|V^t|}$ and $\hat{U}_k^{to} \in \mathbb{R}^{1\times|V^t|}$ denotes the kth row vector in M_{to}^T and $\hat{M}_{to}^T$, respectively. $Diag(P^{O_k})$ denote a diagonal matrix whose eigenvalue is vector P^{O_k}. Then we have

$$\hat{U}_k^{to} = U_k^{to} Diag(P^{O_k})$$

In this way, each candidate's preference is incorporated into original associations based on opinion relation M_{to} through $Diag(P^{O_k})$ and $Diag(P^{T_k})$. And candidates' confidences will mainly come from the contributions of its preferences. Thus, C_t and C_o in Eq.4 become:

$$
\begin{aligned}
C_t &= (1-\lambda-\mu) \times \hat{M}_{to} \times C_o \\
&\quad + \lambda \times M_{tt} \times C_t + \mu \times I_t \\
C_o &= (1-\lambda-\mu) \times \hat{M}_{to}^T \times C_t \\
&\quad + \lambda \times M_{oo} \times C_o + \mu \times I_o
\end{aligned} \tag{6}
$$

3.4 Capturing Semantic and Opinion Relations

In this section, we explain how to capture semantic relations and opinion relations for constructing transition matrices M_{tt}, M_{oo} and M_{to}.

Capturing Semantic Relations: For capturing semantic relations among homogenous candidates, we employ topics. We believe that if two candidates share similar topics in the corpus, there is a strong semantic relation between them. Thus, we employ a LDA variation (Mukherjee and Liu, 2012), an extension of (Zhao et al., 2010), to discover topic distribution on words, which sampled all words into two separated observations: opinion targets and opinion words. It's because that we are only interested in topic distribution of opinion targets/words, regardless of other useless words, including conjunctions, prepositions etc. This model has been proven to be better than the standard LDA model and other LDA variations for opinion mining (Mukherjee and Liu, 2012).

After topic modeling, we obtain the probability of the candidates (v^t and v^o) to topic z, i.e. $p(z|v^t)$ and $p(z|v^o)$, and topic distribution $p(z)$. Then, a symmetric *Kullback-Leibler* divergence as same as Eq.5 is used to calculate the semantical associations between any two homogenous candidates. Thus, we obtain $SA(v^t, v^t)$ and $SA(v^o, v^o)$, which correspond to the entries in M_{tt} and M_{oo}, respectively.

Capturing Opinion Relations: To capture opinion relations among words and construct the transition matrix M_{to}, we used an alignment-based method proposed in (Liu et al., 2013b). This approach models capturing opinion relations as a monolingual word alignment process. Each opinion target can find its corresponding modifiers in sentences through alignment, in which multiple factors are considered globally, such as co-occurrence information, word position in sentence, etc. Moreover, this model adopted a partially supervised framework to combine syntactic information with alignment results, which has been proven to be more precise than the state-of-the-art approaches for opinion relations identification (Liu et al., 2013b).

After performing word alignment, we obtain a set of word pairs composed of a noun (noun phrase) and its corresponding modified word. Then, we simply employ Pointwise Mutual Information (PMI) to calculate the opinion associations among words as the entries in M_{to}. $OA(v^t, v^o) = log\frac{p(v^t, v^o)}{p(v^t)p(v^o)}$, where v^t and v^o denote an opinion target candidate and an opinion word candidate, respectively. $p(v^t, v^o)$ is the co-occurrence probability of v^t and v^o based on the opinion relation identification results. $p(v^t)$ and $p(v^o)$ give the independent occurrence probability of of v^t and v^o, respectively

4 Experiments

4.1 Datasets and Evaluation Metrics

Datasets: To evaluate the proposed method, we used three datasets. The first one is *Customer Review Datasets* (CRD), used in (Hu and Liu, 2004a), which contains reviews about five products. The second one is *COAE2008* dataset2[2], which contains Chinese reviews about four products. The third one is *Large*, also used in (Wang et al., 2011; Liu et al., 2012; Liu et al., 2013a), where two domains are selected (Mp3 and Hotel). As mentioned in (Liu et al., 2012), *Large* contains 6,000 sentences for each domain. Opinion targets/words are manually annotated, where three annotators were involved. Two annotators were required to annotate out opinion words/targets in reviews. When conflicts occur, the third annotator make final judgement. In total, we respectively obtain 1,112, 1,241 opinion targets and 334, 407 opinion words in Hotel, MP3.

Pre-processing: All sentences are tagged to obtain words' part-of-speech tags using Stanford NLP tool[3]. And noun phrases are identified using the method in (Zhu et al., 2009) before extraction.

Evaluation Metrics: We select precision(P), recall(R) and f-measure(F) as metrics. And a significant test is performed, i.e., a t-test with a default significant level of 0.05.

4.2 Our Method vs. The State-of-the-art Methods

To prove the effectiveness of the proposed method, we select some state-of-the-art methods for comparison as follows:

Table 3: Results of Opinion Targets Extraction on *COAE 2008* and *Large*

Hu extracted opinion targets/words using association mining rules (Hu and Liu, 2004a).

DP used syntax-based patterns to capture opinion relations in sentences, and then used a bootstrapping process to extract opinion targets/words (Qiu et al., 2011),.

Zhang is proposed by (Zhang et al., 2010). They also used syntactic patterns to capture opinion relations between words. Then a HITS (Kleinberg, 1999) algorithm is employed to extract opinion targets.

Liu is proposed by (Liu et al., 2013a), an extension of (Liu et al., 2012). They employed a word alignment model to capture opinion relations among words, and then used a random walking algorithm to extract opinion targets.

Hai is proposed by (Hai et al., 2012), which is similar to our method. They employed both of semantic relations and opinion relations to extract opinion words/targets in a bootstrapping framework. But they captured relations only using co-occurrence statistics. Moreover, word preference was not considered.

SAS is proposed by (Mukherjee and Liu, 2012), an extended lda-based model of (Zhao et al., 2010). The top K items for each aspect are extracted as opinion targets/words. It means that only semantic relations among words are considered in SAS. And we set aspects number to be 9 as same as (Mukherjee and Liu, 2012).

CR: is the proposed method in this paper by using co-ranking, referring to Eq.4. CR doesn't consider word preference.

CR_WP: is the full implementation of our method, referring to Eq.6.

Hu, DP, Zhang and Liu are the methods which only consider opinion relations among words. SAS is the methods which only consider semantic relations among words. Hai, CR and CR_WP consider these two types of relations together. The parameter settings of state-of-the-art methods are same as their original paper. In CR and CR_WP, we set $\lambda = 0.4$ and $\mu = 0.1$. The experimental results are shown in Table 2, 3, 4 and 5, where the last column presents the average F-measure scores for multiple domains. Since Liu and Zhang aren't designed for opinion words extraction, we don't present their results in Table 4 and 5. From experimental results, we can see.

1) Our methods (CR and CR_WP) outperform other methods not only on opinion targets extraction but on opinion words extraction in most domains. It proves the effectiveness of the proposed method.

2) CR and CR_WP have much better performance than Liu and Zhang, especially on Recall. Liu and Zhang also use a ranking framework like ours, but they only employ opinion relations for extraction. In contrast, besides opinion relations, CR and CR_WP further take semantic relations into account. Thus, more opinion targets/words can be extracted. Furthermore, we observe that CR and CR_WP outperform SAS. SAS only exploits semantic relations, but ignores opinion relations among words. Its extraction is performed separately and neglects the reinforcement between opinion targets and opinion words. Thus, SAS has worse performance than our methods. It demonstrates the usefulness of considering multiple relation types.

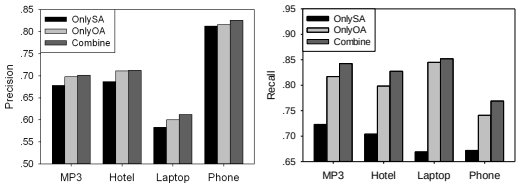
Table 5: Results of Opinion Words Extraction on *COAE 2008* and *Large*

3) CR and CR_WP both outperform Hai. We believe the reasons are as follows. First, CR and CR_WP considers multiple relations in a unified process by using graph co-ranking. In contrast, Hai adopts a bootstrapping framework which performs extraction step by step and may have the problem of error propagation. It demonstrates that our graph co-ranking is more suitable for this task than bootstrapping-based strategy. Second, our method captures semantic relations using topic modeling and captures opinion relations through word alignments, which are more precise than Hai which merely uses co-occurrence information to indicate such relations among words. In addition, word preference is not handled in Hai, but processed in CR_WP. The results show the usefulness of word preference for opinion targets/words extraction.

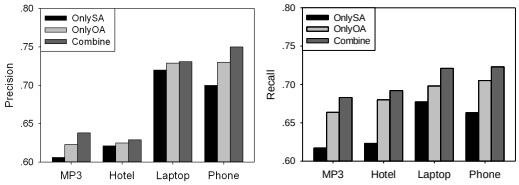
4) CR_WP outperforms CR, especially on precision. The only difference between them is that CR_WP considers word preference when performing graph ranking for candidate confidence estimation, but CR does not. Each candidate confidence estimation in CR_WP gives more weights for this candidate's preferred words than CR. Thus, the precision can be improved.

4.3 Semantic Relation vs. Opinion Relation

In this section, we discuss which relation type is more effective for this task. For comparison, we design two baselines, called **OnlySA** and **OnlyOA**. OnlyOA only employs opinion relations among words, which equals to Eq.1. OnlySA only employs semantic relations among words, which equals to Eq.3. Moreover, **Combine** is our method which considers both of opinion relations and semantic relations together, referring to Eq.4 with



(a) Opinion Target Extraction Results



(b) Opinion Word Extraction Results

Figure 2: Semantic Relations vs. Opinion Relations

$\lambda = 0.5$. Figure 2 presents experimental results. The left graph presents opinion targets extraction results and the right graph presents opinion words extraction results. Because of space limitation, we only shown the results of four domains (MP3, Hotel, Laptop and Phone).

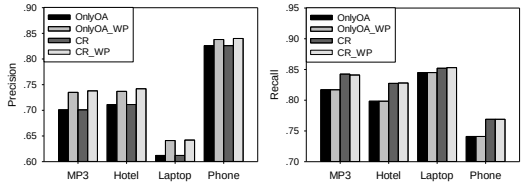
From results, we observe that OnlyOA outperforms OnlySA in all domains. It demonstrates that employing opinion relations are more useful than semantic relations for co-extracting opinion targets/words. And it is necessary to utilize the mutual reinforcement relationship between opinion words and opinion targets. Moreover, Combine outperforms OnlySA and OnlyOA in all domains. It indicates that combining different relations among words together is effective.

4.4 The Effectiveness of Considering Word Preference

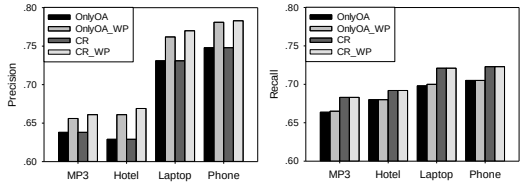
In this section, we try to prove the necessity of considering word preference in Eq.6. Besides the comparison between CR and CR_WP performed

in the main experiment in Section 4.2, we further incorporate word preference in aforementioned **OnlyOA**, named as **OnlyOA_WP**, which only employs opinion relations among words and equals to Eq.6 with $\lambda = 0$. Experimental results are shown in Figure 3. Because of space limitation, we only show the results of the same domains in section 4.3,

Form results, we observe that CR_WP outperforms CR, and OnlyOA_WP outperforms OnlyOA in all domains, especially on precision. These observations demonstrate that considering word preference is very important for opinion targets/words extraction. We believe the reason is that exploiting word preference can provide more fine information for opinion target/word candidates' confidence estimation. Thus the performance can be improved.



(a) Opinion Target Extraction Results



(b) Opinion Word Extraction Results

Figure 3: Experimental results when considering word preference

4.5 Parameter Sensitivity

In this subsection, we discuss the variation of extraction performance when changing λ and μ in Eq.6. Due to space limitation, we only show the F-measure of CR_WP on four domains. Experimental results are shown in Figure 4 and Figure 5. The left graphs in Figure 4 and 5 present the performance variation of CR_WP with varying λ from 0 to 0.9 and fixing $\mu = 0.1$. The right graphs in Figure 4 and 5 present the performance variation of CR_WP with varying μ from 0 to 0.6 and fixing $\lambda = 0.4$.

In the left graphs in Figure 4 and 5, we observe the best performance is obtained when $\lambda = 0.4$. It indicates that opinion relations and semantic relations are both useful for extracting opinion targets/words. The extraction performance is beneficial from their combination. In the right graphs in Figure 4 and 5, the best performance is obtained when $\mu = 0.1$. It indicates prior knowledge is useful for extraction. When μ increases, performance, however, decreases. It demonstrates that incorporating more prior knowledge into our algorithm would restrain other useful clues on estimating candidate confidence, and hurt the performance.

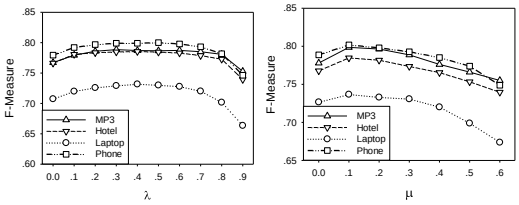


Figure 4: Opinion targets extraction results

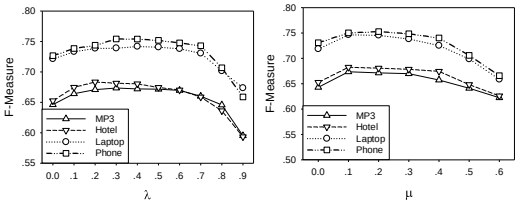

Figure 5: Opinion words extraction results

5 Conclusions

This paper presents a novel method with graph co-ranking to co-extract opinion targets/words. We model extracting opinion targets/words as a co-ranking process, where multiple heterogenous relations are modeled in a unified model to make co-operative effects on the extraction. In addition, we especially consider word preference in co-ranking process to perform more precise extraction. Compared to the state-of-the-art methods, experimental results prove the effectiveness of our method.

Abstract

This paper proposes a novel context-aware method for analyzing sentiment at the level of individual sentences. Most existing machine learning approaches suffer from limitations in the modeling of complex linguistic structures across sentences and often fail to capture non-local contextual cues that are important for sentiment interpretation. In contrast, our approach allows structured modeling of sentiment while taking into account both local and global contextual information. Specifically, we encode intuitive lexical and discourse knowledge as expressive constraints and integrate them into the learning of conditional random field models via posterior regularization. The context-aware constraints provide additional power to the CRF model and can guide semi-supervised learning when labeled data is limited. Experiments on standard product review datasets show that our method outperforms the state-of-the-art methods in both the supervised and semi-supervised settings.

1 Introduction

The ability to extract sentiment from text is crucial for many opinion-mining applications such as opinion summarization, opinion question answering and opinion retrieval. Accordingly, extracting sentiment at the fine-grained level (e.g. at the sentence- or phrase-level) has received increasing attention recently due to its challenging nature and its importance in supporting these opinion analysis tasks (Pang and Lee, 2008).

In this paper, we focus on the task of sentence-level sentiment classification in online reviews. Typical approaches to the task employ supervised machine learning algorithms with rich features and take into account the interactions between words to handle compositional effects such as polarity reversal (e.g. (Nakagawa et al., 2010; Socher et al., 2013)). Still, their methods can encounter difficulty when the sentence on its own does not contain strong enough sentiment signals (due to the lack of statistical evidence or the requirement for background knowledge). Consider the following review for example,

> 1. Hearing the music in real stereo is a true revelation. 2. You can feel that the music is no longer constrained by the mono recording. 3. In fact, it is more like the players are performing on a stage in front of you ...

Existing feature-based classifiers may be effective in identifying the positive sentiment of the first sentence due to the use of the word *revelation*, but they could be less effective in the last two sentences due to the lack of explicit sentiment signals. However, if we examine these sentences within the discourse context, we can see that: the second sentence expresses sentiment towards the same aspect – *the music* – as the first sentence; the third sentence expands the second sentence with the discourse connective *In fact*. These discourse-level relations help indicate that sentence 2 and 3 are likely to have positive sentiment as well.

The importance of discourse for sentiment analysis has become increasingly recognized. Most existing work considers discourse relations between adjacent sentences or clauses and incorporates them as constraints (Kanayama and Nasukawa, 2006; Zhou et al., 2011) or features in classifiers Trivedi and Eisenstein (2013; Lazaridou et al. (2013). Very little work has explored long-distance discourse relations for sentiment analysis. Somasundaran et al. (2008) defines coreference relations on opinion targets and applies them to constrain the polarity of sentences.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 325–335,
Baltimore, Maryland, USA, June 23-25 2014.

However, the discourse relations were obtained from fine-grained annotations and implemented as hard constraints on polarity.

Obtaining sentiment labels at the fine-grained level is costly. Semi-supervised techniques have been proposed for sentence-level sentiment classification (Täckström and McDonald, 2011a; Qu et al., 2012). However, they rely on a large amount of document-level sentiment labels that may not be naturally available in many domains.

In this paper, we propose a sentence-level sentiment classification method that can (1) incorporate rich discourse information at both local and global levels; (2) encode discourse knowledge as soft constraints during learning; (3) make use of unlabeled data to enhance learning. Specifically, we use the Conditional Random Field (CRF) model as the learner for sentence-level sentiment classification, and incorporate rich discourse and lexical knowledge as soft constraints into the learning of CRF parameters via Posterior Regularization (PR) (Ganchev et al., 2010). As a framework for structured learning with constraints, PR has been successfully applied to many structural NLP tasks (Ganchev et al., 2009; Ganchev et al., 2010; Ganchev and Das, 2013). Our work is the first to explore PR for sentiment analysis. Unlike most previous work, we explore a rich set of structural constraints that cannot be naturally encoded in the feature-label form, and show that such constraints can improve the performance of the CRF model.

We evaluate our approach on the sentence-level sentiment classification task using two standard product review datasets. Experimental results show that our model outperforms state-of-the-art methods in both the supervised and semi-supervised settings. We also show that discourse knowledge is highly useful for improving sentence-level sentiment classification.

2 Related Work

There has been a large amount of work on sentiment analysis at various levels of granularity (Pang and Lee, 2008). In this paper, we focus on the study of sentence-level sentiment classification. Existing machine learning approaches for the task can be classified based on the use of two ideas. The first idea is to exploit sentiment signals at the sentence level by learning the relevance of sentiment and words while taking into account the context in which they occur: Nakagawa et al. (2010) uses tree-CRF to model word interactions based on dependency tree structures; Choi and Cardie (2008) applies compositional inference rules to handle polarity reversal; Socher et al. (2011) and Socher et al. (2013) compute compositional vector representations for words and phrases and use them as features in a classifier.

The second idea is to exploit sentiment signals at the inter-sentential level. Polanyi and Zaenen (2006) argue that discourse structure is important in polarity classification. Various attempts have been made to incorporate discourse relations into sentiment analysis: Pang and Lee (2004) explored the consistency of subjectivity between neighboring sentences; Mao and Lebanon (2007),McDonald et al. (2007), and Täckström and McDonald (2011a) developed structured learning models to capture sentiment dependencies between adjacent sentences; Kanayama and Nasukawa (2006) and Zhou et al. (2011) use discourse relations to constrain two text segments to have either the same polarity or opposite polarities; Trivedi and Eisenstein (2013) and Lazaridou et al. (2013) encode the discourse connectors as model features in supervised classifiers. Very little work has explored long-distance discourse relations. Somasundaran et al. (2008) define opinion target relations and apply them to constrain the polarity of text segments annotated with target relations. Recently, Zhang et al. (2013) explored the use of explanatory discourse relations as soft constraints in a Markov Logic Network framework for extracting subjective text segments.

Leveraging both ideas, our approach exploits sentiment signals from both intra-sentential and inter-sentential context. It has the advantages of utilizing rich discourse knowledge at different levels of context and encoding it as soft constraints during learning.

Our approach is also semi-supervised. Compared to the existing work on semi-supervised learning for sentence-level sentiment classification (Täckström and McDonald, 2011a; Täckström and McDonald, 2011b; Qu et al., 2012), our work does not rely on a large amount of coarse-grained (document-level) labeled data, instead, distant supervision mainly comes from linguistically-motivated constraints.

Our work also relates to the study of posterior regularization (PR) (Ganchev et al., 2010). PR has been successfully applied to many structured NLP

tasks such as dependency parsing, information extraction and cross-lingual learning tasks (Ganchev et al., 2009; Bellare et al., 2009; Ganchev et al., 2010; Ganchev and Das, 2013). Most previous work using PR mainly experiments with feature-label constraints. In contrast, we explore a rich set of linguistically-motivated constraints which cannot be naturally formulated in the feature-label form. We also show that constraints derived from the discourse context can be highly useful for disambiguating sentence-level sentiment.

3 Approach

In this section, we present the details of our proposed approach. We formulate the sentence-level sentiment classification task as a sequence labeling problem. The inputs to the model are sentence-segmented documents annotated with sentence-level sentiment labels (positive, negative or neutral) along with a set of unlabeled documents. During prediction, the model outputs sentiment labels for a sequence of sentences in the test document. We utilize conditional random fields and use Posterior Regularization (PR) to learn their parameters with a rich set of context-aware constraints.

In what follows, we first briefly describe the framework of Posterior Regularization. Then we introduce the context-aware constraints derived based on intuitive discourse and lexical knowledge. Finally we describe how to perform learning and inference with these constraints.

3.1 Posterior Regularization

PR is a framework for structured learning with constraints (Ganchev et al., 2010). In this work, we apply PR in the context of CRFs for sentence-level sentiment classification.

Denote $\mathbf{x}$ as a sequence of sentences within a document and $\mathbf{y}$ as a vector of sentiment labels associated with $\mathbf{x}$. The CRF model the following conditional probabilities:

$$p_\theta(\mathbf{y}|\mathbf{x}) = \frac{\exp(\theta \cdot f(\mathbf{x}, \mathbf{y}))}{Z_\theta(\mathbf{x})}$$

where $f(\mathbf{x}, \mathbf{y})$ are the model features, θ are the model parameters, and $Z_\theta(\mathbf{x}) = \sum_{\mathbf{y}} \exp(\theta \cdot f(\mathbf{x}, \mathbf{y}))$ is a normalization constant. The objective function for a standard CRF is to maximize the log-likelihood over a collection of labeled documents plus a regularization term:

$$\max_\theta \mathcal{L}(\theta) = \max_\theta \sum_{(\mathbf{x},\mathbf{y})} \log p_\theta(\mathbf{y}|\mathbf{x}) - \frac{||\theta||_2^2}{2\delta^2}$$

PR makes the assumption that the labeled data we have is not enough for learning good model parameters, but we have a set of constraints on the posterior distribution of the labels. We can define the set of desirable posterior distrbutions as

$$\mathcal{Q} = \{q(\mathbf{Y}) : E_q[\phi(\mathbf{X}, \mathbf{Y})] = \mathbf{b}\} \quad (1)$$

where ϕ is a constraint function, $\mathbf{b}$ is a vector of desired values of the expectations of the constraint functions under the distribution q [1]. Note that the distribution q is defined over a collection of unlabeled documents where the constraint functions apply, and we assume independence between documents.

The PR objective can be written as the original model objective penalized with a regularization term, which minimizes the KL-divergence between the desired model posteriors and the learned model posteriors with an L2 penalty [2] for the constraint violations.

$$\begin{aligned}\max_\theta \mathcal{L}(\theta) - \min_{q\in\mathcal{Q}} \{KL(q(\mathbf{Y})||p_\theta(\mathbf{Y}|\mathbf{X})) \\ + \beta||E_q[\phi(\mathbf{X}, \mathbf{Y})] - \mathbf{b}||_2^2\}\end{aligned} \quad (2)$$

The objective can be optimized by an EM-like scheme that iteratively solves the minimization problem and the maximization problem. Solving the minimization problem is equivalent to solving its dual since the objective is convex. The dual problem is

$$\arg\max_\lambda \lambda \cdot \mathbf{b} - \log Z_\lambda(X) - \frac{1}{4\beta}||\lambda||_2^2 \quad (3)$$

We optimize the objective function 2 using stochastic projected gradient, and compute the learning rate using AdaGrad (Duchi et al., 2010).

3.2 Context-aware Posterior Constraints

We develop a rich set of context-aware posterior constraints for sentence-level sentiment analysis by exploiting lexical and discourse knowledge. Specifically, we construct the lexical constraints by extracting sentiment-bearing patterns

[1] In general, inequality constraints can also be used. We focus on the equality constraints since we found them to express the sentiment-relevant constraints well.

[2] Other convex functions can be used for the penalty. We use L2 norm because it works well in practice. β is a regularization constant

within sentences and construct the discourse-level constraints by extracting discourse relations that indicate sentiment coherence or sentiment changes both within and across sentences. Each constraint can be formulated as equality between the expectation of a constraint function value and a desired value set by prior knowledge. The equality is not strictly enforced (due to the regularization in the PR objective 2). Therefore all the constraints are applied as soft constraints. Table 1 provides intuitive description and examples for all the constraints used in our model.

Lexical Patterns The existence of a polarity-carrying word alone may not correctly indicate the polarity of the sentence, as the polarity can be reversed by other polarity-reversing words. We extract lexical patterns that consist of polar words and negators [3], and apply the heuristics based on compositional semantics (Choi and Cardie, 2008) to assign a sentiment value to each pattern.

We encode the extracted lexical patterns along with their sentiment values as feature-label constraints. The constraint function can be written as

$$\phi_w(x, y) = \sum_i f_w(x_i, y_i)$$

where $f_w(x_i, y_i)$ is a feature function which has value 1 when sentence x_i contains the lexical pattern w and its sentiment label y_i equals to the expected sentiment value and has value 0 otherwise. The constraint expectation value is set to be the prior probability of associating w with its sentiment value. Note that sentences with neutral sentiment can also contain such lexical patterns. Therefore we allow the lexical patterns to be assigned a neutral sentiment with a prior probability r_0 (we compute this value as the empirical probability of neutral sentiment in the training documents). Using the polarity indicated by lexical patterns to constrain the sentiment of sentences is quite aggressive. Therefore we only consider lexical patterns that are strongly discriminative (many opinion words in the lexicon only indicate sentiment with weak strength). The selected lexical patterns include a handful of seed patterns (such as "pros" and "cons") and the lexical patterns that have high precision (larger then 0.9) of predicting sentiment in the training data.

[3]The polar words are identified using the MPQA lexicon and the negators are identified using a handful of seed words extended by the General Inquirer dictionary and WordNet as described in (Choi and Cardie, 2008).

Discourse Connectives. Lexical patterns can be limited in capturing contextual information since they only look at interactions between words within an expression. To capture context at the clause or sentence level, we consider discourse connectives, which are cue phrases or words that indicate discourse relations between adjacent sentences or clauses. To identify discourse connectives, we apply a discourse tagger trained on the Penn Discourse Treebank (Prasad et al., 2008) [4] to our data. Discourse connectives are tagged with four senses: *Expansion, Contingency, Comparison, Temporal*.

Discourse connectives can operate at both intra-sentential and inter-sentential level. For example, the word "although" is often used to connect two polar clauses within a sentence, while the word "however" is often used to at the beginning of the sentence to connect two polar sentences. It is important to distinguish these two types of discourse connectives. We consider a discourse connective to be intra-sentential if it has the *Comparison* sense and connects two polar clauses with opposite polarities (determined by the lexical patterns). We construct a feature-label constraint for each intra-sentential discourse connective and set its expected sentiment value to be neutral.

Unlike the intra-sentential discourse connectives, the inter-sentential discourse connectives can indicate sentiment transitions between sentences. Intuitively, discourse connectives with the senses of *Expansion* (e.g. also, for example, furthermore) and *Contingency* (e.g. as a result, hence, because) are likely to indicate sentiment coherence; discourse connectives with the sense of *Comparison* (e.g. but, however, nevertheless) are likely to indicate sentiment changes. This intuition is reasonable but it assumes the two sentences connected by the discourse connective are both polar sentences. In general, discourse connectives can also be used to connect non-polar (neutral) sentences. Thus it is hard to directly constrain the posterior expectation for each type of sentiment transitions using inter-sentential discourse connectives.

Instead, we impose constraints on the model posteriors by reducing constraint violations. We

[4]http://www.cis.upenn.edu/~epitler/discourse.html

Types	Description and Examples	Inter-sentential
Lexical patterns	The sentence containing a polar lexical pattern w tends to have the polarity indicated by w. Example lexical patterns are *annoying, hate, amazing, not disappointed, no concerns, favorite, recommend*.	
Discourse Connectives (clause)	The sentence containing a discourse connective c which connects its two clauses that have opposite polarities indicated by the lexical patterns tends to have neutral sentiment. Example connectives are *while, although, though, but*.	
Discourse Connectives (sentence)	Two adjacent sentences which are connected by a discourse connective c tends to have the same polarity if c indicates a *Expansion* or *Contingency* relation, e.g. *also, for example, in fact, because* ; opposite polarities if c indicates a *Comparison* relation, e.g. *otherwise, nevertheless, however*.	✓
Coreference	The sentences which contain coreferential entities appeared as targets of opinion expressions tend to have the same polarity.	✓
Listing patterns	A series of sentences connected via a listing tend to have the same polarity.	✓
Global labels	The sentence-level polarity tends to be consistent with the document-level polarity.	✓

Table 1: Summarization of Posterior Constraints for Sentence-level Sentiment Classification

define the following constraint function:

$$\phi_{c,s}(x, y) = \sum_i f_{c,s}(x_i, y_i, y_{i-1})$$

where c denotes a discourse connective, s indicates its sense, and $f_{c,s}$ is a penalty function that takes value 1.0 when y_i and y_{i-1} form a contradictory sentiment transition, that is, $y_i \neq_{polar} y_{i-1}$ if $s \in \{\textit{Expansion}, \textit{Contingency}\}$, or $y_i =_{polar} y_{i-1}$ if $s = \textit{Comparison}$. The desired value for the constraint expectation is set to 0 so that the model is encouraged to have less constraint violations.

Opinion Coreference Sentences in a discourse can be linked by many types of coherence relations (Jurafsky et al., 2000). Coreference is one of the commonly used relations in written text. In this work, we explore coreference in the context of sentence-level sentiment analysis. We consider a set of polar sentences to be linked by the *opinion coreference* relation if they contain coreferring opinion-related entities. For example, the following sentences express opinions towards "the speaker phone", "The speaker phone" and "it" respectively. As these opinion targets are coreferential (referring to the same entity "the speaker phone"), they are linked by the *opinion coreference* relation [5].

> My favorite features are **the speaker phone** and the radio. **The speaker phone** is very functional. I use **it** in the car, very audible even with freeway noise.

[5]In general, the opinion-related entities include both the opinion targets and the opinion holders. In this work, we only consider the targets since we experiment with single-author product reviews. The opinion holders can be included in a similar way as the opinion targets.

Our coreference relations indicated by opinion targets overlap with the *same target* relation introduced in (Somasundaran et al., 2009). The differences are: (1) we encode the coreference relations as soft constraints during learning instead of applying them as hard constraints during inference time; (2) our constraints can apply to both polar and non-polar sentences; (3) our identification of coreference relations is automatic without any fine-grained annotations for opinion targets.

To extract coreferential opinion targets, we apply Stanford's coreference system (Lee et al., 2013) to extract coreferential mentions in the document, and then apply a set of syntactic rules to identify opinion targets from the extracted mentions. The syntactic rules correspond to the shortest dependency paths between an opinion word and an extracted mention. We consider the 10 most frequent dependency paths in the training data. Example dependency paths include *nsubj*(opinion, mention), *nobj*(opinion, mention), and *amod*(mention, opinion).

For sentences connected by the opinion coreference relation, we expect their sentiment to be consistent. To encode this intuition, we define the following constraint function:

$$\phi_{coref}(x, y) = \sum_{i, ant(i)=j, j \geq 0} f_{coref}(x_i, x_j, y_i, y_j)$$

where $ant(i)$ denotes the index of the sentence which contains an antecedent target of the target mentioned in sentence i (the antecedent relations over pairs of opinion targets can be constructed using the coreference resolver), and f_{coref} is a penalty function which takes value 1.0 when the expected sentiment coherency is violated, that is, $y_i \neq_{polar} y_j$. Similar to the inter-sentential dis-

course connectives, modeling opinion coreference via constraint violations allows the model to handle neutral sentiment. The expected value of the constraint functions is set to 0.

Listing Patterns Another type of coherence relations we observe in online reviews is listing, where a reviewer expresses his/her opinions by listing a series of statements followed by a sequence of numbers. For example, "1. It's smaller than the ipod mini .... 2. It has a removable battery ....". We expect sentences connected by a listing to have consistent sentiment. We implement this constraint in the same form as the coreference constraint (the antecedent assignments are constructed from the numberings).

Global Sentiment Previous studies have demonstrated the value of document-level sentiment in guiding the semi-supervised learning of sentence-level sentiment (Täckström and McDonald, 2011b; Qu et al., 2012). In this work, we also take into account this information and encode it as posterior constraints. Note that these constraints are not necessary for our model and can be applied when the document-level sentiment labels are naturally available.

Based on an analysis of the Amazon review data, we observe that sentence-level sentiment usually doesn't conflict with the document-level sentiment in terms of polarity. For example, the proportion of negative sentences in the positive documents is very small compared to the proportion of positive sentences. To encode this intuition, we define the following constraint function:

$$\phi_g(x, y) = \sum_i^n \delta(y_i \neq_{polar} g)/n$$

where $g \in \{positive, negative\}$ denotes the sentiment value of a polar document, n is the total number of sentences in x, and δ is an indicator function. We hope the expectation of the constraint function takes a small value. In our experiments, we set the expected value to be the empirical estimate of the probability of "conflicting" sentiment in polar documents using the training data.

3.3 Training and Inference

During training, we need to compute the constraint expectations and the feature expectations under the auxiliary distribution q at each gradient step. We can derive q by solving the dual problem in 3:

$$q(\mathbf{y}|\mathbf{x}) = \frac{exp(\theta \cdot f(\mathbf{x}, \mathbf{y}) + \lambda \cdot \phi(\mathbf{x}, \mathbf{y}))}{Z_{\lambda,\theta}(X)} \quad (4)$$

where $Z_{\lambda,\theta}(X)$ is a normalization constant. Most of our constraints can be factorized in the same way as factorizing the model features in the first-order CRF model, and we can compute the expectations under q very efficiently using the forward-backward algorithm. However, some of our discourse constraints (opinion coreference and listing) can break the tractable structure of the model. For constraints with higher-order structures, we use Gibbs Sampling (Geman and Geman, 1984) to approximate the expectations. Given a sequence $\mathbf{x}$, we sample a label $\mathbf{y}_i$ at each position i by computing the unnormalized conditional probabilities $p(\mathbf{y}_i = l|\mathbf{y}_{-i}) \propto exp(\theta \cdot f(\mathbf{x}, \mathbf{y}_i = l, \mathbf{y}_{-i}) + \lambda \cdot \phi(\mathbf{x}, \mathbf{y}_i = l, \mathbf{y}_{-i}))$ and renormalizing them. Since the possible label assignments only differ at position i, we can make the computation efficient by maintaining the structure of the coreference clusters and precomputing the constraint function for different types of violations.

During inference, we find the best label assignment by computing $\arg\max_{\mathbf{y}} q(\mathbf{y}|\mathbf{x})$. For documents where the higher-order constraints apply, we use the same Gibbs sampler as described above to infer the most likely label assignment, otherwise, we use the Viterbi algorithm.

4 Experiments

We experimented with two product review datasets for sentence-level sentiment classification: the Customer Review (CR) data (Hu and Liu, 2004)[6] which contains 638 reviews of 14 products such as cameras and cell phones, and the Multi-domain Amazon (MD) data from the test set of Täckström and McDonald (2011a) which contains 294 reivews from 5 different domains. As in Qu et al. (2012), we chose the books, electronics and music domains for evaluation. Each domain also comes with 33,000 extra reviews with only document-level sentiment labels.

We evaluated our method in two settings: supervised and semi-supervised. In the supervised setting, we treated the test data as unlabeled data and performed transductive learning. In the semi-supervised setting, our unlabeled data consists of

[6]Available at `http://www.cs.uic.edu/~liub/FBS/sentiment-analysis.html`.

both the available unlabeled data and the test data. For each domain in the MD dataset, we made use of no more than 100 unlabeled documents in which our posterior constraints apply. We adopted the evaluation schemes used in previous work: 10-fold cross validation for the CR dataset and 3-fold cross validation for the MD dataset. We also report both two-way classification (positive vs. negative) and three-way classification results (positive, negative or neutral). We use accuracy as the performance measure. In our tables, boldface numbers are statistically significant by paired t-test for $p < 0.05$ against the best baseline developed in this paper [7].

We trained our model using a CRF incorporated with the proposed posterior constraints. For the CRF features, we include the tokens, the part-of-speech tags, the prior polarities of lexical patterns indicated by the opinion lexicon and the negator lexicon, the number of positive and negative tokens and the output of the vote-flip algorithm (Choi and Cardie, 2009). In addition, we include the discourse connectives as local or transition features and the document-level sentiment labels as features (only available in the MD dataset).

We set the CRF regularization parameter $\sigma = 1$ and set the posterior regularization parameter β and γ (a trade-off parameter we introduce to balance the supervised objective and the posterior regularizer in 2) by using grid search [8]. For approximation inference with higher-order constraints, we perform 2000 Gibbs sampling iterations where the first 1000 iterations are burn-in iterations. To make the results more stable, we construct three Markov chains that run in parallel, and select the sample with the largest objective value.

All posterior constraints were developed using the training data on each training fold. For the MD dataset, we also used the dvd domain as additional labeled data for developing the constraints.

Baselines. We compared our method to a number of baselines: (1) CRF: CRF with the same set of model features as in our method. (2) CRF-INF: CRF augmented with inference constraints. We can incorporate the proposed constraints (constraints derived from lexical patterns and discourse connectives) as hard constraints into CRF during inference by manually setting λ in equation 4 to a large value,[9]. When λ is large enough, it is equivalent to adding hard constraints to the viterbi inference. To better understand the different effects of lexical and discourse constraints, we report results for applying only the lexical constraints (CRF-INF$_{lex}$) as well as results for applying only the discourse constraints (CRF-INF$_{disc}$). (3) PR$_{lex}$: a variant of our PR model which only applies the lexical constraints. For the three-way classification task on the MD dataset, we also implemented the following baselines: (4) VOTEFLIP: a rule-based algorithm that leverages the positive, negative and neutral cues along with the effect of negation to determine the sentence sentiment (Choi and Cardie, 2009). (5) DOCORACLE: assigns each sentence the label of its corresponding document.

[7] Significance test was not conducted over the previous methods as we do not have their results for each fold.

[8] We conducted 10-fold cross-validation on each training fold with the parameter space: $\beta : [0.01, 0.05, 0.1, 0.5, 1.0]$ and $\gamma : [0.1, 0.5, 1.0, 5.0, 10.0]$.

Table 4: F1 scores for each sentiment category (positive, negative and neutral) for semi-supervised sentiment classification on the MD dataset

that PR significantly outperforms all other baselines in both the CR dataset and the MD dataset (average accuracy across domains is reported). The poor performance of CRF-INF$_{lex}$ indicates that directly applying lexical constraints as hard constraints during inference could only hurt the performance. CRF-INF$_{disc}$ slightly outperforms CRF but the improvement is not significant. In contrast, both PR$_{lex}$ and PR significantly outperform CRF, which implies that incorporating lexical and discourse constraints as posterior constraints is much more effective. The superior performance of PR over PR$_{lex}$ further suggests that the proper use of discourse information can significantly improve accuracy for sentence-level sentiment classification.

We also analyzed the model's performance on a three-way sentiment classification task. By introducing the "neutral" category, the sentiment classification problem becomes harder. Table 4 shows the results in terms of accuracy for each domain in the MD dataset. We can see that both PR and PR$_{lex}$ significantly outperform all other baselines in all domains. The rule-based baseline VOTEFLIP gave the weakest performance because it has no prediction power on sentences with no opinion words. DOCORACLE performs much better than VOTEFLIP and performs especially well on the *Music* domain. This indicates that the document-level sentiment is a very strong indicator of the sentence-level sentiment label. For the CRF baseline and its invariants, we observe a similar performance trend as in the two-way classification task: there is nearly no performance improvement from applying the lexical and discourse-connective-based constraints during CRF inference. In contrast, both PR$_{lex}$ and PR provide substantial improvements over CRF. This confirms that encoding lexical and discourse knowledge as posterior constraints allows the feature-based model to gain additional learning power for sentence-level sentiment prediction. In particular, incorporating discourse constraints leads to consistent improvements to our model. This demonstrates that our modeling of discourse information is effective and that taking into account the discourse context is important for improving sentence-level sentiment analysis. We also compare our results to the previously published results on the same dataset. HCRF (Täckström and McDonald, 2011a) and MEM (Qu et al., 2012) are two state-of-the-art semi-supervised methods for sentence-level sentiment classification. We can see that our best model PR gives the best results in most categories.

Table 4 shows the results in terms of F1 scores for each sentiment category (positive, negative and neutral). We can see that the PR models are able to provide improvements over all the sentiment categories compared to all the baselines in general. We observe that the DOCORACLE baseline provides very strong F1 scores on the positive and negative categories especially in the Books and Music domains, but very poor F1 on the neutral category. This is because it over-predicts the polar sentences in the polar documents, and predicts no polar sentences in the neutral documents. In contrast, our PR models provide more balanced F1 scores among all the sentiment categories. Compared to the CRF baseline and its variants, we found that the PR models can greatly improve the precision of predicting positive and negative sentences, resulting in a significant improvement on the positive/negative F1 scores. However, the improvement on the neutral category is modest. A plausible explanation is that most of our constraints focus on discriminating polar sentences. They can help reduce the errors of misclassifying polar sentences, but the model needs more constraints in order to distinguish neutral sentences from polar sentences. We plan to address this issue in future work.

4.2 Discussion

We analyze the errors to better understand the merits and limitations of the PR model. We found that the PR model is able to correct many CRF errors caused by the lack of labeled data. The first row in Table 5 shows an example of such errors.

Example Sentences	CRF	PR
Example 1: ⟨neg⟩ If I could, I would like to return it or exchange for something better.⟨/neg⟩	⟨neu⟩ ×	✓
Example 2: ⟨neg⟩ Things I wasn't a fan of – the ending was to cutesy for my taste.⟨/neg⟩ ⟨neg⟩ Also, all of the side characters (particularly the mom, vee, and the teacher) were incredibly flat and stereotypical to me.⟨/neg⟩	⟨neu⟩ ⟨pos⟩ ×	✓
Example 3: ⟨neg⟩ I also have excessive noise when I talk and have phone in my pocket while walking.⟨/neg⟩ ⟨neu⟩ But other models are no better.⟨/neu⟩	⟨neg⟩ ⟨pos⟩ ×	⟨neg⟩ ⟨pos⟩ ×

Table 5: Example sentences where PR succeeds and fails to correct the mistakes of CRF

The lexical features *return* and *exchange* may be good indicators of negative sentiment for the sentence. However, with limited labeled data, the CRF learner can only associate very weak sentiment signals to these features. In contrast, the PR model is able to associate stronger sentiment signals to these features by leveraging unlabeled data for indirect supervision. A simple lexicon-based constraint during inference time may also correct this case. However, hard-constraint baselines can hardly improve the performance in general because the contributions of different constraints are not learned and their combination may not lead to better predictions. This is also demonstrated by the limited performance of CRF-INF in our experiments.

We also found that the discourse constraints play an important role in improving the sentiment prediction. The lexical constraints alone are often not sufficient since their coverage is limited by the sentiment lexicon and they can only constrain sentiment locally. On the contrary, discourse constraints are not dependent on sentiment lexicons, and more importantly, they can provide sentiment preferences on multiple sentences at the same time. When combining discourse constraints with features from different sentences, the PR model becomes more powerful in disambiguating sentiment. The second example in Table 5 shows that the PR model learned with discourse constraints correctly predicts the sentiment of two sentences where no lexical constraints apply.

However, discourse constraints are not always helpful. One reason is that they do not constrain the neutral sentiment. As a result they could not help disambiguate neutral sentiment from polar sentiment, such as the third example in Table 5. This is also a problem for most of our lexical constraints. In general, it is hard to learn reliable indicators for the neutral sentiment. In the MD dataset, a neutral label may be given because the sentence contains mixed sentiment or no sentiment or it is off-topic. We plan to explore more refined constraints that can deal with the neutral sentiment in future work. Another limitation of the discourse constraints is that they could be affected by the errors of the discourse parser and the coreference resolver. A potential way to address this issue is to learn discourse constraints jointly with sentiment. We plan to study this in future research.

5 Conclusion

In this paper, we propose a context-aware approach for learning sentence-level sentiment. Our approach incorporates intuitive lexical and discourse knowledge as expressive constraints while training a conditional random field model via posterior regularization. We explore a rich set of context-aware constraints at both intra- and inter-sentential levels, and demonstrate their effectiveness in the analysis of sentence-level sentiment. While we focus on the sentence-level task, our approach can be easily extended to handle sentiment analysis at finer levels of granularity. Our experiments show that our model achieves better accuracy than existing supervised and semi-supervised models for the sentence-level sentiment classification task.

Product Feature Mining: Semantic Clues versus Syntactic Constituents

Liheng Xu, Kang Liu, Siwei Lai and Jun Zhao

{lhxu, kliu, swlai, jzhao}@nlpr.ia.ac.cn

Abstract

Product feature mining is a key subtask in fine-grained opinion mining. Previous works often use syntax constituents in this task. However, syntax-based methods can only use discrete contextual information, which may suffer from data sparsity. This paper proposes a novel product feature mining method which leverages lexical and contextual semantic clues. Lexical semantic clue verifies whether a candidate term is related to the target product, and contextual semantic clue serves as a *soft* pattern miner to find candidates, which exploits semantics of each word in context so as to alleviate the data sparsity problem. We build a semantic similarity graph to encode lexical semantic clue, and employ a convolutional neural model to capture contextual semantic clue. Then Label Propagation is applied to combine both semantic clues. Experimental results show that our semantics-based method significantly outperforms conventional syntax-based approaches, which not only mines product features more accurately, but also extracts more infrequent product features.

1 Introduction

In recent years, opinion mining has helped customers a lot to make informed purchase decisions. However, with the rapid growth of e-commerce, customers are no longer satisfied with the overall opinion ratings provided by traditional sentiment analysis systems. The detailed functions or attributes of products, which are called *product features*, receive more attention. Nevertheless, a product may have thousands of features, which makes it impractical for a customer to investigate them all. Therefore, mining product features automatically from online reviews is shown to be a key step for opinion summarization (Hu and Liu, 2004; Qiu et al., 2009) and fine-grained sentiment analysis (Jiang et al., 2011; Li et al., 2012).

Previous works often mine product features via **syntactic constituent matching** (Popescu and Etzioni, 2005; Qiu et al., 2009; Zhang et al., 2010). The basic idea is that reviewers tend to comment on product features in similar syntactic structures. Therefore, it is natural to mine product features by using syntactic patterns. For example, in Figure 1, the upper box shows a dependency tree produced by Stanford Parser (de Marneffe et al., 2006), and the lower box shows a common syntactic pattern from (Zhang et al., 2010), where <feature/NN> is a wildcard to be fit in reviews and *NN* denotes the required POS tag of the wildcard. Usually, the product name *mp3* is specified, and when *screen* matches the wildcard, it is likely to be a product feature of *mp3*.

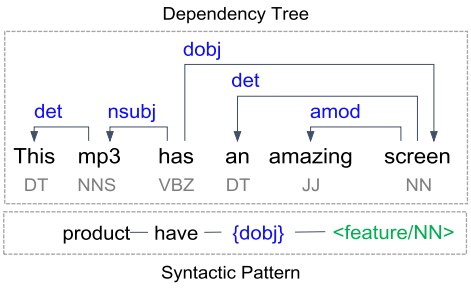

Figure 1: An example of syntax-based product feature mining procedure. The word *screen* matches the wildcard <feature/NN>. Therefore, *screen* is likely to be a product feature of *mp3*.

Generally, such syntactic patterns extract product features well but they still have some limitations. For example, the *product-have-feature* pattern may fail to find the *fm tuner* in a very similar case in Example 1(a), where the product is mentioned by using *player* instead of *mp3*. Similarly, it may also fail on Example 1(b), just with *have* replaced by *support*. In essence, syntactic pattern is

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 336–346,
Baltimore, Maryland, USA, June 23-25 2014.

a kind of *one-hot representation* for encoding the contexts, which can only use partial and discrete features, such as some key words (e.g., *have*) or shallow information (e.g., POS tags). Therefore, such a representation often suffers from the data sparsity problem (Turian et al., 2010).

One possible solution for this problem is using a more general pattern such as *NP-VB-feature*, where *NP* represents a noun or noun phrase and *VB* stands for any verb. However, this pattern becomes too general that it may find many irrelevant cases such as the one in Example 1(c), which is not talking about the product. Consequently, it is very difficult for a pattern designer to balance between precision and generalization.

Example 1:
(a) *This player has an fm tuner.*
(b) *This mp3 supports wma file.*
(c) *This review has helped people a lot.*
(d) *This mp3 has some flaws.*

To solve the problems stated above, it is argued that deeper semantics of contexts shall be exploited. For example, we can try to automatically discover that the verb *have* indicates a part-whole relation (Zhang et al., 2010) and *support* indicates a product-function relation, so that both *sth. have* and *sth. support* suggest that terms following them are product features, where *sth.* can be replaced by any terms that refer to the target product (e.g., *mp3*, *player*, etc.). This is called **contextual semantic clue**. Nevertheless, only using contexts is not sufficient enough. As in Example 1(d), we can see that the word *flaws* follows *mp3 have*, but it is not a product feature. Thus, a noise term may be extracted even with high contextual support. Therefore, we shall also verify whether a candidate is really related to the target product. We call it **lexical semantic clue**.

This paper proposes a novel bootstrapping approach for product feature mining, which leverages both semantic clues discussed above. Firstly, some reliable product feature seeds are automatically extracted. Then, based on the assumption that terms that are more semantically similar to the seeds are more likely to be product features, a graph which measures semantic similarities between terms is built to capture lexical semantic clue. At the same time, a semi-supervised convolutional neural model (Collobert et al., 2011) is employed to encode contextual semantic clue. Finally, the two kinds of semantic clues are combined by a Label Propagation algorithm.

In the proposed method, words are represented by continuous vectors, which capture latent semantic factors of the words (Turian et al., 2010). The vectors can be unsupervisedly trained on large scale corpora, and words with similar semantics will have similar vectors. This enables our method to be less sensitive to lexicon change, so that the data sparsity problem can be alleviated . The contributions of this paper include:

- It uses semantics of words to encode contextual clues, which exploits deeper level information than syntactic constituents. As a result, it mines product features more accurately than syntax-based methods.
- It exploits semantic similarity between words to capture lexical clues, which is shown to be more effective than co-occurrence relation between words and syntactic patterns. In addition, experiments show that the semantic similarity has the advantage of mining infrequent product features, which is crucial for this task. For example, one may say "*This hotel has low water pressure*", where *low water pressure* is seldom mentioned, but fatal to someone's taste.
- We compare the proposed semantics-based approach with three state-of-the-art syntax-based methods. Experiments show that our method achieves significantly better results.

The rest of this paper is organized as follows. Section 2 introduces related work. Section 3 describes the proposed method in details. Section 4 gives the experimental results. Lastly, we conclude this paper in Section 5.

2 Related Work

In product feature mining task, Hu and Liu (2004) proposed a pioneer research. However, the association rules they used may potentially introduce many noise terms. Based on the observation that product features are often commented on by similar syntactic structures, it is natural to use patterns to capture common syntactic constituents around product features.

Popescu and Etzioni (2005) designed some syntactic patterns to search for product feature candidates and then used Pointwise Mutual Information (PMI) to remove noise terms. Qiu et al. (2009) proposed eight heuristic syntactic rules to jointly extract product features and sentiment lexicons, where a bootstrapping algorithm named *Double*

Propagation was applied to expand a given seed set. Zhang et al. (2010) improved Qiu's work by adding more feasible syntactic patterns, and the HITS algorithm (Kleinberg, 1999) was employed to rank candidates. Moghaddam and Ester (2010) extracted product features by automatical opinion pattern mining. Zhuang et al. (2006) used various syntactic templates from an annotated movie corpus and applied them to supervised movie feature extraction. Wu et al. (2009) proposed a phrase level dependency parsing for mining aspects and features of products.

As discussed in the first section, syntactic patterns often suffer from data sparsity. Furthermore, most pattern-based methods rely on term frequency, which have the limitation of finding infrequent but important product features. A recent research (Xu et al., 2013) extracted infrequent product features by a semi-supervised classifier, which used word-syntactic pattern co-occurrence statistics as features for the classifier. However, this kind of feature is still sparse for infrequent candidates. Our method adopts a semantic word representation model, which can train dense features unsupervisedly on a very large corpus. Thus, the data sparsity problem can be alleviated.

3 The Proposed Method

We propose a semantics-based bootstrapping method for product feature mining. Firstly, some product feature seeds are automatically extracted. Then, a semantic similarity graph is created to capture lexical semantic clue, and a Convolutional Neural Network (CNN) (Collobert et al., 2011) is trained in each bootstrapping iteration to encode contextual semantic clue. Finally we use Label Propagation to find some reliable new seeds for the training of the next bootstrapping iteration.

3.1 Automatic Seed Generation

The seed set consists of positive labeled examples (i.e. product features) and negative labeled examples (i.e. noise terms). Intuitively, popular product features are frequently mentioned in reviews, so they can be extracted by simply mining frequently occurring nouns (Hu and Liu, 2004). However, this strategy will also find many noise terms (e.g., commonly used nouns like *thing*, *one*, etc.). To produce high quality seeds, we employ a Domain Relevance Measure (DRM) (Jiang and Tan, 2010), which combines term frequency with a domain-specific measuring metric called Likelihood Ratio Test (LRT) (Dunning, 1993). Let $\lambda(t)$ denotes the LRT score of a product feature candidate t,

$$\lambda(t) = \frac{p^{k_1}(1-p)^{n_1-k_1}p^{k_2}(1-p)^{n_2-k_2}}{p_1^{k_1}(1-p_1)^{n_1-k_1}p_2^{k_2}(1-p_2)^{n_2-k_2}} \quad (1)$$

where k_1 and k_2 are the frequencies of t in the review corpus $\mathcal{R}$ and a background corpus[1] $\mathcal{B}$, n_1 and n_2 are the total number of terms in $\mathcal{R}$ and $\mathcal{B}$, $p = (k_1 + k_2)/(n_1 + n_2)$, $p_1 = k_1/n_1$ and $p_2 = k_2/n_2$. Then a modified DRM[2] is proposed,

$$DRM(t) = \frac{tf(t)}{max[tf(\cdot)]} \times \frac{1}{\log df(t)} \times \frac{|\log\lambda(t)| - min|\log\lambda(\cdot)|}{max|\log\lambda(\cdot)| - min|\log\lambda(\cdot)|} \quad (2)$$

where $tf(t)$ is the frequency of t in $\mathcal{R}$ and $df(t)$ is the frequency of t in $\mathcal{B}$.

All nouns in $\mathcal{R}$ are ranked by $DRM(t)$ in descent order, where top N nouns are taken as the positive example set V_s^+. On the other hand, Xu et al. (2013) show that a set of general nouns seldom appear to be product features. Therefore, we employ their General Noun Corpus to create the negative example set V_s^-, where N most frequent terms are selected. Besides, it is guaranteed that $V_s^+ \cap V_s^- = \emptyset$, i.e., conflicting terms are taken as negative examples.

3.2 Capturing Lexical Semantic Clue in a Semantic Similarity Graph

To capture lexical semantic clue, each word is first converted into *word embedding*, which is a continuous vector with each dimension's value corresponds to a semantic or grammatical interpretation (Turian et al., 2010). Learning large-scale word embeddings is very time-consuming (Collobert et al., 2011), we thus employ a faster method named Skip-gram model (Mikolov et al., 2013).

3.2.1 Learning Word Embedding for Semantic Representation

Given a sequence of training words $W = \{w_1, w_2, ..., w_m\}$, the goal of the Skip-gram model is to learn a continuous vector space $EB = \{e_1, e_2, ..., e_m\}$, where e_i is the word embedding of w_i. The training objective is to maximize the

[1] Google-n-Gram (http://books.google.com/ngrams) is used as the background corpus.

[2] The $df(t)$ part of the original DRM is slightly modified because we want a $tf \times idf$-like scheme (Liu et al., 2012).

average log probability of using word w_t to predict a surrounding word w_{t+j},

$$\hat{EB} = \underset{e_t \in EB}{\text{argmax}} \frac{1}{m} \sum_{t=1}^{m} \sum_{-c \le j \le c, j \neq 0} \log p(w_{t+j}|w_t; e_t) \quad (3)$$

where c is the size of the training window. Basically, $p(w_{t+j}|w_t; e_t)$ is defined as,

$$p(w_{t+j}|w_t; e_t) = \frac{exp(e'^T_{t+j} e_t)}{\sum_{w=1}^{m} exp(e'^T_w e_t)} \quad (4)$$

where e'_i is an additional training vector associated with e_i. This basic formulation is impractical because it is proportional to m. A hierarchical softmax approximation can be applied to reduce the computational cost to $log_2(m)$, see (Morin and Bengio, 2005) for details.

To alleviate the data sparsity problem, EB is first trained on a very large corpus[3] (denoted by $\mathcal{C}$), and then fine-tuned on the target review corpus $\mathcal{R}$. Particularly, for phrasal product features, a statistic-based method in (Zhu et al., 2009) is used to detect noun phrases in $\mathcal{R}$. Then, an Unfolding Recursive Autoencoder (Socher et al., 2011) is trained on $\mathcal{C}$ to obtain embedding vectors for noun phrases. In this way, semantics of infrequent terms in $\mathcal{R}$ can be well captured. Finally, the phrase-based Skip-gram model in (Mikolov et al., 2013) is applied on $\mathcal{R}$.

3.2.2 Building the Semantic Similarity Graph

Lexical semantic clue is captured by measuring semantic similarity between terms. The underlying motivation is that if we have known some product feature seeds, then terms that are more semantically similar to these seeds are more likely to be product features. For example, if *screen* is known to be a product feature of *mp3*, and *lcd* is of high semantic similarity with *screen*, we can infer that *lcd* is also a product feature. Analogously, terms that are semantically similar to negative labeled seeds are not product features.

Word embedding naturally meets the demand above: words that are more semantically similar to each other are located closer in the embedding space (Collobert et al., 2011). Therefore, we can use cosine distance between two embedding vectors as the semantic distance measuring metric. Thus, our method does not rely on term frequency to rank candidates. This could potentially improve the ability of mining infrequent product features.

Formally, we create a semantic similarity graph $G = (V, E, W)$, where $V = \{V_s \cup V_c\}$ is the vertex set, which contains the labeled seed set V_s and the unlabeled candidate set V_c; E is the edge set which connects every vertex pair (u, v), where $u, v \in V$; $W = \{w_{uv} : \cos(EB_u, EB_v)\}$ is a function which associates a weight to each edge.

3.3 Encoding Contextual Semantic Clue Using Convolutional Neural Network

The CNN is trained on each occurrence of seeds that is found in review texts. Then for a candidate term t, the CNN classifies all of its occurrences. Since seed terms tend to have high frequency in review texts, only a few seeds will be enough to provide plenty of occurrences for the training.

3.3.1 The architecture of the Convolutional Neural Network

The architecture of the Convolutional Neural Network is shown in Figure 2. For a product feature candidate t in sentence s, every consecutive subsequence q_i of s that containing t with a window of length l is fed to the CNN. For example, as in Figure 2, if $t = \{screen\}$, and $l = 3$, there are three inputs: $q_1 = [the, ipod, \textbf{screen}]$, $q_2 = [ipod, \textbf{screen}, is]$, $q_3 = [\textbf{screen}, is, impressive]$. Partially, t is replaced by a token "*PF*" to remove its lexicon influence[4].

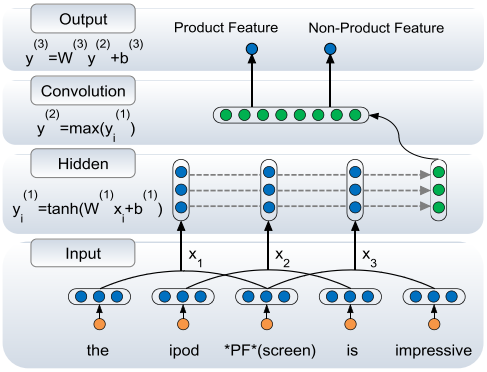

Figure 2: The architecture of the Convolutional Neural Network.

To get the output score, q_i is first converted into a concatenated vector $x_i = [e_1; e_2; ...; e_l]$, where e_j is the word embedding of the *j*-th word. In this way, the CNN serves as a *soft* pattern miner:

[3]Wikipedia(http://www.wikipedia.org) is used in practice.

[4]Otherwise, the CNN will quickly get overfitting on *t*, because very few seed lexicons are used for the training.

since words that have similar semantics have similar low-dimension embedding vectors, the CNN is less sensitive to lexicon change. The network is computed by,

$$y_i^{(1)} = tanh(W^{(1)}x_i + b^{(1)}) \quad (5)$$

$$y^{(2)} = max(y_i^{(1)}) \quad (6)$$

$$y^{(3)} = W^{(3)}y^{(2)} + b^{(3)} \quad (7)$$

where $y^{(i)}$ is the output score of the *i*-th layer, and $b^{(i)}$ is the bias of the *i*-th layer; $W^{(1)} \in \mathbb{R}^{h\times(nl)}$ and $W^{(3)} \in \mathbb{R}^{2\times h}$ are parameter matrixes, where n is the dimension of word embedding, and h is the size of nodes in the hidden layer.

In conventional neural models, the candidate term t is placed in the center of the window. However, from Example 2, when $l = 5$, we can see that the best windows should be the bracketed texts (Because, intuitively, the windows should contain *mp3*, which is a strong evidence for finding the product feature), where $t = \{screen\}$ is at the boundary. Therefore, we use Equ. 6 to formulate a max-convolutional layer, which is aimed to enable the CNN to find more evidences in contexts than conventional neural models.

Example 2:
(a) *The [**screen** of this mp3 is] great.*
(b) *This [mp3 has a great **screen**].*

3.3.2 Training

Let $\theta = \{EB, W^{(\cdot)}, b^{(\cdot)}\}$ denotes all the trainable parameters. The softmax function is used to convert the output score of the CNN to a probability,

$$p(t|X;\theta) = \frac{exp(y^{(3)})}{\sum_{j=1}^{|C|} exp(y_j^{(3)})} \quad (8)$$

where X is the input set for term t, and $C = \{0, 1\}$ is the label set representing product feature and non-product feature, respectively.

To train the CNN, we first use V_s to collect each occurrence of the seeds in $\mathcal{R}$ to form a training set T_s. Then, the training criterion is to minimize cross-entropy over T_s,

$$\hat{\theta} = \underset{\theta}{\operatorname{argmin}} \sum_{i=1}^{|T_s|} -\log \delta_i p(t_i|X_i;\theta) \quad (9)$$

where δ_i is the binomial target label distribution for one entry. Backpropagation algorithm with mini-batch stochastic gradient descent is used to solve this optimization problem. In addition, some useful tricks can be applied during the training. The weight matrixes $W^{(\cdot)}$ are initialized by *normalized initialization* (Glorot and Bengio, 2010). $W^{(1)}$ is pre-trained by an autoencoder (Hinton, 1989) to capture semantic compositionality. To speed up the learning, a momentum method is applied (Sutskever et al., 2013).

3.4 Combining Lexical and Contextual Semantic Clues by Label Propagation

We propose a Label Propagation algorithm to combine both semantic clues in a unified process. Each term $t \in V$ is assumed to have a label distribution $L_t = (p_t^+, p_t^-)$, where p_t^+ denotes the probability of the candidate being a product feature, and on the contrary, $p_t^- = 1 - p_t^+$. The classified results of the CNN which encode contextual semantic clue serve as the prior knowledge,

$$I_t = \begin{cases} (1,0), & if\ t \in V_s^+ \\ (0,1), & if\ t \in V_s^- \\ (r_t^+, r_t^-), & if\ t \in V_c \end{cases} \quad (10)$$

where (r_t^+, r_t^-) is estimated by,

$$r_t^+ = \frac{count^+(t)}{count^+(t) + count^-(t)} \quad (11)$$

where $count^+(t)$ is the number of occurrences of term t that are classified as positive by the CNN, and $count^-(t)$ represents the negative count.

Label Propagation is applied to propagate the prior knowledge distribution I to the product feature distribution L via semantic similarity graph G, so that a product feature candidate is determined by exploring its semantic relations to all of the seeds and other candidates globally. We propose an adapted version on the random walking view of the Adsorption algorithm (Baluja et al., 2008) by updating the following formula until L converges,

$$L^{i+1} = (1-\alpha)\mathbf{M}^T L^i + \alpha \mathbf{D} I \quad (12)$$

where $\mathbf{M}$ is the semantic transition matrix built from G; $\mathbf{D} = Diag[\log tf(t)]$ is a diagonal matrix of log frequencies, which is designed to assign higher "confidence" scores to more frequent seeds; and α is a balancing parameter. Particularly, when $\alpha = 0$, we can set the prior knowledge I without V_c to L^0 so that only lexical semantic clue is used; otherwise if $\alpha = 1$, only contextual semantic clue is used.

3.5 The Bootstrapping Framework

We summarize the bootstrapping framework of the proposed method in Algorithm 1. During bootstrapping, the CNN is enhanced by Label Propagation which finds more labeled examples for training, and then the performance of Label Propagation is also improved because the CNN outputs a more accurate prior distribution. After running for several iterations, the algorithm gets enough seeds, and a final Label Propagation is conducted to produce the results.

Algorithm 1: Bootstrapping using semantic clues

Input: The review corpus $\mathcal{R}$, a large corpus $\mathcal{C}$
Output: The mined product feature list P
Initialization: Train word embedding set EB first on $\mathcal{C}$, and then on $\mathcal{R}$

Step 1: Generate product feature seeds V_s (Section 3.1)

Step 2: Build semantic similarity graph G (Section 3.2)

while *iter* $<$ *MAX_ITER* **do**

  Step 3: Use V_s to collect occurrence set T_s from $\mathcal{R}$ for training

  Step 4: Train a CNN $\mathcal{N}$ on T_s (Section 3.3)
  Apply mini-batch SGD on Equ. 9;

  Step 5: Run Label Propagation (Section 3.4)
  Classify candidates using $\mathcal{N}$ to setup I;
  $L^0 \leftarrow I$;
  repeat
    $L^{i+1} \leftarrow (1-\alpha)\mathbf{M}^T L^i + \alpha \mathbf{D} I$;
  until $||L^{i+1} - L^i||^2 < \varepsilon$;

  Step 6: Expand product feature seeds
  Move top T terms from V_c to V_s;

  iter++

end

Step 7: Run Label Propagation for a final result L_f
Rank terms by L_f^+ to get P, where $L_f^+ > L_f^-$;

4 Experiments

4.1 Datasets and Evaluation Metrics

Datasets: We select two real world datasets to evaluate the proposed method. The first one is a benchmark dataset in Wang et al. (2011), which contains English review sets on two domains (*MP3* and *Hotel*)[5]. The second dataset is proposed by Chinese Opinion Analysis Evaluation 2008 (COAE 2008)[6], where two review sets (*Camera* and *Car*) are selected. Xu et al. (2013) had manually annotated product features on these four domains, so we directly employ their annotation as the gold standard. The detailed information can be found in their original paper.

[5]http://timan.cs.uiuc.edu/downloads.html
[6]http://ir-china.org.cn/coae2008.html

Evaluation Metrics: We evaluate the proposed method in terms of precision(P), recall(R) and F-measure(F). The English results are evaluated by *exact* string match. And for Chinese results, we use an *overlap* matching metric, because determining the exact boundaries is hard even for human (Wiebe et al., 2005).

4.2 Experimental Settings

For English corpora, the pre-processing are the same as that in (Qiu et al., 2009), and for Chinese corpora, the Stanford Word Segmenter (Chang et al., 2008) is used to perform word segmentation. We select three state-of-the-art syntax-based methods to be compared with our method:

DP uses a bootstrapping algorithm named as *Double Propagation* (Qiu et al., 2009), which is a conventional syntax-based method.

DP-HITS is an enhanced version of *DP* proposed by Zhang et al. (2010), which ranks product feature candidates by

$$s(t) = \log tf(t) * importance(t) \qquad (13)$$

where $importance(t)$ is estimated by the HITS algorithm (Kleinberg, 1999).

SGW is the Sentiment Graph Walking algorithm proposed in (Xu et al., 2013), which first extracts syntactic patterns and then uses random walking to rank candidates. Afterwards, word-syntactic pattern co-occurrence statistic is used as feature for a semi-supervised classifier TSVM (Joachims, 1999) to further refine the results. This two-stage method is denoted as ***SGW-TSVM***.

LEX only uses lexical semantic clue. Label Propagation is applied alone in a self-training manner. The dimension of word embedding $n = 100$, the convergence threshold $\varepsilon = 10^{-7}$, and the number of expanded seeds $T = 40$. The size of the seed set N is 40. To output product features, it ranks candidates in descent order by using the positive score $L_f^+(t)$.

CONT only uses contextual semantic clue, which only contains the CNN. The window size l is 5. The CNN is trained with a mini-batch size of 50. The hidden layer size $h = 250$. Finally, $importance(t)$ in Equ. 13 is replaced with r_t^+ in Equ. 11 to rank candidates.

LEX&CONT leverages both semantic clues.

Table 1: Experimental results of product feature mining. The precision or recall of *CONT* is the average performance over five runs with different random initialization of parameters of the CNN. Avg. stands for the average score.

4.3 The Semantics-based Methods vs. State-of-the-art Syntax-based Methods

The experimental results are shown in Table 1, from which we have the following observations:

(i) Our method achieves the best performance among all of the compared methods. We also equally split the dataset into five subsets, and perform one-tailed t-test ($p \leq 0.05$), which shows that the proposed semantics-based method (*LEX&CONT*) significantly outperforms the three syntax-based strong competitors (*DP*, *DP-HITS* and *SGW-TSVM*).

(ii) *LEX&CONT* which leverages both lexical and contextual semantic clues outperforms approaches that only use one kind of semantic clue (*LEX* and *CONT*), showing that the combination of the semantic clues is helpful.

(iii) Our methods which use only one kind of semantic clue (*LEX* and *CONT*) outperform syntax-based methods (*DP*, *DP-HITS* and *SGW*). Comparing *DP-HITS* with *LEX* and *CONT*, the difference between them is that *DP-HITS* uses a syntax-pattern-based algorithm to estimate $importance(t)$ in Equ. 13, while our methods use lexical or contextual semantic clue instead. We believe the reason that *LEX* or *CONT* is better is that syntactic patterns only use discrete and local information. In contrast, *CONT* exploits latent semantics of each word in context, and *LEX* takes advantage of word embedding, which is induced from global word co-occurrence statistic. Furthermore, comparing *SGW* and *LEX*, both methods are base on random surfer model, but *LEX* gets better results than *SGW*. Therefore, the word-word semantic similarity relation used in *LEX* is more reliable than the word-syntactic pattern relation used in *SGW*.

(iv) *LEX&CONT* achieves the highest recall among all of the evaluated methods. Since *DP* and *DP-HITS* rely on frequency for ranking product features, infrequent candidates are ranked low in their extracted list. As for *SGW-TSVM*, the features they used for the TSVM suffer from the data sparsity problem for infrequent terms. In contrast, *LEX&CONT* is frequency-independent to the review corpus. Further discussions on this observation are given in the next section.

4.4 The Results on Extracting Infrequent Product Features

We conservatively regard 30% product features with the highest frequencies in $\mathcal{R}$ as *frequent features*, so the remaining terms in the gold standard are *infrequent features*. In product feature mining task, frequent features are relatively easy to find. Table 2 shows the recall of all the four approaches for mining frequent product features. We can see that the performance are very close among different methods. Therefore, the recall mainly depends on mining the infrequent features.

Method	MP3	Hotel	Camera	Car
DP	0.89	0.92	0.86	0.84
DP-HITS	0.89	0.91	0.86	0.85
SGW-TSVM	0.87	0.92	0.88	0.87
LEX&CONT	0.89	0.91	0.89	0.87

Table 2: The recall of frequent product features.

Figure 3 gives the recall of infrequent product features, where *LEX&CONT* achieves the best performance. So our method is less influenced by term frequency. Furthermore, *LEX* gets better recall than *CONT* and all syntax-based methods, which indicates that lexical semantic clue does aid to mine more infrequent features as expected.

4.5 Lexical Semantic Clue vs. Contextual Semantic Clue

This section studies the effects of lexical semantic clue and contextual semantic clue during seed expansion (Step 6 in Algorithm 1), which is controlled by α. When $\alpha = 1$, we get the *CONT*; and if α is set 0, we get the *LEX*. To take into account the correctly expanded terms for both positive and negative seeds, we use Accuracy as the evaluation metric,

$$Accuracy = \frac{\#TP + \#TN}{\#\ Extracted\ Seeds}$$

where TP denotes the *true positive* seeds, and TN denotes the *true negative* seeds.

Figure 4 shows the performance of seed expansion during bootstrapping, in which the accuracy is computed on 40 seeds (20 being positive and 20 being negative) expanded in each iteration. We can see that the accuracies of *CONT* and *LEX&CONT* retain at a high level, which shows that they can find reliable new product feature seeds. However, the performance of *LEX* oscillates sharply and it is very low for some points, which indicates that using lexical semantic clue alone is infeasible. On another hand, comparing *CONT* with *LEX* in Table 1, we can see that *LEX* performs generally better than *CONT*. Although *LEX* is not so accurate as *CONT* during seed expansion, its final performance surpasses *CONT*. Consequently, we can draw conclusion that *CONT* is more suitable for the seed expansion, and *LEX* is more robust for the final result production.

To combine advantages of the two kinds of semantic clues, we set $\alpha = 0.7$ in Step 5 of Algorithm 1, so that contextual semantic clue plays a key role to find new seeds accurately. For Step 7, we set $\alpha = 0.3$. Thus, lexical semantic clue is emphasized for producing the final results.

4.6 The Effect of Convolutional Layer

Two non-convolutional variations of the proposed method are used to be compared with the convolutional method in *CONT*. ***FW-5*** uses a traditional neural network with a fixed window size of 5 to replace the CNN in *CONT*, and the candidate term to be classified is placed in the center of the window. Similarly, ***FW-9*** uses a fixed window size of 9. Note that *CONT* uses a 5-term dynamic window containing the candidate term, so the exploited number of words in the context is equivalent to *FW-9*.

Table 3 shows the experimental results. We can see that the performance of *FW-5* is much worse than *CONT*. The reason is that *FW-5* only exploits half of the context as that of *CONT*, which is not sufficient enough. Meanwhile, although *FW-9* exploits equivalent range of context as that of *CONT*, it gets lower precisions. It is because *FW-9* has approximately two times parameters in the parameter matrix $W^{(1)}$ than that in Equ. 5 of *CONT*, which makes it more difficult to be trained with the same amount of data. Also, lengths of many sentences in the review corpora are shorter than 9. Therefore, the convolutional approach in *CONT* is the most effective way among these settings.

4.7 Parameter Study

We investigate two key parameters of the proposed method: the initial number of seeds N, and the size of the window l used by the CNN.

Figure 5 shows the performance under different N, where the F-Measure saturates when N equates to 40 and beyond. Hence, very few seeds are needed for starting our algorithm.

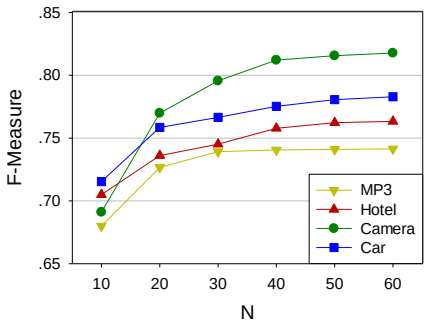

Figure 5: F-Measure vs. N for the final results.

Figure 6 shows F-Measure under different window size l. We can see that the performance is improved little when l is larger than 5. Therefore, $l = 5$ is a proper window size for these datasets.

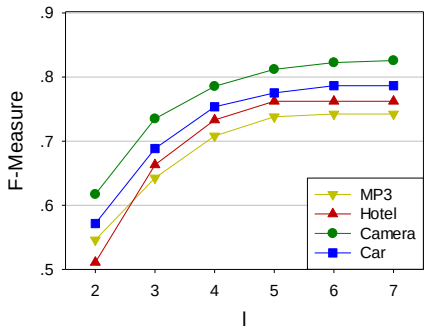

Figure 6: F-Measure vs. l for the final results.

5 Conclusion and Future Work

This paper proposes a product feature mining method by leveraging contextual and lexical semantic clues. A semantic similarity graph is built to capture lexical semantic clue, and a convolutional neural network is used to encode contextual semantic clue. Then, a Label Propagation algorithm is applied to combine both semantic clues. Experimental results prove the effectiveness of the proposed method, which not only mines product features more accurately than conventional syntax-based method, but also extracts more infrequent product features.

In future work, we plan to extend the proposed method to jointly mine product features along with customers' opinions on them. The learnt semantic representations of words may also be utilized to predict fine-grained sentiment distributions over product features.

Abstract

Aspect extraction is an important task in sentiment analysis. Topic modeling is a popular method for the task. However, unsupervised topic models often generate incoherent aspects. To address the issue, several knowledge-based models have been proposed to incorporate prior knowledge provided by the user to guide modeling. In this paper, we take a major step forward and show that in the big data era, without any user input, it is possible to learn prior knowledge automatically from a large amount of review data available on the Web. Such knowledge can then be used by a topic model to discover more coherent aspects. There are two key challenges: (1) learning quality knowledge from reviews of diverse domains, and (2) making the model fault-tolerant to handle possibly wrong knowledge. A novel approach is proposed to solve these problems. Experimental results using reviews from 36 domains show that the proposed approach achieves significant improvements over state-of-the-art baselines.

1 Introduction

Aspect extraction aims to extract target entities and their aspects (or attributes) that people have expressed opinions upon (Hu and Liu, 2004, Liu, 2012). For example, in "*The voice is not clear*," the aspect term is "*voice*." Aspect extraction has two subtasks: *aspect term extraction* and *aspect term resolution*. Aspect term resolution groups extracted synonymous aspect terms together. For example, "voice" and "sound" should be grouped together as they refer to the same aspect of phones.

Recently, topic models have been extensively applied to aspect extraction because they can perform both subtasks at the same time while other existing methods all need two separate steps (see Section 2). Traditional topic models such as LDA (Blei et al., 2003) and pLSA (Hofmann, 1999) are unsupervised methods for extracting latent topics in text documents. Topics are aspects in our task. Each aspect (or topic) is a distribution over (aspect) terms. However, researchers have shown that fully unsupervised models often produce incoherent topics because the objective functions of topic models do not always correlate well with human judgments (Chang et al., 2009).

To tackle the problem, several semi-supervised topic models, also called knowledge-based topic models, have been proposed. DF-LDA (Andrzejewski et al., 2009) can incorporate two forms of prior knowledge from the user: *must-links* and *cannot-links*. A must-link implies that two terms (or words) should belong to the same topic whereas a cannot-link indicates that two terms should not be in the same topic. In a similar but more generic vein, *must-sets* and *cannot-sets* are used in MC-LDA (Chen et al., 2013b). Other related works include (Andrzejewski et al., 2011, Chen et al., 2013a, Chen et al., 2013c, Mukherjee and Liu, 2012, Hu et al., 2011, Jagarlamudi et al., 2012, Lu et al., 2011, Petterson et al., 2010). They all allow prior knowledge to be specified by the user to guide the modeling process.

In this paper, we take a major step further. We mine the prior knowledge directly from a large amount of relevant data without any user intervention, and thus make this approach fully automatic. We hypothesize that it is possible to learn quality prior knowledge from the big data (of reviews) available on the Web. The intuition is that although every domain is different, there is a decent amount of aspect overlapping across domains. For example, every product domain has the aspect/topic of "*price*," most electronic products share the aspect "*battery*" and some also share "*screen*." Thus, the shared aspect knowl-

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 347–358,
Baltimore, Maryland, USA, June 23-25 2014.

edge mined from a set of domains can potentially help improve aspect extraction in each of these domains, as well as in new domains. Our proposed method aims to achieve this objective. There are two major challenges: (1) learning quality knowledge from a large number of domains, and (2) making the extraction model fault-tolerant, i.e., capable of handling possibly incorrect learned knowledge. We briefly introduce the proposed method below, which consists of two steps.

Learning quality knowledge: Clearly, learned knowledge from only a single domain can be erroneous. However, if the learned knowledge is shared by multiple domains, the knowledge is more likely to be of high quality. We thus propose to first use LDA to learn topics/aspects from each individual domain and then discover the shared aspects (or topics) and aspect terms among a subset of domains. These shared aspects and aspect terms are more likely to be of good quality. They can serve as the prior knowledge to guide a model to extract aspects. A piece of knowledge is a set of semantically coherent (aspect) terms which are likely to belong to the same topic or aspect, i.e., similar to a must-link, but mined automatically.

Extraction guided by learned knowledge: For reliable aspect extraction using the learned prior knowledge, we must account for possible errors in the knowledge. In particular, a piece of automatically learned knowledge may be wrong or domain specific (i.e., the words in the knowledge are semantically coherent in some domains but not in others). To leverage such knowledge, the system must detect those inappropriate pieces of knowledge. We propose a method to solve this problem, which also results in a new topic model, called AKL (*Automated Knowledge LDA*), whose inference can exploit the automatically learned prior knowledge and handle the issues of incorrect knowledge to produce superior aspects.

In summary, this paper makes the following contributions:

1. It proposes to exploit the big data to learn prior knowledge and leverage the knowledge in topic models to extract more coherent aspects. The process is fully automatic. To the best of our knowledge, none of the existing models for aspect extraction is able to achieve this.
2. It proposes an effective method to learn quality knowledge from raw topics produced using review corpora from many different domains.
3. It proposes a new inference mechanism for topic modeling, which can handle incorrect knowledge in aspect extraction.

2 Related Work

Aspect extraction has been studied by many researchers in sentiment analysis (Liu, 2012, Pang and Lee, 2008), e.g., using supervised sequence labeling or classification (Choi and Cardie, 2010, Jakob and Gurevych, 2010, Kobayashi et al., 2007, Li et al., 2010, Yang and Cardie, 2013) and using word frequency and syntactic patterns (Hu and Liu, 2004, Ku et al., 2006, Liu et al., 2013, Popescu and Etzioni, 2005, Qiu et al., 2011, Somasundaran and Wiebe, 2009, Wu et al., 2009, Xu et al., 2013, Yu et al., 2011, Zhao et al., 2012, Zhou et al., 2013, Zhuang et al., 2006). However, these works only perform extraction but not aspect term grouping or resolution. Separate aspect term grouping has been done in (Carenini et al., 2005, Guo et al., 2009, Zhai et al., 2011). They assume that aspect terms have been extracted beforehand.

To extract and group aspects simultaneously, topic models have been applied by researchers (Branavan et al., 2008, Brody and Elhadad, 2010, Chen et al., 2013b, Fang and Huang, 2012, He et al., 2011, Jo and Oh, 2011, Kim et al., 2013, Lazaridou et al., 2013, Li et al., 2011, Lin and He, 2009, Lu et al., 2009, Lu et al., 2012, Lu and Zhai, 2008, Mei et al., 2007, Moghaddam and Ester, 2013, Mukherjee and Liu, 2012, Sauper and Barzilay, 2013, Titov and McDonald, 2008, Wang et al., 2010, Zhao et al., 2010). Our proposed AKL model belongs to the class of knowledge-based topic models. Besides the knowledge-based topic models discussed in Section 1, document labels are incorporated as implicit knowledge in (Blei and McAuliffe, 2007, Ramage et al., 2009). Geographical region knowledge has also been considered in topic models (Eisenstein et al., 2010). All of these models assume that the prior knowledge is correct. GK-LDA (Chen et al., 2013a) is the only knowledge-based topic model that deals with wrong lexical knowledge to some extent. As we will see in Section 6, AKL outperformed GK-LDA significantly due to AKL's more effective error handling mechanism. Furthermore, GK-LDA does not learn any prior knowledge.

Our work is also related to transfer learning to some extent. Topic models have been used to help

Figure 1: The proposed overall algorithm.

transfer learning (He et al., 2011, Pan and Yang, 2010, Xue et al., 2008). However, transfer learning in these papers is for traditional classification rather than topic/aspect extraction. In (Kang et al., 2012), labeled documents from source domains are transferred to the target domain to produce topic models with better fitting. However, we do not use any labeled data. In (Yang et al., 2011), a user provided parameter indicating the technicality degree of a domain was used to model the language gap between topics. In contrast, our method is fully automatic without human intervention.

3 Overall Algorithm

This section introduces the proposed overall algorithm. It consists of two main steps: *learning quality knowledge* and *using the learned knowledge*. Figure 1 gives the algorithm.

Step 1 (learning quality knowledge, Lines 1-16): The input is the review corpora $\boldsymbol{D_L}$ from multiple domains, from which the knowledge is automatically learned. Lines 3 and 5 run LDA on each review domain corpus $D_i \in \boldsymbol{D_L}$ to generate a set of aspects/topics A_i (lines 2, 4, and 6-9 will be discussed below). Line 10 unions the topics from all domains to give $\boldsymbol{A}$. Lines 11-14 cluster the topics in $\boldsymbol{A}$ into some coherent groups (or clusters) and then discover knowledge K_j from each group of topics using frequent pattern mining (FPM) (Han et al., 2007). We will detail these in Section 4. Each piece of the learned knowledge is a set of terms which are likely to belong to the same aspect.

Iterative improvement: The above process can actually run iteratively because the learned knowledge $\boldsymbol{K}$ can help the topic model learn better topics in each domain $D_i \in \boldsymbol{D_L}$, which results in better knowledge $\boldsymbol{K}$ in the next iteration. This iterative process is reflected in lines 2, 4, 6-9 and 16. We will examine the performance of the process at different iterations in Section 6.2. From the second iteration, we can use the knowledge learned from the previous iteration (lines 6-8). The learned knowledge is leveraged by the new model AKL, which is discussed below in Step 2.

Step 2 (using the learned knowledge, Lines 17-20): The proposed model AKL is employed to use the learned knowledge $\boldsymbol{K}$ to help topic modeling in test domains $\boldsymbol{D_T}$, which can be $\boldsymbol{D_L}$ or other unseen domains. The key challenge of this step is how to use the learned prior knowledge $\boldsymbol{K}$ effectively in AKL and deal with possible errors in $\boldsymbol{K}$. We will elaborate them in Section 5.

Scalability: the proposed algorithm is naturally scalable as both LDA and AKL run on each domain independently. Thus, for all domains, the algorithm can run in parallel. Only the resulting topics need to be brought together for knowledge learning (Step 1). These resulting topics used in learning are much smaller than the domain corpus as only a list of top terms from each topic are utilized due to their high reliability.

4 Learning Quality Knowledge

This section details Step 1 in the overall algorithm, which has three sub-steps: running LDA (or AKL) on each domain corpus, clustering the resulting topics, and mining frequent patterns from the topics in each cluster. Since running LDA is simple, we will not discuss it further. The proposed AKL model will be discussed in Section 5. Below we focus on the other two sub-steps.

4.1 Topic Clustering

After running LDA (or AKL) on each domain corpus, a set of topics is obtained. Each topic is a distribution over terms (or words), i.e., terms with their associated probabilities. Here, we use only the top terms with high probabilities. As discussed earlier, quality knowledge should be shared

by topics across several domains. Thus, it is natural to exploit a frequency-based approach to discover frequent set of terms as quality knowledge. However, we need to deal with two issues.

1. Generic aspects, such as *price* with aspect terms like *cost* and *pricy*, are shared by many (even all) product domains. But specific aspects such as *screen*, occur only in domains with products having them. It means that different aspects may have distinct frequencies. Thus, using a single frequency threshold in the frequency-based approach is not sufficient to extract both generic and specific aspects because the generic aspects will result in numerous spurious aspects (Han et al., 2007).
2. A term may have multiple senses in different domains. For example, *light* can mean "of little weight" or "something that makes things visible". A good knowledge base should have the capacity of handling this ambiguity.

To deal with these two issues, we propose to discover knowledge in two stages: topic clustering and frequent pattern mining (FPM).

The purpose of clustering is to group raw topics from a topic model (LDA or AKL) into clusters. Each cluster contains semantically related topics likely to indicate the same real-world aspect. We then mine knowledge from each cluster using an FPM technique. Note that the multiple senses of a term can be distinguished by the semantic meanings represented by the topics in different clusters.

For clustering, we tried k-means and k-medoids (Kaufman and Rousseeuw, 1990), and found that k-medoids performs slightly better. One possible reason is that k-means is more sensitive to outliers. In our topic clustering, each data point is a topic represented by its top terms (with their probabilities normalized). The distance between two data points is measured by symmetrised KL-Divergence.

4.2 Frequent Pattern Mining

Given topics within each cluster, this step finds sets of terms that appear together in multiple topics, i.e., shared terms among similar topics across multiple domains. Terms in such a set are likely to belong to the same aspect. To find such sets of terms within each cluster, we use *frequent pattern mining* (FPM) (Han et al., 2007), which is suited for the task. The probability of each term is ignored in FPM.

FPM is stated as follows: Given a set of transactions $\mathbb{T}$, where each transaction $t_i \in \mathbb{T}$ is a set of items from a global item set $\mathbb{I}$, i.e., $t_i \in \mathbb{I}$. In our context, t_i is the topic vector comprising the top terms of a topic (no probability attached). $\mathbb{T}$ is the collection of all topics within a cluster and $\mathbb{I}$ is the set of all terms in $\mathbb{T}$. The goal of FPM is to find all patterns that satisfy some user-specified frequency threshold (also called minimum support count), which is the minimum number of times that a pattern should appear in $\mathbb{T}$. Such patterns are called frequent patterns. In our context, a pattern is a set of terms which have appeared multiple times in the topics within a cluster. Such patterns compose our knowledge base as shown below.

4.3 Knowledge Representation

As the knowledge is extracted from each cluster individually, we represent our knowledge base as a set of clusters, where each cluster consists of a set of frequent 2-patterns mined using FPM, e.g.,

Cluster 1: {battery, life}, {battery, hour}, {battery, long}, {charge, long}

Cluster 2: {service, support}, {support, customer}, {service, customer}

Using two terms in a set is sufficient to cover the semantic relationship of the terms belonging to the same aspect. Longer patterns tend to contain more errors since some terms in a set may not belong to the same aspect as others. Such partial errors hurt performance in the downstream model.

5 AKL: Using the Learned Knowledge

We now present the proposed topic model AKL, which is able to use the automatically learned knowledge to improve aspect extraction.

5.1 Plate Notation

Differing from most topic models based on topic-term distribution, AKL incorporates a latent cluster variable $\boldsymbol{c}$ to connect topics and terms. The plate notation of AKL is shown in Figure 2. The inputs of the model are M documents, T topics and C clusters. Each document m has N_m terms. We model distribution $P(cluster|topic)$ as ψ and distribution $P(term|topic, cluster)$ as φ with Dirichlet priors β and γ respectively. $P(topic|document)$ is modeled by θ with a Dirichlet prior α. The terms in each document are assumed to be generated by first sampling a topic z, and then a cluster c given topic z, and finally

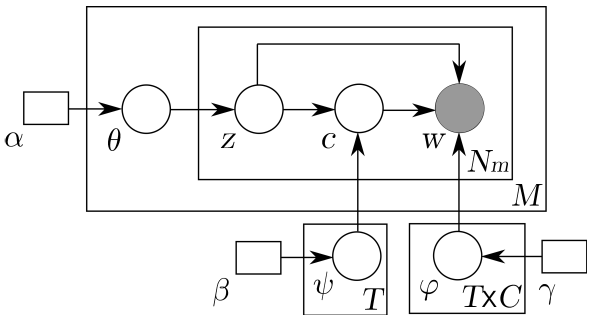

Figure 2: Plate notation for AKL.

a term w given topic z and cluster c. This plate notation of AKL and its associated generative process are similar to those of MC-LDA (Chen et al., 2013b). However, there are three key differences.

1. Our knowledge is automatically mined which may have errors (or noises), while the prior knowledge for MC-LDA is manually provided and assumed to be correct. As we will see in Section 6, using our knowledge, MC-LDA does not generate as coherent aspects as AKL.
2. Our knowledge is represented as clusters. Each cluster contains a set of frequent 2-patterns with semantically correlated terms. They are different from must-sets used in MC-LDA.
3. Most importantly, due to the use of the new form of knowledge, AKL's inference mechanism (Gibbs sampler) is entirely different from that of MC-LDA (Section 5.2), which results in superior performances (Section 6). Note that the inference mechanism and the prior knowledge cannot be reflected in the plate notation for AKL in Figure 2.

In short, our modeling contributions are (1) the capability of handling more expressive knowledge in the form of clusters, (2) a novel Gibbs sampler to deal with inappropriate knowledge.

5.2 The Gibbs Sampler

As the automatically learned prior knowledge may contain errors for a domain, AKL has to learn the usefulness of each piece of knowledge dynamically during inference. Instead of assigning weights to each piece of knowledge as a fixed prior in (Chen et al., 2013a), we propose a new Gibbs sampler, which can dynamically balance the use of prior knowledge and the information in the corpus during the Gibbs sampling iterations.

We adopt a Blocked Gibbs sampler (Rosen-Zvi et al., 2010) as it improves convergence and reduces autocorrelation when the variables (topic z and cluster c in AKL) are highly related. For each term w_i in each document, we jointly sample a topic z_i and cluster c_i (containing w_i) based on the conditional distribution in Gibbs sampler (will be detailed in Equation 4). To compute this distribution, instead of considering how well z_i matches with w_i only (as in LDA), we also consider two other factors:

1. The extent c_i corroborates w_i given the corpus. By "corroborate", we mean whether those frequent 2-patterns in c_i containing w_i are also supported by the actual information in the domain corpus to some extent (see the measure in Equation 1 below). If c_i corroborates w_i well, c_i is likely to be useful, and thus should also provide guidance in determining z_i. Otherwise, c_i may not be a suitable piece of knowledge for w_i in the domain.
2. Agreement between c_i and z_i. By agreement we mean the degree that the terms (union of all frequent 2-patterns of c_i) in cluster c_i are reflected in topic z_i. Unlike the first factor, this is a global factor as it concerns all the terms in a knowledge cluster.

For the first factor, we measure how well c_i corroborates w_i given the corpus based on co-document frequency ratio. As shown in (Mimno et al., 2011), co-document frequency is a good indicator of term correlation in a domain. Following (Mimno et al., 2011), we define a symmetric co-document frequency ratio as follows:

$$Co\text{-}Doc(w, w') = \frac{D(w, w') + 1}{(D(w) + D(w')) \times \frac{1}{2} + 1} \quad (1)$$

where (w, w') refers to each frequent 2-pattern in the knowledge cluster c_i. $D(w, w')$ is the number of documents that contain both terms w and w' and $D(w)$ is the number of documents containing w. A smoothing count of 1 is added to avoid the ratio being 0.

For the second factor, if cluster c_i and topic z_i agree, the intuition is that the terms in c_i (union of all frequent 2-patterns of c_i) should appear as top terms under z_i (i.e., ranked top according to the term probability under z_i). We define the agreement using symmetrised KL-Divergence between the two distributions ($DIST_c$ and $DIST_z$) corresponding to c_i and z_i respectively. As there is no prior preference on the terms of c_i, we use the uniform distribution over all terms in c_i for $DIST_c$. For $DIST_z$, as only top 20 terms under z_i are usually reliable, we use these top terms

with their probabilities (re-normalized) to represent the topic. Note that a smoothing probability (i.e., a very small value) is also given to every term for calculating KL-Divergence. Given $DIST_c$ and $DIST_z$, the agreement is computed with:

$$Agreement(c, z) = \frac{1}{KL(DIST_c, DIST_z)} \quad (2)$$

The rationale of Equation 2 is that the lesser divergence between $DIST_c$ and $DIST_z$ implies the more agreement between c_i and z_i.

We further employ the *Generalized Plya urn* (GPU) model (Mahmoud, 2008) which was shown to be effective in leveraging semantically related words (Chen et al., 2013a, Chen et al., 2013b, Mimno et al., 2011). The GPU model here basically states that assigning topic z_i and cluster c_i to term w_i will not only increase the probability of connecting z_i and c_i with w_i, but also make it more likely to associate z_i and c_i with term w' where w' shares a 2-pattern with w_i in c_i. The amount of probability increase is determined by matrix $\mathbb{A}_{c,w',w}$ defined as:

$$\mathbb{A}_{c,w',w} = \begin{cases} 1, & \text{if } w = w' \\ \sigma, & \text{if } (w, w') \in c, w \neq w' \\ 0, & \text{otherwise} \end{cases} \quad (3)$$

where value 1 controls the probability increase of w by seeing w itself, and σ controls the probability increase of w' by seeing w. Please refer to (Chen et al., 2013b) for more details.

Putting together Equations 1, 2 and 3 into a blocked Gibbs Sampler, we can define the following sampling distribution in Gibbs sampler so that it provides helpful guidance in determining the usefulness of the prior knowledge and in selecting the semantically coherent topic.

$$\begin{aligned} &P(z_i = t, c_i = c | \boldsymbol{z}^{-i}, \boldsymbol{c}^{-i}, \boldsymbol{w}, \alpha, \beta, \gamma, \mathbb{A}) \\ &\propto \sum_{(w,w') \in c} Co\text{-}Doc(w, w') \times Agreement(c, t) \\ &\times \frac{n^{-i}_{m,t} + \alpha}{\sum_{t'=1}^{T}(n^{-i}_{m,t'} + \alpha)} \\ &\times \frac{\sum_{w'=1}^{V}\sum_{v'=1}^{V} \mathbb{A}_{c,v',w'} \times n^{-i}_{t,c,v'} + \beta}{\sum_{c'=1}^{C}(\sum_{w'=1}^{V}\sum_{v'=1}^{V} \mathbb{A}_{c',v',w'} \times n^{-i}_{t,c',v'} + \beta)} \\ &\times \frac{\sum_{w'=1}^{V} \mathbb{A}_{c,w',w_i} \times n^{-i}_{t,c,w'} + \gamma}{\sum_{v'=1}^{V}(\sum_{w'=1}^{V} \mathbb{A}_{c,w',v'} \times n^{-i}_{t,c,w'} + \gamma)} \end{aligned} \quad (4)$$

where n^{-i} denotes the count excluding the current assignment of z_i and c_i, i.e., $\boldsymbol{z}^{-i}$ and $\boldsymbol{c}^{-i}$. $n_{m,t}$ denotes the number of times that topic t was assigned to terms in document m. $n_{t,c}$ denotes the times that cluster c occurs under topic t. $n_{t,c,v}$ refers to the number of times that term v appears in cluster c under topic t. α, β and γ are predefined Dirichlet hyperparameters.

Note that although the above Gibbs sampler is able to distinguish useful knowledge from wrong knowledge, it is possible that there is no cluster corroborates for a particular term. For every term w, apart from its knowledge clusters, we also add a singleton cluster for w, i.e., a cluster with one pattern $\{w, w\}$ only. When no knowledge cluster is applicable, this singleton cluster is used. As a singleton cluster does not contain any knowledge information but only the word itself, Equations 1 and 2 cannot be computed. For the values of singleton clusters for these two equations, we assign them as the averages of those values of all non-singleton knowledge clusters.

6 Experiments

This section evaluates and compares the proposed AKL model with three baseline models LDA, MC-LDA, and GK-LDA. LDA (Blei et al., 2003) is the most popular unsupervised topic model. MC-LDA (Chen et al., 2013b) is a recent knowledge-based model for aspect extraction. GK-LDA (Chen et al., 2013a) handles wrong knowledge by setting prior weights using the ratio of word probabilities. Our automatically extracted knowledge is provided to these models. Note that cannot-set of MC-LDA is not used in AKL.

6.1 Experimental Settings

Dataset. We created a large dataset containing reviews from 36 product domains or types from Amazon.com. The product domain names are listed in Table 1. Each domain contains $1,000$ reviews. This gives us 36 domain corpora. We have made the dataset publically available at the website of the first author.

Pre-processing. We followed (Chen et al., 2013b) to employ standard pre-processing like lemmatization and stopword removal. To have a fair comparison, we also treat each sentence as a document as in (Chen et al., 2013a, Chen et al., 2013b).

Parameter Settings. For all models, posterior estimates of latent variables were taken with a sampling lag of 20 iterations in the post burn-in phase (first 200 iterations for burn-in) with $2,000$ iterations in total. The model parameters were tuned on the development set in our pilot experiments

Table 1: List of 36 domain names.

and set to $\alpha = 1$, $\beta = 0.1$, $T = 15$, and $\sigma = 0.2$. Furthermore, for each cluster, γ is set proportional to the number of terms in it. The other parameters for MC-LDA and GK-LDA were set as in their original papers. For parameters of AKL, we used the top 15 terms for each topic in the clustering phrase. The number of clusters is set to the number of domains. We will test the sensitivity of these clustering parameters in Section 6.4. The minimum support count for frequent pattern mining was set empirically to $min(5, 0.4 \times \#\mathbb{T})$, where $\#\mathbb{T}$ is the number of transactions (i.e., the number of topics from all domains) in a cluster.

Test Settings: We use two test settings as below:

1. (Sections 6.2, 6.3 and 6.4) Test on the same corpora as those used in learning the prior knowledge. This is meaningful as the learning phrase is automatic and unsupervised (Figure 1). We call this *self-learning-and-improvement*.
2. (Section 6.5) Test on new/unseen domain corpora after knowledge learning.

6.2 Topic Coherence

This sub-section evaluates the topics/aspects generated by each model based on Topic Coherence (Mimno et al., 2011) in test setting 1. Traditionally, topic models have been evaluated using perplexity. However, perplexity on the held-out test set does not reflect the semantic coherence of topics and may be contrary to human judgments (Chang et al., 2009). Instead, the metric Topic Coherence has been shown in (Mimno et al., 2011) to correlate well with human judgments. Recently, it has become a standard practice to use Topic Coherence for evaluation of topic models (Arora et al., 2013). A higher Topic Coherence value indicates a better topic interpretability, i.e., semantically more coherent topics.

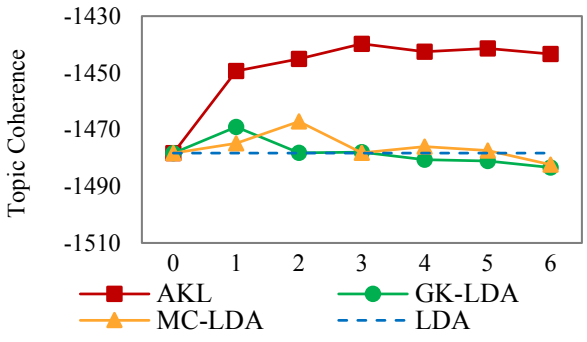

Figure 3: Average Topic Coherence of each model at different learning iterations (Iteration 0 is equivalent to LDA).

Figure 3 shows the average Topic Coherence of each model using knowledge learned at different learning iterations (Figure 1). For MC-LDA or GK-LDA, this is done by replacing AKL in lines 7 and 19 of Figure 1 with MC-LDA or GK-LDA. Each value is the average over all 36 domains. From Figure 3, we can observe the followings:

1. AKL performs the best with the highest Topic Coherence values at all iterations. It is actually the best in all 36 domains. These show that AKL finds more interpretable topics than the baselines. Its values stabilize after iteration 3.
2. Both GK-LDA and MC-LDA perform slightly better than LDA in iterations 1 and 2. MC-LDA does not handle wrong knowledge. This shows that the mined knowledge is of good quality. Although GK-LDA uses large word probability differences under a topic to detect wrong lexical knowledge, it is not as effective as AKL. The reason is that as the lexical knowledge is from general dictionaries rather than mined from relevant domain data, the words in a wrong piece of knowledge usually have a very large probability difference under a topic. However, our knowledge is mined from top words in related topics including topics from the current domain. The words in a piece of incorrect (or correct) knowledge often have similar probabilities under a topic. The proposed dynamic knowledge adjusting mechanism in AKL is superior.

Paired t-test shows that AKL outperforms all baselines significantly ($p < 0.0001$).

6.3 User Evaluation

As our objective is to discover more coherent aspects, we recruited two human judges. Here we also use the test setting 1. Each topic is annotated as coherent if the judge feels that most of its top

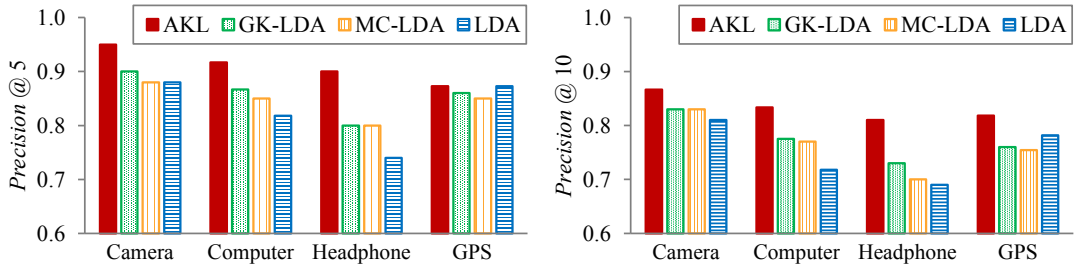

Figure 4: Average $Precision@5$ (Left) and $Precision@10$ (Right) of coherent topics from four models in each domain. (*Headphone* has a lot of overlapping topics in other domains while *GPS* has little.)

terms coherently represent a real-world product aspect; otherwise incoherent. For a coherent topic, each top term is annotated as correct if it reflects the aspect represented by the topic; otherwise incorrect. We labeled the topics of each model at learning iteration 1 where the same pieces of knowledge (extracted from LDA topics at learning iteration 0) are provided to each model. After learning iteration 1, the gap between AKL and the baseline models tends to widen. To be consistent, the results later in Sections 6.4 and 6.5 also show each model at learning iteration 1. We also notice that after a few learning iterations, the topics from AKL model tend to have some resemblance across domains. We found that AKL with 2 learning iterations achieved the best topics. Note that LDA cannot use any prior knowledge.

We manually labeled results from four domains, i.e., Camera, Computer, Headphone, and GPS. We chose Headphone as it has a lot of overlapping of topics with other domains because many electronic products use headphone. GPS was chosen because it does not have much topic overlapping with other domains as its aspects are mostly about Navigation and Maps. Domains Camera and Computer lay in between. We want to see how domain overlapping influences the performance of AKL. Cohen's Kappa scores for annotator agreement are 0.918 (for topics) and 0.872 (for terms).

To measure the results, we compute $Precision@n$ (or $p@n$) based on the annotations, which was also used in (Chen et al., 2013b, Mukherjee and Liu, 2012).

Figure 4 shows the $precision@n$ results for $n = 5$ and 10. We can see that AKL makes improvements in all 4 domains. The improvement varies in domains with the most increase in Headphone and the least in GPS as Headphone overlaps more with other domains than GPS. Note that if a domain shares aspects with many other domains, its model should benefit more; otherwise, it is reasonable to expect lesser improvements. For the baselines, GK-LDA and MC-LDA perform similarly to LDA with minor variations, all of which are inferior to AKL. AKL's improvements over other models are statistically significant based on paired t-test ($p < 0.002$).

In terms of the number of *coherent* topics, AKL discovers one more coherent topic than LDA in Computer and one more coherent topic than GK-LDA and MC-LDA in Headphone. For the other domains, the numbers of coherent topics are the same for all models.

Table 2 shows an example aspect (*battery*) and its top 10 terms produced by AKL and LDA for each domain to give a flavor of the kind of improvements made by AKL. The results for GK-LDA and MC-LDA are about the same as LDA (see also Figure 4). Table 2 focuses on the aspects generated by AKL and LDA. From Table 2, we can see that AKL discovers more correct and meaningful aspect terms at the top. Note that those terms marked in red and italicized are errors. Apart from Table 2, many aspects are dramatically improved by AKL, including some commonly shared aspects such as *Price*, *Screen*, and *Customer Service*.

6.4 Sensitivity to Clustering Parameters

This sub-section investigates the sensitivity of the clustering parameters of AKL (again in test setting 1). The top sub-figure in Figure 5 shows the average Topic Coherence values versus the top k terms per topic used in topic clustering (Section 4.1). The number of clusters is set to the number of domains (see below). We can observe that using $k = 15$ top terms gives the highest value. This is intuitive as too few (or too many) top terms may generate insufficient (or noisy) knowledge.

The bottom sub-figure in Figure 5 shows the average Topic Coherence given different number

Camera		Computer		Headphone		GPS

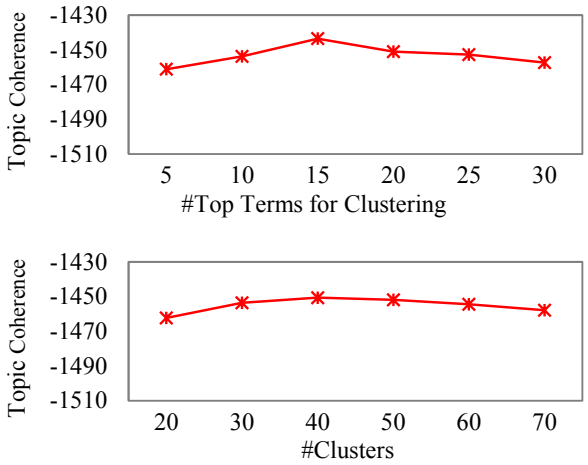

Figure 5: Average topic coherence of AKL versus #top k terms (Top) and #clusters (Bottom).

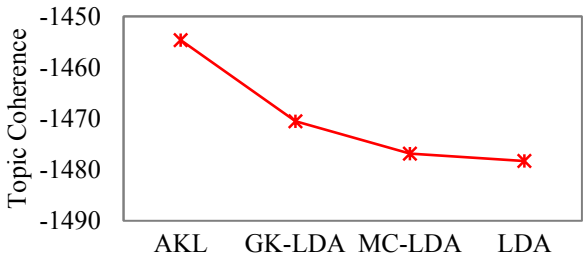

Figure 6: Average topic coherence of each model tested on new/unseen domain.

of clusters. We fix the number of top terms per topic to 15 as it yields the best result (see the top sub-figure in Figure 5). We can see that the performance is not very sensitive to the number of clusters. The model performs similarly for 30 to 50 clusters, with lower Topic Coherence for less than 30 or more than 50 clusters. The significance test indicates that using 30, 40, and 50 clusters, AKL achieved significant improvements over all baseline models ($p < 0.0001$). With more domains, we should expect a larger number of clusters. However, it is difficult to obtain the optimal number of clusters. Thus, we empirically set the number of clusters to the number of domains in our experiments. Note that the number of clusters (C) is expected to be larger than the number of topics in one domain (T) because C is for all domains while T is for one particular domain.

6.5 Test on New Domains

We now evaluate AKL in test setting 2, i.e., the automatically extracted knowledge $\boldsymbol{K}$ (Figure 1) is applied in new/unseen domains other than those in domains $\boldsymbol{D_L}$ used in knowledge learning. The aim is to see how $\boldsymbol{K}$ can help modeling in an unseen domain. In this set of experiments, each domain is tested by using the learned knowledge from the rest 35 domains. Figure 6 shows the average Topic Coherence of each model. The values are also averaged over the 36 tested domains. We can see that AKL achieves the highest Topic Coherence value while LDA has the lowest. The improvements of AKL over all baseline models are significant with $p < 0.0001$.

7 Conclusions

This paper proposed an advanced aspect extraction framework which can learn knowledge automatically from a large number of review corpora and exploit the learned knowledge in extracting more coherent aspects. It first proposed a technique to learn knowledge automatically by clustering and FPM. Then a new topic model with an advanced inference mechanism was proposed to exploit the learned knowledge in a fault-tolerant manner. Experimental results using review corpora from 36 domains showed that the proposed method outperforms state-of-the-art methods significantly.

Abstract

Spectral methods offer scalable alternatives to Markov chain Monte Carlo and expectation maximization. However, these new methods lack the rich priors associated with probabilistic models. We examine Arora et al.'s anchor words algorithm for topic modeling and develop new, regularized algorithms that not only mathematically resemble Gaussian and Dirichlet priors but also improve the interpretability of topic models. Our new regularization approaches make these efficient algorithms more flexible; we also show that these methods can be combined with informed priors.

1 Introduction

Topic models are of practical and theoretical interest. Practically, they have been used to understand political perspective (Paul and Girju, 2010), improve machine translation (Eidelman et al., 2012), reveal literary trends (Jockers, 2013), and understand scientific discourse (Hall et al., 2008). Theoretically, their latent variable formulation has served as a foundation for more robust models of other linguistic phenomena (Brody and Lapata, 2009).

Modern topic models are formulated as a latent variable model. Like hidden Markov models (Rabiner, 1989, HMM), each token comes from one of K unknown distributions. Unlike a HMM, topic models assume that each document is an *admixture* of these hidden components called topics. Posterior inference discovers the hidden variables that best explain a dataset. Typical solutions use MCMC (Griffiths and Steyvers, 2004) or variational EM (Blei et al., 2003), which can be viewed as local optimization: searching for the latent variables that maximize the data likelihood.

An exciting vein of new research provides provable polynomial-time alternatives. These approaches provide solutions to hidden Markov models (Anandkumar et al., 2012), mixture models (Kannan et al., 2005), and latent variable grammars (Cohen et al., 2013). The key insight is not to directly optimize observation likelihood but to instead discover latent variables that can reconstruct statistics of the assumed generative model. Unlike search-based methods, which can be caught in local minima, these techniques are often guaranteed to find global optima.

These general techniques can be improved by making reasonable assumptions about the models. For example, Arora et al. (2012b)'s approach for inference in topic models assume that each topic has a unique "anchor" word (thus, we call this approach **anchor**). This approach is fast and effective; because it only uses word co-occurrence information, it can scale to much larger datasets than MCMC or EM alternatives. We review the **anchor** method in Section 2.

Despite their advantages, these techniques are not a panacea. They do not accommodate the rich priors that modelers have come to expect. Priors can improve performance (Wallach et al., 2009), provide domain adaptation (Daumé III, 2007; Finkel and Manning, 2009), and guide models to reflect users' needs (Hu et al., 2013). In Section 3, we regularize the **anchor** method to trade-off the reconstruction fidelity with the penalty terms that mimic Gaussian and Dirichlet priors.

Another shortcoming is that these models have not been scrutinized using standard NLP evaluations. Because these approaches emerged from the theory community, **anchor**'s evaluations, when present, typically use training reconstruction. In Section 4, we show that our regularized models can generalize to previously unseen data—as measured by held-out likelihood (Blei et al., 2003)—and are more interpretable (Chang et al., 2009; Newman et al., 2010). We also show that our extension to the **anchor** method enables new applications: for

example, using an informed priors to discover concepts of interest.

Having shown that regularization does improve performance, in Section 5 we explore why. We discuss the trade-off of training data reconstruction with sparsity and why regularized topics are more interpretable.

2 Anchor Words: Scalable Topic Models

In this section, we briefly review the **anchor** method and place it in the context of topic model inference. Once we have established the **anchor** objective function, in the next section we regularize the objective function.

Rethinking Data: Word Co-occurrence Inference in topic models can be viewed as a black box: given a set of documents, discover the topics that best explain the data. The difference between **anchor** and conventional inference is that while conventional methods take a collection of documents as input, **anchor** takes *word co-occurrence* statistics. Given a vocabulary of size V, we represent this joint distribution as $\boldsymbol{Q}_{i,j} = p(w_1 = i, w_2 = j)$, each cell represents the probability of words appearing together in a document.

Like other topic modeling algorithms, the output of the **anchor** method is the topic word distributions $\boldsymbol{A}$ with size $V * K$, where K is the total number of topics desired, a parameter of the algorithm. The k^{th} column of A will be the topic distribution over all words for topic k, and $\boldsymbol{A}_{w,k}$ is the probability of observing type w given topic k.

Anchors: Topic Representatives The **anchor** method (Arora et al., 2012a) is based on the separability assumption (Donoho and Stodden, 2003), which assumes that each topic contains at least one namesake "anchor word" that has non-zero probability only in that topic. Intuitively, this means that each topic has unique, specific word that, when used, identifies that topic. For example, while "run", "base", "fly", and "shortstop" are associated with a topic about baseball, only "shortstop" is unambiguous, so it could serve as this topic's anchor word.

Let's assume that we knew what the anchor words were: a set $\mathcal{S}$ that indexes rows in $\boldsymbol{Q}$. Now consider the **conditional distribution** of word i, the probability of the rest of the vocabulary given an observation of word i; we represent this as $\bar{\boldsymbol{Q}}_{i,\cdot}$, as we can construct this by normalizing the rows of $\boldsymbol{Q}$. For an anchor word $s_a \in \mathcal{S}$, this will look like a topic; $\bar{\boldsymbol{Q}}_{\text{"shortstop"},\cdot}$ will have high probability for words associated with baseball.

The key insight of the **anchor** algorithm is that the conditional distribution of polysemous non-anchor words can be reconstructed as a linear combination of the conditional distributions of anchor words. For example, $\bar{\boldsymbol{Q}}_{\text{"fly"},\cdot}$ could be reconstructed by combining the anchor words "insecta", "boeing", and "shortshop". We represent the coefficients of this reconstruction as a matrix $\boldsymbol{C}$, where $C_{i,k} = p(z = k \mid w = i)$. Thus, for any word i,

$$\bar{\boldsymbol{Q}}_{i,\cdot} \approx \sum_{s_k \in \mathcal{S}} C_{i,k} \bar{\boldsymbol{Q}}_{s_k,\cdot} \tag{1}$$

The coefficient matrix is **not** the usual output of a topic modeling algorithm. The usual output is the probability of a word *given a topic*. The coefficient matrix C is the probability of a topic *given a word*. We use Bayes rule to recover the topic distribution $p(w = i|z = k) \equiv$

$$\begin{aligned} A_{i,k} &\propto p(z = k|w = i)p(w = i) \\ &= C_{i,k} \sum_j \bar{Q}_{i,j} \end{aligned} \tag{2}$$

where $p(w)$ is the normalizer of $\boldsymbol{Q}$ to obtain $\bar{\boldsymbol{Q}}_{w,\cdot}$.

The geometric argument for finding the anchor words is one of the key contributions of Arora et al. (2012a) and is beyond the scope of this paper. The algorithms in Section 3 use the anchor selection subroutine unchanged. The difference in our approach is in how we discover the anchor coefficients C.

From Anchors to Topics After we have the anchor words, we need to find the coefficients that

best reconstruct the data $\bar{Q}$ (Equation 1). Arora et al. (2012a) chose the C that minimizes the KL divergence between $\bar{Q}_{i,\cdot}$ and the reconstruction based on the anchor word's conditional word vectors $\sum_{s_k \in \mathcal{S}} C_{i,k} \bar{\boldsymbol{Q}}_{s_k,\cdot}$,

$$\boldsymbol{C}_{i,\cdot} = \text{argmin}_{\boldsymbol{C}_{i,\cdot}} D_{\text{KL}} \left(\bar{\boldsymbol{Q}}_{i,\cdot} \,||\, \sum_{s_k \in S} C_{i,k} \bar{\boldsymbol{Q}}_{s_k,\cdot} \right). \tag{3}$$

The **anchor** method is fast, as it only depends on the size of the vocabulary once the co-occurrence statistics $\boldsymbol{Q}$ are obtained. However, it does not support rich priors for topic models, while MCMC (Griffiths and Steyvers, 2004) and variational EM (Blei et al., 2003) methods can. This prevents models from using priors to guide the models to discover particular themes (Zhai et al., 2012), or to encourage sparsity in the models (Yao et al., 2009). In the rest of this paper, we correct this lacuna by adding regularization inspired by Bayesian priors to the **anchor** algorithm.

3 Adding Regularization

In this section, we add regularizers to the **anchor** objective (Equation 3). In this section, we briefly review regularizers and then add two regularizers, inspired by Gaussian (L_2, Section 3.1) and Dirichlet priors (Beta, Section 3.2), to the **anchor** objective function (Equation 3).

Regularization terms are ubiquitous. They typically appear as an additional term in an optimization problem. Instead of optimizing a function just of the data x and parameters β, $f(x, \beta)$, one optimizes an objective function that includes a regularizer that is only a function of parameters: $f(w, \beta) + r(\beta)$. Regularizers are critical in staid methods like linear regression (Ng, 2004), in workhorse methods such as maximum entropy modeling (Dudík et al., 2004), and also in emerging fields such as deep learning (Wager et al., 2013).

In addition to being useful, regularization terms are appealing theoretically because they often correspond to probabilistic interpretations of parameters. For example, if we are seeking the MLE of a probabilistic model parameterized by β, $p(x|\beta)$, adding a regularization term $r(\beta) = \sum_{i=1}^{L} \beta_i^2$ corresponds to adding a Gaussian prior

$$f(\beta_i) = \frac{1}{\sqrt{2\pi\sigma^2}} \text{exp} \left\{ -\frac{\beta_i^2}{2\sigma^2} \right\} \tag{4}$$

and maximizing log probability of the posterior (ignoring constant terms) (Rennie, 2003).

3.1 L_2 Regularization

The simplest form of regularization we can add is L_2 regularization. This is similar to assuming that probability of a word given a topic comes from a Gaussian distribution. While the distribution over topics is typically Dirichlet, Dirichlet distributions have been replaced by logistic normals in topic modeling applications (Blei and Lafferty, 2005) and for probabilistic grammars of language (Cohen and Smith, 2009).

Augmenting the **anchor** objective with an L_2 penalty yields

$$\begin{aligned} \boldsymbol{C}_{i,\cdot} = &\text{argmin}_{C_{i,\cdot}} D_{\text{KL}} \left(\bar{\boldsymbol{Q}}_{i,\cdot} \,||\, \sum_{s_k \in S} C_{i,k} \bar{\boldsymbol{Q}}_{s_k,\cdot} \right) \\ &+ \lambda \|\boldsymbol{C}_{i,\cdot} - \mu_{i,\cdot}\|_2^2, \end{aligned} \tag{5}$$

where regularization weight λ balances the importance of a high-fidelity reconstruction against the regularization, which encourages the anchor coefficients to be close to the vector μ. When the mean vector μ is zero, this encourages the topic coefficients to be zero. In Section 4.3, we use a non-zero mean μ to encode an informed prior to encourage topics to discover specific concepts.

3.2 Beta Regularization

The more common prior for topic models is a Dirichlet prior (Minka, 2000). However, we cannot apply this directly because the optimization is done on a row-by-row basis of the anchor coefficient matrix $\boldsymbol{C}$, optimizing $\boldsymbol{C}$ for a fixed word w for and all topics. If we want to model the probability of a word, it must be the probability of word w in a topic versus all other words.

Modeling this dichotomy (one versus all others in a topic) is possible. The constructive definition of the Dirichlet distribution (Sethuraman, 1994) states that if one has a V-dimensional multinomial $\theta \sim \text{Dir}(\alpha_1 \ldots \alpha_V)$, then the marginal distribution

of θ_w follows $\theta_w \sim \text{Beta}(\alpha_w, \sum_{i \neq w} \alpha_i)$. This is the tool we need to consider the distribution of a single word's probability.

This requires including the topic matrix as part of the objective function. The topic matrix is a linear transformation of the coefficient matrix (Equation 2). The objective for beta regularization becomes

$$\boldsymbol{C}_{i,\cdot} = \text{argmin}_{C_{i,\cdot}} D_{\text{KL}} \left(\bar{\boldsymbol{Q}}_{i,\cdot} \mid\mid \sum_{s_k \in S} C_{i,k} \bar{\boldsymbol{Q}}_{s_k,\cdot} \right) - \lambda \sum_{s_k \in S} \log \left(\text{Beta}(A_{i,k}; a, b) \right), \quad (6)$$

where λ again balances reconstruction against the regularization. To ensure the tractability of this algorithm, we enforce a convex regularization function, which requires that $a > 1$ and $b > 1$. If we enforce a uniform prior—$\mathbb{E}_{\text{Beta}(a,b)}[A_{i,k}] = \frac{1}{V}$—and that the *mode* of the distribution is also $\frac{1}{V}$,[1] this gives us the following parametric form for a and b:

$$a = \frac{x}{V} + 1, \text{ and } b = \frac{(V-1)x}{V} + 1 \quad (7)$$

for real x greater than zero.

3.3 Initialization and Convergence

Equation 5 and Equation 6 are optimized using L-BFGS gradient optimization (Galassi et al., 2003). We initialize $\boldsymbol{C}$ randomly from $\text{Dir}(\alpha)$ with $\alpha = \frac{60}{V}$ (Wallach et al., 2009). We update $\boldsymbol{C}$ after optimizing all V rows. The newly updated $\boldsymbol{C}$ replaces the old topic coefficients. We track how much the topic coefficients $\boldsymbol{C}$ change between two consecutive iterations i and $i+1$ and represent it as $\Delta \boldsymbol{C} \equiv \|\boldsymbol{C}^{i+1} - \boldsymbol{C}^{i}\|_2$. We stop optimization when $\Delta \boldsymbol{C} \leq \delta$. When $\delta = 0.1$, the L_2 and unregularized anchor algorithm converges after a single iteration, while beta regularization typically converges after fewer than ten iterations (Figure 4).

4 Regularization Improves Topic Models

In this section, we measure the performance of our proposed regularized anchor word algorithms. We will refer to specific algorithms in bold. For example, the original anchor algorithm is **anchor**. Our L_2 regularized variant is **anchor-L_2**, and our beta regularized variant is **anchor-beta**. To provide conventional baselines, we also compare our methods against topic models from variational inference (Blei et al., 2003, **variational**) and MCMC (Griffiths and Steyvers, 2004; McCallum, 2002, **MCMC**).

We apply these inference strategies on three diverse corpora: scientific articles from the Neural Information Processing Society (NIPS),[2] Internet newsgroups postings (20NEWS),[3] and New York Times editorials (Sandhaus, 2008, NYT). Statistics for the datasets are summarized in Table 2. We split each dataset into a training fold (70%), development fold (15%), and a test fold (15%): the training data are used to fit models; the development set are used to select parameters (anchor threshold M, document prior α, regularization weight λ); and final results are reported on the test fold.

We use two evaluation measures, held-out likelihood (Blei et al., 2003, **HL**) and topic interpretability (Chang et al., 2009; Newman et al., 2010, **TI**). Held-out likelihood measures how well the model can reconstruct held-out documents that the model has never seen before. This is the typical evaluation for probabilistic models. Topic interpretability is a more recent metric to capture how useful the topics can be to human users attempting to make sense of a large datasets.

Held-out likelihood cannot be computed with existing **anchor** algorithms, so we use the topic distributions learned from **anchor** as input to a reference variational inference implementation (Blei et al., 2003) to compute **HL**. This requires an additional parameter, the Dirichlet prior α for the per-document distribution over topics. We select α using grid search on the development set.

To compute **TI** and evaluate topic coherence, we use normalized pairwise mutual information (NPMI) (Lau et al., 2014) over topics' twenty most probable words. Topic coherence is computed against the NPMI of a reference corpus. For coherence evaluations, we use both intrinsic and extrinsic text collections to compute NPMI. Intrinsic coherence (TI-i) is computed on training and development data at development time and on training and test data at test time. Extrinsic coherence (TI-e) is computed from English Wikipedia articles, with disjoint halves (1.1 million pages each) for distinct development and testing TI-e evaluation.

[1] For $a, b < 1$, the expected value is still the uniform distribution but the mode lies at the boundaries of the simplex. This corresponds to a sparse Dirichlet distribution, which our optimization cannot at present model.

[2] http://cs.nyu.edu/~roweis/data.html

[3] http://qwone.com/~jason/20Newsgroups/

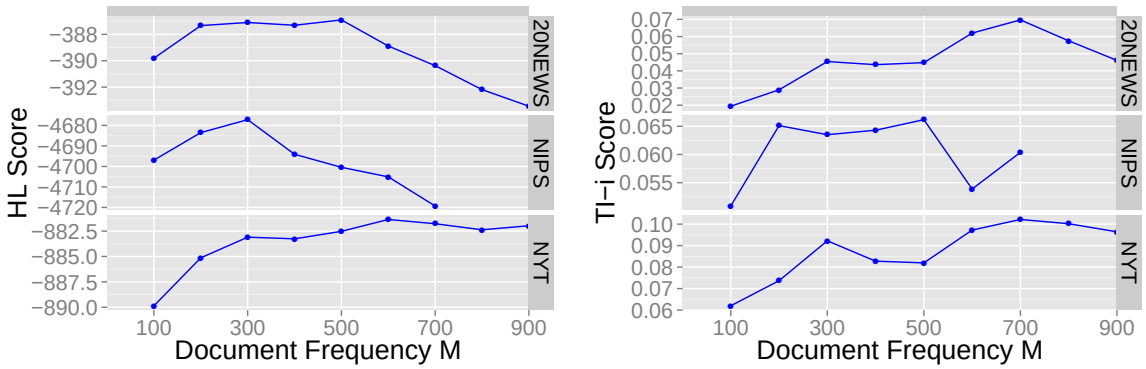

Figure 1: Grid search for document frequency M for our datasets with 20 topics (other configurations not shown) on development data. The performance on both HL and TI score indicate that the unregularized **anchor** algorithm is very sensitive to M. The M selected here is applied to subsequent models.

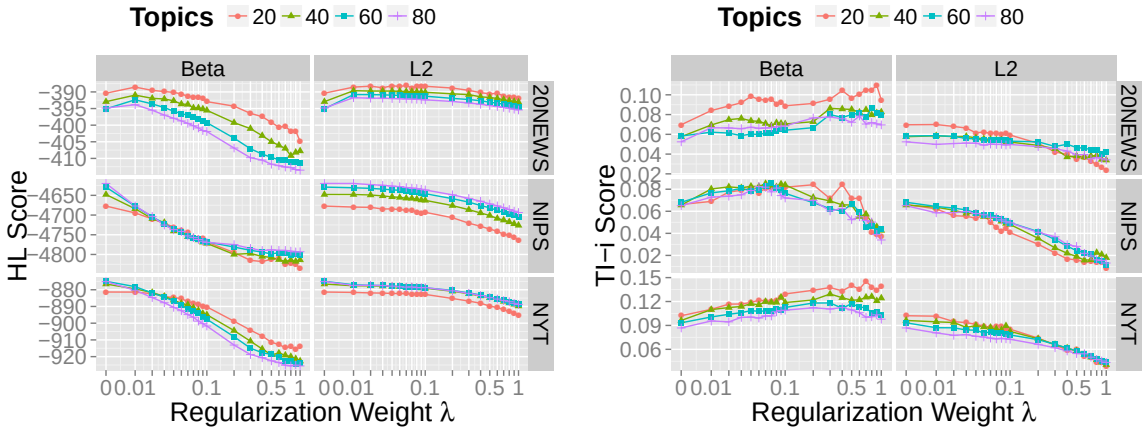

Figure 2: Selection of λ based on HL and TI scores on the development set. The value of $\lambda = 0$ is equivalent to the original **anchor** algorithm; regularized versions find better solutions as the regularization weight λ becomes non-zero.

4.1 Grid Search for Parameters on Development Set

Anchor Threshold A good anchor word must have a unique, specific context but also explain other words well. A word that appears only once will have a very specific cooccurence pattern but will explain other words' coocurrence poorly because the observations are so sparse. As discussed in Section 2, the **anchor** method uses document frequency M as a threshold to only consider words with robust counts.

Because all regularizations benefit equally from higher-quality anchor words, we use cross-validation to select the document frequency cutoff M using the unregularized **anchor** algorithm. Figure 1 shows the performance of **anchor** with different M on our three datasets with 20 topics for our two measures HL and TI-i.

Regularization Weight Once we select a cutoff M for each combination of dataset, number of topics K and a evaluation measure, we select a regularization weight λ on the development set. Figure 2 shows that **beta** regularization framework improves topic interpretability TI-i on all datasets and improved the held-out likelihood HL on 20NEWS. The L_2 regularization also improves held-out likelihood HL for the 20NEWS corpus (Figure 2).

In the interests of space, we do not show the figures for selecting M and λ using TI-e, which is similar to TI-i: **anchor-beta** improves TI-e score on all datasets, **anchor-L_2** improves TI-e on 20NEWS and NIPS with 20 topics and NYT with 40 topics.

4.2 Evaluating Regularization

With document frequency M and regularization weight λ selected from the development set, we

compare the performance of those models on the test set. We also compare with standard implementations of Latent Dirichlet Allocation: Blei's LDAC (**variational**) and Mallet (**mcmc**). We run 100 iterations for LDAC and 5000 iterations for Mallet.

Each result is averaged over three random runs and appears in Figure 3. The highly-tuned, widely-used implementations uniformly have better held-out likelihood than **anchor**-based methods, but the much faster **anchor** methods are often comparable. Within **anchor**-based methods, L_2-regularization offers comparable held-out likelihood as unregularized **anchor**, while **anchor-beta** often has better interpretability. Because of the mismatch between the specialized vocabulary of NIPS and the general-purpose language of Wikipedia, TI-e has a high variance.

4.3 Informed Regularization

A frequent use of priors is to add information to a model. This is not possible with the existing **anchor** method. An informed prior for topic models seeds a topic with words that describe a topic of interest. In a topic model, these seeds will serve as a "magnet", attracting similar words to the topic (Zhai et al., 2012).

We can achieve a similar goal with **anchor-**L_2. Instead of encouraging anchor coefficients to be zero in Equation 5, we can instead encourage word probabilities to close to an arbitrary mean $\mu_{i,k}$. This vector can reflect expert knowledge.

One example of a source of expert knowledge is Linguistic Inquiry and Word Count (Pennebaker and Francis, 1999, LIWC), a dictionary of keywords related to sixty-eight psychological concepts such as positive emotions, negative emotions, and death. For example, it associates "excessive, estate, money, cheap, expensive, living, profit, live, rich, income, poor, etc." for the concept materialism.

We associate each anchor word with its closest LIWC category based on the cooccurrence matrix $\boldsymbol{Q}$. This is computed by greedily finding the anchor word that has the highest cooccurrence score for any LIWC category: we define the score of a category to anchor word w_{s_k} as $\sum_i Q_{s_k,i}$, where i ranges over words in this category; we compute the scores of all categories to all anchor words; then we find the highest score and assign the category to that anchor word; we greedily repeat this process until all anchor words have a category.

Given these associations, we create a goal mean $\mu_{i,k}$. If there are L_i anchor words associated with LIWC word i, $\mu_{i,k} = \frac{1}{L_i}$ if this keyword i is associated with anchor word w_{s_k} and zero otherwise.

We apply **anchor-**L_2 with informed priors on NYT with twenty topics and compared the topics against the original topics from **anchor**. Table 3 shows that the topic with anchor word "soviet", when combined with LIWC, draws in the new words "bush" and "nuclear"; reflecting the threats of force during the cold war. For the topic with topic word "arms", when associated with the LIWC category with the terms "agree" and "agreement", draws in "clinton", who represented a more conciliatory foreign policy compared to his republican predecessors.

5 Discussion

Having shown that regularization can improve the **anchor** topic modeling algorithm, in this section we discuss *why* these regularizations can improve the model and the implications for practitioners.

Efficiency Efficiency is a function of the number of iterations and the cost of each iteration. Both **anchor** and **anchor-**L_2 require a single iteration, although the latter's iteration is slightly more expensive. For **beta**, as described in Section 3.2, we update anchor coefficients C row by row, and then repeat the process over several iterations until it converges. However, it often converges within ten iterations (Figure 4) on all three datasets: this requires much fewer iterations than MCMC or variational inference, and the iterations are less expensive. In addition, since we optimize each row $C_{i,\cdot}$ independently, the algorithm can be easily parallelized.

Sensitivity to Document Frequency While the original **anchor** is sensitive to the document frequency M (Figure 1), adding regularization makes this less critical. Both **anchor-**L_2 and **anchor-beta** are less sensitive to M than **anchor**.

To highlight this, we compare the topics of **anchor** and **anchor-beta** when $M = 100$. As Table 4 shows, the words "article", "write", "don" and "doe" appear in most of **anchor**'s topics. While **anchor-**L_2 also has some bad topics, it still can find reasonable topics, demonstrating **anchor-beta**'s greater robustness to suboptimal M.

L_2 (Sometimes) Improves Generalization As Figure 2 shows, **anchor-**L_2 sometimes improves held-out development likelihood for the smaller

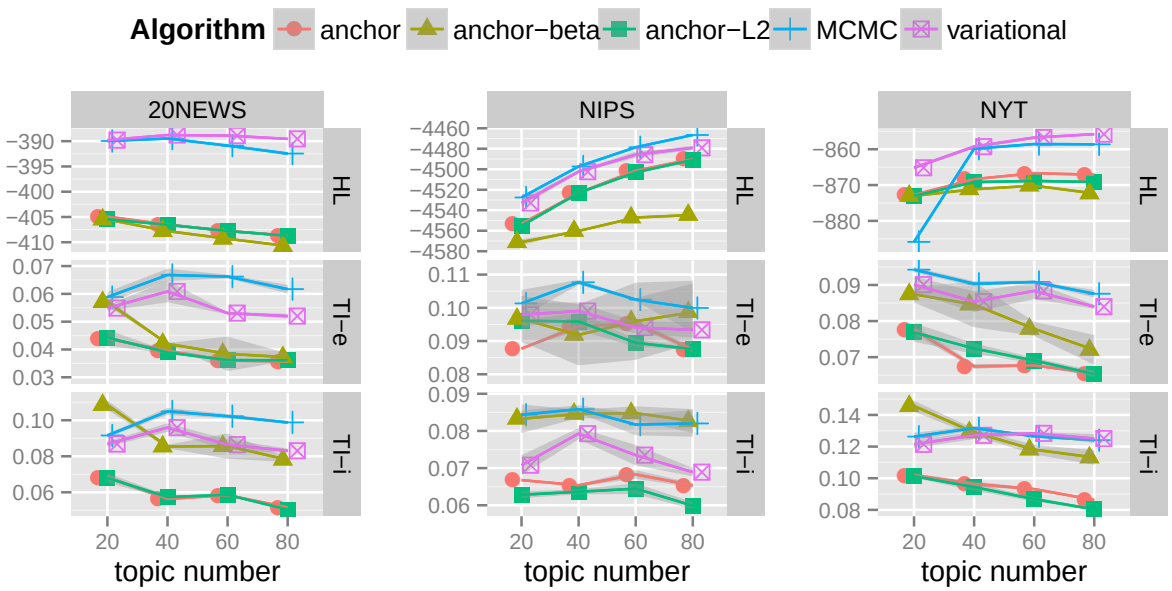

Figure 3: Comparing **anchor-beta** and **anchor-**L_2 against the original **anchor** and the traditional **variational** and **MCMC** on HL score and TI score. **variational** and **mcmc** provide the best held-out generalization. **anchor-beta** sometimes gives the best TI score and is consistently better than **anchor**. The specialized vocabulary of NIPS causes high variance for the extrinsic interpretability evaluation (TI-e).

Topic	Shared Words	Original (Top, green) vs. Informed L_2 (Bottom, orange)

Table 3: Examples of topic comparison between **anchor** and informed **anchor-**L_2. A topic is labeled with the anchor word for that topic. The **bold** words are the informed prior from LIWC. With an informed prior, relevant words appear in the top words of a topic; this also draws in other related terms (red).

20NEWS corpus. However, the λ selected on development data does not always improve test set performance. This, in Figure 3, **anchor-beta** closely tracks **anchor**. Thus, L_2 regularization does not hurt generalization while imparting expressiveness and robustness to parameter settings.

Beta Improves Interpretability Figure 3 shows that **anchor-beta** improves topic interpretability (TI) compared to unregularized anchor methods. In this section, we try to understand why.

We first compare the topics from the original **anchor** against **anchor-beta** to analyze the topics qualitatively. Table 5 shows that **beta** regularization promotes rarer words within a topic and demotes common words. For example, in the topic about hockey with the anchor word game, "run" and "good"—ambiguous, polysemous words—in the unregularized topic are replaced by "playoff"

Topic	anchor	anchor-beta

Table 4: Topics from **anchor** and **anchor-beta** with $M = 100$ on 20NEWS with 20 topics. Each topic is identified with its associated anchor word. When $M = 100$, the topics of **anchor** suffer: the four colored words appear in almost every topic. **anchor-beta**, in contrast, is less sensitive to suboptimal M.

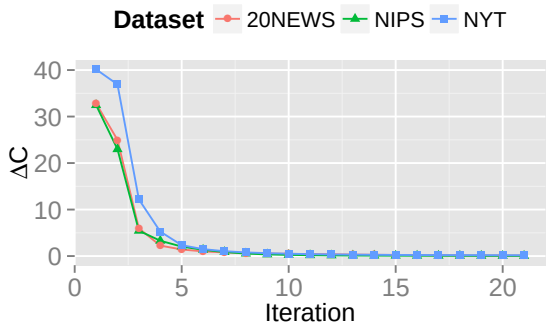

Figure 4: Convergence of anchor coefficient C for **anchor-beta**. ΔC is the difference of current C from the C at the previous iteration. C is converged within ten iterations for all three datasets.

and "trade" in the regularized topic. These words are less ambiguous and more likely to make sense to a consumer of topic models.

Figure 5 shows why this happens. Compared to the unregularized topics from **anchor**, the beta regularized topic steals from the rich and creates a more uniform distribution. Thus, highly frequent words do not as easily climb to the top of the distribution, and the topics reflect topical, relevant words rather than globally frequent terms.

6 Conclusion

A topic model is a popular tool for quickly getting the gist of large corpora. However, running such an analysis on these large corpora entail a substantial computational cost. While techniques such as **anchor** algorithms offer faster solutions, it comes at the cost of the expressive priors common in Bayesian formulations.

This paper introduces two different regularizations that offer users more interpretable models and the ability to inject prior knowledge without sacrificing the speed and generalizability of the underlying approach. However, one sacrifice that this approach does make is the beautiful theoretical guarantees of previous work. An important piece of future work is a theoretical understanding of generalizability in extensible, regularized models.

Incorporating other regularizations could further improve performance or unlock new applications. Our regularizations do not explicitly encourage sparsity; applying other regularizations such as L_1 could encourage true sparsity (Tibshirani, 1994), and structured priors (Andrzejewski et al., 2009) could efficiently incorporate constraints on topic models.

These regularizations could improve spectral algorithms for latent variables models, improving the performance for other NLP tasks such as latent variable PCFGs (Cohen et al., 2013) and HMMs (Anandkumar et al., 2012), combining the flexibility and robustness offered by priors with the speed and accuracy of new, scalable algorithms.

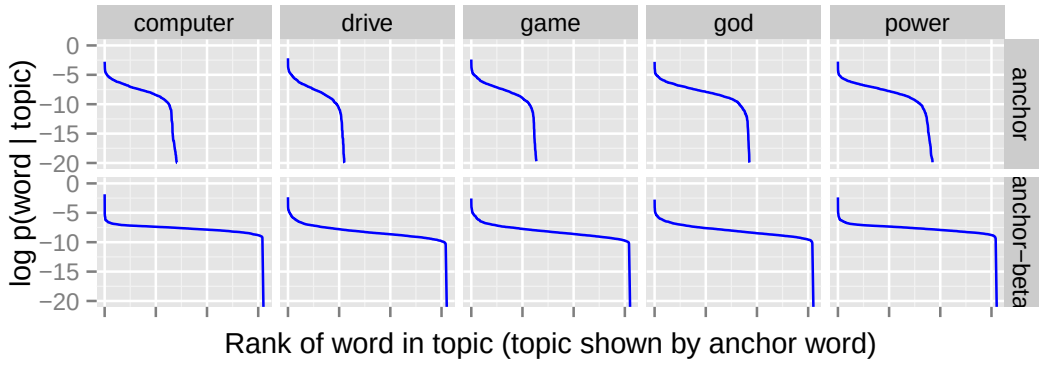

Figure 5: How beta regularization influences the topic distribution. Each topic is identified with its associated anchor word. Compared to the unregularized **anchor** method, **anchor-beta** steals probability mass from the "rich" and prefers a smoother distribution of probability mass. These words often tend to be unimportant, polysemous words common across topics.

Abstract

We consider the problem of automatically inferring latent character types in a collection of 15,099 English novels published between 1700 and 1899. Unlike prior work in which character types are assumed responsible for probabilistically generating *all* text associated with a character, we introduce a model that employs multiple effects to account for the influence of extra-linguistic information (such as author). In an empirical evaluation, we find that this method leads to improved agreement with the preregistered judgments of a literary scholar, complementing the results of alternative models.

1 Introduction

Recent work in NLP has begun to exploit the potential of entity-centric modeling for a variety of tasks: Chambers (2013) places entities at the center of probabilistic frame induction, showing gains over a comparable event-centric model (Cheung et al., 2013); Bamman et al. (2013) explicitly learn character types (or "personas") in a dataset of Wikipedia movie plot summaries; and entity-centric models form one dominant approach in coreference resolution (Durrett et al., 2013; Haghighi and Klein, 2010).

One commonality among all of these very different probabilistic approaches is that each learns statistical regularities about how entities are depicted in text (whether for the sake of learning a set of semantic roles, character types, or linking anaphora to the entities to which they refer). In each case, the text we observe associated with an entity in a document is directly dependent on the class of entity—and only that class. This relationship between entity and text is a theoretical assumption, with important consequences for learning: entity types learned in this way will be increasingly similar the more similar the domain, author, and other extra-linguistic effects are between them.[1] While in many cases the topically similar types learned under this assumption may be desirable, we explore here the alternative, in which entity types are learned in a way that controls for such effects. In introducing a model based on different assumptions, we provide a method that complements past work and provides researchers with more flexible tools to infer different kinds of character types.

We focus here on the literary domain, exploring a large collection of 15,099 English novels published in the 18th and 19th centuries. By accounting for the influence of individual authors while inferring latent character types, we are able to learn personas that cut across different authors more effectively than if we learned types conditioned on the text alone. Modeling the language used to describe a character as the joint result of that character's latent type and of other formal variables allows us to test multiple models of character and assess their value for different interpretive problems. As a test case, we focus on separating character from authorial diction, but this approach can readily be generalized to produce models that provisionally distinguish character from other factors (such as period, genre, or point of view) as well.

2 Literary Background

Inferring character is challenging from a literary perspective partly because scholars have not reached consensus about the meaning of the term. It may seem obvious that a "character" is a representation of a (real or imagined) person, and many humanists do use the term that way. But there is

[1] For example, many entities in Early Modern English texts may be judged to be more similar to each other than to entities from later texts simply by virtue of using *hath* and other archaic verb forms.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 370–379,
Baltimore, Maryland, USA, June 23-25 2014.

an equally strong critical tradition that treats character as a formal dimension of narrative. To describe a character as a "blocking figure" or "first-person narrator," for instance, is a statement less about the attributes of an imagined person than about a narrative function (Keen, 2003). Characters are in one sense collections of psychological or moral attributes, but in another sense "word-masses" (Forster, 1927). This tension between "referential" and "formalist" models of character has been a centrally "divisive question in ... literary theory" (Woloch, 2003).

Considering primary source texts (as distinct from plot summaries) forces us to confront new theoretical questions about character. In a plot summary (such as those explored by Bamman et al., 2013), a human reader may already have used implicit models of character to extract high-level features. To infer character types from raw narrative text, researchers need to explicitly model the relationship of character to narrative form. This is not a solved problem, even for human readers.

For instance, it has frequently been remarked that the characters of Charles Dickens share certain similarities—including a reliance on tag phrases and recurring tics. A referential model of character might try to distinguish this common stylistic element from underlying "personalities." A strictly formalist model might refuse to separate authorial diction from character at all. In practice, human readers can adopt either perspective: we recognize that characters have a "Dickensian" quality but also recognize that a Dickens villain is (in one sense) more like villains in other authors than like a Dickensian philanthropist. Our goal is to show that computational methods can support the same range of perspectives—allowing a provisional, flexible separation between the referential and formal dimensions of narrative.

3 Data

The dataset for this work consists of 15,099 distinct narratives drawn from HathiTrust Digital Library.[2] From an initial collection of 469,200 volumes written in English and published between 1700 and 1899 (including poetry, drama, and nonfiction as well as prose narrative), we extract 32,209 volumes of prose fiction, remove duplicates and fuse multi-volume works to create the final dataset. Since the original texts were produced by scanning and running OCR on physical books, we automatically correct common OCR errors and trim front and back matter from the volumes using the page-level classifiers and HMM of Underwood et al. (2013)

Many aspects of this process would be simpler if we used manually-corrected texts, such as those drawn from Project Gutenberg. But we hope to produce research that has historical as well as computational significance, and doing so depends on the provenance of a collection. Gutenberg's decentralized selection process tends to produce exceptionally good coverage of currently-popular genres like science fiction, whereas HathiTrust aggregates university libraries. Library collections are not guaranteed to represent the past perfectly, but they are larger, and less strongly shaped by contemporary preferences.

The goal of this work is to provide a method to infer a set of character types in an unsupervised fashion from the data. As with prior work (Bamman et al., 2013), we define this target, a character *persona*, as a distribution over several categories of typed dependency relations:[3]

1. agent: the actions of which a character is the agent (i.e., verbs for which the character holds an nsubj or agent relation).
2. patient: the actions of which a character is the patient (i.e., verbs for which the character holds a dobj or nsubjpass relation).
3. possessive: the objects that a character possesses (i.e., all words for which the character holds a poss relation).
4. predicative: attributes predicated of a character (i.e., adjectives or nouns holding an nsubj relation to the character, with an inflection of *be* as a child).

This set captures the constellation of what a character *does* and *has done to them*, what they *possess*, and what they are described as *being*.

While previous work uses the Stanford CoreNLP toolkit to identify characters and extract typed dependencies for them, we found this approach to be too slow for the scale of our data (a total of 1.8 billion tokens); in particular, syntactic parsing, with cubic complexity in sentence length, and out-of-the-box coreference resolution (with thousands of potential antecedents) prove to be

[2] http://www.hathitrust.org

[3] All categories are described using the Stanford typed dependencies (de Marneffe and Manning, 2008), but any syntactic formalism is equally applicable.

the biggest bottlenecks.

Before addressing character inference, we present here a prerequisite NLP pipeline that scales well to book-length documents.[4] This pipeline uses the Stanford POS tagger (Toutanova et al., 2003), the linear-time MaltParser (Nivre et al., 2007) for dependency parsing (trained on Stanford typed dependencies), and the Stanford named entity recognizer (Finkel et al., 2005). It includes the following components for clustering character name mentions, resolving pronominal coreference, and reducing vocabulary dimensionality.

3.1 Character Clustering

First, let us terminologically distinguish between a character *mention* in a text (e.g., the token *Tom* on page 141 of *The Adventures of Tom Sawyer*) and a character *entity* (e.g., TOM SAWYER the character, to which that token refers). To resolve the former to the latter, we largely follow Davis et al. (2003) and Elson et al. (2010): we define a set of initial characters corresponding to each unique character name that is not a subset of another (e.g., *Mr. Tom Sawyer*) and deterministically create a set of allowable variants for each one (*Mr. Tom Sawyer* → *Tom*, *Sawyer*, *Tom Sawyer*, *Mr. Sawyer*, and *Mr. Tom*); then, from the beginning of the book to the end, we greedily assign each mention to the most recently linked entity for whom it is a variant. The result constitutes our set of characters, with all mentions partitioned among them.

3.2 Pronominal Coreference Resolution

While the character clustering stage is essentially performing proper noun coreference resolution, approximately 74% of references to characters in books come in the form of pronouns.[5] To resolve this more difficult class at the scale of an entire book, we train a log-linear discriminative classifier only on the task of resolving *pronominal* anaphora (i.e., ignoring generic noun phrases such as *the paint* or *the rascal*).

For this task, we annotated a set of 832 coreference links in 3 books (*Pride and Prejudice*, *The Turn of the Screw*, and *Heart of Darkness*) and featurized coreference/antecedent pairs with:

1. The syntactic dependency path from a pronoun to its potential antecedent (e.g., dobj↑pred→↓pred↓nsubj (where → denotes movement across sentence boundaries).
2. The salience of the antecedent character (defined as the count of that character's named mentions in the previous 500 words).
3. The antecedent part of speech.
4. Whether or not the pronoun and antecedent appear in the same quotation scope (false if one appears in a quotation and one outside).
5. Whether or not the two agree for gender.
6. The syntactic tree distance between the two.
7. The linear (word) distance between the two.

With this featurization and training data, we train a binary logistic regression classifier with ℓ_1 regularization (where negative examples are comprised of all character entities in the previous 100 words not labeled as the true antecedent). In a 10-fold cross-validation on predicting the true nearest antecedent for a pronominal anaphor, this method achieves an average accuracy of 82.7%.

With this trained model, we then select the highest-scoring antecedent within 100 words for each pronominal anaphor in our data.

3.3 Dimensionality Reduction

To manage the degrees of freedom in the model described in §4, we perform dimensionality reduction on the vocabulary by learning word embeddings with a log-linear continuous skip-gram language model (Mikolov et al., 2013) on the entire collection of 15,099 books. This method learns a low-dimensional real-valued vector representation of each word to predict all of the words in a window around it; empirically, we find that with a sufficient window size (we use $n = 10$), these word embeddings capture semantic similarity (placing topically similar words near each other in vector space).[6] We learn a 100-dimensional embedding for each of the 512,344 words in our vocabulary.

To create a partition over the vocabulary, we use hard K-means clustering (with Euclidean distance) to group the 512,344 word types into 1,000 clusters. We then agglomeratively cluster those 1,000 groups to assign bitstring representations to each one, forming a balanced binary tree by only merging existing clusters at equal levels in the hi-

[4] All code is available at `http://www.ark.cs.cmu.edu/literaryCharacter`

[5] Over all 15,099 narratives, the average number of character proper name mentions is 1,673; the average number of gendered singular pronouns (*he, she, him, his, her*) is 4,641.

[6] In comparison, Brown et al. (1992) clusters learned from the same data capture *syntactic* similarity (placing functionally similar words in the same cluster).

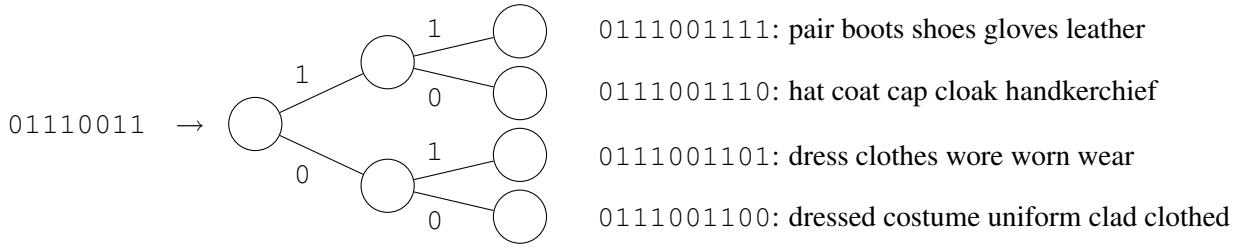

Figure 1: Bitstring representations of neural agglomerative clusters, illustrating the leaf nodes in a binary tree rooted in the prefix `01110011`. Bitstring encodings of intermediate nodes and terminal leaves result by following the left (`0`) and right (`1`) branches of the merge tree created through agglomerative clustering.

erarchy. We use Euclidean distance as a fundamental metric and a group-average similarity function for calculating the distance between groups. Fig. 1 illustrates four of the 1,000 learned clusters.

4 Model

In order to separate out the effects that a character's persona has on the words that are associated with them (as opposed to other factors, such as time period, genre, or author), we adopt a hierarchical Bayesian approach in which the words we observe are generated conditional on a combination of different effects captured in a log-linear (or "maximum entropy") distribution.

Maximum entropy approaches to language modeling have been used since Rosenfeld (1996) to incorporate long-distance information, such as previously-mentioned trigger words, into n-gram language models. This work has since been extended to a Bayesian setting by applying both a Gaussian prior (Chen and Rosenfeld, 2000), which dampens the impact of any individual feature, and sparsity-inducing priors (Kazama and Tsujii, 2003; Goodman, 2004), which can drive many feature weights to 0. The latter have been applied specifically to the problem of estimating word probabilities with sparse additive generative (SAGE) models (Eisenstein et al., 2011), where sparse extra-linguistic effects can influence a word probability in a larger generative setting.

In contrast to previous work in which the probability of a word linked to a character is dependent entirely on the character's latent persona, in our model, we see the probability of a word as dependent on: (i) the **background** likelihood of the word, (ii) the **author**, so that a word becomes more probable if a particular author tends to use it more, and (iii) the character's **persona**, so that a word is more probable if appearing with a particular persona. Intuitively, if the author *Jane Austen* is associated with a high weight for the word *manners*, and all personas have little effect for this word, then *manners* will have little impact on deciding which persona a particular Austen character embodies, since its presence is explained largely by Austen having penned the word. While we address only the author as an observed effect, this model is easily extended to other features as well, including period, genre, point of view, and others.

The generative story runs as follows (Figure 2 depicts the full graphical model): Let there be M unique authors in the data, P latent personas (a hyperparameter to be set), and V words in the vocabulary (in the general setting these may be word types; in our data the vocabulary is the set of 1,000 unique cluster IDs). Each role type $r \in \{\textsf{agent}, \textsf{patient}, \textsf{possessive}, \textsf{predicative}\}$ and vocabulary word v (here, a cluster ID) is associated with a real-valued vector $\eta_{r,v} = [\eta^{meta}_{r,v}, \eta^{pers}_{r,v}, \eta^{0}_{r,v}]$ of length $M + P + 1$. The first $M + P$ elements are drawn from a Laplace prior with mean $\mu = 0$ and scale $\lambda = 1$; the last element $\eta^{0}_{r,v}$ is an unregularized bias term accounting for the background. Each element in this vector captures the log-additive effect of each author, persona, and the background distribution on the word's probability (Eq. 1, below).

Much like latent Dirichlet allocation (Blei et al., 2003), each document d in our dataset draws a multinomial distribution θ_d over personas from a shared Dirichlet prior α, which captures the proportion of each character type in that particular document. Every character c in the document draws its persona p from this document-specific multinomial. Given document metadata m (here, one of a set of M authors) and persona p, each tuple of a role r with word w is assumed to be drawn from Eq. 1 in Fig. 3. This SAGE model can be understood as a log-linear distribution with three kinds of features (metadata, persona, and back-

$$P(w \mid m, p, r, \eta) = \exp\left(\eta^{meta}_{r,w}[m] + \eta^{pers}_{r,w}[p] + \eta^{0}_{r,w}\right) \Big/ \sum_{v=1}^{V} \exp\left(\eta^{meta}_{r,v}[m] + \eta^{pers}_{r,v}[p] + \eta^{0}_{r,v}\right) \quad (1)$$

$$P(b \mid m, p, r, \eta) = \prod_{j=0}^{n-1} \begin{cases} \text{logit}^{-1}\left(\eta^{meta}_{r,b_{1:j}}[m] + \eta^{pers}_{r,b_{1:j}}[p] + \eta^{0}_{r,b_{1:j}}\right) & \text{if } b_{j+1} = 1 \\ 1 - \text{logit}^{-1}\left(\eta^{meta}_{r,b_{1:j}}[m] + \eta^{pers}_{r,b_{1:j}}[p] + \eta^{0}_{r,b_{1:j}}\right) & \text{otherwise} \end{cases} \quad (2)$$

Figure 3: Parameterizations of the SAGE word distribution. Eq. 1 is a "flat" multinomial logistic regression with one η-vector per role and word. Eq. 2 uses the hierarchical softmax formulation, with one η-vector per role and node in the binary tree of word clusters, giving a distribution over bit strings (b) with the same number of parameters as Eq. 1.

ground bias).

4.1 Hierarchical Softmax

The partition function in Eq. 1 can lead to slow inference for any reasonably-sized vocabulary. To address this, we reparameterize the model by exploiting the structure of the agglomerative clustering in §3.3 to perform a hierarchical softmax, following Goodman (2001), Morin and Bengio (2005) and Mikolov et al. (2013).

The bitstring representations by which we encode each word in the vocabulary serve as natural, and inherently meaningful, intermediate classes that correspond to semantically related subsets of the vocabulary, with each bitstring prefix denoting one such class. Longer bitstrings correspond to more fine-grained classes. In the example shown in Figure 1, `011100111` is one such intermediate class, containing the union of *pair, boots, shoes, gloves leather* and *hat, coat, cap cloak, handkerchief*. Because these classes recursively partition the vocabulary, they offer a convenient way to reparameterize the model through the chain rule of probability.

Consider, for example, a word represented as the bitstring $c = \texttt{01011}$; calculating $P(c = \texttt{01011})$—we suppress conditioning variables for clarity—involves the product: $P(c_1 = \texttt{0}) \times P(c_2 = \texttt{1} \mid c_1 = \texttt{0}) \times P(c_3 = \texttt{0} \mid c_{1:2} = \texttt{01}) \times P(c_4 = \texttt{1} \mid c_{1:3} = \texttt{010}) \times P(c_5 = \texttt{1} \mid c_{1:4} = \texttt{0101})$.

Since each multiplicand involves a binary prediction, we can avoid partition functions and use the classic binary logistic regression.[7] We have converted the V-way multiclass logistic regression problem of Eq. 1 into a sequence of $\log V$ evaluations (assuming a perfectly balanced tree). Given m, p, and r (as above) we let $b = b_1 b_2 \cdots b_n$ denote the bitstring representation of a word cluster, and the distribution is given by Eq. 2 in Fig. 3.

In this paramaterization, rather than one η-vector for each role and vocabulary term, we have one η-vector for each role and conditional binary decision in the tree (each bitstring prefix). Since the tree is binary with V leaves, this yields the same total number of parameters. As Goodman (2001) points out, while this reparameterization is exact for true probabilities, it remains an approximation for estimated models (with generalization behavior dependent on how well the class hierarchy is supported by the data). In addition to enabling faster inference, one advantage of the bitstring representation and the hierarchical softmax parameterization is that we can easily calculate probabilities of clusters at different granularities.

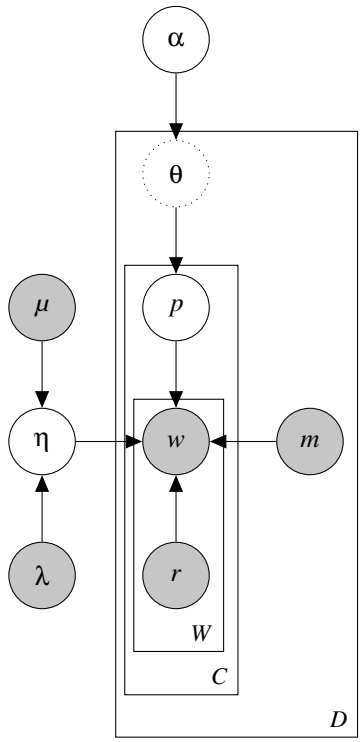
4.2 Inference

Our primary quantities of interest in this model are p (the personas for each character) and η, the effects that each author and persona have on the probability of a word. Rather than adopting a fully Bayesian approach (e.g., sampling all variables), we infer these values using stochastic EM, alternating between collapsed Gibbs sampling for each p and maximizing with respect to η.

Collapsed Gibbs for personas.[8] At each step, the required quantity is the probability that character c in document d has persona z, given everything else. This is proportional to the number of other characters in document d who also (currently) have that persona (plus the Dirichlet hyperparameter which acts as a smoother) times the probability (under $p_{d,c} = z$) of all of the words

[7] Recall that logistic regression lets $P_{LR}(y = 1 \mid x, \beta) = \text{logit}^{-1}(x^\top \beta) = 1/(1 + \exp -x^\top \beta)$ for binary dependent variable y, independent variables x, and coefficients β.

[8] We assume the reader is familiar with collapsed Gibbs sampling as used in latent-variable NLP models.



P	Number of personas (hyperparameter)
D	Number of documents
C_d	Number of characters in document d
$W_{d,c}$	Number of (cluster, role) tuples for character c
m_d	Metadata for document d (ranges over M authors)
θ_d	Document d's distribution over personas
$p_{d,c}$	Character c's persona
j	An index for a $\langle r, w \rangle$ tuple in the data
w_j	Word cluster ID for tuple j
r_j	Role for tuple $j \in \{\textsf{agent}, \textsf{patient}, \textsf{poss}, \textsf{pred}\}$
η	Coefficients for the log-linear language model
μ, λ	Laplace mean and scale (for regularizing η)
α	Dirichlet concentration parameter

Figure 2: **Above:** Probabilistic graphical model. Observed variables are shaded, latent variables are clear, and collapsed variables are dotted. **Below:** Definition of variables.

observed in each role r for that character:

$$(count(z; p_{d,-c}) + \alpha_z) \times \prod_{r=1}^{R} \prod_{j:r_j=r} P(b_j \mid m, p, r, \eta) \quad (3)$$

The metadata features (like author, etc.) influence this probability by being constant for all choices of z; e.g., if the coefficient learned for *Austen* for vocabulary term *manners* is high and all coefficients for all z are close to zero, then the probability of *manners* will change little under different choices of z. Eq. 3 contains one multiplicand for every word associated with a character, and only one term reflecting the influence of the shared document multinomial. The implication is that, for major characters with many observed words, the words will dominate the choice of persona; where the document influence would have a bigger effect is with characters for whom we don't have much data. In that case, it can act as a kind of informed background; given what little data we have for that character, it would nudge us toward the character types that the other characters in the book embody.

Given an assignment of all p, we choose η to maximize the conditional log-likelihood of the words, as represented by their bitstring cluster IDs, given the observed author and background effects and the sampled personas. This equates to solving $4V$ ℓ_1-regularized logistic regressions (see Eq. 2 in Figure 3), one for each role type and bitstring prefix, each with $M + P + 1$ parameters. We apply OWL-QN (Andrew and Gao, 2007) to minimize the ℓ_1-regularized objective with an absolute convergence threshold of 10^{-5}.

5 Evaluation

While standard NLP and machine learning practice is to evaluate the performance of an algorithm on a held-out gold standard, articulating what a true "persona" might be for a character is inherently problematic. Rather, we evaluate the performance and output of our model by preregistering a set of 29 hypotheses of varying scope and difficulty and comparing the performance of different models in either confirming, or failing to confirm, those hypotheses. This kind of evaluation was previously applied to a subjective text measurement problem by Sim et al. (2013).

All hypotheses were created by a literary scholar with specialization in the period to not only give an empirical measure of the strengths and weaknesses of different models, but also to help explore exactly what the different models may, or may not, be learning. All preregistered hypotheses establish the degrees of similarity among three characters, taking the form: "character X is more similar to character Y than either X or Y is to a distractor character Z"; for a given model and definition of distance under that model, each hypothesis yields two yes/no decisions that we can evaluate:

- $distance(X, Y) < distance(X, Z)$
- $distance(X, Y) < distance(Y, Z)$

To tease apart the different kinds of similarities we hope to explore, we divide the hypotheses into four classes:

A. This class constitutes **sanity checks**: character X and Y are more similar to each other in every way than to character Z. E.g.: Elizabeth Bennet in *Pride and Prejudice* resembles Elinor Dashwood in *Sense and Sensibility* (Jane Austen) more than either character resembles Allen Quatermain in *Allen Quatermain* (H. Rider Haggard). (Austenian protagonists should resemble each other more than they resemble a grizzled hunter.)
B. This class captures our ability to identify two characters in the same author as being more similar to each other than to a closely related character in a **different** author. E.g.: Wickham in *Pride and Prejudice* resembles Willoughby in *Sense and Sensibility* (Jane Austen) more than either character resembles Mr. Rochester in *Jane Eyre* (Charlotte Brontë).
C. This class captures our ability to discriminate among similar characters in the **same** author. In these hypotheses, two characters X and Y from the same author are more similar to each other than to a third character Z from that same author. E.g.: Wickham in *Pride and Prejudice* (Jane Austen) resembles Willoughby in *Sense and Sensibility* more than either character resembles Mr. Darcy in *Pride and Prejudice.*
D. This class constitutes more difficult, **exploratory** hypotheses, including differences among point of view. E.g.: Montoni in *Mysteries of Udolpho* (Radcliffe) resembles Heathcliff in *Wuthering Heights* (Emily Brontë) more than either resembles Mr. Bennet in *Pride and Prejudice.* (Testing our model's ability to discern similarities in spite of elapsed time.)

All 29 hypotheses can be found in a supplementary technical report (Bamman et al., 2014). We emphasize that the full set of hypotheses was locked *before* the model was estimated.

6 Experiments

Part of the motivation of our mixed effects model is to be able to tackle hypothesis class C—by factoring out the influence of a particular author on the learning of personas, we would like to be able to discriminate between characters that all have a common authorial voice. In contrast, the Persona Regression model of Bamman et al. (2013), which uses metadata variables (like authorship) to encourage entities with similar covariates to have similar personas, reflects an assumption that makes it likely to perform well at class B.

To judge their respective strengths on different hypothesis classes, we evaluate three models:

1. The mixed-effects Author/Persona model (described above), which includes author information as a metadata effect; here, each η-vector (of length $M + P + 1$) contains a parameter for each of the distinct authors in our data, a parameter for each persona, and a background parameter.
2. A Basic persona model, which ablates author information but retains the same log-linear architecture; here, the η-vector is of size $P + 1$ and does not model author effects.
3. The Persona Regression model of Bamman et al. (2013).

All models are run with $P \in \{10, 25, 50, 100, 250\}$ personas; Persona Regression additionally uses $K = 25$ latent topics. All configurations use the full dataset of 15,099 novels, and all characters with at least 25 total roles (a total of 257,298 entities). All experiments are run with 50 iterations of Gibbs sampling to collect samples for the personas p, alternating with maximization steps for η. The value of α is optimized using slice sampling (with a non-informative prior) every 5 iterations. The value of λ is held constant at 1. At the end of inference, we calculate the posterior distributions over personas for all characters as the sampling probability of the final iteration.

To formally evaluate "similarity" between two characters, we measure the Jensen-Shannon divergence between personas (calculated as the average JS distance over the cluster distributions for each role type), marginalizing over the characters' posterior distributions over personas; two characters with a lower JS divergence are judged to be more similar than two characters with a higher one.

As a Baseline, we also evaluate all hypotheses on a model with no latent variables whatsoever, which instead measures similarity as the average JS divergence between the empirical word distributions over each role type.

Table 1 presents the results of this comparison; for all models with latent variables, we report the average of 5 sampling runs with different random initializations. Figure 4 provides a syn-

P	Model	Hypothesis Class A	B	C	D
250	Author/Persona	1.00	0.58	0.75	0.42
	Basic Persona	1.00	0.73	0.58	0.53
	Persona Reg.	0.90	0.70	0.58	0.44
100	Author/Persona	0.98	0.68	0.70	0.46
	Basic Persona	0.95	0.73	0.53	0.47
	Persona Reg.	0.93	0.78	0.63	0.49
50	Author/Persona	0.95	0.73	0.63	0.50
	Basic Persona	0.98	0.75	0.48	0.53
	Persona Reg.	1.00	0.75	0.65	0.38
25	Author/Persona	1.00	0.63	0.65	0.50
	Basic Persona	1.00	0.63	0.50	0.50
	Persona Reg.	0.90	0.78	0.60	0.39
10	Author/Persona	0.95	0.63	0.70	0.51
	Basic Persona	0.78	0.80	0.48	0.46
	Persona Reg.	0.90	0.73	0.43	0.41
Baseline		1.00	0.63	0.58	0.37

Table 1: Agreement rates with preregistered hypotheses, averaged over 5 sampling runs with different initializations.

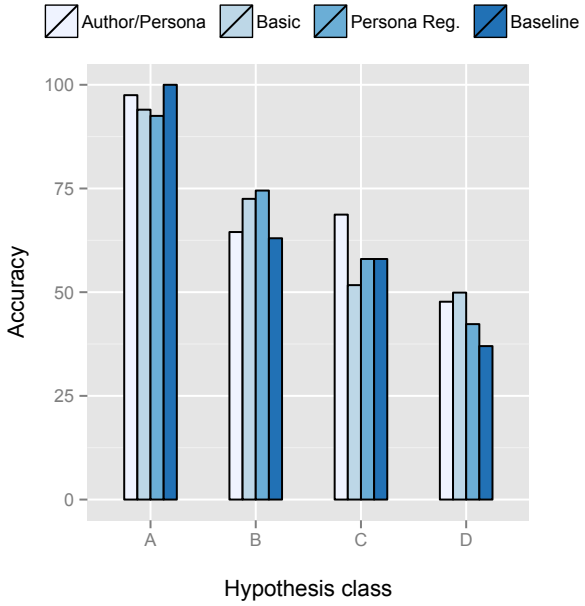


Figure 4: Synopsis of table 1: average accuracy across all P. Persona regression is best able to judge characters in one author to be more similar to each other than to characters in another (B), while our mixed-effects Author/Persona model outperforms other models at discriminating characters in the same author (C).

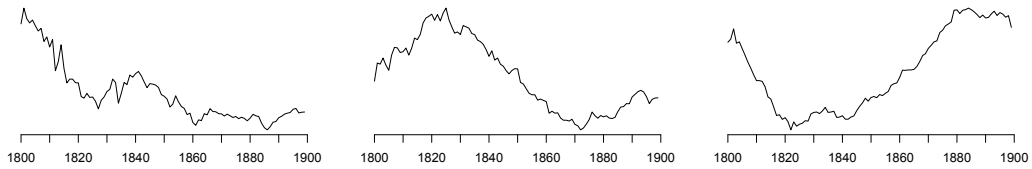
opsis of this table by illustrating the average accuracy across all choice of P. All models, including the baseline, perform well on the sanity checks (A). As expected, the Persona Regression model performs best at hypothesis class B (correctly judging two characters from the same author to be more similar to each other than to a character from a different author); this behavior is encouraged in this model by allowing an author (as an external metadata variable) to directly influence the persona choice, which has the effect of pushing characters from the same author to embody the same character type. Our mixed effects Author/Persona model, in contrast, outperforms the other models at hypothesis class C (correctly discriminating different character types present in the same author). By discounting author-specific lexical effects during persona inference, we are better able to detect variation among the characters of a single author that we are not able to capture otherwise. While these different models complement each other in this manner, we note that there is no absolute separation among them, which may be suggestive of the degree to which the formal and referential dimensions are fused in novels. Nevertheless, the strengths of these different models on these different hypothesis classes gives us flexible alternatives to use depending on the kinds of character types we are looking to infer.

7 Analysis

The latent personas inferred from this model will support further exploratory analysis of literary history. Figure 2 illustrates this with a selection of three character types learned, displaying characteristic clusters for all role types, along with the distribution of that persona's use across time and the gender distribution of characters embodying that persona. In general, the personas learned so far do not align neatly with character types known to literary historians. But they do have legible associations both with literary genres and with social categories. Even though gender is not an observable variable known to the model during inference, personas tend to be clearly gendered. This is not in itself surprising (since literary scholars know that assumptions about character are strongly gendered), but it does suggest that diachronic analysis of latent character types might cast new light on the history of gender in fiction. This is especially true since the distribution of personas across the time axis similarly reveals coherent trends.

Table 3 likewise illustrates what our model learns by presenting a sample of the fixed effects learned for a set of five major 19th-century authors. These are clusters that are conditionally more likely to appear associated with a character in a work by the given author than they are in the overall data; by factoring this information out of the inference process for learning character types (by attributing its presence in a text to the author



Agent	carried ran threw rose fell suddenly is seems	sent received arrived appeared struck showed returned immediately waiting	turns begins returns thinks loves calls does knows comes
Patient	wounded killed murdered suffer yield acknowledge free saved unknown	wounded killed murdered destroy bind crush attend haste proceed	thinks loves calls love hope true turn hold show
Poss	death happiness future lips cheek brow mouth fingers tongue	army officers troops soldiers band armed party join camp	lips cheek brow eyes face eye table bed chair
Pred	crime guilty murder youth lover hers dead living died	king emperor throne general officer guard soldier knight hero	beautiful fair fine good kind ill dead living died
% Female	12.2	3.7	54.7

Table 2: Snapshots of three personas learned from the $P = 50$, Author/Persona model. Gender and time proportions are calculated by summing and normalizing the posterior distributions over all characters with that feature. We truncate time series at 1800 due to data sparsity before that date; the y-axis illustrates the frequency of its use in a given year, relative to its lifetime.

Author	clusters
Jane Austen	praise gift consolation letter read write character natural taste
Charlotte Brontë	lips cheek brow book paper books hat coat cap
Charles Dickens	hat coat cap table bed chair hand head hands
Herman Melville	boat ship board hat coat cap feet ground foot
Jules Verne	journey travel voyage master company presence success plan progress

Table 3: Characteristic possessive clusters in a sample of major 19th-century authors.

rather than the persona), we are able to learn personas that cut across different topics more effectively than if a character type is responsible for explaining the presence of these terms as well.

8 Conclusion

Our method establishes the possibility of representing the relationship between character and narrative form in a hierarchical Bayesian model. Postulating an interaction between authorial diction and character allows models that consider the effect of the author to more closely reproduce a human reader's judgments, especially by learning to distinguish different character types within a single author's oeuvre. This opens the door to considering other structural and formal dimensions of narration. For instance, representation of character is notoriously complicated by narrative point of view (Booth, 1961); and indeed, comparisons between first-person narrators and other characters are a primary source of error for all models tested above. The strategy we have demonstrated suggests that it might be productive to address this by modeling the interaction of character and point of view as a separate effect analogous to authorship.

It is also worth noting that the models tested above diverge from many structuralist theories of narrative (Propp, 1998) by allowing multiple instances of the same persona in a single work. Learning structural limitations on the number of "protagonists" likely to coexist in a single story, for example, may be another fruitful area to explore. In all cases, the machinery of hierarchical models gives us the flexibility to incorporate such effects at will, while also being explicit about the theoretical assumptions that attend them.

9 Acknowledgments

We thank the reviewers for their helpful comments. The research reported here was supported by a National Endowment for the Humanities start-up grant to T.U., U.S. National Science Foundation grant CAREER IIS-1054319 to N.A.S., and an ARCS scholarship to D.B. This work was made possible through the use of computing resources made available by the Pittsburgh Supercomputing Center. Eleanor Courtemanche provided advice about the history of narrative theory.

Abstract

Wikification for tweets aims to automatically identify each concept mention in a tweet and link it to a concept referent in a knowledge base (e.g., Wikipedia). Due to the shortness of a tweet, a collective inference model incorporating global evidence from multiple mentions and concepts is more appropriate than a non-collecitve approach which links each mention at a time. In addition, it is challenging to generate sufficient high quality labeled data for supervised models with low cost. To tackle these challenges, we propose a novel semi-supervised graph regularization model to incorporate both local and global evidence from multiple tweets through three fine-grained relations. In order to identify semantically-related mentions for collective inference, we detect meta path-based semantic relations through social networks. Compared to the state-of-the-art supervised model trained from 100% labeled data, our proposed approach achieves comparable performance with 31% labeled data and obtains 5% absolute F1 gain with 50% labeled data.

1 Introduction

With millions of tweets posted daily, Twitter enables both individuals and organizations to disseminate information, from current affairs to breaking news in a timely fashion. In this work, we study the wikification (Disambiguation to Wikipedia) task (Mihalcea and Csomai, 2007) for tweets, which aims to automatically identify each *concept mention* in a tweet, and link it to a *concept* referent in a knowledge base (KB) (e.g., Wikipedia). For example, as shown in Figure 1, *Hawks* is an identified mention, and its correct referent concept in Wikipedia is *Atlanta Hawks*. An end-to-end wikification system needs to solve two sub-problems: (i) concept mention detection, (ii) concept mention disambiguation.

Wikification is a particularly useful task for short messages such as tweets because it allows a reader to easily grasp the related topics and enriched information from the KB. From a system-to-system perspective, wikification has demonstrated its usefulness in a variety of applications, including coreference resolution (Ratinov and Roth, 2012) and classification (Vitale et al., 2012).

Sufficient labeled data is crucial for supervised models. However, manual wikification annotation for short documents is challenging and time-consuming (Cassidy et al., 2012). The challenges are: (i) *unlinkability*, a valid concept may not exist in the KB. (ii) *ambiguity*, it is impossible to determine the correct concept due to the dearth of information within a single tweet or multiple correct answer. For instance, it would be difficult to determine the correct referent concept for "*Gators*" in t_1 in Figure 1. Linking "*UCONN*" in t_3 to *University of Connecticut* may also be acceptable since *Connecticut Huskies* is the athletic team of the university. (iii) *prominence*, it is challenging to select a set of linkable mentions that are important and relevant. It is not tricky to select "*Fans*", "*slump*", and "*Hawks*" as linkable mentions, but other mentions such as "*stay up*" and "*stay positive*" are not prominent. Therefore, it is challenging to create sufficient high quality labeled tweets for supervised models and worth considering semi-supervised learning with the exploration of unlabeled data.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 380–390,
Baltimore, Maryland, USA, June 23-25 2014.

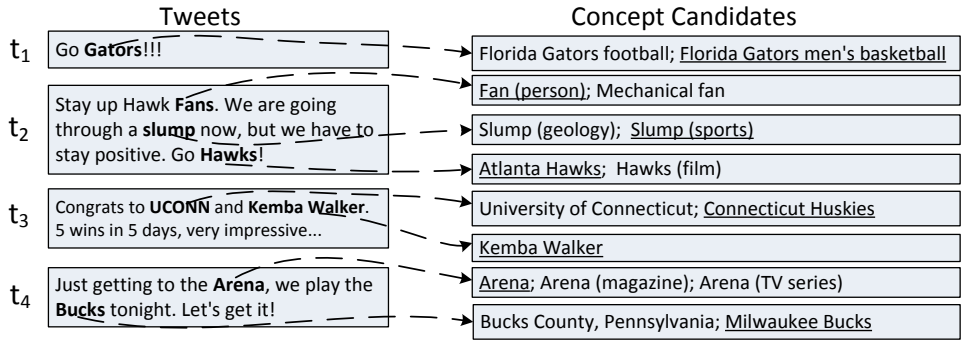

Figure 1: An illustration of Wikification Task for Tweets. Concept mentions detected in tweets are marked as bold, and correctly linked concepts are underlined. The concept candidates are ranked by their prior popularity which will be explained in section 4.1, and only top 2 ranked concepts are listed.

However, when selecting semi-supervised learning frameworks, we noticed another unique challenge that tweets pose to wikification due to their informal writing style, shortness and noisiness. The context of a single tweet usually cannot provide enough information for prominent mention detection and similarity computing for disambiguation. Therefore, a collective inference model over multiple tweets in the semi-supervised setting is desirable. For instance, the four tweets in Figure 1 are posted by the same author within a short time period. If we perform collective inference over them we can reliably link ambiguous mentions such as "*Gators*", "*Hawks*", and "*Bucks*" to basketball teams instead of other concepts such as the county *Bucks County*.

In order to address these unique challenges for wikification for the short tweets, we employ graph-based semi-supervised learning algorithms (Zhu et al., 2003; Smola and Kondor, 2003; Blum et al., 2004; Zhou et al., 2004; Talukdar and Crammer, 2009) for collective inference by exploiting the manifold (cluster) structure in both unlabeled and labeled data. These approaches normally assume label smoothness over a defined graph, where the nodes represent a set of labeled and unlabeled instances, and the weighted edges reflect the closeness of each pair of instances. In order to construct a semantic-rich graph capturing the similarity between mentions and concepts for the model, we introduce three novel fine-grained relations based on a set of local features, social networks and meta paths.

The main contributions of this paper are summarized as follows:

- To the best of our knowledge, this is the first effort to explore graph-based semi-supervised learning algorithms for the wikification task.
- We propose a novel semi-supervised graph regularization model performing collective inference for joint mention detection and disambiguation. Our approach takes advantage of three proposed principles to incorporate both local and global evidence from multiple tweets.
- We propose a meta path-based unified framework to detect both explicitly and implicitly relevant mentions.

2 Preliminaries

Concept and Concept Mention We define a *concept* c as a Wikipedia article (e.g., *Atlanta Hawks*), and a *concept mention* m as an n-gram from a specific tweet. Each concept has a set of textual representation fields (Meij et al., 2012), including *title* (the title of the article), *sentence* (the first sentence of the article), *paragraph* (the first paragraph of the article), *content* (the entire content of the article), and *anchor* (the set of all anchor texts with incoming links to the article).

Wikipedia Lexicon Construction We first construct an offline lexicon with each entry as $\langle m, \{c_1, ..., c_k\}\rangle$, where $\{c_1, ..., c_k\}$ is the set of possible referent concepts for the mention m. Following the previous work (Bunescu, 2006; Cucerzan, 2007; Hachey et al., 2013), we extract the possible mentions for a given concept c using the following resources: the title of c; the aliases appearing in the introduction and infoboxes of c (e.g., *The Evergreen State* is an alias of *Washington state*); the titles of pages redirecting to c (e.g., *State of Washington* is a redirecting page of *Washington (state)*); the titles of the disambigua-

tion pages containing c; and all the anchor texts appearing in at least 5 pages with hyperlinks to c (e.g., *WA* is a mention for the concept *Washington (state)* in the text "*401 5th Ave N [[Seattle]], [[Washington (state)—WA]] 98109 USA*". We also propose three heuristic rules to extract mentions (i.e., different combinations of the family name and given name for a person, the headquarters of an organization, and the city name for a sports team).

Concept Mention Extraction Based on the constructed lexicon, we then consider all n-grams of size $\leq n$ (n=7 in this paper) as concept mention candidates if their entries in the lexicon are not empty. We first segment @usernames and #hashtags into regular tokens (e.g., @amandapalmer is segmented as *amanda palmer* and #WorldWaterDay is split as *World Water Day*) using the approach proposed by (Wang et al., 2011). Segmentation assists finding concept candidates for these non-regular mentions.

3 Principles and Approach Overview

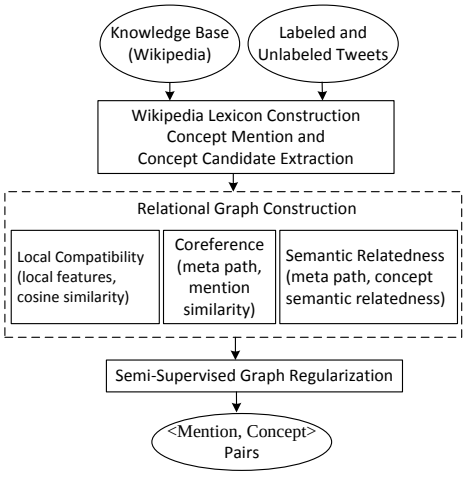

Figure 2: Approach Overview.

3.1 Principles

A single tweet may not provide enough evidence to identify prominent mentions and infer their correct referent concepts due to the lack of contextual information. To tackle this problem, we propose to incorporate global evidence from multiple tweets and performing collective inference for both mention identification and disambiguation. We first introduce the following three principles that our approach relies on.

Principle 1 (Local compatibility): *Two pairs of $\langle m, c\rangle$ with strong local compatibility tend to have similar labels.* Mentions and their correct referent concepts usually tend to share a set of characteristics such as string similarity between m and c (e.g., $\langle$*Chicago*, *Chicago*$\rangle$ and $\langle$*Facebook*, *Facebook*$\rangle$). We define the *local compatibility* to model such set of characteristics.

Principle 2 (Coreference): *Two coreferential mentions should be linked to the same concept.* For example, if we know "*nc*" and "*North Carolina*" are coreferential, then they should both be linked to *North Carolina*.

Principle 3 (Semantic Relatedness): *Two highly semantically-related mentions are more likely to be linked to two highly semantically-related concepts.* For instance, when "*Sweet 16*" and "*Hawks*" often appear together within relevant contexts, they can be reliably linked to two baseketball-related concepts *NCAA Men's Division I Basketball Championship* and *Atlanta Hawks*, respectively.

3.2 Approach Overview

Given a set of tweets $\langle t_1, ..., t_{|T|}\rangle$, our system first generates a set of candidate concept mentions, and then extracts a set of candidate concept referents for each mention based on the Wikipedia lexicon. Given a pair of mention and its candidate referent concept $\langle m, c\rangle$, the remaining task of wikification is to assign either a positive label if m should be selected as a prominently linkable mention and c is its correct referent concept, or otherwise a negative label. The label assignment is obtained by our semi-supervised graph regularization framework based on a relational graph, which is constructed from *local compatibility*, *coreference*, and *semantic relatedness* relations. The overview of our approach is as illustrated in Figure 2.

4 Relational Graph Construction

We first construct the relational graph $G = \langle V, E\rangle$, where $V = \{v_1, ..., v_n\}$ is a set of nodes and $E = \{e_1, ..., e_m\}$ is a set of edges. Each $v_i = \langle m_i, c_i\rangle$ represents a tuple of mention m_i and its referent concept candidate c_i. An edge is added between two nodes v_i and v_j if there is a proposed relation based on the three principles described in section 3.1.

4.1 Local Compatibility

We first compute local compatibility (Principle 1) by considering a set of novel local features to cap-

ture the importance and relevance of a mention m to a tweet t, as well as the correctness of its linkage to a concept c. We have designed a number of features which are similar to those commonly used in wikification and entity linking work (Meij et al., 2012; Guo et al., 2013; Mihalcea and Csomai, 2007).

Mention Features We define the following features based on information from mentions.

- $IDF_f(m) = \log(\frac{|C|}{df(m)})$, where $|C|$ is the total number of concepts in Wikipedia and $df(m)$ is the total number of concepts in which m occurs, and f indicates the field property, including *title*, *content*, and *anchor*.
- $Keyphraseness(m) = \frac{|C_a(m)|}{df(m)}$ to measure how likely m is used as an anchor in Wikipedia, where $C_a(m)$ is the set of concepts where m appears as an anchor.
- $LinkProb(m) = \frac{\sum_{c \in C_a(m)} count(m,c)}{\sum_{c \in C} count(m,c)}$, where $count(m, c)$ indicates the number of occurrence of m in c.
- $SNIL(m)$ and $SNCL(m)$ to count the number of concepts that are equal to or contain a sub-n-gram of m, respectively (Meij et al., 2012).

Concept Features The concept features are solely based on Wikipedia, including the number of incoming and outgoing links for c, and the number of words and characters in c.

Mention + Concept Features This set of features considers information from both mentions and concepts:

- **prior popularity** $prior(m, c) = \frac{count(m,c)}{\sum_{c'} count(m,c')}$, where $count(m, c)$ measures the frequency of the anchor links from m to c in Wikipedia.
- $TF_f(m, c) = \frac{count_f(m,c)}{|f|}$ to measure the relative frequency of m in each field representation f of c, normalized by the length of f. The fields include *title*, *sentence*, *paragraph*, *content* and *anchor*.
- $NCT(m, c)$, $TCN(m, c)$, and $TEN(m, c)$ to measure whether m contains the title of c, whether the title of c contains m, and whether m equals to the title of c, respectively.

Context Features This set of features include (i) Context Capitalization features, which indicate whether the current mention, the token before, and the token after are capitalized. (ii) tf-idf based features, which include the dot product of two word vectors v_c and v_t, and the average tf-idf value of common items in v_c and v_t, where v_c and v_t are the top 100 tf-idf word vectors in c and t.

Local Compatibility Computation For each node $v_i = \langle m_i, c_i \rangle$, we collect its local features as a feature vector $F_i = \langle f_1, f_2, ..., f_d \rangle$. To avoid features with large numerical values that dominate other features, the value of each feature is re-scaled using feature standardization approach. The cosine similarity is then adopted to compute the local compatibility of two nodes and construct a k *nearest neighbor* (kNN) graph, where each node is connected to its k nearest neighboring nodes. We compute the weight matrix that represents the local compatibility relation as:

$$W_{ij}^{loc} = \begin{cases} cosine(F_i, F_j) & j \in kNN(i) \\ 0 & \text{Otherwise} \end{cases}$$

4.2 Meta Path

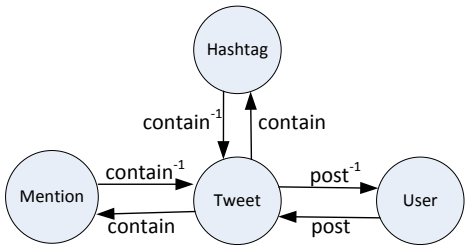

Figure 3: Schema of the Twitter network.

In this subsection, we introduce the concept meta path which will be used to detect coreference (section 4.3) and semantic relatedness relations (section 4.4).

A meta-path is a path defined over a network and composed of a sequence of relations between different object types (Sun et al., 2011b). In our experimental setting, we can construct a natural Twitter network summarized by the network schema in Figure 3. The network contains four types of objects: *Mention* (M), *Tweet* (T), *User* (U), and *Hashtag* (H). Tweets and mentions are connected by links "contain" and "contained by" (denoted as "$contain^{-1}$"); and other linked relationships can be described similarly.

We then define the following five types of meta paths to connect two mentions as:

- "M - T - M",
- "M - T - U - T - M",
- "M - T - H - T - M",
- "M - T - U - T - M - T - H - T - M",
- "M - T - H - T - M - T - U - T - M".

Each meta path represents one particular semantic relation. For instance, the first three paths are *basic* ones expressing the explicit relations that two mentions are from the same tweet, posted by the same user, and share the same #hashtag, respectively. The last two paths are *concatenated* ones which are constructed by concatenating the first three simple paths to express the implicit relations that two mentions co-occur with a third mention sharing either the same authorship or #hashtag. Such complicated paths can be exploited to detect more semantically-related mentions from wider contexts. For example, the relational link between "*narita airport*" and "*Japan*" would be missed without using the path "*narita airport* - t_1 - u_1 - t_2 - *american* - t_3 - h_1 - t_4 - *Japan*" since they don't directly share any authorships or #hashtags.

4.3 Coreference

A coreference relation (Principle 2) usually occurs across multiple tweets due to the highly redundant information in Twitter. To ensure high precision, we propose a simple yet effective approach utilizing the rich social network relations in Twitter.

We consider two mentions m_i and m_j coreferential if m_i and m_j share the same surface form or one is an abbreviation of the other, and at least one meta path exists between m_i and m_j. Then we define the weight matrix representing the coreferential relation as:

$$W_{ij}^{coref} = \begin{cases} 1.0 & \text{if } m_i \text{ and } m_j \text{ are coreferential,} \\ & \text{and } c_i = c_j \\ 0 & \text{Otherwise} \end{cases}$$

4.4 Semantic Relatedness

Ensuring topical coherence (Principle 3) has been beneficial for wikification on formal texts (e.g., News) by linking a set of semantically-related mentions to a set of semantically-related concepts simultaneously (Han et al., 2011; Ratinov et al., 2011; Cheng and Roth, 2013). However, the shortness of a single tweet means that it may not provide enough topical clues. Therefore, it is important to extend this evidence to capture semantic relatedness information from multiple tweets.

We define the semantic relatedness score between two mentions as $SR(m_i, m_j) = 1.0$ if at least one meta path exists between m_i and m_j, otherwise $SR(m_i, m_j) = 0$. In order to compute the semantic relatedness of two concepts c_i and c_j, we adopt the approach proposed by (Milne and Witten, 2008a):

$$SR(c_i, c_j) = 1 - \frac{\log \max(|C_i|, |C_j|) - \log |C_i \cap C_j|}{\log(|C|) - \log \min(|C_i|, |C_j|)},$$

where $|C|$ is the total number of concepts in Wikipedia, and C_i and C_j are the set of concepts that have links to c_i and c_j, respectively.

Then we compute a weight matrix representing the semantic relatedness relation as:

$$W_{ij}^{rel} = \begin{cases} SR(N_i, N_j) & \text{if } SR(N_i, N_j) \geq \delta \\ 0 & \text{Otherwise} \end{cases}$$

where $SR(N_i, N_j) = SR(m_i, m_j) \times SR(c_i, c_j)$ and $\delta = 0.3$, which is optimized from a development set.

4.5 The Combined Relational Graph

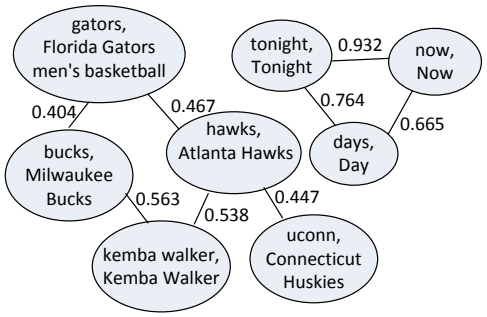

Figure 4: A example of the relational graph constructed for the example tweets in Figure 1. Each node represents a pair of $\langle m, c \rangle$, separated by a comma. The edge weight is obtained from the linear combination of the weights of the three proposed relations. Not all mentions are included due to the space limitations.

Based on the above three weight matrices W^{loc}, W^{coref}, and W^{rel}, we first obtain their corresponding transition matrices P^{loc}, P^{coref}, and P^{rel}, respectively. The entry P_{ij} of the transition matrix P for a weight matrix W is computed as $P_{ij} = \frac{W_{ij}}{\sum_k W_{ik}}$ such that $\sum_k P_{ik} = 1$. Then we obtain the combined graph G with weight matrix W, where $W_{ij} = \alpha P_{ij}^{loc} + \beta P_{ij}^{coref} + \gamma P_{ij}^{rel}$. α, β, and γ are three coefficients between 0 and 1 with the constraint that $\alpha + \beta + \gamma = 1$. They control the contributions of these three relations in our semi-supervised graph regularization model. We choose transition matrix to avoid the domination of one relation over others. An example graph of G is shown in Figure 4. Compared to the *referent graph* which considers each mention or concept as a node in previous graph-based re-ranking approaches (Han et al., 2011; Shen et al., 2013), our

novel graph representation has two advantages: (i) It can easily incorporate more features related to both mentions and concepts. (ii) It is more appropriate for our graph-based semi-supervised model since it is difficult to assign labels to a pair of mention and concept in the referent graph.

5 Semi-supervised Graph Regularization

Given the constructed relational graph with the weighted matrix W and the label vector Y of all nodes, we assume the first l nodes are labeled as Y_l and the remaining u nodes ($u = n - l$) are initialized with labels Y_u^0. Then our goal is to refine Y_u^0 and obtain the final label vector Y_u.

Intuitively, if two nodes are strongly connected, they tend to hold the same label. We propose a novel semi-supervised graph regularization framework based on the graph-based semi-supervised learning algorithm (Zhu et al., 2003):

$$\mathcal{Q}(\mathcal{Y}) = \mu \sum_{i=l+1}^{n} (y_i - y_i^0)^2 + \frac{1}{2} \sum_{i,j} W_{ij}(y_i - y_j)^2.$$

The first term is a loss function that incorporates the initial labels of unlabeled examples into the model. In our method, we adopt *prior popularity* (section 4.1) to initialize the labels of the unlabeled examples. The second term is a regularizer that smoothes the refined labels over the constructed graph. μ is a regularization parameter that controls the trade-off between initial labels and the consistency of labels on the graph. The goal of the proposed framework is to ensure that the refined labels of unlabeled nodes are consistent with their strongly connected nodes, as well as not too far away from their initial labels.

The above optimization problem can be solved directly since $\mathcal{Q}(\mathcal{Y})$ is convex (Zhu et al., 2003; Zhou et al., 2004). Let I be an identity matrix and D_W be a diagonal matrix with entries $D_{ii} = \sum_j W_{ij}$. We can split the weighted matrix W into four blocks as $W = \begin{bmatrix} W_{ll} & W_{lu} \\ W_{ul} & W_{uu} \end{bmatrix}$, where W_{mn} is an $m \times n$ matrix. D_w is split similarly. We assume that the vector of the labeled examples Y_l is fixed, so we only need to infer the refined label vector of the unlabeled examples Y_u. In order to minimize $\mathcal{Q}(\mathcal{Y})$, we need to find Y_u^* such that

$$\left.\frac{\partial Q}{\partial Y_u}\right|_{Y_u = Y_u^*} = (D_{uu} + \mu I_{uu})Y_u - W_{uu}Y_u - W_{ul}Y_l - \mu Y_u^0 = 0.$$

Therefore, a closed form solution can be derived as $Y_u^* = (D_{uu} + \mu I_{uu} - W_{uu})^{-1}(W_{ul}Y_l + \mu Y_u^0)$.

However, for practical application to a large-scale data set, an iterative solution would be more efficient to solve the optimization problem. Let Y_u^t be the refined labels after the t^{th} iteration, the iterative solution can be derived as:

$$Y_u^{t+1} = (D_{uu} + \mu I_{uu})^{-1}(W_{uu}Y_u^t + W_{ul}Y_l + \mu Y_u^0).$$

The iterative solution is more efficient since $(D_{uu} + \mu I_{uu})$ is a diagonal matrix and its inverse is very easy to compute.

6 Experiments

In this section we compare our approach with state-of-the-art methods as shown in Table 1.

6.1 Data and Scoring Metric

For our experiments we use a public data set (Meij et al., 2012) including 502 tweets posted by 28 verified users. The data set was annotated by two annotators. We randomly sample 102 tweets for development and the remaining for evaluation. We use a Wikipedia dump on May 3, 2013 as our knowledge base, which includes 30 million pages. For computational efficiency, we also filter some mention candidates by applying the preprocessing approach proposed in (Ferragina and Scaiella, 2010), and remove all the concepts with prior popularity less than 2% from an mention's concept set for each mention, similar to (Guo et al., 2013).

A mention and concept pair $\langle m, c \rangle$ is judged as correct if and only if m is linkable and c is the correct referent concept for m. To evaluate the performance of a wikification system, we use the standard precision, recall and F1 measures.

6.2 Experimental Results

The overall performance of various approaches is shown in Table 2. The results of the supervised method proposed by (Meij et al., 2012) are obtained from 5-fold cross validation. For our semi-supervised setting, we experimentally sample 200 tweets for training and use the remaining set as unlabeled and testing sets. In our semi-supervised regularization model, the matrix W^{loc} is constructed by a kNN graph ($k = 20$). The regularization parameter μ is empirically set to 0.1, and the coefficients α, β, and γ are learnt from the development set by considering all the combina-

Methods	Descriptions
TagMe	The same approach that is described in (Ferragina and Scaiella, 2010), which aims to annotate short texts based on prior popularity and semantic relatedness of concepts. It is basically an unsupervised approach, except that it needs a development set to tune the probability threshold for linkable mentions.
Meij	A state-of-the-art system described in (Meij et al., 2012), which is a supervised approach based on the random forest model. It performs mention detection and disambiguation jointly, and it is trained from 400 labeled tweets.
SSRegu$_1$	Our proposed model based on Principle 1, using 200 labeled tweets.
SSRegu$_{12}$	Our proposed model based on Principle 1 and 2, using 200 labeled tweets.
SSRegu$_{13}$	Our proposed model based on Principle 1 and 3, using 200 labeled tweets.
SSRegu$_{123}$	Our proposed full model based on Principle 1, 2 and 3, using 200 labeled tweets.

Table 1: Description of Methods.

Methods	Precision	Recall	F1
TagMe	0.329	0.423	0.370
Meij	0.393	0.598	0.475
SSRegu$_1$	0.538	0.435	0.481
SSRegu$_{12}$	0.638	0.438	0.520
SSRegu$_{13}$	0.541	0.457	0.495
SSRegu$_{123}$	0.650	0.441	**0.525**

Table 2: Overall Performance.

tions of values from 0 to 1 at 0.1 intervals[1]. In order to randomize the experiments and make the comparison fair, we conduct 20 test runs for each method and report the average scores across the 20 trials.

The relatively low performance of the baseline system *TagMe* demonstrates that only relying on prior popularity and topical information within a single tweet is not enough for an end-to-end wikification system for the short tweets. As an example, it is difficult to obtain topical clues in order to link the mention "*Clinton*" to *Hillary Rodham Clinton* by relying on the single tweet "*wolfblitzercnn: Behind the scenes on Clinton's Mideast trip #cnn*". Therefore, the system mistakenly links it to the most popular concept *Bill Clinton*.

In comparision with the supervised baseline proposed by (Meij et al., 2012), our model *SSRegu*$_1$ relying on *local compatibility* already achieves comparable performance with 50% of labeled data. This is because that our model performs collective inference by making use of the manifold (cluster) structure of both labeled and unlabeled data, and that the local compatibility relation is detected with high precision[2] (89.4%). For example, the following three pairs of mentions and concepts ⟨*pelosi, Nancy Pelosi*⟩, ⟨*obama, Barack Obama*⟩, and ⟨*gaddafi, Muammar Gaddafi*⟩ have strong local compatibility with each other since they share many similar characteristics captured by the local features such as string similarity between the mention and the concept. Suppose the first pair is labeled, then its positive label will be propagated to other unlabeled nodes through the local compatibility relation, and correctly predict the labels of other nodes.

Incorporating coreferential or semantic relatedness relation into *SSRegu*$_1$ provides further gains, demonstrating the effectiveness of these two relations. For instance, "*wh*" is correctly linked to *White House* by incorporating evidence from its coreferential mention "*white house*". The coreferential relation (Principle 2) is demonstrated to be more beneficial than the semantic relatedness relation (Principle 3) because the former is detected with much higher precision (99.7%) than the latter (65.4%).

Our full model *SSRegu*$_{123}$ achieves significant improvement over the supervised baseline (5% absolute F1 gain with 95.0% confidence level by the Wilcoxon Matched-Pairs Signed-Ranks Test), showing that incorporating global evidence from multiple tweets with fine-grained relations is beneficial. For instance, the supervised baseline fails to link "*UCONN*" and "*Bucks*" in our examples to *Connecticut Huskies* and *Milwaukee Bucks*, respectively. Our full model corrects these two wrong links by propagating evidence through the semantic links as shown in Figure 4 to obtain mutual ranking improvement. The best performance of our full model also illustrates that the three relations complement each other.

We also study the disambiguation performance for the annotated mentions, as shown in Table 3. We can easily see that our proposed approach using 50% labeled data achieves similar performance with the state-of-the-art supervised model with 100% labeled data. When the mentions are given, the unpervised approach *TagMe* has already

[1]These three coefficients are slightly different with different training data, a sample of them is: $\alpha = 0.4$, $\beta = 0.5$, and $\gamma = 0.1$

[2]Here we define precision as the percentage of links that holds the same label.

Methods	TagMe	Meij	SSRegu_{123}
Accuracy	0.710	0.779	0.772

Table 3: Disambiguation Performance.

Methods	Precision	Recall	F1
$\textbf{SSRegu}_{12}$	0.644	0.423	0.510
$\textbf{SSRegu}_{13}$	0.543	0.441	0.486
$\textbf{SSRegu}_{123}$	0.657	0.419	0.512

Table 4: The Performance of Systems Without Using Concatenated Meta Paths.

achieved reasonable performance. In fact, mention detection actually is the performance bottleneck of a tweet wikification system (Guo et al., 2013). Our system performs better in identifying the prominent mention.

6.3 Effect of Concatenated Meta Paths

In this work, we propose a unified framework utilizing meta path-based semantic relations to explore richer relevant context. Beyond the *basic* meta paths, we introduce *concatenated* ones by concatenating the basic ones. The performance of the system without using the concatenated meta paths is shown in Table 4. In comparison with the system based on all defined meta paths, we can clearly see that the systems using concatenated ones outperform those relying on the simple ones. This is because the concatenated meta paths can incorporate more relevant information with implicit relations into the models by increasing 1.6% coreference links and 9.3% semantic relatedness links. For example, the mention "*narita airport*" is correctly disambiguated to the concept "*Narita International Airport*" with higher confidence since its semantic relatedness relation with "*Japan*" is detected with the concatenated meta path as described in section 4.2.

6.4 Effect of Labeled Data Size

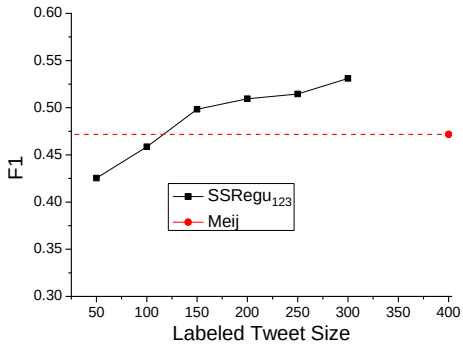

Figure 5: The effect of Labeled Tweet Size.

In previous experiments, we experimentally set the number of labeled tweets to be 200 for overall performance comparision with the baselines. In this subsection, we study the effect of labeled data size on our full model. We randomly sample 100 tweets as testing data, and randomly select 50, 100, 150, 200, 250, and 300 tweets as labeled data. 20 test runs are conducted and the average results are reported across the 20 trials, as shown in Figure 5. We find that as the size of the labeled data increases, our proposed model achieves better performance. It is encouraging to see that our approach, with only $\mathbf{31.3}\%$ labeled tweets (125 out of 400), already achieves a performance that is comparable to the state-of-the-art supervised model trained from 100% labeled tweets.

6.5 Parameter Analysis

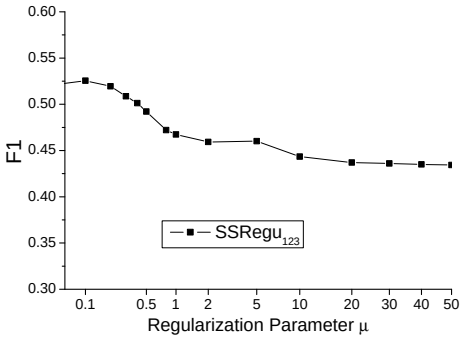

Figure 6: The effect of parameter μ.

In previous experiments, we empirically set the parameter $\mu = 0.1$. μ is the regularization parameter that controls the trade-off between initial labels and the consistency of labels on the graph. When μ increases, the model tends to trust more in the initial labels. Figure 6 shows the performance of our models by varying μ from 0.02 to 50. We can easily see that the system performce is stable when $\mu < 0.4$. However, when $\mu \geq 0.4$, the system performance dramatically decreases, showing that prior popularity is not enough for an end-to-end wikification system.

7 Related Work

The task of linking concept mentions to a knowledge base has received increased attentions over the past several years, from the linking of concept mentions in a single text (Mihalcea and Csomai, 2007; Milne and Witten, 2008b; Milne and Witten, 2008a; Kulkarni et al., 2009; He et al., 2011; Ratinov et al., 2011; Cassidy et al., 2012; Cheng and Roth, 2013), to the linking of a cluster of corefer-

ent named entity mentions spread throughout different documents (Entity Linking) (McNamee and Dang, 2009; Ji et al., 2010; Zhang et al., 2010; Ji et al., 2011; Zhang et al., 2011; Han and Sun, 2011; Han et al., 2011; Gottipati and Jiang, 2011; He et al., 2013; Li et al., 2013; Guo et al., 2013; Shen et al., 2013; Liu et al., 2013).

A significant portion of recent work considers the two sub-problems *mention detection* and *mention disambiguation* separately and focus on the latter by first defining candidate concepts for a deemed mention based on anchor links. Mention disambiguation is then formulated as a ranking problem, either by resolving one mention at each time (non-collective approaches), or by disambiguating a set of relevant mentions simultaneously (collective approaches). Non-collective methods usually rely on prior popularity and context similarity with supervised models (Mihalcea and Csomai, 2007; Milne and Witten, 2008b; Han and Sun, 2011), while collective approaches further leverage the global coherence between concepts normally through supervised or graph-based re-ranking models (Cucerzan, 2007; Milne and Witten, 2008b; Han and Zhao, 2009; Kulkarni et al., 2009; Pennacchiotti and Pantel, 2009; Ferragina and Scaiella, 2010; Fernandez et al., 2010; Radford et al., 2010; Cucerzan, 2011; Guo et al., 2011; Han and Sun, 2011; Han et al., 2011; Ratinov et al., 2011; Chen and Ji, 2011; Kozareva et al., 2011; Cassidy et al., 2012; Shen et al., 2013; Liu et al., 2013). Especially note that when applying the collective methods to short messages from social media, evidence from other messages usually needs to be considered (Cassidy et al., 2012; Shen et al., 2013; Liu et al., 2013). Our method is a collective approach with the following novel advancements: (i) A novel graph representation with fine-grained relations, (ii) A unified framework based on meta paths to explore richer relevant context, (iii) Joint identification and linking of mentions under semi-supervised setting.

Two most similar methods to ours were proposed by (Meij et al., 2012; Guo et al., 2013) by performing joint detection and disambiguation of mentions. (Meij et al., 2012) studied several supervised machine learning models, but without considering any global evidence either from a single tweet or other relevant tweets. (Guo et al., 2013) explored second order entity-to-entity relations but did not incorporate evidence from multiple tweets.

This work is also related to graph-based semi-supervised learning (Zhu et al., 2003; Smola and Kondor, 2003; Zhou et al., 2004; Talukdar and Crammer, 2009), which has been successfully applied in many Natural Language Processing tasks (Niu et al., 2005; Chen et al., 2006). We introduce a novel graph that incorporates three fine-grained relations. Our work is further related to meta path-based heterogeneous information network analysis (Sun et al., 2011b; Sun et al., 2011a; Kong et al., 2012; Huang et al., 2013), which has demonstrated advantages over homogeneous information network analysis without differentiating object types and relational links.

8 Conclusions

We have introduced a novel semi-supervised graph regularization framework for wikification to simultaneously tackle the unique challenges of annotation and information shortage in short tweets. To the best of our knowledge, this is the first work to explore the semi-supervised collective inference model to jointly perform mention detection and disambiguation. By studying three novel fine-grained relations, detecting semantically-related information with semantic meta paths, and exploiting the data manifolds in both unlabeled and labeled data for collective inference, our work can dramatically save annotation cost and achieve better performance, thus shed light on the challenging wikification task for tweets.

Abstract

In order to extract entities of a fine-grained category from semi-structured data in web pages, existing information extraction systems rely on seed examples or redundancy across multiple web pages. In this paper, we consider a new zero-shot learning task of extracting entities specified by a natural language query (in place of seeds) given only a single web page. Our approach defines a log-linear model over latent extraction predicates, which select lists of entities from the web page. The main challenge is to define features on widely varying candidate entity lists. We tackle this by abstracting list elements and using aggregate statistics to define features. Finally, we created a new dataset of diverse queries and web pages, and show that our system achieves significantly better accuracy than a natural baseline.

1 Introduction

We consider the task of extracting entities of a given category (e.g., *hiking trails*) from web pages. Previous approaches either (i) assume that the same entities appear on multiple web pages, or (ii) require information such as seed examples (Etzioni et al., 2005; Wang and Cohen, 2009; Dalvi et al., 2012). These approaches work well for common categories but encounter data sparsity problems for more specific categories, such as the products of a small company or the dishes at a local restaurant. In this context, we may have only a single web page that contains the information we need and no seed examples.

In this paper, we propose a novel task, *zero-shot entity extraction*, where the specification of the desired entities is provided as a natural language query. Given a query (e.g., *hiking trails near Baltimore*) and a web page (e.g., `http://www.everytrail.com/best/hiking-baltimore-maryland`), the goal is to extract all entities corresponding to the query on that page (e.g., *Avalon Super Loop*, etc.). Figure 1 summarizes the task setup.

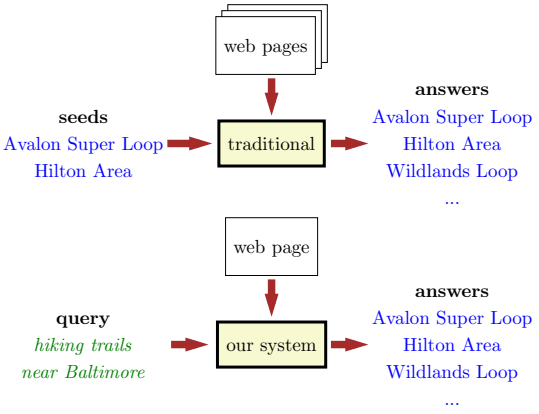

Figure 1: Entity extraction typically requires additional knowledge such as a small set of seed examples or depends on multiple web pages. In our setting, we take as input a natural language query and extract entities from a single web page.

The task introduces two challenges. Given a single web page to extract entities from, we can no longer rely on the redundancy of entities across multiple web pages. Furthermore, in the zero-shot learning paradigm (Larochelle et al., 2008), where entire categories might be unseen during training, the system must generalize to new queries and web pages without the additional aid of seed examples.

To tackle these challenges, we cast the task as a structured prediction problem where the input is the query and the web page, and the output is a list of entities, mediated by a latent *extraction predicate*. To generalize across different inputs, we rely on two types of features: *structural* features, which look at the layout and placement of the entities being extracted; and *denotation* fea-

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 391–401,
Baltimore, Maryland, USA, June 23-25 2014.

tures, which look at the list of entities as a whole and assess their linguistic coherence. When defining features on lists, one technical challenge is being robust to widely varying list sizes. We approach this challenge by defining features over a histogram of abstract tokens derived from the list elements.

For evaluation, we created the OPENWEB dataset comprising natural language queries from the Google Suggest API and diverse web pages returned from web search. Despite the variety of queries and web pages, our system still achieves a test accuracy of 40.5% and an accuracy at 5 of 55.8%.

2 Problem statement

We define the *zero-shot entity extraction* task as follows: let x be a natural language query (e.g., *hiking trails near Baltimore*), and w be a web page. Our goal is to construct a mapping from (x, w) to a list of entities y (e.g., [*Avalon Super Loop*, *Patapsco Valley State Park*, ...]) which are extracted from the web page.

Ideally, we would want our data to be annotated with the correct entity lists y, but this would be very expensive to obtain. We instead define each training and test example as a triple (x, w, c), where the *compatibility function* c maps each y to $c(y) \in \{0, 1\}$ denoting the (approximate) correctness of the list y. In this paper, an entity list y is *compatible* ($c(y) = 1$) when the first, second, and last elements of y match the annotation; otherwise, it is *incompatible* ($c(y) = 0$).

2.1 Dataset

To experiment with a diverse set of queries and web pages, we created a new dataset, OPENWEB, using web pages from Google search results.[1] We use the method from Berant et al. (2013) to generate search queries by performing a breadth-first search over the query space. Specifically, we use the Google Suggest API, which takes a partial query (e.g., *"list of ____ movies"*) and outputs several complete queries (e.g., *"list of horror movies"*). We start with seed partial queries *"list of •____"* where • is one or two initial letters. In each step, we call the Google Suggest API on the partial queries to obtain complete queries,

[1]The OPENWEB dataset and our code base are available for download at `http://www-nlp.stanford.edu/software/web-entity-extractor-ACL2014`.

Full query	New partial queries
list of X IN Y where IN is a preposition (*list of* $[hotels]_X$ *in* $[Guam]_Y$)	*list of* X ____ *list of* ____ X *list of* X IN ____ *list of* ____ IN Y
list of X CC Y where CC is a conjunction (*list of* $[food]_X$ *and* $[drink]_Y$)	*list of* X ____ *list of* ____ X *list of* Y ____ *list of* ____ Y
list of X w (*list of* $[good\ 2012]_X$ $[movies]_w$)	*list of* w ____ *list of* ____ w *list of* X ____

Table 1: Rules for generating new partial queries from complete queries. (X and Y are sequences of words; w is a single word.)

and then apply the transformation rules in Table 1 to generate more partial queries from complete queries. We run the procedure until we obtained 100K queries.

Afterwards, we downloaded the top 2–3 Google search results of each query, sanitized the web pages, and randomly submitted 8000 query / web page pairs to Amazon Mechanical Turk (AMT). Each AMT worker must either mark the web page as irrelevant or extract the first, second, and last entities from the page. We only included examples where at least two AMT workers agreed on the answer.

The resulting OPENWEB dataset consists of 2773 examples from 2269 distinct queries. Among these queries, there are 894 headwords ranging from common categories (e.g., movies, companies, characters) to more specific ones (e.g., enzymes, proverbs, headgears). The dataset contains web pages from 1438 web domains, of which 83% appear only once in our dataset.

Figure 2 shows some queries and web pages from the OPENWEB dataset. Besides the wide range of queries, another main challenge of the dataset comes from the diverse data representation formats, including complex tables, grids, lists, headings, and paragraphs.

3 Approach

Figure 3 shows the framework of our system. Given a query x and a web page w, the system generates a set $\mathcal{Z}(w)$ of *extraction predicates* z which can extract entities from semi-structured data in w. Section 3.1 describes extraction predicates in more detail. Afterwards, the system chooses $z \in \mathcal{Z}(w)$ that maximizes the model probability $p_\theta(z \mid x, w)$, and then executes z on

Queries

songs on glee season 5
singers who use auto tune
san francisco radio stations
actors from boston

Examples (web page, query)

airlines of italy *natural causes of global warming* *lsu football coaches*

Figure 2: Some examples illustrating the diversity of queries and web pages from the OPENWEB dataset.

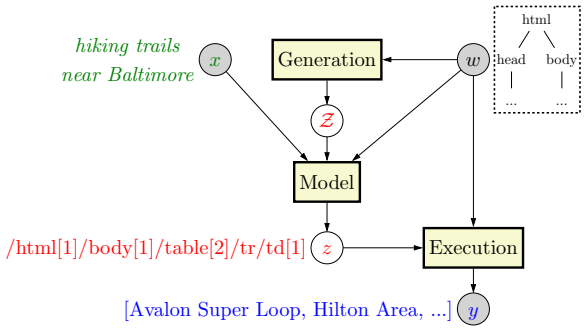

Figure 3: An overview of our system. The system uses the input query x and web page w to produce a list of entities y via an extraction predicate z.

w to get the list of entities $y = [\![z]\!]_w$. Section 3.2 describes the model and the training procedure, while Section 3.3 presents the features used in our model.

3.1 Extraction predicates

We represent each web page w as a DOM tree, a common representation among wrapper induction and web information extraction systems (Sahuguet and Azavant, 1999; Liu et al., 2000; Crescenzi et al., 2001). The text of any DOM tree node that is shorter than 140 characters is a candidate entity. However, without further restrictions, the number of possible entity lists grows exponentially with the number of candidate entities.

To make the problem tractable, we introduce an *extraction predicate* z as an intermediate representation for extracting entities from w. In our system, we let an extraction predicate be a simplified XML path (XPath) such as

```
/html[1]/body[1]/table[2]/tr/td[1]
```

Informally, an extraction predicate is a list of *path entries*. Each path entry is either a tag (e.g., `tr`), which selects all children with that tag; or a tag and an index i (e.g., `td[1]`), which selects only the ith child with that tag. The denotation $y = [\![z]\!]_w$ of an extraction predicate z is the list of entities selected by the XPath. Figure 4 illustrates the execution of the extraction predicate above on a DOM tree.

In the literature, many information extraction systems employ more versatile extraction predicates (Wang and Cohen, 2009; Fumarola et al., 2011). However, despite the simplicity, we are able to find an extraction predicate that extracts a compatible entity list in 69.7% of the development examples. In some examples, we cannot extract a compatible list due to unrecoverable issues such as incorrect annotation. Section 4.4 provides a detailed analysis of these issues. Additionally, extraction predicates can be easily extended to increase the coverage. For example, by introducing new index types `[1:]` (selects all but the first node) and `[:-1]` (selects all but the last node), we can increase the coverage to 76.2%.

Extraction predicate generation. We generate a set $\mathcal{Z}(w)$ of extraction predicates for a given web page w as follows. For each node in the DOM tree, we find an extraction predicate which selects only that node, and then generalizes the predicate by removing any subset of the indices of the last k path entries. For instance, when $k = 2$, an extraction predicate ending in `.../tr[5]/td[2]` will be generalized to `.../tr[5]/td[2]`, `.../tr/td[2]`, `.../tr[5]/td`, and `.../tr/td`. In all experiments, we use $k = 8$, which gives at most 2^8 generalized predicates for each original predicate. This generalization step allows the system to select multiple nodes with the same structure (e.g.,

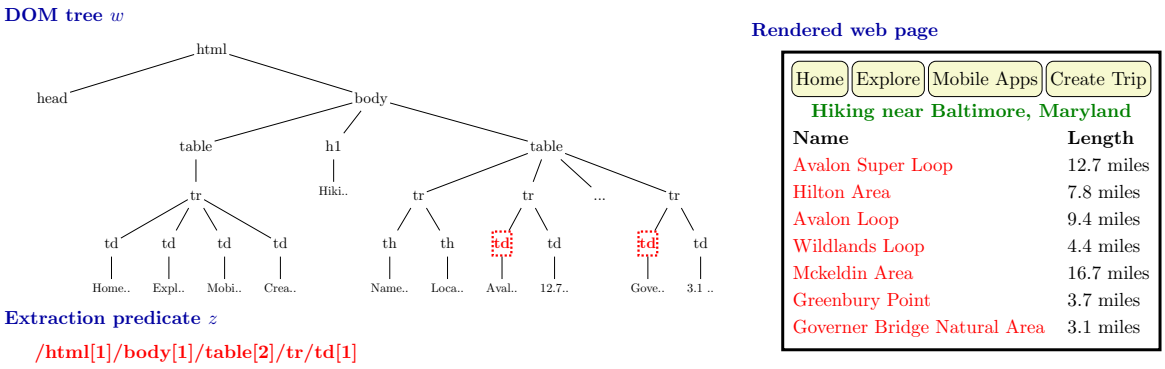

Figure 4: A simplified example of a DOM tree w and an extraction predicate z, which selects a list of entity strings $y = [\![z]\!]_w$ from the page (highlighted in red).

table cells from the same column or list items from the same section of the page).

Out of all generalized extraction predicates, we retain the ones that extract at least two entities from w. Note that several extraction predicates may select the same list of nodes and thus produce the same list of entities.

The procedure above gives a manageable number of extraction predicates. Among the development examples of the OPENWEB dataset, we generate an average of 8449 extraction predicates per example, which evaluate to an average of 1209 unique entity lists.

3.2 Modeling

Given a query x and a web page w, we define a log-linear distribution over all extraction predicates $z \in \mathcal{Z}(w)$ as

$$p_\theta(z \mid x, w) \propto \exp\{\theta^\top \phi(x, w, z)\}, \qquad (1)$$

where $\theta \in \mathbb{R}^d$ is the parameter vector and $\phi(x, w, z)$ is the feature vector, which will be defined in Section 3.3.

To train the model, we find a parameter vector θ that maximizes the regularized log marginal probability of the compatibility function being satisfied. In other words, given training data $\mathcal{D} = \{(x^{(i)}, w^{(i)}, c^{(i)})\}_{i=1}^n$, we find θ that maximizes

$$\sum_{i=1}^{n} \log p_\theta(c^{(i)} = 1 \mid x^{(i)}, w^{(i)}) - \frac{\lambda}{2}\|\theta\|_2^2$$

where

$$p_\theta(c = 1 \mid x, w) = \sum_{z \in \mathcal{Z}(w)} p_\theta(z \mid x, w) \cdot c([\![z]\!]_w).$$

Note that $c([\![z]\!]_w) = 1$ when the entity list $y = [\![z]\!]_w$ selected by z is compatible with the annotation; otherwise, $c([\![z]\!]_w) = 0$.

We use AdaGrad, an online gradient descent with an adaptive per-feature step size (Duchi et al., 2010), making 5 passes over the training data. We use $\lambda = 0.01$ obtained from cross-validation for all experiments.

3.3 Features

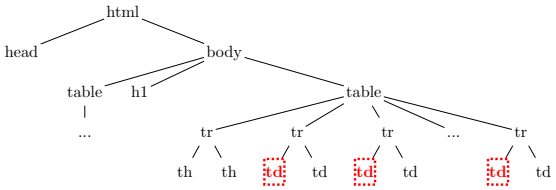
To construct the log-linear model, we define a feature vector $\phi(x, w, z)$ for each query x, web page w, and extraction predicate z. The final feature vector is the concatenation of *structural* features $\phi_{\text{s}}(w, z)$, which consider the selected nodes in the DOM tree, and *denotation* features $\phi_{\text{d}}(x, y)$, which look at the extracted entities.

We will use the query *hiking trails near Baltimore* and the web page in Figure 4 as a running example. Figure 5 lists some features extracted from the example.

3.3.1 Recipe for defining features on lists

One main focus of our work is finding good feature representations for a list of objects (DOM tree nodes for structural features and entity strings for denotation features). One approach is to define the feature vector of a list to be the sum of the feature vectors of individual elements. This is commonly done in structured prediction, where the elements are local configurations (e.g., rule applications in parsing). However, this approach raises a normalization issue when we have to compare and rank lists of drastically different sizes.

As an alternative, we propose a recipe for generating features from a list as follows:



Structural feature	Value
Features on selected nodes:	
TAG-MAJORITY = td	1
INDEX-ENTROPY	0.0
Features on parent nodes:	
CHILDRENCOUNT-MAJORITY = 2	1
PARENT-SINGLE	1
INDEX-ENTROPY	1.0
HEADHOLE (The first node is skipped)	1
Features on grandparent nodes:	
PAGECOVERAGE	0.6
...	...

Selected entities

Avalon Super Loop
Hilton Area
Avalon Loop
Wildlands Loop
Mckeldin Area
Greenbury Point
Governer Bridge Natural Area

Denotation feature	Value
WORDSCOUNT-MEAN	2.42
PHRASESHAPE-MAJORITY = Aa Aa	1
PHRASESHAPE-MAJORITYRATIO	0.71
WORDSHAPE-MAJORITY = Aa	1
PHRASEPOS-MAJORITY = NNP NN	1
LASTWORD-ENTROPY	0.74
WORDPOS = NN (normalized count)	0.53
...	...

Figure 5: A small subset of features from the example *hiking trails near Baltimore* in Figure 4.

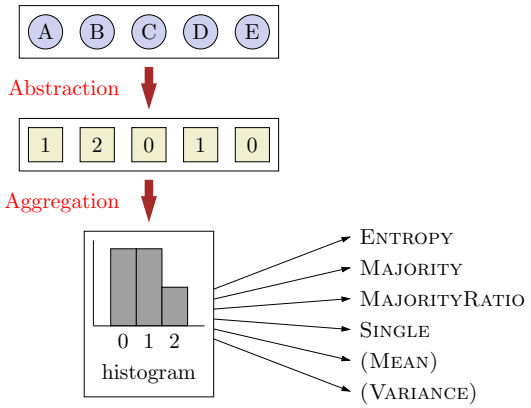


Figure 6: The recipe for defining features on a list of objects: (i) the *abstraction* step converts list elements into abstract tokens; (ii) the *aggregation* step defines features using the histogram of the abstract tokens.

Step 1: Abstraction. We map each list element into an abstract token. For example, we can map each DOM tree node onto an integer equal to the number of children, or map each entity string onto its part-of-speech tag sequence.

Step 2: Aggregation. We create a histogram of the abstract tokens and define features on properties of the histogram. Generally, we use ENTROPY (entropy normalized to the maximum value of 1), MAJORITY (mode), MAJORITYRATIO (percentage of tokens sharing the majority value), and SINGLE (whether all tokens are identical). For abstract tokens with finitely many possible values (e.g., part-of-speech), we also use the normalized histogram count of each possible value as a feature. And for real-valued abstract tokens, we also use the mean and the standard deviation. In the actual system, we convert real-valued features (entropy, histogram count, mean, and standard deviation) into indicator features by binning.

Figure 6 summarizes the steps explained above. We use this recipe for defining both structural and denotation features, which are discussed below.

3.3.2 Structural features

Although different web pages represent data in different formats, they still share some common hierarchical structures in the DOM tree. To capture this, we define structural features $\phi_s(w, z)$, which consider the properties of the selected nodes in the DOM tree, as follows:

Features on selected nodes. We apply our recipe on the list of nodes in w selected by z using the following abstract tokens:

- TAG, ID, CLASS, etc. (HTML attributes)
- CHILDRENCOUNT and SIBLINGSCOUNT (number of children and siblings)
- INDEX (position among its siblings)
- PARENT (parent node; e.g., PARENT-SINGLE means that all nodes share the same parent.)

Additionally, we define the following features based on the coverage of all selected nodes:

- NOHOLE, HEADHOLE, etc. (node coverage in the same DOM tree level; e.g., HEADHOLE activates when the first sibling of the selected nodes is not selected.)

- PAGECOVERAGE (node coverage relative to the entire tree; we use depth-first traversal timestamps to estimate the fraction of nodes in the subtrees of the selected nodes.)

Features on ancestor nodes. We also define the same feature set on the list of ancestors of the selected nodes in the DOM tree. In our experiments, we traverse up to 5 levels of ancestors and define features from the nodes in each level.

3.3.3 Denotation features

Structural features are not powerful enough to distinguish between entity lists appearing in similar structures such as columns of the same table or fields of the same record. To solve this ambiguity, we introduce denotation features $\phi_{\mathrm{d}}(x, y)$ which considers the coherence or appropriateness of the selected entity strings $y = [\![z]\!]_w$.

We observe that the correct entities often share some linguistic statistics. For instance, entities in many categories (e.g., people and place names) usually have only 2–3 word tokens, most of which are proper nouns. On the other hand, random words on the web page tend to have more diverse lengths and part-of-speech tags.

We apply our recipe on the list of selected entities using the following abstract tokens:

- WORDSCOUNT (number of words)
- PHRASESHAPE (abstract shape of the phrase; e.g., *Barack Obama* becomes `Aa Aa`)
- WORDSHAPE (abstract shape of each word; the number of abstract tokens will be the total number of words over all selected entities)
- FIRSTWORD and LASTWORD
- PHRASEPOS and WORDPOS (part-of-speech tags for whole phrases and individual words)

4 Experiments

In this section we evaluate our system on the OPENWEB dataset.

4.1 Evaluation metrics

Accuracy. As the main metric, we use a notion of *accuracy* based on compatibility; specifically, we define the accuracy as the fraction of examples where the system predicts a compatible entity list as defined in Section 2. We also report *accuracy at 5*, the fraction of examples where the top five predictions contain a compatible entity list.

Path suffix pattern (multiset)	Count
{a, table, tbody, td[*], tr}	1792
{a, tbody, td[*], text, tr}	1591
{a, table[*], tbody, td[*], tr}	1325
{div, table, tbody, td[*], tr}	1259
{b, div, div, div, div[*]}	1156
{div[*], table, tbody, td[*], tr}	1059
{div, table[*], tbody, td[*], tr}	844
{table, tbody, td[*], text, tr}	828
{div[*], table[*], tbody, td[*], tr}	793
{a, table, tbody, td, tr}	743

Table 2: Top 10 path suffix patterns found by the baseline learner in the development data. Since we allow path entries to be permuted, each suffix pattern is represented by a multiset of path entries. The notation `[*]` denotes any path entry index.

To see how our compatibility-based accuracy tracks exact correctness, we sampled 100 web pages which have at least one valid extraction predicate and manually annotated the full list of entities. We found that in 85% of the examples, the longest compatible list y is the correct list of entities, and many lists in the remaining 15% miss the correct list by only a few entities.

Oracle. In some examples, our system cannot find any list of entities that is compatible with the gold annotation. The *oracle* score is the fraction of examples in which the system can find at least one compatible list.

4.2 Baseline

As a baseline, we list the suffixes of the correct extraction predicates in the training data, and then sort the resulting suffix patterns by frequency. To improve generalization, we treat path entries with different indices (e.g., `td[1]` vs. `td[2]`) as equivalent and allow path entries to be permuted. Table 2 lists the top 10 suffix patterns from the development data. At test time, we choose an extraction predicate with the most frequent suffix pattern. The baseline should work considerably well if the web pages were relatively homogeneous.

4.3 Main results

We held out 30% of the dataset as test data. For the results on development data, we report the average across 10 random 80-20 splits. Table 3 shows the results. The system gets an accuracy of 41.1% and 40.5% for the development and test data, respectively. If we consider the top 5 lists of entities, the accuracy increases to 58.4% on the development data and 55.8% on the test data.

	Development data		Test data	
	Acc	**A@5**	**Acc**	**A@5**
Baseline	10.8 ± 1.3	25.6 ± 2.0	10.3	20.9
Our system	41.1 ± 3.4	58.4 ± 2.7	40.5	55.8
Oracle	68.7 ± 2.4	68.7 ± 2.4	66.6	66.6

Table 3: Main results on the OPENWEB dataset using the default set of features. (Acc = accuracy, A@5 = accuracy at 5)

4.4 Error analysis

We now investigate the errors made by our system using the development data. We classify the errors into two types: (i) *coverage errors*, which are when the system cannot find any entity list satisfying the compatibility function; and (ii) *ranking errors*, which are when a compatible list of entities exists, but the system outputs an incompatible list.

Tables 4 and 5 show the breakdown of coverage and ranking errors from an experiment on the development data.

Analysis of coverage errors. From Table 4, about 36% of coverage errors happen when the extraction predicate for the correct entities also captures unrelated parts of the web page (Reason C1). For example, many Wikipedia articles have the *See Also* section that lists related articles in an unordered list (`/ul/li/a`), which causes a problem when the entities are also represented in the same format.

Another main source of errors is the inconsistency in HTML tag usage (Reason C2). For instance, some web pages use `<b>` and `<strong>` tags for bold texts interchangeably, or switch between `<b><a>...</a></b>` and `<a><b>...</b></a>` across entities. We expect that this problem can be solved by normalizing the web page, using an alternative web page representation (Cohen et al., 2002; Wang and Cohen, 2009; Fumarola et al., 2011), or leveraging more expressive extraction predicates (Dalvi et al., 2011).

One interesting source of errors is Reason C3, where we need to *filter* the selected entities to match the complex requirement in the query. For example, the query *tech companies in China* requires the system to select only the company names with *China* in the corresponding location column. To handle such queries, we need a deeper understanding of the relation between the linguistic structure of the query and the hierarchical structure of the web page. Tackling this error requires compositionality and is critical to generalize to more complex queries.

Setting	**Acc**	**A@5**
All features	41.1 ± 3.4	58.4 ± 2.7
Oracle	68.7 ± 2.4	68.7 ± 2.4
(Section 4.5)		
Structural features only	36.2 ± 1.9	54.5 ± 2.5
Denotation features only	19.8 ± 2.5	41.7 ± 2.7
(Section 4.6)		
Structural + query-denotation	41.7 ± 2.5	58.1 ± 2.4
Query-denotation features only	25.0 ± 2.3	48.0 ± 2.7
Concat. a random web page + structural + denotation	19.3 ± 2.6	41.2 ± 2.3
Concat. a random web page + structural + query-denotation	29.2 ± 1.7	49.2 ± 2.2
(Section 4.7)		
Add 1 seed entity	52.9 ± 3.0	66.5 ± 2.5

Table 6: System accuracy with different feature and input settings on the development data. (Acc = accuracy, A@5 = accuracy at 5)

Analysis of ranking errors. From Table 5, a large number of errors are attributed to the system selecting non-content elements such as navigation links and content headings (Reason R1). Feature analysis reveals that both structural and linguistic statistics of these non-content elements can be more coherent than those of the correct entities. We suspect that since many of our features try to capture the coherence of entities, the system sometimes erroneously favors the more homonogenous non-content parts of the page. To disfavor these parts, One possible solution is to add visual features that capture how the web page is rendered and favor more salient parts of the page. (Liu et al., 2003; Song et al., 2004; Zhu et al., 2005; Zheng et al., 2007).

4.5 Feature variations

We now investigate the contribution of each feature type. The ablation results on the development set over 10 random splits are shown in Table 6. We observe that denotation features improves accuracy on top of structural features.

Table 7 shows an example of an error that is eliminated by each feature type. Generally, if the entities are represented as records (e.g., rows of a table), then denotation features will help the system select the correct field from each record. On the other hand, structural features prevent the system from selecting random entities outside the main part of the page.

Reason		Short example	Count
C1	Answers and contextual elements are selected by the same extraction predicate.	Select entries in *See Also* section in addition to the content because they are all list entries.	48
C2	HTML tag usage is inconsistent.	The page uses both `b` and `strong` for headers.	16
C3	The query applies to only some sections of the matching entities.	Need to select only companies in China from the table of all Asian companies.	20
C4	Answers are embedded in running text.	Answers are in a comma-separated list.	13
C5	Text normalization issues.	Selected *Silent Night Lyrics* instead of *Silent Night*.	19
C6	Other issues.	Incorrect annotation. / Entities are permuted when the web page is rendered. / etc.	18
Total			134

Table 4: Breakdown of coverage errors from the development data.

Reason		Short example	Count
R1	Select non-content strings.	Select navigation links, headers, footers, or sidebars.	25
R2	Select entities from a wrong field.	Select book authors instead of book names.	22
R3	Select entities from the wrong section(s).	For the query *schools in Texas*, select all schools on the page, or select the schools in Alabama instead.	19
R4	Also select headers or footers.	Select the table header in addition to the answers.	7

Table 5: Breakdown of ranking errors from the development data.

All features	Structural only	Denotation only
The Sun	CIRC: 2,279,492	Paperboy Australia
Daily Mail	CIRC: 1,821,684	Paperboy UK
Daily Mirror	CIRC: 1,032,144	Paperboy Home Page
...	...	...

Table 7: System outputs for the query *UK newspapers* with different feature sets. Without denotation features, the system selects the daily circulation of each newspaper instead of the newspaper names. And without structural features, the system selects the hidden navigation links from the top of the page.

4.6 Incorporating query information

So far, note that all our features depend only on the extraction predicate z and not the input query x. Remarkably, we were still able to obtain reasonable results. One explanation is that since we obtained the web pages from a search engine, the most prominent entities on the web pages, such as entities in table cells in the middle of the page, are likely to be good independent of the query.

However, different queries often denote entities with different linguistic properties. For example, queries *mayors of Chicago* and *universities in Chicago* will produce entities of different lengths, part-of-speech sequences, and word distributions. This suggests incorporating features that depend on the query.

To explore the potential of query information, we conduct the following oracle experiment. We replace each denotation feature $f(y)$ with a corresponding query-denotation feature $(f(y), g(x))$, where $g(x)$ is the category of the query x. We manually classified all queries in our dataset into 7 categories: person, media title, location/organization, abtract entity, word/phrase, object name, and miscellaneous.

Table 8 shows some examples where adding these query-denotation features improves the selected entity lists by favoring answers that are more suitable to the query category. However, Table 6 shows that these new features do not significantly improve the accuracy of our original system on the development data.

We suspect that any gains offered by the query-denotation features are subsumed by the structural features. To test this hypothesis, we conducted two experiments, the results of which are shown in Table 6. First, we removed structural features and found that using query-denotation features improves accuracy significantly over using denotation features alone from 19.8% to 25.0%. Second, we created a modified dataset where the web page in each example is a concatenation of the original web page and an unrelated web page. On

Query	euclid's elements book titles	soft drugs	professional athletes with concussions
Default features	"Prematter", "Book I.", "Book II.", "Book III.", ...	"Hard drugs", "Soft drugs", "Some drugs cannot be classified that way", ...	"Pistons-Knicks Game Becomes Site of Incredible Dance Battle", "Toronto Mayor Rob Ford Attends ...", ...
Structural + Query-Denotation	(category = *media title*) "Book I. The fundamentals ...", "Book II. Geometric algebra", ...	(category = *object name*) "methamphetamine", "psilocybin", "caffeine"	(category = *person*) "Mike Richter", "Stu Grimson", "Geoff Courtnall", ...

Table 8: System outputs after changing denotation features into query-denotation features.

this modified dataset, the prominent entities may not be the answers to the query. Here, query-denotation features improves accuracy over denotation features alone from 19.3% to 29.2%.

4.7 Comparison with other problem settings

Since zero-shot entity extraction is a new task, we cannot directly compare our system with other systems. However, we can mimic the settings of other tasks. In one experiment, we augment each input query with a single seed entity (the second annotated entity in our experiments); this setting is suggestive of Wang and Cohen (2009). Table 6 shows that this augmentation increases accuracy from 41.1% to 52.9%, suggesting that our system can perform substantially better with a small amount of additional supervision.

5 Discussion

Our work shares a base with the wrapper induction literature (Kushmerick, 1997) in that it leverages regularities of web page structures. However, wrapper induction usually focuses on a small set of web domains, where the web pages in each domain follow a fixed template (Muslea et al., 2001; Crescenzi et al., 2001; Cohen et al., 2002; Arasu and Garcia-Molina, 2003). Later work in web data extraction attempts to generalize across different web pages, but relies on either restricted data formats (Wong et al., 2009) or prior knowledge of web page structures with respect to the type of data to extract (Zhang et al., 2013).

In our case, we only have the natural language query, which presents the more difficult problem of associating the entity class in the query (e.g., *hiking trails*) to concrete entities (e.g., *Avalon Super Loop*). In contrast to information extraction systems that extract homogeneous records from web pages (Liu et al., 2003; Zheng et al., 2009), our system must choose the correct field from each record and also identify the relevant part of the page based on the query.

Another related line of work is information extraction from text, which relies on natural language patterns to extract categories and relations of entities. One classic example is Hearst patterns (Hearst, 1992; Etzioni et al., 2005), which can learn new entities and extraction patterns from seed examples. More recent approaches also leverage semi-structured data to obtain more robust extraction patterns (Mintz et al., 2009; Hoffmann et al., 2011; Surdeanu et al., 2012; Riedel et al., 2013). Although our work focuses on semi-structured web pages rather than raw text, we use linguistic patterns of queries and entities as a signal for extracting appropriate answers.

Additionally, our efforts can be viewed as building a lexicon on the fly. In recent years, there has been a drive to scale semantic parsing to large databases such as Freebase (Cai and Yates, 2013; Berant et al., 2013; Kwiatkowski et al., 2013). However, despite the best efforts of information extraction, such databases will always lag behind the open web. For example, Berant et al. (2013) found that less than 10% of naturally occurring questions are answerable by a simple Freebase query. By using the semi-structured data from the web as a knowledge base, we hope to increase fact coverage for semantic parsing.

Finally, as pointed out in the error analysis, we need to filter or aggregate the selected entities for complex queries (e.g., *tech companies in China* for a web page with all Asian tech companies). In future work, we would like to explore the issue of compositionality in queries by aligning linguistic structures in natural language with the relative position of entities on web pages.

Incremental Joint Extraction of Entity Mentions and Relations

Qi Li **Heng Ji**

Abstract

We present an incremental joint framework to simultaneously extract entity mentions and relations using structured perceptron with efficient beam-search. A segment-based decoder based on the idea of semi-Markov chain is adopted to the new framework as opposed to traditional token-based tagging. In addition, by virtue of the inexact search, we developed a number of new and effective global features as soft constraints to capture the interdependency among entity mentions and relations. Experiments on Automatic Content Extraction (ACE)[1] corpora demonstrate that our joint model significantly outperforms a strong pipelined baseline, which attains better performance than the best-reported end-to-end system.

1 Introduction

The goal of end-to-end entity mention and relation extraction is to discover relational structures of entity mentions from unstructured texts. This problem has been artificially broken down into several components such as entity mention boundary identification, entity type classification and relation extraction. Although adopting such a pipelined approach would make a system comparatively easy to assemble, it has some limitations: First, it prohibits the interactions between components. Errors in the upstream components are propagated to the downstream components without any feedback. Second, it over-simplifies the problem as multiple local classification steps without modeling long-distance and cross-task dependencies. By contrast, we re-formulate this task as a structured prediction problem to reveal the linguistic and logical properties of the hidden structures. For example, in Figure 1, the output structure of each sentence can be interpreted as a graph in which entity mentions are nodes and relations are directed arcs with relation types. By jointly predicting the structures, we aim to address the aforementioned limitations by capturing: (i) The interactions between two tasks. For example, in Figure 1a, although it may be difficult for a mention extractor to predict "1,400" as a Person (PER) mention, the context word "employs" between "tire maker" and "1,400" strongly indicates an Employment-Organization (EMP-ORG) relation which must involve a PER mention. (ii) The global features of the hidden structure. Various entity mentions and relations share linguistic and logical constraints. For example, we can use the triangle feature in Figure 1b to ensure that the relations between "forces", and each of the entity mentions "Somalia$_{\text{GPE}}$", "Haiti$_{\text{GPE}}$" and "Kosovo$_{\text{GPE}}$", are of the same type (Physical (PHYS), in this case).

Following the above intuitions, we introduce a joint framework based on structured perceptron (Collins, 2002; Collins and Roark, 2004) with beam-search to extract entity mentions and relations simultaneously. With the benefit of inexact search, we are also able to use arbitrary global features with low cost. The underlying learning algorithm has been successfully applied to some other Natural Language Processing (NLP) tasks. Our task differs from dependency parsing (such as (Huang and Sagae, 2010)) in that relation structures are more flexible, where each node can have arbitrary relation arcs. Our previous work (Li et al., 2013) used perceptron model with token-based tagging to jointly extract event triggers and arguments. By contrast, we aim to address a more challenging task: identifying mention boundaries and types together with relations, which raises the issue that assignments for the same sentence with different mention boundaries are difficult to syn-

(a) Interactions between Two Tasks (b) Example of Global Feature

Figure 1: End-to-End Entity Mention and Relation Extraction.

chronize during search. To tackle this problem, we adopt a segment-based decoding algorithm derived from (Sarawagi and Cohen, 2004; Zhang and Clark, 2008) based on the idea of semi-Markov chain (a.k.a, multiple-beam search algorithm).

Most previous attempts on joint inference of entity mentions and relations (such as (Roth and Yih, 2004; Roth and Yih, 2007)) assumed that entity mention boundaries were given, and the classifiers of mentions and relations are separately learned. As a key difference, we incrementally extract entity mentions together with relations using a single model. The main contributions of this paper are as follows:

1. This is the first work to incrementally predict entity mentions and relations using a single joint model (Section 3).
2. Predicting mention boundaries in the joint framework raises the challenge of synchronizing different assignments in the same beam. We solve this problem by detecting entity mentions on segment-level instead of traditional token-based approaches (Section 3.1.1).
3. We design a set of novel global features based on soft constraints over the entire output graph structure with low cost (Section 4).

Experimental results show that the proposed framework achieves better performance than pipelined approaches, and global features provide further significant gains.

2 Background

2.1 Task Definition

The entity mention extraction and relation extraction tasks we are addressing are those of the Automatic Content Extraction (ACE) program[2]. ACE defined 7 main entity types including Person (PER), Organization (ORG), Geographical Entities (GPE), Location (LOC), Facility (FAC), Weapon (WEA) and Vehicle (VEH). The goal of relation extraction[3] is to extract semantic relations of the targeted types between a pair of entity mentions which appear in the same sentence. ACE'04 defined 7 main relation types: Physical (PHYS), Person-Social (PER-SOC), Employment-Organization (EMP-ORG), Agent-Artifact (ART), PER/ORG Affiliation (Other-AFF), GPE-Affiliation (GPE-AFF) and Discourse (DISC). ACE'05 kept PER-SOC, ART and GPE-AFF, split PHYS into PHYS and a new relation type Part-Whole, removed DISC, and merged EMP-ORG and Other-AFF into EMP-ORG.

Throughout this paper, we use $\perp$ to denote non-entity or non-relation classes. We consider relation asymmetric. The same relation type with opposite directions is considered to be two classes, which we refer to as *directed relation types*.

Most previous research on relation extraction assumed that entity mentions were given In this work we aim to address the problem of end-to-end entity mention and relation extraction from raw texts.

2.2 Baseline System

In order to develop a baseline system representing state-of-the-art pipelined approaches, we trained a linear-chain Conditional Random Fields model (Lafferty et al., 2001) for entity mention extraction and a Maximum Entropy model for relation extraction.

Entity Mention Extraction Model We re-cast the problem of entity mention extraction as a sequential token tagging task as in the state-of-the-art system (Florian et al., 2006). We applied the BILOU scheme, where each tag means a token is the **B**eginning, **I**nside, **L**ast, **O**utside, and **U**nit of an entity mention, respectively. Most of our features are similar to the work of (Florian et al.,

[2]http://www.nist.gov/speech/tests/ace

[3]Throughout this paper we refer to relation mention as relation since we do not consider relation mention coreference.

2004; Florian et al., 2006) except that we do not have their gazetteers and outputs from other mention detection systems as features. Our additional features are as follows:

- Governor word of the current token based on dependency parsing (Marneffe et al., 2006).
- Prefix of each word in Brown clusters learned from TDT5 corpus (Sun et al., 2011).

Relation Extraction Model Given a sentence with entity mention annotations, the goal of baseline relation extraction is to classify each mention pair into one of the pre-defined relation types with direction or $\perp$ (non-relation). Most of our relation extraction features are based on the previous work of (Zhou et al., 2005) and (Kambhatla, 2004). We designed the following additional features:

- The label sequence of phrases covering the two mentions. For example, for the sentence in Figure 1a, the sequence is "NP VP NP". We also augment it by head words of each phrase.
- Four syntactico - semantic patterns described in (Chan and Roth, 2010).
- We replicated each lexical feature by replacing each word with its Brown cluster.

3 Algorithm

3.1 The Model

Our goal is to predict the hidden structure of each sentence based on arbitrary features and constraints. Let $x \in \mathcal{X}$ be an input sentence, $y' \in \mathcal{Y}$ be a candidate structure, and $\mathbf{f}(x, y')$ be the feature vector that characterizes the entire structure. We use the following linear model to predict the most probable structure $\hat{y}$ for x:

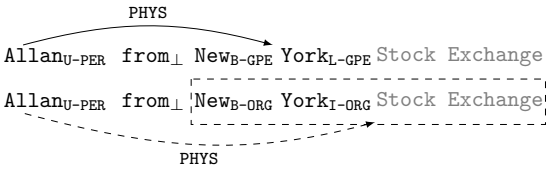
$$\hat{y} = \underset{y' \in \mathcal{Y}(x)}{\operatorname{argmax}} \mathbf{f}(x, y') \cdot \mathbf{w} \quad (1)$$

where the score of each candidate assignment is defined as the inner product of the feature vector $\mathbf{f}(x, y')$ and feature weights $\mathbf{w}$.

Since the structures contain both entity mentions relations, and we also aim to exploit global features. There does not exist a polynomial-time algorithm to find the best structure. In practice we apply beam-search to expand partial configurations for the input sentence incrementally to find the structure with the highest score.

3.1.1 Joint Decoding Algorithm

One main challenge to search for entity mentions and relations incrementally is the alignment of different assignments. Assignments for the same sentence can have different numbers of entity mentions and relation arcs. The entity mention extraction task is often re-cast as a token-level sequential labeling problem with BIO or BILOU scheme (Ratinov and Roth, 2009; Florian et al., 2006). A naive solution to our task is to adopt this strategy by treating each token as a state. However, different assignments for the same sentence can have various mention boundaries. It is unfair to compare the model scores of a partial mention and a complete mention. It is also difficult to synchronize the search process of relations. For example, consider the two hypotheses ending at "York" for the same sentence:



The model would bias towards the incorrect assignment "New/B-GPE York/L-GPE" since it can have more informative features as a complete mention (e.g., a binary feature indicating if the entire mention appears in a GPE gazetter). Furthermore, the predictions of the two PHYS relations cannot be synchronized since "New/B-FAC York/I-FAC" is not yet a complete mention.

To tackle these problems, we employ the idea of semi-Markov chain (Sarawagi and Cohen, 2004), in which each state corresponds to a segment of the input sequence. They presented a variant of Viterbi algorithm for exact inference in semi-Markov chain. We relax the max operation by beam-search, resulting in a segment-based decoder similar to the multiple-beam algorithm in (Zhang and Clark, 2008). Let $\hat{d}$ be the upper bound of entity mention length. The k-*best* partial assignments ending at the i-th token can be calculated as:

$$B[i] = \underset{y' \in \{y_{[1..i]} | y_{[1:i-d]} \in B[i-d],\, d=1...\hat{d}\}}{\text{k-}BEST} \mathbf{f}(x, y') \cdot \mathbf{w}$$

where $y_{[1:i-d]}$ stands for a partial configuration ending at the $(i\text{-}d)$-th token, and $y_{[i-d+1,i]}$ corresponds to the structure of a new segment (i.e., subsequence of x) $x_{[i-d+1,i]}$. Our joint decoding algorithm is shown in Figure 2. For each token index i, it maintains a beam for the partial assignments whose last segments end at the i-th token. There are two types of actions during the search:

Input: input sentence $x = (x_1, x_2, ..., x_m)$.
k: beam size.
$\mathcal{T} \cup \{\perp\}$: entity mention type alphabet.
$\mathcal{R} \cup \{\perp\}$: directed relation type alphabet.[4]
d_t: max length of type-t segment, $t \in \mathcal{T} \cup \{\perp\}$.
Output: best configuration $\hat{y}$ for x

```
1  initialize m empty beams B[1..m]
2  for i ← 1...m do
3    for t ∈ T ∪ {⊥} do
4      for d ← 1...d_t, y' ∈ B[i − d] do
5        k ← i − d + 1
6        B[i] ← B[i] ∪ APPEND(y', t, k, i)
7    B[i] ← k-BEST(B[i])
8    for j ← (i − 1)...1 do
9      buf ← ∅
10     for y' ∈ B[i] do
11       if HASPAIR(y', i, j) then
12         for r ∈ R ∪ {⊥} do
13           buf ← buf ∪ LINK(y', r, i, j)
14       else
15         buf ← buf ∪ {y'}
16     B[i] ← k-BEST(buf)
17 return B[m][0]
```

Figure 2: Joint Decoding for Entity Mentions and Relations. *HASPAIR*(y', i, j) checks if there are two entity mentions in y' that end at token x_i and token x_j, respectively. *APPEND*(y', t, k, i) appends y' with a type-t segment spanning from x_k to x_i. Similarly *LINK*(y', r, i, j) augments y' by assigning a directed relation r to the pair of entity mentions ending at x_i and x_j respectively.

1. *APPEND* (Lines 3-7). First, the algorithm enumerates all possible segments (i.e., subsequences) of x ending at the current token with various entity types. A special type of segment is a single token with non-entity label ($\perp$). Each segment is then appended to existing partial assignments in one of the previous beams to form new assignments. Finally the top k results are recorded in the current beam.
2. *LINK* (Lines 8-16). After each step of *APPEND*, the algorithm looks backward to link the newly identified entity mentions and previous ones (if any) with relation arcs. At the j-th sub-step, it only considers the previous mention ending at the j-th previous token. Therefore different configurations are guaranteed to have the same number of sub-steps. Finally, all assignments are re-ranked with new relation information.

[4]The same relation type with opposite directions is considered to be two classes in $\mathcal{R}$.

There are m *APPEND* actions, each is followed by at most $(i-1)$ *LINK* actions (line 8). Therefore the worst-case time complexity is $O(\hat{d} \cdot k \cdot m^2)$, where $\hat{d}$ is the upper bound of segment length.

3.1.2 Example Demonstration

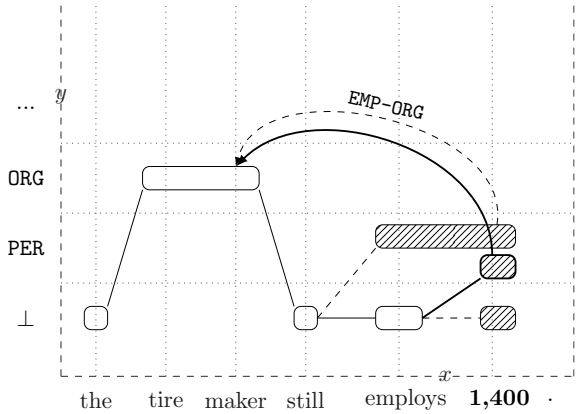


Figure 3: Example of decoding steps. x-axis and y-axis represent the input sentence and entity types, respectively. The rectangles denote segments with entity types, among which the shaded ones are three competing hypotheses ending at "1,400". The solid lines and arrows indicate correct *APPEND* and *LINK* actions respectively, while the dashed indicate incorrect actions.

Here we demonstrate a simple but concrete example by considering again the sentence described in Figure 1a. Suppose we are at the token "1,400". At this point we can propose multiple entity mentions with various lengths. Assuming "1,400$_{/\texttt{PER}}$", "1,400$_{/\perp}$" and "(employs 1,400)$_{/\texttt{PER}}$" are possible assignments, the algorithm appends these new segments to the partial assignments in the beams of the tokens "employs" and "still", respectively. Figure 3 illustrates this process. For simplicity, only a small part of the search space is presented. The algorithm then links the newly identified mentions to the previous ones in the same configuration. In this example, the only previous mention is "(tire maker)$_{/\texttt{ORG}}$". Finally, "1,400$_{/\texttt{PER}}$" will be preferred by the model since there are more indicative context features for EMP−ORG relation between "(tire maker)$_{/\texttt{PER}}$" and "1,400$_{/\texttt{PER}}$".

3.2 Structured-Perceptron Learning

To estimate the feature weights, we use structured perceptron (Collins, 2002), an extension of the standard perceptron for structured prediction, as the learning framework. Huang et al. (2012) proved the convergency of structured perceptron when inexact search is applied with violation-fixing update methods such as early-update (Collins and Roark, 2004). Since we use beam-search in this work, we apply early-update. In addition, we use averaged parameters to reduce overfitting as in (Collins, 2002).

Figure 4 shows the pseudocode for structured perceptron training with early-update. Here *BEAMSEARCH* is identical to the decoding algorithm described in Figure 2 except that if y', the prefix of the gold standard y, falls out of the beam after each execution of the k-*BEST* function (line 7 and 16), then the top assignment z and y' are returned for parameter update. It is worth noting that this can only happen if the gold-standard has a segment ending at the current token. For instance, in the example of Figure 1a, $B[2]$ cannot trigger any early-update since the gold standard does not contain any segment ending at the second token.

Input: training set $\mathcal{D} = \{(x^{(j)}, y^{(j)})\}_{i=1}^{N}$, maximum iteration number T
Output: model parameters $\mathbf{w}$
1 initialize $\mathbf{w} \leftarrow \mathbf{0}$
2 **for** $t \leftarrow 1...T$ **do**
3 **foreach** $(x, y) \in \mathcal{D}$ **do**
4 $(x, y', z) \leftarrow$ *BEAMSEARCH* $(x, y, \mathbf{w})$
5 **if** $z \neq y$ **then**
6 $\mathbf{w} \leftarrow \mathbf{w} + \mathbf{f}(x, y') - \mathbf{f}(x, z)$
7 return $\mathbf{w}$

Figure 4: Perceptron algorithm with beam-search and early-update. y' is the prefix of the gold-standard and z is the top assignment.

3.3 Entity Type Constraints

Entity type constraints have been shown effective in predicting relations (Roth and Yih, 2007; Chan and Roth, 2010). We automatically collect a mapping table of permissible entity types for each relation type from our training data. Instead of applying the constraints in post-processing inference, we prune the branches that violate the type constraints during search. This type of pruning can reduce search space as well as make the input for parameter update less noisy. In our experiments, only 7 relation mentions (0.5%) in the dev set and 5 relation mentions (0.3%) in the test set violate the constraints collected from the training data.

4 Features

An advantage of our framework is that we can easily exploit arbitrary features across the two tasks. This section describes the local features (Section 4.1) and global features (Section 4.2) we developed in this work.

4.1 Local Features

We design segment-based features to directly evaluate the properties of an entity mention instead of the individual tokens it contains. Let $\hat{y}$ be a predicted structure of a sentence x. The entity segments of $\hat{y}$ can be expressed as a list of triples $(e_1, ..., e_m)$, where each segment $e_i = \langle u_i, v_i, t_i \rangle$ is a triple of start index u_i, end index v_i, and entity type t_i. The following is an example of segment-based feature:

$$f_{001}(x, \hat{y}, i) = \begin{cases} 1 & \text{if } x_{[\hat{y}.u_i, \hat{y}.v_i]} = \text{ tire maker} \\ & \hat{y}.t_{(i-1)}, \hat{y}.t_i = \perp, \texttt{ORG} \\ 0 & \text{otherwise} \end{cases}$$

This feature is triggered if the labels of the $(i-1)$-th and the i-th segments are "$\perp$, ORG", and the text of the i-th segment is "tire maker". Our segment-based features are described as follows:

Gazetteer features Entity type of each segment based on matching a number of gazetteers including persons, countries, cities and organizations.

Case features Whether a segment's words are initial-capitalized, all lower cased, or mixture.

Contextual features Unigrams and bigrams of the text and part-of-speech tags in a segment's contextual window of size 2.

Parsing-based features Features derived from constituent parsing trees, including (a) the phrase type of the lowest common ancestor of the tokens contained in the segment, (b) the depth of the lowest common ancestor, (c) a binary feature indicating if the segment is a base phrase or a suffix of a base phrase, and (d) the head words of the segment and its neighbor phrases.

In addition, we convert each triple $\langle u_i, v_i, t_i \rangle$ to BILOU tags for the tokens it contains to implement token-based features. The token-based men-

tion features and local relation features are identical to those of our pipelined system (Section 2.2).

4.2 Global Entity Mention Features

By virtue of the efficient inexact search, we are able to use arbitrary features from the entire structure of $\hat{y}$ to capture long-distance dependencies. The following features between related entity mentions are extracted once a new segment is appended during decoding.

Coreference consistency Coreferential entity mentions should be assigned the same entity type. We determine high-recall coreference links between two segments in the same sentence using some simple heuristic rules:

- Two segments exactly or partially string match.
- A pronoun (e.g., "*their*","*it*") refers to previous entity mentions. For example, in "***they** have no insurance on **their** cars*", "*they*" and "*their*" should have the same entity type.
- A relative pronoun (e.g., "*which*","*that*", and "*who*") refers to the noun phrase it modifies in the parsing tree. For example, in "*the starting kicker is **nikita kargalskiy**, **who** may be 5,000 miles from his hometown*", "*nikita kargalskiy*" and "*who*" should both be labeled as persons.

Then we encode a global feature to check whether two coreferential segments share the same entity type. This feature is particularly effective for pronouns because their contexts alone are often not informative.

Neighbor coherence Neighboring entity mentions tend to have coherent entity types. For example, in "***Barbara Starr** was reporting from the **Pentagon***", "*Barbara Starr*" and "*Pentagon*" are connected by a dependency link *prep_from* and thus they are unlikely to be a pair of PER mentions. Two types of neighbor are considered: (i) the first entity mention before the current segment, and (ii) the segment which is connected by a single word or a dependency link with the current segment. We take the entity types of the two segments and the linkage together as a global feature. For instance, "PER *prep_from* PER" is a feature for the above example when "*Barbara Starr*" and "*Pentagon*" are both labeled as PER mentions.

Part-of-whole consistency If an entity mention is semantically part of another mention (connected by a *prep_of* dependency link), they should be assigned the same entity type. For example, in "***some** of Iraq's **exiles***", "*some*" and "*exiles*" are both PER mentions; in "***one** of the town's two meat-packing **plants***", "*one*" and "*plants*" are both FAC mentions; in "*the **rest** of **America***", "*rest*" and "*America*" are both GPE mentions.

4.3 Global Relation Features

Relation arcs can also share inter-dependencies or obey soft constraints. We extract the following relation-centric global features when a new relation hypothesis is made during decoding.

Role coherence If an entity mention is involved in multiple relations with the same type, then its roles should be coherent. For example, a PER mention is unlikely to have more than one employer. However, a GPE mention can be a physical location for multiple entity mentions. We combine the relation type and the entity mention's argument roles as a global feature, as shown in Figure 5a.

Triangle constraint Multiple entity mentions are unlikely to be fully connected with the same relation type. We use a negative feature to penalize any configuration that contains this type of structure. An example is shown in Figure 5b.

Inter-dependent compatibility If two entity mentions are connected by a dependency link, they tend to have compatible relations with other entities. For example, in Figure 5c, the *conj_and* dependency link between "*Somalia*" and "*Kosovo*" indicates they may share the same relation type with the third entity mention "*forces*".

Neighbor coherence Similar to the entity mention neighbor coherence feature, we also combine the types of two neighbor relations in the same sentence as a bigram feature.

5 Experiments

5.1 Data and Scoring Metric

Most previous work on ACE relation extraction has reported results on ACE'04 data set. As we will show later in our experiments, ACE'05 made significant improvement on both relation type definition and annotation quality. Therefore we present the overall performance on ACE'05 data. We removed two small subsets in informal genres - *cts* and *un*, and then randomly split the remaining 511 documents into 3 parts: 351 for training, 80 for development, and the rest 80 for blind test. In order to compare with state-of-the-art we also performed the same 5-fold cross-validation on *bnews* and *nwire* subsets of ACE'04 corpus as in previous work. The statistics of these data sets

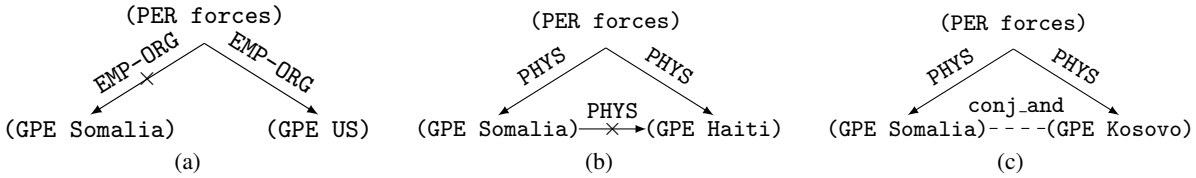

Figure 5: Examples of Global Relation Features.

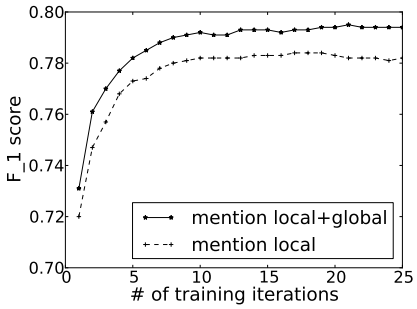
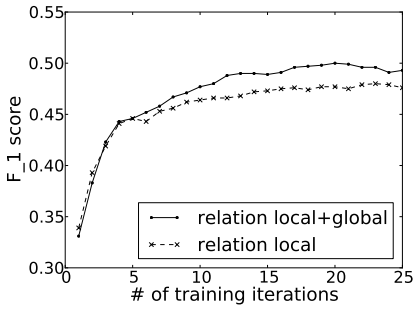


(a) Entity Mention Performance



(b) Relation Performance

Figure 6: Learning Curves on Development Set.

are summarized in Table 1. We ran the Stanford CoreNLP toolkit[5] to automatically recover the true cases for lowercased documents.

Data Set		# sentences	# mentions	# relations
ACE'05	Train	7,273	26,470	4,779
	Dev	1,765	6,421	1,179
	Test	1,535	5,476	1,147
ACE'04		6,789	22,740	4,368

Table 1: Data Sets.

We use the standard F_1 measure to evaluate the performance of entity mention extraction and relation extraction. An entity mention is considered correct if its entity type is correct and the offsets of its mention head are correct. A relation mention is considered correct if its relation type is correct, and the head offsets of two entity mention arguments are both correct. As in Chan and Roth (2011), we excluded the DISC relation type, and removed relations in the system output which are implicitly correct via coreference links for fair comparison. Furthermore, we combine these two criteria to evaluate the performance of end-to-end entity mention and relation extraction.

[5]http://nlp.stanford.edu/software/corenlp.shtml

5.2 Development Results

In general a larger beam size can yield better performance but increase training and decoding time. As a tradeoff, we set the beam size as 8 throughout the experiments. Figure 6 shows the learning curves on the development set, and compares the performance with and without global features. From these figures we can clearly see that global features consistently improve the extraction performance of both tasks. We set the number of training iterations as 22 based on these curves.

5.3 Overall Performance

Table 2 shows the overall performance of various methods on the ACE'05 test data. We compare our proposed method (Joint w/ Global) with the pipelined system (Pipeline), the joint model with only local features (Joint w/ Local), and two human annotators who annotated 73 documents in ACE'05 corpus.

We can see that our approach significantly outperforms the pipelined approach for both tasks. As a real example, for the partial sentence "*a marcher from Florida*" from the test data, the pipelined approach failed to identify "*marcher*" as a PER mention, and thus missed the GEN-AFF relation between "*marcher*" and "*Florida*". Our joint model correctly identified the entity mentions and their relation. Figure 7 shows the details when the joint model is applied to this sentence. At the token "*marcher*", the top hypothesis in the beam is "$\langle \perp, \perp \rangle$", while the correct one is ranked second best. After the decoder processes the token "*Florida*", the correct hypothesis is promoted to the top in the beam by the *Neighbor Coherence* features for PER-GPE pair. Furthermore, after

Model	Entity Mention (%)			Relation (%)			Entity Mention + Relation (%)		
Score	P	R	F_1	P	R	F_1	P	R	F_1
Pipeline	83.2	73.6	78.1	67.5	39.4	49.8	65.1	38.1	48.0
Joint w/ Local	84.5	76.0	80.0	68.4	40.1	50.6	65.3	38.3	48.3
Joint w/ Global	85.2	76.9	**80.8**	68.9	41.9	**52.1**	65.4	39.8	**49.5**
Annotator 1	91.8	89.9	90.9	71.9	69.0	70.4	69.5	66.7	68.1
Annotator 2	88.7	88.3	88.5	65.2	63.6	64.4	61.8	60.2	61.0
Inter-Agreement	85.8	87.3	86.5	55.4	54.7	55.0	52.3	51.6	51.9

Table 2: Overall performance on ACE'05 corpus.

steps	hypotheses	rank
(a)	$\langle \texttt{a}_\perp \ \texttt{marcher}_\perp \rangle$	1
	$\langle \texttt{a}_\perp \ \texttt{marcher}_{\texttt{PER}} \rangle$	2
(b)	$\langle \texttt{a}_\perp \ \texttt{marcher}_\perp \ \ \texttt{from}_\perp \rangle$	1
	$\langle \texttt{a}_\perp \ \texttt{marcher}_{\texttt{PER}} \ \texttt{from}_\perp \rangle$	4
(c)	$\langle \texttt{a}_\perp \ \texttt{marcher}_{\texttt{PER}} \ \texttt{from}_\perp \ \ \texttt{Florida}_{\texttt{GPE}} \rangle$	1
	$\langle \texttt{a}_\perp \ \texttt{marcher}_\perp \ \ \texttt{from}_\perp \ \ \texttt{Florida}_{\texttt{GPE}} \rangle$	2
(d)	$\langle \texttt{a}_\perp \ \overset{\texttt{GEN-AFF}}{\texttt{marcher}_{\texttt{PER}}} \ \texttt{from}_\perp \ \ \texttt{Florida}_{\texttt{GPE}} \rangle$	1
	$\langle \texttt{a}_\perp \ \texttt{marcher}_\perp \ \ \texttt{from}_\perp \ \ \texttt{Florida}_{\texttt{GPE}} \rangle$	4

Figure 7: Two competing hypotheses for "*a marcher from Florida*" during decoding.

linking the two mentions by GEN-AFF relation, the ranking of the incorrect hypothesis "$\langle \perp, \perp \rangle$" is dropped to the 4-th place in the beam, resulting in a large margin from the correct hypothesis.

The human F_1 score on end-to-end relation extraction is only about 70%, which indicates it is a very challenging task. Furthermore, the F_1 score of the inter-annotator agreement is 51.9%, which is only 2.4% above that of our proposed method.

Compared to human annotators, the bottleneck of automatic approaches is the low recall of relation extraction. Among the 631 remaining missing relations, 318 (50.3%) of them were caused by missing entity mention arguments. A lot of nominal mention heads rarely appear in the training data, such as persons ("supremo", "shepherd", "oligarchs", "rich"), geo-political entity mentions ("stateside"), facilities ("roadblocks", "cells"), weapons ("sim lant", "nukes") and vehicles ("prams"). In addition, relations are often implicitly expressed in a variety of forms. Some examples are as follows:

- "*Rice has been chosen by President Bush to become the new Secretary of State*" indicates "Rice" has a PER-SOC relation with "Bush".
- "*U.S. troops are now knocking on the door of Baghdad*" indicates "troops" has a PHYS relation with "Baghdad".
- "*Russia and France sent planes to Baghdad*" indicates "Russia" and "France" are involved in an ART relation with "planes" as owners.

In addition to contextual features, deeper semantic knowledge is required to capture such implicit semantic relations.

5.4 Comparison with State-of-the-art

Table 3 compares the performance on ACE'04 corpus. For entity mention extraction, our joint model achieved 79.7% on 5-fold cross-validation, which is comparable with the best F_1 score 79.2% reported by (Florian et al., 2006) on single-fold. However, Florian et al. (2006) used some gazetteers and the output of other Information Extraction (IE) models as additional features, which provided significant gains ((Florian et al., 2004)). Since these gazetteers, additional data sets and external IE models are all not publicly available, it is not fair to directly compare our joint model with their results.

For end-to-end entity mention and relation extraction, both the joint approach and the pipelined baseline outperform the best results reported by (Chan and Roth, 2011) under the same setting.

6 Related Work

Entity mention extraction (e.g., (Florian et al., 2004; Florian et al., 2006; Florian et al., 2010; Zitouni and Florian, 2008; Ohta et al., 2012)) and relation extraction (e.g., (Reichartz et al., 2009; Sun et al., 2011; Jiang and Zhai, 2007; Bunescu and Mooney, 2005; Zhao and Grishman, 2005; Culotta and Sorensen, 2004; Zhou et al., 2007; Qian and Zhou, 2010; Qian et al., 2008; Chan and Roth, 2011; Plank and Moschitti, 2013)) have drawn much attention in recent years but were

Model	Entity Mention (%)			Relation (%)			Entity Mention + Relation (%)		
Score	P	R	F_1	P	R	F_1	P	R	F_1
Chan and Roth (2011)		-		42.9	38.9	40.8		-	
Pipeline	81.5	74.1	77.6	62.5	36.4	46.0	58.4	33.9	42.9
Joint w/ Local	82.7	75.2	78.8	64.2	37.0	46.9	60.3	34.8	44.1
Joint w/ Global	83.5	76.2	**79.7**	64.7	38.5	**48.3**	60.8	36.1	**45.3**

Table 3: 5-fold cross-validation on ACE'04 corpus. Bolded scores indicate highly statistical significant improvement as measured by paired t-test ($p < 0.01$)

usually studied separately. Most relation extraction work assumed that entity mention boundaries and/or types were given. Chan and Roth (2011) reported the best results using predicted entity mentions.

Some previous work used relations and entity mentions to enhance each other in joint inference frameworks, including re-ranking (Ji and Grishman, 2005), Integer Linear Programming (ILP) (Roth and Yih, 2004; Roth and Yih, 2007; Yang and Cardie, 2013), and Card-pyramid Parsing (Kate and Mooney, 2010). All these work noted the advantage of exploiting cross-component interactions and richer knowledge. However, they relied on models separately learned for each subtask. As a key difference, our approach jointly extracts entity mentions and relations using a single model, in which arbitrary soft constraints can be easily incorporated. Some other work applied probabilistic graphical models for joint extraction (e.g., (Singh et al., 2013; Yu and Lam, 2010)). By contrast, our work employs an efficient joint search algorithm without modeling joint distribution over numerous variables, therefore it is more flexible and computationally simpler. In addition, (Singh et al., 2013) used gold-standard mention boundaries.

Our previous work (Li et al., 2013) used structured perceptron with token-based decoder to jointly predict event triggers and arguments based on the assumption that entity mentions and other argument candidates are given as part of the input. In this paper, we solve a more challenging problem: take raw texts as input and identify the boundaries, types of entity mentions and relations all together in a single model. Sarawagi and Cohen (2004) proposed a segment-based CRFs model for name tagging. Zhang and Clark (2008) used a segment-based decoder for word segmentation and pos tagging. We extended the similar idea to our end-to-end task by incrementally predicting relations along with entity mention segments.

7 Conclusions and Future Work

In this paper we introduced a new architecture for more powerful end-to-end entity mention and relation extraction. For the first time, we addressed this challenging task by an incremental beam-search algorithm in conjunction with structured perceptron. While detecting mention boundaries jointly with other components raises the challenge of synchronizing multiple assignments in the same beam, a simple yet effective segment-based decoder is adopted to solve this problem. More importantly, we exploited a set of global features based on linguistic and logical properties of the two tasks to predict more coherent structures. Experiments demonstrated our approach significantly outperformed pipelined approaches for both tasks and dramatically advanced state-of-the-art.

In future work, we plan to explore more soft and hard constraints to reduce search space as well as improve accuracy. In addition, we aim to incorporate other IE components such as event extraction into the joint model.

That's Not What I Meant! Using Parsers to Avoid Structural Ambiguities in Generated Text

Manjuan Duan and **Michael White**
Department of Linguistics
The Ohio State University
Columbus, OH 43210, USA
{duan,mwhite}@ling.osu.edu

Abstract

We investigate whether parsers can be used for self-monitoring in surface realization in order to avoid egregious errors involving "vicious" ambiguities, namely those where the intended interpretation fails to be considerably more likely than alternative ones. Using parse accuracy in a simple reranking strategy for self-monitoring, we find that with a state-of-the-art averaged perceptron realization ranking model, BLEU scores cannot be improved with any of the well-known Treebank parsers we tested, since these parsers too often make errors that human readers would be unlikely to make. However, by using an SVM ranker to combine the realizer's model score together with features from multiple parsers, including ones designed to make the ranker more robust to parsing mistakes, we show that significant increases in BLEU scores can be achieved. Moreover, via a targeted manual analysis, we demonstrate that the SVM reranker frequently manages to avoid vicious ambiguities, while its ranking errors tend to affect fluency much more often than adequacy.

1 Introduction

Rajkumar & White (2011; 2012) have recently shown that some rather egregious surface realization errors—in the sense that the reader would likely end up with the wrong interpretation—can be avoided by making use of features inspired by psycholinguistics research together with an otherwise state-of-the-art averaged perceptron realization ranking model (White and Rajkumar, 2009), as reviewed in the next section. However, one is apt to wonder: could one use a parser to check whether the intended interpretation is easy to recover, either as an alternative or to catch additional mistakes? Doing so would be tantamount to self-monitoring in Levelt's (1989) model of language production.

Neumann & van Noord (1992) pursued the idea of self-monitoring for generation in early work with reversible grammars. As Neumann & van Noord observed, a simple, brute-force way to generate unambiguous sentences is to enumerate possible realizations of an input logical form, then to parse each realization to see how many interpretations it has, keeping only those that have a single reading; they then went on to devise a more efficient method of using self-monitoring to avoid generating ambiguous sentences, targeted to the ambiguous portion of the output. We might question, however, whether it is really possible to avoid ambiguity entirely in the general case, since Abney (1996) and others have argued that nearly every sentence is potentially ambiguous, though we (as human comprehenders) may not notice the ambiguities if they are unlikely. Taking up this issue, Khan et al. (2008)—building on Chantree et al.'s (2006) approach to identifying "innocuous" ambiguities—conducted several experiments to test whether ambiguity could be balanced against length or fluency in the context of generating referring expressions involving coordinate structures. Though Khan et al.'s study was limited to this one kind of structural ambiguity, they do observe that generating the brief variants when the intended interpretation is clear instantiates Van Deemter's (2004) general strategy of only avoiding **vicious ambiguities**—that is, ambiguities where the intended interpretation fails to be considerably more likely than any other distractor interpretations—rather than trying to avoid all ambiguities.

In this paper, we investigate whether Neumann & van Noord's brute-force strategy for avoid-

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 413–423,
Baltimore, Maryland, USA, June 23-25 2014.

ing ambiguities in surface realization can be updated to only avoid vicious ambiguities, extending (and revising) Van Deemter's general strategy to all kinds of structural ambiguity, not just the one investigated by Khan et al. To do so—in a nutshell—we enumerate an n-best list of realizations and rerank them if necessary to avoid vicious ambiguities, as determined by one or more automatic parsers. A potential obstacle, of course, is that automatic parsers may not be sufficiently representative of human readers, insofar as errors that a parser makes may not be problematic for human comprehension; moreover, parsers are rarely successful in fully recovering the intended interpretation for sentences of moderate length, even with carefully edited news text. Consequently, we examine two reranking strategies, one a simple baseline approach and the other using an SVM reranker (Joachims, 2002).

Our simple reranking strategy for self-monitoring is to rerank the realizer's n-best list by parse accuracy, preserving the original order in case of ties. In this way, if there is a realization in the n-best list that can be parsed more accurately than the top-ranked realization—even if the intended interpretation cannot be recovered with 100% accuracy—it will become the preferred output of the combined realization-with-self-monitoring system. With this simple reranking strategy and each of three different Treebank parsers, we find that it is possible to improve BLEU scores on Penn Treebank development data with White & Rajkumar's (2011; 2012) baseline generative model, but not with their averaged perceptron model. In inspecting the results of reranking with this strategy, we observe that while it does sometimes succeed in avoiding egregious errors involving vicious ambiguities, common parsing mistakes such as PP-attachment errors lead to unnecessarily sacrificing conciseness or fluency in order to avoid ambiguities that would be easily tolerated by human readers. Therefore, to develop a more nuanced self-monitoring reranker that is more robust to such parsing mistakes, we trained an SVM using dependency precision and recall features for all three parses, their n-best parsing results, and per-label precision and recall for each type of dependency, together with the realizer's normalized perceptron model score as a feature. With the SVM reranker, we obtain a significant improvement in BLEU scores over White & Rajkumar's averaged perceptron model on both development and test data. Additionally, in a targeted manual analysis, we find that in cases where the SVM reranker improves the BLEU score, improvements to fluency and adequacy are roughly balanced, while in cases where the BLEU score goes down, it is mostly fluency that is made worse (with reranking yielding an acceptable paraphrase roughly one third of the time in both cases).

The paper is structured as follows. In Section 2, we review the realization ranking models that serve as a starting point for the paper. In Section 3, we report on our experiments with the simple reranking strategy, including a discussion of the ways in which this method typically fails. In Section 4, we describe how we trained an SVM reranker and report our results using BLEU scores (Papineni et al., 2002). In Section 5, we present a targeted manual analysis of the development set sentences with the greatest change in BLEU scores, discussing both successes and errors. In Section 6, we briefly review related work on broad coverage surface realization. Finally, in Section 7, we sum up and discuss opportunities for future work in this direction.

2 Background

We use the OpenCCG[1] surface realizer for the experiments reported in this paper. The OpenCCG realizer generates surface strings for input semantic dependency graphs (or logical forms) using a chart-based algorithm (White, 2006) for Combinatory Categorial Grammar (Steedman, 2000) together with a "hypertagger" for probabilistically assigning lexical categories to lexical predicates in the input (Espinosa et al., 2008). An example input appears in Figure 1. In the figure, nodes correspond to discourse referents labeled with lexical predicates, and dependency relations between nodes encode argument structure (gold standard CCG lexical categories are also shown); note that semantically empty function words such as infinitival-*to* are missing. The grammar is extracted from a version of the CCGbank (Hockenmaier and Steedman, 2007) enhanced for realization; the enhancements include: better analyses of punctuation (White and Rajkumar, 2008); less error prone handling of named entities (Rajkumar et al., 2009); re-inserting quotes into the CCGbank;

[1] `http://openccg.sf.net`

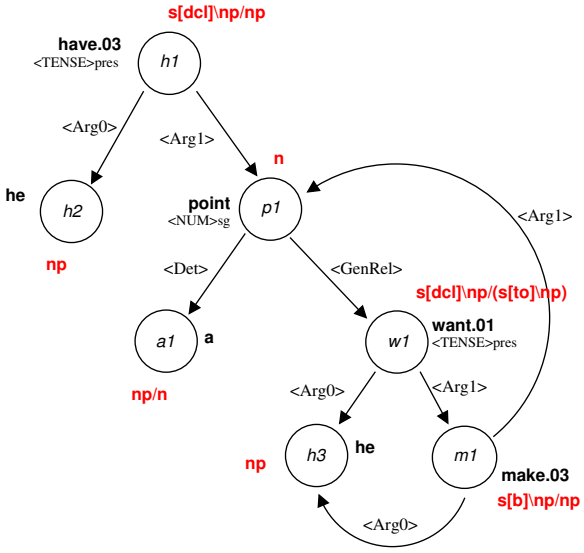

Figure 1: Example OpenCCG semantic dependency input for *he has a point he wants to make*, with gold standard lexical categories for each node

and assignment of consistent semantic roles across diathesis alternations (Boxwell and White, 2008), using PropBank (Palmer et al., 2005).

To select preferred outputs from the chart, we use White & Rajkumar's (2009; 2012) realization ranking model, recently augmented with a large-scale 5-gram model based on the Gigaword corpus. The ranking model makes choices addressing all three interrelated sub-tasks traditionally considered part of the surface realization task in natural language generation research (Reiter and Dale, 2000; Reiter, 2010): inflecting lemmas with grammatical word forms, inserting function words and linearizing the words in a grammatical and natural order. The model takes as its starting point two probabilistic models of syntax that have been developed for CCG parsing, Hockenmaier & Steedman's (2002) generative model and Clark & Curran's (2007) normal-form model. Using the averaged perceptron algorithm (Collins, 2002), White & Rajkumar (2009) trained a structured prediction ranking model to combine these existing syntactic models with several n-gram language models. This model improved upon the state-of-the-art in terms of automatic evaluation scores on held-out test data, but nevertheless an error analysis revealed a surprising number of word order, function word and inflection errors. For each kind of error, subsequent work investigated the utility of employing more linguistically motivated features to improve the ranking model.

To improve word ordering decisions, White & Rajkumar (2012) demonstrated that incorporating a feature into the ranker inspired by Gibson's (2000) dependency locality theory can deliver statistically significant improvements in automatic evaluation scores, better match the distributional characteristics of sentence orderings, and significantly reduce the number of serious ordering errors (some involving vicious ambiguities) as confirmed by a targeted human evaluation. Supporting Gibson's theory, comprehension and corpus studies have found that the tendency to **minimize dependency length** has a strong influence on constituent ordering choices; see Temperley (2007) and Gildea and Temperley (2010) for an overview.

Table 1 shows examples from White and Rajkumar (2012) of how the dependency length feature (DEPLEN) affects the OpenCCG realizer's output even in comparison to a model (DEPORD) with a rich set of discriminative syntactic and dependency ordering features, but no features directly targeting relative weight. In wsj_0015.7, the dependency length model produces an exact match, while the DEPORD model fails to shift the short temporal adverbial *next year* next to the verb, leaving a confusingly repetitive *this year next year* at the end of the sentence. Note how shifting *next year* from its canonical VP-final position to appear next to the verb shortens its dependency length considerably, while barely lengthening the dependency to *based on*; at the same time, it avoids ambiguity in what *next year* is modifying. In wsj_0020.1 we see the reverse case: the dependency length model produces a nearly exact match with just an equally acceptable inversion of *closely watching*, keeping the direct object in its canonical position. By contrast, the DEPORD model mistakenly shifts the direct object *South Korea, Taiwan and Saudia Arabia* to the end of the sentence where it is difficult to understand following two very long intervening phrases.

With function words, Rajkumar and White (2011) showed that they could improve upon the earlier model's predictions for when to employ *that*-complementizers using features inspired by Jaeger's (2010) work on using the principle of **uniform information density**, which holds that human language use tends to keep information density relatively constant in order to optimize communicative efficiency. In news text, com-

Table 1: Examples of realized output for full models with and without the dependency length feature (White and Rajkumar, 2012)

plementizers are left out two times out of three, but in some cases the presence of *that* is crucial to the interpretation. Generally, inserting a complementizer makes the onset of a complement clause more predictable, and thus less information dense, thereby avoiding a potential spike in information density that is associated with comprehension difficulty. Rajkumar & White's experiments confirmed the efficacy of the features based on Jaeger's work, including information density–based features, in a local classification model.[2] Their experiments also showed that the improvements in prediction accuracy apply to cases in which the presence of a *that*-complementizer arguably makes a substantial difference to fluency or intelligiblity. For example, in (1), the presence of *that* avoids a local ambiguity, helping the reader to understand that *for the second month in a row* modifies the reporting of the shortage; without *that*, it is very easy to mis-parse the sentence as having *for the second month in a row* modifying the saying event.

(1) He said that/∅? for the second month in a row, food processors reported a shortage of nonfat dry milk. (PTB WSJ0036.61)

Finally, to reduce the number of subject-verb agreement errors, Rajkumar and White (2010) extended the earlier model with features enabling it to make correct verb form choices in sentences involving complex coordinate constructions and with expressions such as *a lot of* where the correct choice is not determined solely by the head noun. They also improved animacy agreement with relativizers, reducing the number of errors where *that* or *which* was chosen to modify an animate noun rather than *who* or *whom* (and vice-versa), while also allowing both choices where corpus evidence was mixed.

[2]Note that the features from the local classification model for *that*-complementizer choice have not yet been incorporated into OpenCCG's global realization ranking model, and thus do not inform the baseline realization choices in this work.

3 Simple Reranking

3.1 Methods

We ran two OpenCCG surface realization models on the CCGbank dev set (derived from Section 00 of the Penn Treebank) and obtained n-best ($n = 10$) realizations. The first one is the baseline generative model (hereafter, generative model) used in training the averaged perceptron model. This model ranks realizations using the product of the Hockenmaier syntax model, n-gram models over words, POS tags and supertags in the training sections of the CCGbank, and the large-scale 5-gram model from Gigaword. The second one is the averaged perceptron model (hereafter, perceptron model), which uses all the features reviewed in Section 2. In order to experiment with multiple parsers, we used the Stanford dependencies (de Marneffe et al., 2006), obtaining gold dependencies from the gold-standard PTB parses and automatic dependencies from the automatic parses of each realization. Using dependencies allowed us to measure parse accuracy independently of word order. We chose the Berkeley parser (Petrov et al., 2006), Brown parser (Charniak and Johnson, 2005) and Stanford parser (Klein and Manning, 2003) to parse the realizations generated by the

	Berkeley	Brown	Stanford
No reranking	87.93	87.93	87.93
Labeled	87.77	87.87	87.12
Unlabeled	87.90	**87.97**	86.97

Table 2: Devset BLEU scores for simple ranking on top of n-best perceptron model realizations

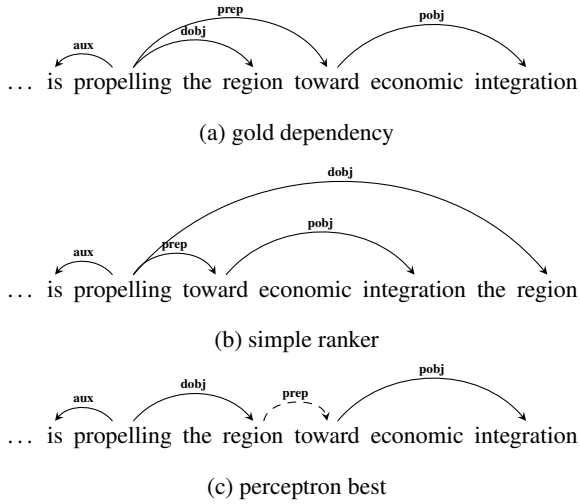

Figure 2: Example parsing mistake in PP-attachment (wsj_0043.1)

two realization models and calculated precision, recall and F_1 of the dependencies for each realization by comparing them with the gold dependencies. We then ranked the realizations by their F_1 score of parse accuracy, keeping the original ranking in case of ties. We also tried using unlabeled (and unordered) dependencies, in order to possibly make better use of parses that were close to being correct. In this setting, as long as the right pair of tokens occur in a dependency relation, it was counted as a correctly recovered dependency.

3.2 Results

Simple ranking with the Berkeley parser of the generative model's n-best realizations raised the BLEU score from 85.55 to 86.07, well below the averaged perceptron model's BLEU score of 87.93. However, as shown in Table 2, none of the parsers yielded significant improvements on the top of the perceptron model.

Inspecting the results of simple ranking revealed that while simple ranking did successfully avoid vicious ambiguities in some cases, parser mistakes with PP-attachments, noun-noun compounds and coordinate structures too often blocked the gold realization from emerging on top. To illustrate, Figure 2 shows an example with a PP-attachment mistake. In the figure, the key gold dependencies of the reference sentence are shown in (a), the dependencies of the realization selected by the simple ranker are shown in (b), and the dependencies of the realization selected by the perceptron ranker (same as gold) appear in (c), with the parsing mistake indicated by the dashed line. The simple ranker ends up choosing (b) as the best realization because it has the most accurate parse compared to the reference sentence, given the mistake with (c).

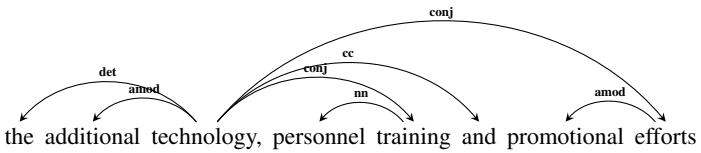
Other common parse errors are illustrated in Figure 3. Here, (b) ends up getting chosen by the simple ranker as the realization with the most accurate parse given the failures in (c), where *the additional technology, personnel training* is mistakenly analyzed as one noun phrase, a reading unlikely to be considered by human readers.

In sum, although simple ranking helps to avoid vicious ambiguity in some cases, the overall results of simple ranking are no better than the perceptron model (according to BLEU, at least), as parse failures that are not reflective of human intepretive tendencies too often lead the ranker to choose dispreferred realizations. As such, we turn now to a more nuanced model for combining the results of multiple parsers in a way that is less sensitive to such parsing mistakes, while also letting the perceptron model have a say in the final ranking.

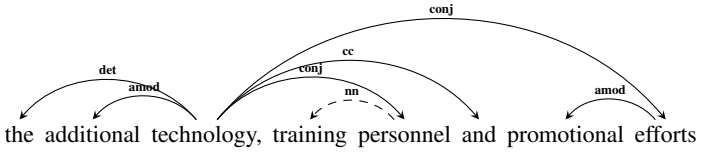
4 Reranking with SVMs

4.1 Methods

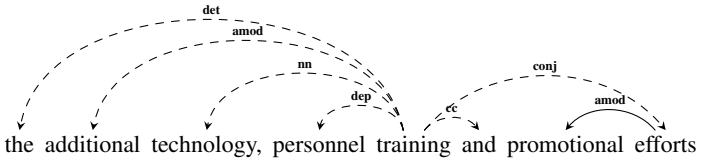
Since different parsers make different errors, we conjectured that dependencies in the intersection of the output of multiple parsers may be more reliable and thus may more reliably reflect human comprehension preferences. Similarly, we conjectured that large differences in the realizer's perceptron model score may more reliably reflect human fluency preferences than small ones, and thus we combined this score with features for parser accuracy in an SVM ranker. Additionally, given that parsers may more reliably recover some kinds of dependencies than others, we included features for each dependency type, so that the SVM ranker might learn how to weight them appropriately. Finally, since the differences among the n-best parses reflect the least certain parsing decisions,



(a) gold dependency



(b) simple ranker



(c) perceptron best

Figure 3: Example parsing mistakes in a noun-noun compound and a coordinate structure (wsj_0085.45)

and thus ones that may require more common sense inference that is easy for humans but not machines, we conjectured that including features from the n-best parses may help to better match human performance. In more detail, we made use of the following feature classes for each candidate realization:

perceptron model score the score from the realizer's model, normalized to [0,1] for the realizations in the n-best list

precision and recall labeled and unlabeled precision and recall for each parser's best parse

per-label precision and recall (*dep*) precision and recall for each type of dependency obtained from each parser's best parse (using zero if not defined for lack of predicted or gold dependencies with a given label)

n-best precision and recall (*nbest*) labeled and unlabeled precision and recall for each parser's top five parses, along with the same features for the most accurate of these parses

In training, we used the BLEU scores of each realization compared with its reference sentence to establish a preference order over pairs of candidate realizations, assuming that the original corpus sentences are generally better than related alternatives, and that BLEU can somewhat reliably predict human preference judgments.

We trained the SVM ranker (Joachims, 2002) with a linear kernel and chose the hyper-parameter c, which tunes the trade-off between training error and margin, with 6-fold cross-validation on the devset. We trained different models to investigate the contribution made by different parsers and different types of features, with the perceptron model score included as a feature in all models. For each parser, we trained a model with its overall precision and recall features, as shown at the top of Table 3. Then we combined these three models to get a new model (Bkl+Brw+St in the table) . Next, to this combined model we separately added (i) the per-label precision and recall features from all the parsers (BBS+dep), and (ii) the n-best features from the parsers (BBS+nbest). The full model (BBS+dep+nbest) includes all the features listed above. Finally, since the Berkeley parser yielded the best results on its own, we also tested models using all the feature classes but only using this parser by itself.

4.2 Results

Table 3 shows the results of different SVM ranking models on the devset. We calculated significance using paired bootstrap resampling (Koehn, 2004).[3] Both the per-label precision & recall fea-

tures and the n-best parse features contributed to achieving a significant improvement compared to the perceptron model. Somewhat surprisingly, the Berkeley parser did as well as all three parsers using just the overall precision and recall features, but not quite as well using all features. The complete model, BBS+dep+nbest, achieved a BLEU score of 88.73, significantly improving upon the perceptron model ($p < 0.02$). We then confirmed this result on the final test set, Section 23 of the CCGbank, as shown in Table 4 ($p < 0.02$ as well).

5 Analysis and Discussion

5.1 Targeted Manual Analysis

In order to gain a better understanding of the successes and failures of our SVM ranker, we present here a targeted manual analysis of the development set sentences with the greatest change in BLEU scores, carried out by the second author (a native speaker). In this analysis, we consider whether the reranked realization improves upon or detracts from realization quality—in terms of adequacy, fluency, both or neither—along with a linguistic categorization of the differences between the reranked realization and the original top-ranked realization according to the averaged perceptron model. Unlike the broad-based and objective evaluation in terms of BLEU scores presented above, this analysis is narrowly targeted and subjective, though the interested reader is invited to review the complete set of analyzed examples that accompany the paper as a supplement. We leave a more broad-based human evaluation by naive subjects for future work.

Table 5 shows the results of the analysis, both overall and for the most frequent categories of changes. Of the 50 sentences where the BLEU score went up the most, 15 showed an improvement in adequacy (i.e., in conveying the intended meaning), 22 showed an improvement in fluency (with 3 cases also improving adequacy), and 16 yielded no discernible change in fluency or adequacy. By contrast, with the 50 sentences where the BLEU score went down the most, adequacy was only affected 4 times, though fluency was affected 32 times, and 15 remained essentially unchanged.[4] The table also shows that differences in the order of VP constituents usually led to a change in adequacy or fluency, as did ordering changes within NPs, with noun-noun compounds and named entities as the most frequent subcategories of NP-ordering changes. Of the cases where adequacy and fluency were not affected, contractions and subject-verb inversions were the most frequent differences.

Examples of the changes yielded by the SVM ranker appear in Table 6. With wsj_0036.54, the averaged perceptron model selects a realization that regrettably (though amusingly) swaps *purchasing* and *more than 250*—yielding a sentence that suggests that the executives have been purchased!—while the SVM ranker succeeds in ranking the original sentence above all competing realizations. With wsj_0088.25, self-monitoring with the SVM ranker yields a realization nearly identical to the original except for an extra comma, where it is clear that *in public* modifies *do this*; by contrast, in the perceptron-best realization, *in public* mistakenly appears to modify *be disclosed*. With wsj_0041.18, the SVM ranker unfortunately prefers a realization where *presumably* seems to modify *shows* rather than *of two politicians* as

[4]The difference in the distribution of adequacy change, fluency change and no change counts between the two conditions is highly significant statistically ($\chi^2 = 9.3, df = 2, p < 0.01$). In this comparison, items where both fluency and adequacy were affected were counted as adequacy cases.

	±adq	±flu	=eq	±vpord	±npord	±nn	±ne	=vpord	=sbjinv	=cntrc
BLEU wins	15	22	16	10	9	7	3	4	-	11
BLEU losses	4	32	15	8	13	5	5	4	7	-

Table 5: Manual analysis of devset sentences where the SVM ranker achieved the greatest increase/decrease in BLEU scores (50 each of wins/losses) compared to the averaged perceptron baseline model in terms of positive or negative changes in adequacy (±adq), fluency (±flu) or neither (=eq); changes in VP ordering (±vpord), NP ordering (±npord), noun-noun compound ordering (±nn) and named entities (±ne); and neither positive nor negative changes in VP ordering (=vpord), subject-inversion (=sbjinv) and contractions (=cntrc). In all but one case (counted as =eq here), the BLEU wins saw positive changes and the BLEU losses saw negative changes.

5.2 Discussion

The BLEU evaluation and targeted manual analysis together show that the SVM ranker increases the similarity to the original corpus of realizations produced with self-monitoring, often in ways that are crucial for the intended meaning to be apparent to human readers.

A limitation of the experiments reported in this paper is that OpenCCG's input semantic dependency graphs are not the same as the Stanford dependencies used with the Treebank parsers, and thus we have had to rely on the gold parses in the PTB to derive gold dependencies for measuring accuracy of parser dependency recovery. In a realistic application scenario, however, we would need to measure parser accuracy relative to the realizer's input. We initially tried using OpenCCG's parser in a simple ranking approach, but found that it did not improve upon the averaged perceptron model, like the three parsers used subsequently. Given that with the more refined SVM ranker, the Berkeley parser worked nearly as well as all three parsers together using the complete feature set, the prospects for future work on a more realistic scenario using the OpenCCG parser in an SVM ranker for self-monitoring now appear much more promising, either using OpenCCG's reimplementation of Hockenmaier & Steedman's generative CCG model, or using the Berkeley parser trained on OpenCCG's enhanced version of the CCGbank, along the lines of Fowler and Penn (2010).

6 Related Work

Approaches to surface realization have been developed for LFG, HPSG, and TAG, in addition to CCG, and recently statistical dependency-based approaches have been developed as well; see the report from the first surface realization shared

task (Belz et al., 2010; Belz et al., 2011) for an overview. To our knowledge, however, a comprehensive investigation of avoiding vicious structural ambiguities with broad coverage statistical parsers has not been previously explored. As our SVM ranking model does not make use of CCG-specific features, we would expect our self-monitoring method to be equally applicable to realizers using other frameworks.

7 Conclusion

In this paper, we have shown that while using parse accuracy in a simple reranking strategy for self-monitoring fails to improve BLEU scores over a state-of-the-art averaged perceptron realization ranking model, it is possible to significantly increase BLEU scores using an SVM ranker that combines the realizer's model score together with features from multiple parsers, including ones designed to make the ranker more robust to parsing mistakes that human readers would be unlikely to make. Additionally, via a targeted manual analysis, we showed that the SVM reranker frequently manages to avoid egregious errors involving "vicious" ambiguities, of the kind that would mislead human readers as to the intended meaning.

As noted in Reiter's (2010) survey, many NLG systems use surface realizers as off-the-shelf components. In this paper, we have focused on broad coverage surface realization using widely-available PTB data—where there are many sentences of varying complexity with gold-standard annotations—following the common assumption that experiments with broad coverage realization are (or eventually will be) relevant for NLG applications. Of course, the kinds of ambiguity that can be problematic in news text may or may not be the same as the ones encountered in particular applications. Moreover, for certain applications (e.g. ones with medical or legal implications), it may be better to err on the side of ambiguity avoidance, even at some expense to fluency, thereby requiring training data reflecting the desired trade-off to adapt the methods described here. We leave these application-centered issues for investigation in future work.

The current approach is primarily suitable for offline use, for example in report generation where there are no real-time interaction demands. In future work, we also plan to investigate ways that self-monitoring might be implemented more efficiently as a combined process, rather than running independent parsers as a post-process following realization.

Abstract

We present a simple, data-driven approach to generation from knowledge bases (KB). A key feature of this approach is that grammar induction is driven by the extended domain of locality principle of TAG (Tree Adjoining Grammar); and that it takes into account both syntactic and semantic information. The resulting extracted TAG includes a unification based semantics and can be used by an existing surface realiser to generate sentences from KB data. Experimental evaluation on the KBGen data shows that our model outperforms a data-driven generate-and-rank approach based on an automatically induced probabilistic grammar; and is comparable with a handcrafted symbolic approach.

1 Introduction

In this paper we present a grammar based approach for generating from knowledge bases (KB) which is linguistically principled and conceptually simple. A key feature of this approach is that grammar induction is driven by the extended domain of locality principle of TAG (Tree Adjoining Grammar) and takes into account both syntactic and semantic information. The resulting extracted TAGs include a unification based semantics and can be used by an existing surface realiser to generate sentences from KB data.

To evaluate our approach, we use the benchmark provided by the KBGen challenge (Banik et al., 2012; Banik et al., 2013), a challenge designed to evaluate generation from knowledge bases; where the input is a KB subset; and where the expected output is a complex sentence conveying the meaning represented by the input. When compared with two other systems having taken part in the KBGen challenge, our system outperforms a data-driven, generate-and-rank approach based on an automatically induced probabilistic grammar; and produces results comparable to those obtained by a symbolic, rule based approach. Most importantly, we obtain these results using a general purpose approach that we believe is simpler and more transparent than current state of the art surface realisation systems generating from KB or DB data.

2 Related Work

Our work is related to work on concept to text generation.

Earlier work on concept to text generation mainly focuses on generation from logical forms using rule-based methods. (Wang, 1980) uses hand-written rules to generate sentences from an extended predicate logic formalism; (Shieber et al., 1990) introduces a head-driven algorithm for generating from logical forms; (Kay, 1996) defines a chart based algorithm which enhances efficiency by minimising the number of semantically incomplete phrases being built; and (Shemtov, 1996) presents an extension of the chart based generation algorithm presented in (Kay, 1996) which supports the generation of multiple paraphrases from underspecified semantic input. In all these approaches, grammar and lexicon are developed manually and it is assumed that the lexicon associates semantic sub-formulae with natural language expressions. Our approach is similar to these approaches in that it assumes a grammar encoding a compositional semantics. It differs from them however in that, in our approach, grammar and lexicon are automatically acquired from the data.

With the development of the semantic web and the proliferation of knowledge bases, generation from knowledge bases has attracted increased interest and so called ontology verbalisers have been proposed which support the generation of text from (parts of) knowledge bases. One main

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 424–434,
Baltimore, Maryland, USA, June 23-25 2014.

strand of work maps each axiom in the knowledge base to a clause. Thus the OWL verbaliser integrated in the Protégé tool (Kaljurand and Fuchs, 2007) provides a verbalisation of every axiom present in the ontology under consideration and (Wilcock, 2003) describes an ontology verbaliser using XML-based generation. As discussed in (Power and Third, 2010), one important limitation of these approaches is that they assume a simple deterministic mapping between knowledge representation languages and some controlled natural language (CNL). Specifically, the assumption is that each atomic term (individual, class, property) maps to a word and each axiom maps to a sentence. As a result, the verbalisation of larger ontology parts can produce very unnatural text such as, *Every cat is an animal. Every dog is an animal. Every horse is an animal. Every rabbit is an animal.* More generally, the CNL based approaches to ontology verbalisation generate clauses (one per axiom) rather than complex sentences and thus cannot adequately handle the verbalisation of more complex input such as the KBGen data where the KB input often requires the generation of a complex sentence rather than a sequence of base clauses.

To generate more complex output from KB data, several alternative approaches have been proposed.

The MIAKT project (Bontcheva and Wilks., 2004) and the ONTOGENERATION project (Aguado et al., 1998) use symbolic NLG techniques to produce textual descriptions from some semantic information contained in a knowledge base. Both systems require some manual input (lexicons and domain schemas). More sophisticated NLG systems such as TAILOR (Paris, 1988), MIGRAINE (Mittal et al., 1994), and STOP (Reiter et al., 2003) offer tailored output based on user/patient models. While offering more flexibility and expressiveness, these systems are difficult to adapt by non-NLG experts because they require the user to understand the architecture of the NLG systems (Bontcheva and Wilks., 2004). Similarly, the NaturalOWL system (Galanis et al., 2009) has been proposed to generate fluent descriptions of museum exhibits from an OWL ontology. This approach however relies on extensive manual annotation of the input data.

The SWAT project has focused on producing descriptions of ontologies that are both coherent and efficient (Williams and Power, 2010). For instance, instead of the above output, the SWAT system would generate the sentence: *The following are kinds of animals: cats, dogs, horses and rabbits.* . In this approach too however, the verbaliser output is strongly constrained by a simple Definite Clause Grammar covering simple clauses and sentences verbalising aggregation patterns such as the above. More generally, the sentences generated by ontology verbalisers cover a limited set of linguistics constructions; the grammar used is manually defined; and the mapping between semantics and strings is assumed to be deterministic (e.g., a verb maps to a relation and a noun to a concept). In constrast, we propose an approach which can generate complex sentences from KB data; where the grammar is acquired from the data; and where no assumption is made about the mapping between semantics and NL expressions.

Recent work has focused on data-driven generation from frames, lambda terms and data base entries.

(DeVault et al., 2008) describes an approach for generating from the frames produced by a dialog system. They induce a probabilistic Tree Adjoining Grammar from a training set aligning frames and sentences using the grammar induction technique of (Chiang, 2000) and use a beam search that uses weighted features learned from the training data to rank alternative expansions at each step.

(Lu and Ng, 2011) focuses on generating natural language sentences from logical form (i.e., lambda terms) using a synchronous context-free grammar. They introduce a novel synchronous context free grammar formalism for generating from lambda terms; induce such a synchronous grammar using a generative model; and extract the best output sentence from the generated forest using a log linear model.

(Wong and Mooney, 2007; Lu et al., 2009) focuses on generating from variable-free tree-structured representations such as the CLANG formal language used in the ROBOCUP competition and the database entries collected by (Liang et al., 2009) for weather forecast generation and for the air travel domain (ATIS dataset) by (Dahl et al., 1994). (Wong and Mooney, 2007) uses synchronous grammars to transform a variable free tree structured meaning representation into sentences. (Lu et al., 2009) uses a Conditional Ran-

Figure 1: Example KBGEN Scenario

dom Field to generate from the same meaning representations.

Finally, more recent papers propose approaches which perform both surface realisation and content selection. (Angeli et al., 2010) proposes a log linear model which decomposes into a sequence of discriminative local decisions. The first classifier determines which records to mention; the second, which fields of these records to select; and the third, which words to use to verbalise the selected fields. (Kim and Mooney, 2010) uses a generative model for content selection and verbalises the selected input using WASP^{-1}, an existing generator. Finally, (Konstas and Lapata, 2012b; Konstas and Lapata, 2012a) develop a joint optimisation approach for content selection and surface realisation using a generic, domain independent probabilistic grammar which captures the structure of the database and the mapping from fields to strings. They intersect the grammar with a language model to improve fluency; use a weighted hypergraph to pack the derivations; and find the best derivation tree using Viterbi algorithm.

Our approach differs from the approaches which assume variable free tree structured representations (Wong and Mooney, 2007; Lu et al., 2009) and data-based entries (Kim and Mooney, 2010; Konstas and Lapata, 2012b; Konstas and Lapata, 2012a) in that it handles graph-based, KB input and assumes a compositional semantics. It is closest to (DeVault et al., 2008) and (Lu and Ng, 2011) who extract a grammar encoding syntax and semantics from frames and lambda terms respectively. It differs from the former however in that it enforces a tighter syntax/semantics integration by requiring that the elementary trees of our extracted grammar encode the appropriate linking information. While (DeVault et al., 2008) extracts a TAG grammar associating each elementary tree with a semantics, we additionnally require that these trees encode the appropriate linking between syntactic and semantic arguments thereby restricting the space of possible tree combinations and drastically reducing the search space. Although conceptually related to (Lu and Ng, 2011), our approach extracts a unification based grammar rather than one with lambda terms. The extraction process and the generation algorithms are also fundamentally different. We use a simple mainly symbolic approach whereas they use a generative approach for grammar induction and a discriminative approach for sentence generation.

3 The KBGen Task

The KBGen task was introduced as a new shared task at Generation Challenges 2013 (Banik et al., 2013)[1] and aimed to compare different generation systems on KB data. Specifically, the task is to verbalise a subset of a knowledge base. For instance, the KB input shown in Figure 1 can be verbalised as:

(1) The function of a gated channel is to release particles from the endoplasmic reticulum

The KB subsets forming the KBGen input data were pre-selected from the AURA biology knowledge base (Gunning et al., 2010), a knowledge base about biology which was manually encoded by biology teachers and encodes knowledge about events, entities, properties and relations where relations include event-to-entity, event-to-event,

[1] http://www.kbgen.org

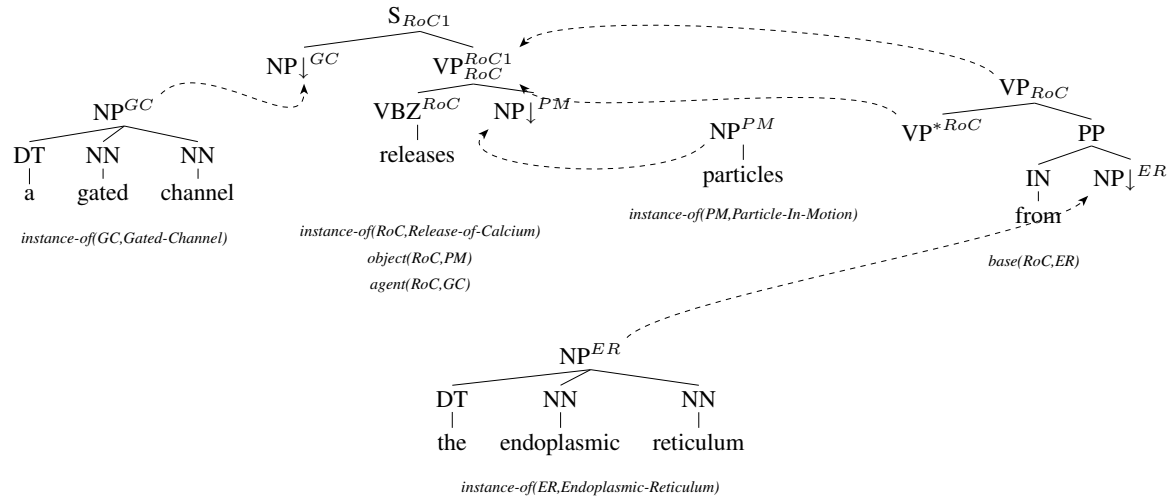

Figure 2: Example FB-LTAG with Unification-Based Semantics. Dotted lines indicate substitution and adjunction operations between trees. The variables decorating the tree nodes (e.g., GC) abbreviate feature structures of the form $[idx : V]$ where V is a unification variable shared with the semantics.

event-to-property and entity-to-property relations. AURA uses a frame-based knowledge representation and reasoning system called Knowledge Machine (Clark and Porter, 1997) which was translated into first-order logic with equality and from there, into multiple different formats including SILK (Grosof, 2012) and OWL2 (Motik et al., 2009). It is available for download in various formats including OWL[2].

4 Generating from the KBGen Knowledge-Base

To generate from the KBGen data, we induce a Feature-Based Lexicalised Tree Adjoining Grammar (FB-LTAG, (Vijay-Shanker and Joshi, 1988)) augmented with a unification-based semantics (Gardent and Kallmeyer, 2003) from the training data. We then use this grammar and an existing surface realiser to generate from the test data.

4.1 Feature-Based Lexicalised Tree Adjoining Grammar

Figure 2 shows an example FB-LTAG augmented with a unification-based semantics.

Briefly, an FB-LTAG consists of a set of elementary trees which can be either initial or auxiliary. Initial trees are trees whose leaves are labeled with substitution nodes (marked with a down-arrow) or terminal categories. Auxiliary trees are distinguished by a foot node (marked with a star) whose category must be the same as that of the root node. In addition, in an FB-LTAG, each elementary tree is anchored by a lexical item (lexicalisation) and the nodes in the elementary trees are decorated with two feature structures called *top* and *bottom* which are unified during derivation. Two tree-composition operations are used to combine trees namely, substitution and adjunction. While substitution inserts a tree in a substitution node of another tree, adjunction inserts an auxiliary tree into a tree. In terms of unifications, substitution unifies the top feature structure of the substitution node with the top feature structure of the root of the tree being substituted in. Adjunction unifies the top feature structure of the root of the tree being adjoined with the top feature structure of the node being adjoined to; and the bottom feature structure of the foot node of the auxiliary tree being adjoined with the bottom feature structure of the node being adjoined to.

In an FB-LTAG augmented with a unification-based semantics, each tree is associated with a semantics i.e., a set of literals whose arguments may be constants or unification variables. The semantics of a derived tree is the union of the semantics of the tree contributing to its derivation modulo unification. Importantly, semantic variables are shared with syntactic variables (i.e., variables occurring in the feature structures decorating the tree nodes) so that when trees are combined, the appropriate syntax/semantics linking is enforced. For instance given the semantics:

[2] http://www.ai.sri.com/halo/halobook2010/exported-kb/biokb.html

instance-of(RoC,Release-Of-Calcium),
object(RoC,PM),agent(RoC,GC),base(RoC,ER),
instance-of(ER,Endoplasmic-Reticulum),
instance-of(GC,Gated-Channel),
instance-of(PM,Particle-In-Motion)

the grammar will generate *A gated channel releases particles from the endoplasmic reticulum* but not e.g., *Particles releases a gated channel from the endoplasmic reticulum*.

4.2 Grammar Extraction

We extract our FB-LTAG with unification semantics from the KBGen training data in two main steps. First, we align the KB data with the input string. Second, we induce a Tree Adjoining Grammar augmented with a unification-based semantics from the aligned data.

4.2.1 Alignment

Given a Sentence/Input pair (S, I) provided by the KBGen Challenge, the alignment procedure associates each entity and event variable in I to a substring in S. To do this, we use the entity and the event lexicon provided by the KBGen organiser. The event lexicon maps event types to verbs, their inflected forms and nominalizations while the entity lexicon maps entity types to a noun and its plural form. For instance, the lexicon entries for the event and entity types shown in Figure 1 are as shown in Figure 3.

For each entity and each event variable V in I, we retrieve the corresponding type (e.g., `Particle-In-Motion` for `Particle-In-Motion64582`); search the KBGen lexicon for the corresponding phrases (e.g., *molecule in motion,molecules in motion*); and associate V with the phrase in S which matches one of these phrases. Figure 3 shows an example lexicon and the resulting alignment obtained for the scenario shown in Figure 1. Note that there is not always an exact match between the phrase associated in the KBGen lexicon with a type and the phrase occurring in the training sentence. To account for this, we use some additional similarity based heuristics to identify the phrase in the input string that is most likely to be associated with a variable lacking an exact match in the input string. E.g., for entity variables (e.g., `Particle-In-Motion64582`), we search the input string for nouns (e.g., particles) whose overlap with the variable type (e.g., Particle-In-Motion) is not empty.

4.2.2 Inducing a based FB-LTAG from the aligned data

To extract a Feature-Based Lexicalised Tree Adjoining Grammar (FB-LTAG) from the KBGen data, we parse the sentences of the training corpus; project the entity and event variables to the syntactic projection of the strings they are aligned with; and extract the elementary trees of the resulting FB-LTAG from the parse tree using semantic information. Figure 4 shows the trees extracted from the scenario given in Figure 1.

To associate each training example sentence with a syntactic parse, we use the Stanford parser. After alignment, the entity and event variables occurring in the input semantics are associated with substrings of the yield of the syntactic parse tree. We project these variables up the syntactic tree to reflect headedness. A variable aligned with a noun is projected to the NP level or to the immediately dominating PP if it occurs in the subtree dominated by the leftmost daughter of that PP. A variable aligned with a verb is projected to the first S node immediately dominating that verb or, in the case of a predicative sentence, to the root of that sentence[3].

Once entity and event variables have been projected up the parse trees, we extract elementary FB-LTAG trees and their semantics from the input scenario as follows.

First, the subtrees whose root node is indexed with an entity variable are extracted. This results in a set of NP and PP trees anchored with entity names and associated with the predication true of the indexing variable.

Second, the subtrees capturing relations between variables are extracted. To perform this extraction, each input variable X is associated with a set of dependent variables i.e., the set of variables Y such that X is related to Y $(R(X, Y))$. The minimal tree containing all and only the dependent variables $D(X)$ of a variable X is then extracted and associated with the set of literals Φ such that $\Phi = \{R(Y, Z) \mid (Y = X \wedge Z \in D(X)) \vee (Y, Z \in D(X))\}$. This procedure extracts the subtrees relating the argument variables of a semantic functors such as an event or a role e.g., a tree describing a verb and its arguments as shown in the top

[3]Initially, we used the head information provided by the Stanford parser. In practice however, we found that the heuristics we defined to project semantic variables to the corresponding syntactic projection were more accurate and better supported our grammar extraction process.

`Particle-In-Motion`	molecule in motion,molecules in motion
`Endoplasmic-Reticulum`	endoplasmic reticulum,endoplasmic reticulum
`Gated-Channel`	gated Channel,gated Channels
`Release-Of-Calcium`	releases,release,released,release

The function of a (gated channel, `Gated-Channel64605`) is to (release, `Release-Of-Calcium646`) (particles, `Particle-In-Motion64582`) from the (endoplasmic reticulum, `Endoplasmic-Reticulum64603`)

Figure 3: Example Entries from the KBGen Lexicon and example alignment

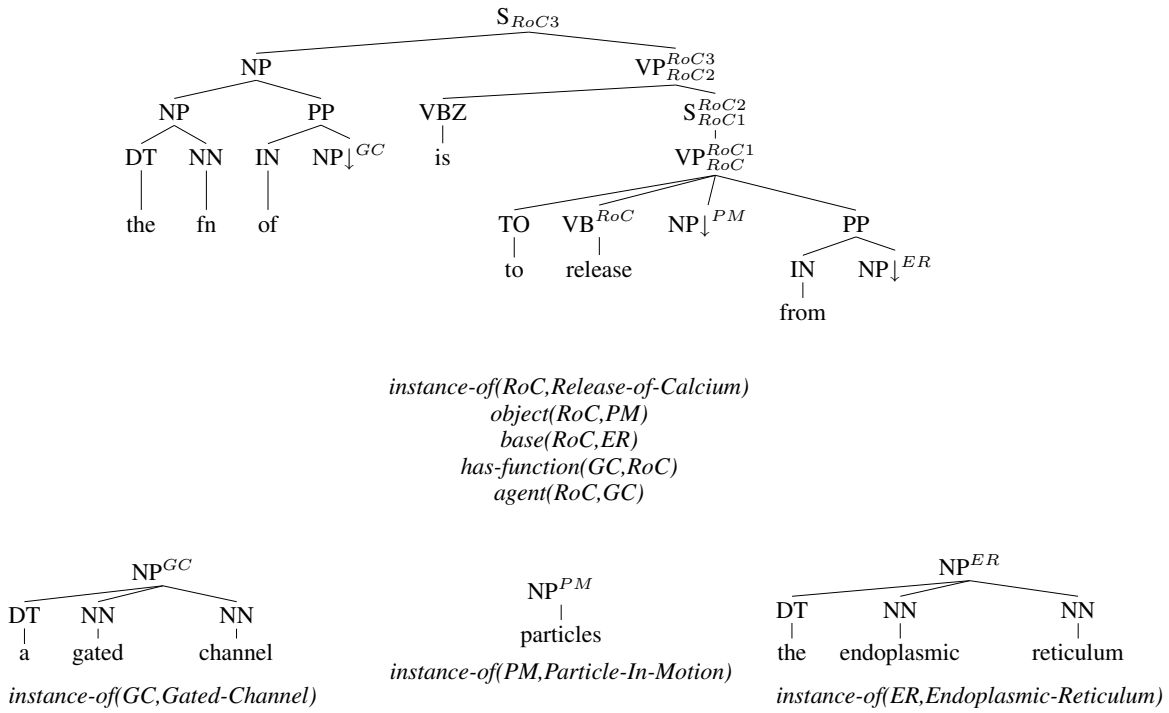

Figure 4: Extracted Grammar for "*The function of a gated channel is to release particles from the endoplasmic reticulum*". Variable names have been abbreviated and the KBGen tuple notation converted to terms so as to fit the input format expected by our surface realiser.

part of Figure 4. Note that such a tree may capture a verb occurring in a relative or a subordinate clause (together with its arguments) thus allowing for complex sentences including a relative or relating a main and a subordinate clause.

The resulting grammar extracted from the parse trees (cf. e.g., Figure 4) is a Feature-Based Tree Adjoining Grammar with a Unification-based compositional semantics as described in (Gardent and Kallmeyer, 2003). In particular, our grammars differs from the traditional probabilistic Tree Adjoining Grammar extracted as described in e.g., (Chiang, 2000) in that they encode both syntax and semantics rather than just syntax. They also differ from the semantic FB-TAG extracted by (DeVault et al., 2008) in that (i) they encode the linking between syntactic and semantic arguments; (ii) they allow for elementary trees spanning discontiguous strings (e.g., *The function of X is to release Y*); and (iii) they enforce the semantic principle underlying TAG namely that an elementary tree containing a syntactic functor also contains its syntactic arguments.

4.3 Generation

To generate with the grammar extracted from the KBGen data, we use the GenI surface realiser (Gardent et al., 2007). Briefly, given an input semantics and a FB-LTAG with a unification based semantics, GenI selects all grammar entries whose semantics subsumes the input semantics; combines these entries using the FB-LTAG combination operations (i.e., adjunction and substitution); and outputs the yield of all derived trees which are syntactically complete and whose semantics is the input semantics. To rank the generator output, we train a language model on the GeniA corpus [4], a corpus of 2000 MEDLINE asbtracts about biology containing more than 400000 words (Kim et al., 2003) and use this model to rank the generated sentences by decreasing probability.

Thus for instance, given the input semantics shown in Figure 1 and the grammar depicted in Figure 4, the surface realiser will select all of these trees; combine them using FB-LTAG substitution operation; and output as generated sentence the yield of the resulting derived tree namely the sentence *The function of a gated channel is to release particles from the endoplasmic reticulum*.

However, this procedure only works if the entries necessary to generate from the given input are present in the grammar. To handle new, unseen input, we proceed in two ways. First, we try to guess a grammar entry from the shape of the input and the existing grammar. Second, we expand the grammar by decomposing the extracted trees into simpler ones.

4.4 Guessing new grammar entries.

Given the limited size of the training data, it is often the case that input from the test data will have no matching grammar unit. To handle such previously unseen input, we start by partitioning the input semantics into sub-semantics corresponding to events, entities and role.

For each entity variable X of type $Type$, we create a default NP tree whose semantics is a literal of the form *instance-of(X,Type)*.

For event variables, we search the lexicon for an entry with a matching or similar semantics i.e., an entry with the same number and same type of literals (literals with same arity and with identical relations). When one is found, a grammar entry is constructed for the unseen event variable by substituting the event type of the matching entry with the type of the event variable. For instance, given the input semantics *instance-of(C,Carry), object(C,X), base(C,Y), has-function(Z,C), agent(C,Z)*, this procedure will create a grammar entry identical to that shown at the top of Figure 4 except that the event type *Release-of-Calcium* is changed to *Carry* and the terminal *release* to the word form associated in the KBGen lexicon with this concept, namely to the verb *carry*.

4.5 Expanding the Grammar

While the extracted grammar nicely captures predicate/argument dependencies, it is very specific to the items seen in the training data. To reduce overfitting, we generalise the extracted grammar by extracting from each event tree, subtrees that capture structures with fewer arguments and optional modifiers.

For each event tree τ extracted from the training data which contains a subject-verb-object subtree τ', we add τ' to the grammar and associate it with the semantics of τ minus the relations associated with the arguments that have been removed. For instance, given the extracted tree for the sentence *"Aquaporin facilitates the movement of water molecules through hydrophilic channels."*, this

[4] http://www.nactem.ac.uk/genia/

procedure will construct a new grammar tree corresponding to the subphrase *"Aquaporin facilitates the movement of water molecules"*.

We also construct both simpler event trees and optional modifiers trees by extracting from event trees, PP trees which are associated with a relational semantics. For instance, given the tree shown in Figure 4, the PP tree associated with the relation *base(RoC,ET)* is removed thus creating two new trees as illustrated in Figure 5: an S tree corresponding to the sentence *The function of a gated channel is to release particles* and an auxiliary PP tree corresponding to the phrase *from the endoplasmic reticulum*. Similarly in the above example, a PP tree corresponding to the phrase *"through hydrophilic channels."* will be extracted.

As with the base grammar, missing grammar entries are guessed from the expanded grammar. However we do this only in cases where a correct grammar entry cannot be guessed from the base grammar.

5 Experimental Setup

We evaluate our approach on the KBGen data and compare it with the KBGen reference and two other systems having taken part to the KBGen challenge.

5.1 Training and test data.

Following a practice introduced by (Angeli et al., 2010), we use the term *scenario* to denote a KB subset paired with a sentence. The KBGen benchmark contains 207 scenarii for training and 72 for testing. Each KB subset consists of a set of triples and each scenario contains on average 16 triples and 17 words.

5.2 Systems

We evaluate three configurations of our approach on the KBGen test data: one without grammar expansion (BASE); a second with a manual grammar expansion MANEXP; and a third one with automated grammar expansion AUTEXP. We compare the results obtained with those obtained by two other systems participating in the KBGen challenge, namely the UDEL system, a symbolic rule based system developed by a group of students at the University of Delaware; and the IMS system, a statistical system using a probabilistic grammar induced from the training data.

5.3 Metrics.

We evaluate system output automatically, using the BLEU-4 modified precision score (Papineni et al., 2002) with the human written sentences as reference. We also report results from a human based evaluation. In this evaluation, participants were asked to rate sentences along three dimensions: **fluency** (Is the text easy to read?), **grammaticality** and meaning similarity or **adequacy** (Does the meaning conveyed by the generated sentence correspond to the meaning conveyed by the reference sentence?). The evaluation was done on line using the LG-Eval toolkit (Kow and Belz, 2012), subjects used a sliding scale from -50 to +50 and a Latin Square Experimental Design was used to ensure that each evaluator sees the same number of outputs from each system and for each test set item. 12 subjects participated in the evaluation and 3 judgments were collected for each output.

6 Results and Discussion

System	All	Covered	Coverage	# Trees
IMS	0.12	0.12	100%	
UDEL	0.32	0.32	100%	
Base	0.04	0.39	30.5%	371
ManExp	0.28	0.34	83 %	412
AutExp	0.29	0.29	100%	477

Figure 6: BLEU scores and Grammar Size (Number of Elementary TAG trees

Table 6 summarises the results of the automatic evaluation and shows the size (number of elementary TAG trees) of the grammars extracted from the KBGen data.

The average BLEU score is given with respect to all input (All) and to those inputs for which the systems generate at least one sentence (Covered). While both the IMS and the UDEL system have full coverage, our BASE system strongly undergenerates failing to account for 69.5% of the test data. However, because the extracted grammar is linguistically principled and relatively compact, it is possible to manually edit it. Indeed, the MANEXP results show that, by adding 41 trees to the grammar, coverage can be increased by 52.5 points reaching a coverage of 83%. Finally, the AUTEXP results demonstrate that the automated expansion mechanism permits achieving full coverage while keeping a relative small grammar (477 trees).

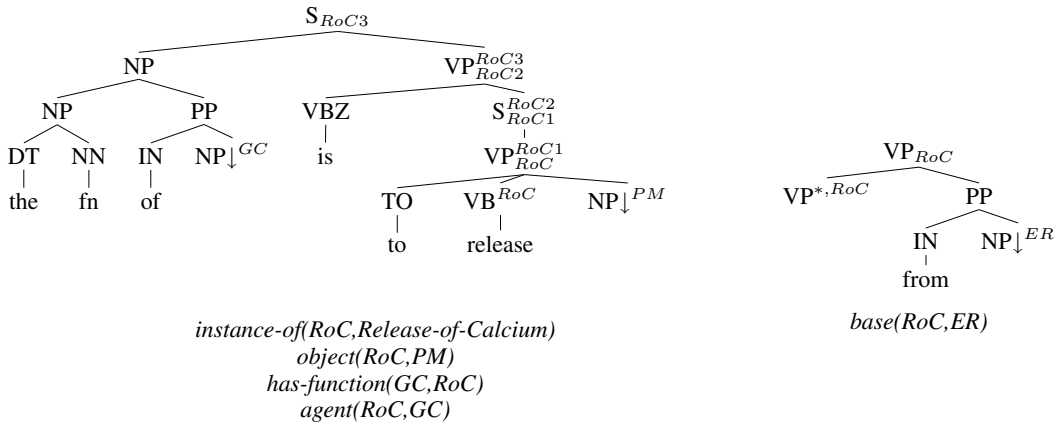

Figure 5: Trees Added by the Expansion Process

	Fluency		Grammaticality		Meaning Similarity	
System	Mean	Homogeneous Subsets	Mean	Homogeneous Subsets	Mean	Homogeneous Subsets
UDEL	4.36	A	4.48	A	3.69	A
AutExp	3.45	B	3.55	B	3.65	A
IMS	1.91	C	2.05	C	1.31	B

Figure 7: Human Evaluation Results on a scale of 0 to 5. Homogeneous subsets are determined using Tukey's Post Hoc Test with $p < 0.05$

In terms of BLEU score, the best version of our system (AUTEXP) outperforms the probabilistic approach of IMS by a large margin (+0.17) and produces results similar to the fully handcrafted UDEL system (-0.03).

In sum, our approach permits obtaining BLEU scores and a coverage which are similar to that obtained by a hand crafted system and outperforms a probabilistic approach. One key feature of our approach is that the grammar extracted from the training data is linguistically principled in that it obeys the extended locality principle of Tree Adjoining Grammars. As a result, the extracted grammar is compact and can be manually modified to fit the need of an application as shown by the good results obtained when using the MANEXP configuration.

We now turn to the results of the human evaluation. Table 7 summarises the results whereby systems are grouped by letters when there is no significant difference between them (significance level: $p < 0.05$). We used ANOVAs and post-hoc Tukey tests to test for significance. The differences between systems are statistically significant throughout except for meaning similarity (adequacy) where UDEL and our system are on the same level. Across the metrics, our system consistently ranks second behind the symbolic, UDEL system and before the statistical IMS one thus confirming the ranking based on BLEU.

7 Conclusion

In Tree Adjoining Grammar, the *extended domain of locality principle* ensures that TAG trees group together in a single structure a syntactic predicate and its arguments. Moreover, the *semantic principle* requires that each elementary tree captures a single semantic unit. Together these two principles ensure that TAG elementary trees capture basic semantic units and their dependencies. In this paper, we presented a grammar extraction approach which ensures that extracted grammars comply with these two basic TAG principles. Using the KBGen benchmark, we then showed that the resulting induced FB-LTAG compares favorably with competing symbolic and statistical approaches when used to generate from knowledge base data.

In the current version of the generator, the output is ranked using a simple language model trained on the GENIA corpus. We observed that this often fails to return the best output in terms of BLEU score, fluency, grammaticality and/or meaning. In the future, we plan to remedy this using a ranking approach such as proposed in (Velldal and Oepen, 2006; White and Rajkumar, 2009).

Abstract

We present a hybrid approach to sentence simplification which combines deep semantics and monolingual machine translation to derive simple sentences from complex ones. The approach differs from previous work in two main ways. First, it is semantic based in that it takes as input a deep semantic representation rather than e.g., a sentence or a parse tree. Second, it combines a simplification model for splitting and deletion with a monolingual translation model for phrase substitution and reordering. When compared against current state of the art methods, our model yields significantly simpler output that is both grammatical and meaning preserving.

1 Introduction

Sentence simplification maps a sentence to a simpler, more readable one approximating its content. Typically, a simplified sentence differs from a complex one in that it involves simpler, more usual and often shorter, words (e.g., *use* instead of *exploit*); simpler syntactic constructions (e.g., no relative clauses or apposition); and fewer modifiers (e.g., *He slept* vs. *He also slept*). In practice, simplification is thus often modeled using four main operations: *splitting* a complex sentence into several simpler sentences; *dropping* and *reordering* phrases or constituents; *substituting* words/phrases with simpler ones.

As has been argued in previous work, sentence simplification has many potential applications. It is useful as a preprocessing step for a variety of NLP systems such as parsers and machine translation systems (Chandrasekar et al., 1996), summarisation (Knight and Marcu, 2000), sentence fusion (Filippova and Strube, 2008) and semantic role labelling (Vickrey and Koller, 2008). It also has wide ranging potential societal application as a reading aid for people with aphasis (Carroll et al., 1999), for low literacy readers (Watanabe et al., 2009) and for non native speakers (Siddharthan, 2002).

There has been much work recently on developing computational frameworks for sentence simplification. Synchronous grammars have been used in combination with linear integer programming to generate and rank all possible rewrites of an input sentence (Dras, 1999; Woodsend and Lapata, 2011). Machine Translation systems have been adapted to translate complex sentences into simple ones (Zhu et al., 2010; Wubben et al., 2012; Coster and Kauchak, 2011). And handcrafted rules have been proposed to model the syntactic transformations involved in simplifications (Siddharthan et al., 2004; Siddharthan, 2011; Chandrasekar et al., 1996).

In this paper, we present a hybrid approach to sentence simplification which departs from this previous work in two main ways.

First, it combines a model encoding probabilities for splitting and deletion with a monolingual machine translation module which handles reordering and substitution. In this way, we exploit the ability of statistical machine translation (SMT) systems to capture phrasal/lexical substitution and reordering while relying on a dedicated probabilistic module to capture the splitting and deletion operations which are less well (deletion) or not at all (splitting) captured by SMT approaches.

Second, our approach is semantic based. While previous simplification approaches starts from either the input sentence or its parse tree, our model takes as input a deep semantic representation namely, the Discourse Representation Structure (DRS, (Kamp, 1981)) assigned by Boxer (Curran et al., 2007) to the input complex sentence. As we

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 435–445,
Baltimore, Maryland, USA, June 23-25 2014.

shall see in Section 4, this permits a linguistically principled account of the splitting operation in that semantically shared elements are taken to be the basis for splitting a complex sentence into several simpler ones; this facilitates completion (the re-creation of the shared element in the split sentences); and this provide a natural means to avoid deleting obligatory arguments.

When compared against current state of the art methods (Zhu et al., 2010; Woodsend and Lapata, 2011; Wubben et al., 2012), our model yields significantly simpler output that is both grammatical and meaning preserving.

2 Related Work

Earlier work on sentence simplification relied on handcrafted rules to capture syntactic simplification e.g., to split coordinated and subordinated sentences into several, simpler clauses or to model active/passive transformations (Siddharthan, 2002; Chandrasekar and Srinivas, 1997; Bott et al., 2012; Canning, 2002; Siddharthan, 2011; Siddharthan, 2010). While these handcrafted approaches can encode precise and linguistically well-informed syntactic transformation (using e.g., detailed morphological and syntactic information), they are limited in scope to purely syntactic rules and do not account for lexical simplifications and their interaction with the sentential context.

Using the parallel dataset formed by Simple English Wikipedia (SWKP)[1] and traditional English Wikipedia (EWKP)[2], more recent work has focused on developing machine learning approaches to sentence simplification.

Zhu et al. (2010) constructed a parallel corpus (PWKP) of 108,016/114,924 complex/simple sentences by aligning sentences from EWKP and SWKP and used the resulting bitext to train a simplification model inspired by *syntax-based* machine translation (Yamada and Knight, 2001). Their simplification model encodes the probabilities for four rewriting operations on the parse tree of an input sentences namely, substitution, reordering, splitting and deletion. It is combined with a language model to improve grammaticality and the decoder translates sentences into simpler ones by greedily selecting the output sentence with highest probability.

Using both the PWKP corpus developed by Zhu et al. (2010) and the edit history of Simple Wikipedia, Woodsend and Lapata (2011) learn a quasi synchronous grammar (Smith and Eisner, 2006) describing a loose alignment between parse trees of complex and of simple sentences. Following Dras (1999), they then generate all possible rewrites for a source tree and use integer linear programming to select the most appropriate simplification. They evaluate their model on the same dataset used by Zhu et al. (2010) namely, an aligned corpus of 100/131 EWKP/SWKP sentences and show that they achieve better BLEU score. They also conducted a human evaluation on 64 of the 100 test sentences and showed again a better performance in terms of simplicity, grammaticality and meaning preservation.

In (Wubben et al., 2012; Coster and Kauchak, 2011), simplification is viewed as a monolingual translation task where the complex sentence is the source and the simpler one is the target. To account for deletions, reordering and substitution, Coster and Kauchak (2011) trained a phrase based machine translation system on the PWKP corpus while modifying the word alignment output by GIZA++ in Moses to allow for null phrasal alignments. In this way, they allow for phrases to be deleted during translation. No human evaluation is provided but the approach is shown to result in statistically significant improvements over a traditional phrase based approach. Similarly, Wubben et al. (2012) use Moses and the PWKP data to train a phrase based machine translation system augmented with a post-hoc reranking procedure designed to rank the output based on their dissimilarity from the source. A human evaluation on 20 sentences randomly selected from the test data indicates that, in terms of fluency and adequacy, their system is judged to outperform both Zhu et al. (2010) and Woodsend and Lapata (2011) systems.

3 Simplification Framework

We start by motivating our approach and explaining how it relates to previous proposals w.r.t., the four main operations involved in simplification namely, splitting, deletion, substitution and reordering. We then introduce our framework.

[1] SWKP (`http://simple.wikipedia.org`) is a corpus of simple texts targeting "children and adults who are learning English Language" and whose authors are requested to "use easy words and short sentences".

[2] `http://en.wikipedia.org`

Sentence Splitting. Sentence splitting is arguably semantic based in that in many cases, splitting occurs when the same semantic entity participates in two distinct eventualities. For instance, in example (1) below, the split is on the noun *bricks* which is involved in two eventualities namely, *"being resistant to cold"* and *"enabling the construction of permanent buildings"*.

(1) **C.** Being more resistant to cold, bricks enabled the construction of permanent buildings.
S. Bricks were more resistant to cold. Bricks enabled the construction of permanent buildings.

While splitting opportunities have a clear counterpart in syntax (i.e., splitting often occurs whenever a relative, a subordinate or an appositive clause occurs in the complex sentence), completion i.e., the reconstruction of the shared element in the second simpler clause, is arguably semantically governed in that the reconstructed element corefers with its matching phrase in the first simpler clause. While our semantic based approach naturally accounts for this by copying the phrase corresponding to the shared entity in both phrases, syntax based approach such as Zhu et al. (2010) and Woodsend and Lapata (2011) will often fail to appropriately reconstruct the shared phrase and introduce agreement mismatches because the alignment or rules they learn are based on syntax alone. For instance, in example (2), Zhu et al. (2010) fails to copy the shared argument *"The judge"* to the second clause whereas Woodsend and Lapata (2011) learns a synchronous rule matching (VP and VP) to (VP. NP(It) VP) thereby failing to produce the correct subject pronoun (*"he"* or *"she"*) for the antecedent *"The judge"*.

(2) **C.** The judge ordered that Chapman should receive psychiatric treatment in prison and sentenced him to twenty years to life.
S_1. The judge ordered that Chapman should get psychiatric treatment. In prison and sentenced him to twenty years to life. (Zhu et al., 2010)
S_2. The judge ordered that Chapman should receive psychiatric treatment in prison. It sentenced him to twenty years to life. (Woodsend and Lapata, 2011)

Deletion. By handling deletion using a probabilistic model trained on semantic representations, we can avoid deleting obligatory arguments. Thus in our approach, semantic subformulae which are related to a predicate by a core thematic roles (e.g., *agent* and *patient*) are never considered for deletion. By contrast, syntax based approaches (Zhu et al., 2010; Woodsend and Lapata, 2011) do not distinguish between optional and obligatory arguments. For instance Zhu et al. (2010) simplifies (3C) to (3S) thereby incorrectly deleting the obligatory theme (*gifts*) of the complex sentence and modifying its meaning to *giving knights and warriors* (instead of *giving gifts to knights and warriors*).

(3) **C.** Women would also often give knights and warriors gifts that included thyme leaves as it was believed to bring courage to the bearer.
S. Women also often give knights and warriors. Gifts included thyme leaves as it was thought to bring courage to the saint. (Zhu et al., 2010)

We also depart from Coster and Kauchak (2011) who rely on null phrasal alignments for deletion during phrase based machine translation. In their approach, deletion is constrained by the training data and the possible alignments, independent of any linguistic knowledge.

Substitution and Reordering SMT based approaches to paraphrasing (Barzilay and Elhadad, 2003; Bannard and Callison-Burch, 2005) and to sentence simplification (Wubben et al., 2012) have shown that by utilising knowledge about alignment and translation probabilities, SMT systems can account for the substitutions and the reorderings occurring in sentence simplification. Following on these approaches, we therefore rely on phrase based SMT to learn substitutions and reordering. In addition, the language model we integrate in the SMT module helps ensuring better fluency and grammaticality.

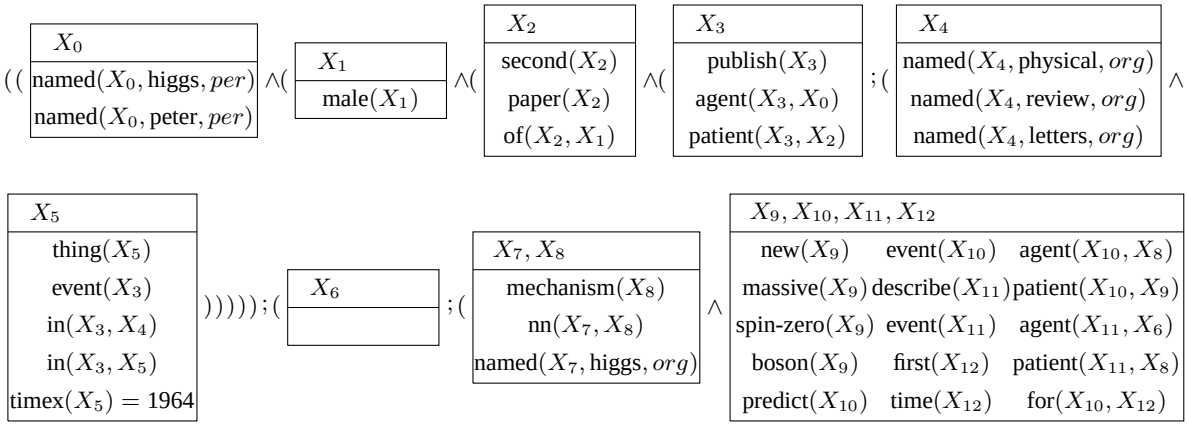
3.1 An Example

Figure 1 shows how our approach simplifies (4C) into (4S).

(4) **C.** In 1964 Peter Higgs published his second paper in Physical Review Letters describing Higgs mechanism which predicted a new massive spin-zero boson for the first time.
S. Peter Higgs wrote his paper explaining Higgs mechanism in 1964. Higgs mechanism predicted a new elementary particle.

The DRS for (4C) produced using Boxer (Curran et al., 2007) is shown at the top of the Figure and a graph representation[3] of the dependencies between its variables is shown immediately below. Each DRS variable labels a node in the graph and each edge is labelled with the relation holding between the variables labelling its end vertices. The

[3]The DRS to graph conversion goes through several preprocessing steps: the relation *nn* is inverted making modifier noun (*higgs*) dependent of modified noun (*mechanism*), *named* and *timex* are converted to unary predicates, e.g., $named(x, peter)$ is mapped to $peter(x)$ and $timex(x) = 1964$ is mapped to $1964(x)$; and nodes are introduced for orphan words (e.g., *which*).



[Discourse Representation Structure produced by BOXER]

Figure 1: Simplification of "*In 1964 Peter Higgs published his second paper in Physical Review Letters describing Higgs mechanism which predicted a new massive spin-zero boson for the first time .*"

two tables to the right of the picture show the predicates (top table) associated with each variable and the relation label (bottom table) associated with each edge. Boxer also outputs the associated positions in the complex sentence for each predicate (not shown in the DRS but in the graph tables). Orphan words (OW) i.e., words which have no corresponding material in the DRS (e.g., *which* at position 16), are added to the graph (node O_1) thus ensuring that the position set associated with the graph exactly matches the positions in the input sentence and thus deriving the input sentence.

Split Candidate	isSplit	prob.
$(agent, for, patient)$ - $(agent, in, in, patient)$	true	0.63
	false	0.37

Table 1: Simplification: SPLIT

Given the input DRS shown in Figure 1, simplification proceeds as follows.

Splitting. The splitting candidates of a DRS are event pairs contained in that DRS. More precisely, the splitting candidates are pairs[4] of event variables associated with at least one of the core thematic roles (e.g., *agent* and *patient*). The features conditioning a split are the set of thematic roles associated with each event variable. The DRS shown in Figure 1 contains three such event variables X_3, X_{11} and X_{10} with associated thematic role sets {*agent, in, in, patient*}, {*agent, patient*} and {*agent, for, patient*} respectively. Hence, there are 3 splitting candidates (X_3-X_{11}, X_3-X_{10} and X_{10}-X_{11}) and 4 split options: no split or split at one of the splitting candidates. Here the split with highest probability (cf. Table 1) is chosen and the DRS is split into two sub-DRS, one containing X_3, and the other containing X_{10}. After splitting, dangling subgraphs are attached to the root of the new subgraph maximizing either proximity or position overlap. Here the graph rooted in X_{11} is attached to the root dominating X_3 and the orphan word O_1 to the root dominating X_{10}.

Deletion. The deletion model (cf. Table 2) regulates the deletion of relations and their associated subgraph; of adjectives and adverbs; and of orphan words. Here, the relations *in* between X_3 and X_4 and *for* between X_{10} and X_{12} are deleted resulting in the deletion of the phrases *"in Physical Review Letters"* and *"for the first time"* as well as the adjectives *second, massive, spin-zero* and the orphan word *which*.

Substitution and Reordering. Finally the translation and language model ensures that *published, describing* and *boson* are simplified to *wrote, explaining* and *elementary particle* respectively; and that the phrase *"In 1964"* is moved from the beginning of the sentence to its end.

3.2 The Simplification Model

Our simplification framework consists of a probabilistic model for splitting and dropping which we call DRS simplification model (DRS-SM); a phrase based translation model for substitution and reordering (PBMT); and a language model learned on Simple English Wikipedia (LM) for fluency and grammaticality. Given a complex sentence c, we split the simplification process into two steps. First, DRS-SM is applied to D_c (the DRS representation of the complex sentence c) to produce one or more (in case of splitting) intermediate simplified sentence(s) s'. Second, the simplified sentence(s) s' is further simplified to s using a phrase based machine translation system (PBMT+LM). Hence, our model can be formally defined as:

$$\begin{aligned}\hat{s} &= \operatorname*{argmax}_s p(s|c) \\ &= \operatorname*{argmax}_s p(s'|c)p(s|s') \\ &= \operatorname*{argmax}_s p(s'|\mathrm{D}_c)p(s'|s)p(s)\end{aligned}$$

where the probabilities $p(s'|\mathrm{D}_c)$, $p(s'|s)$ and $p(s)$ are given by the DRS simplification model, the phrase based machine translation model and the language model respectively.

To get the DRS simplification model, we combine the probability of splitting with the probability of deletion:

$$p(s'|\mathrm{D}_c) = \sum_{\theta: str(\theta(\mathrm{D}_c))=s'} p(\mathrm{D}_{split}|\mathrm{D}_c)p(\mathrm{D}_{del}|\mathrm{D}_{split})$$

where θ is a sequence of simplification operations and $str(\theta(\mathrm{D}_c))$ is the sequence of words associated with a DRS resulting from simplifying D_c using θ.

The probability of a splitting operation for a given DRS D_c is:

$$p(\mathrm{D}_{split}|\mathrm{D}_c) = \begin{cases} \textsc{split}(sp^{\text{true}}_{\text{cand}}), & \text{split at } sp_{\text{cand}} \\ \prod_{sp_{\text{cand}}} \textsc{split}(sp^{\text{false}}_{\text{cand}}), & \text{otherwise} \end{cases}$$

[4]The splitting candidates could be sets of event variables depending on the number of splits required. Here, we consider pairs for 2 splits.

relation candidate		isDrop	prob.
relation word	length range		
in	0-2	true false	0.22 0.72
in	2-5	true false	0.833 0.167

mod. cand.	isDrop	prob.
mod word		
new	true false	0.22 0.72
massive	true false	0.833 0.167

OW candidate		isDrop	prob.
orphan word	isBoundary		
and	true	true false	0.82 0.18
which	false	true false	0.833 0.167

Table 2: Simplification: DELETION (Relations, modifiers and OW respectively)

That is, if the DRS is split on the splitting candidate sp_{cand}, the probability of the split is then given by the *SPLIT* table (Table 1) for the *isSplit* value "true" and the split candidate sp_{cand}; else it is the product of the probability given by the *SPLIT* table for the *isSplit* value "false" for all split candidate considered for D_c. As mentioned above, the features used for determining the split operation are the role sets associated with pairs of event variables (cf. Table 1).

The deletion probability is given by three models: a model for relations determining the deletion of prepositional phrases; a model for modifiers (adjectives and adverbs) and a model for orphan words (Table 2). All three deletion models use the associated word itself as a feature. In addition, the model for relations uses the PP length-range as a feature while the model for orphan words relies on boundary information i.e., whether or not, the OW occurs at the associated sentence boundary.

$$p(\text{D}_{del}|\text{D}_{split}) = \prod_{\text{rel}_{\text{cand}}} \text{DEL}_{\text{rel}}(\text{rel}_{\text{cand}}) \prod_{\text{mod}_{\text{cand}}} \text{DEL}_{\text{mod}}(\text{mod}_{\text{cand}}) \prod_{\text{ow}_{\text{cand}}} \text{DEL}_{\text{ow}}(\text{ow}_{\text{cand}})$$

3.3 Estimating the parameters

We use the EM algorithm (Dempster et al., 1977) to estimate our split and deletion model parameters. For an efficient implementation of EM algorithm, we follow the work of Yamada and Knight (2001) and Zhu et al. (2010); and build training graphs (Figure 2) from the pair of complex and simple sentence pairs in the training data.

Each training graph represents a complex-simple sentence pair and consists of two types of nodes: major nodes (M-nodes) and operation nodes (O-nodes). An M-node contains the DRS representation D_c of a complex sentence c and the associated simple sentence(s) s_i while O-nodes determine split and deletion operations on their parent M-node. Only the root M-node is considered for the split operations. For example, given

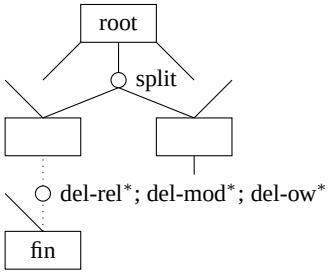

Figure 2: An example training graph

the root M-node $(\text{D}_c, (s_1, s_2))$, multiple successful split O-nodes will be created, each one further creating two M-nodes (D_{c1}, s_1) and (D_{c2}, s_2). For the training pair (c, s), the root M-node (D_c, s) is followed by a single split O-node producing an M-node (D_c, s) and counting all split candidates in D_c for failed split. The M-nodes created after split operations are then tried for multiple deletion operations of relations, modifiers and OW respectively. Each deletion candidate creates a deletion O-node marking successful or failed deletion of the candidate and a result M-node. The deletion process continues on the result M-node until there is no deletion candidate left to process. The governing criteria for the construction of the training graph is that, at each step, it tries to minimize the Levenshtein edit distance between the complex and the simple sentences. Moreover, for the splitting operation, we introduce a split only if the reference sentence consists of several sentences (i.e., there is a split in the training data); and only consider splits which maximises the overlap between split and simple reference sentences.

We initialize our probability tables Table 1 and Table 2 with the uniform distribution, i.e., 0.5 because all our features are binary. The EM algorithm iterates over training graphs counting model features from O-nodes and updating our probability tables. Because of the space constraints, we do not describe our algorithm in details. We refer the reader to (Yamada and Knight, 2001) for more details.

Our phrase based translation model is trained using the Moses toolkit[5] with its default command line options on the PWKP corpus (except the sentences from the test set) considering the complex sentence as the source and the simpler one as the target. Our trigram language model is trained using the SRILM toolkit[6] on the SWKP corpus[7].

Decoding. We explore the decoding graph similar to the training graph but in a greedy approach always picking the choice with maximal probability. Given a complex input sentence c, a split O-node will be selected corresponding to the decision of whether to split and where to split. Next, deletion O-nodes are selected indicating whether or not to drop each of the deletion candidate. The DRS associated with the final M-node D_{fin} is then mapped to a simplified sentence s'_{fin} which is further simplified using the phrase-based machine translation system to produce the final simplified sentence s_{simple}.

4 Experiments

We trained our simplification and translation models on the PWKP corpus. To evaluate performance, we compare our approach with three other state of the art systems using the test set provided by Zhu et al. (2010) and relying both on automatic metrics and on human judgments.

4.1 Training and Test Data

The DRS-Based simplification model is trained on PWKP, a bi-text of complex and simple sentences provided by Zhu et al. (2010). To construct this bi-text, Zhu et al. (2010) extracted complex and simple sentences from EWKP and SWKP respectively and automatically aligned them using TF*IDF as a similarity measure. PWKP contains $108016/114924$ complex/simple sentence pairs. We tokenize PWKP using Stanford CoreNLP toolkit[8]. We then parse all complex sentences in PWKP using Boxer[9] to produce their DRSs. Finally, our DRS-Based simplification model is trained on 97.75% of PWKP; we drop out 2.25% of the complex sentences in PWKP which are repeated in the test set or for which Boxer fails to produce DRSs.

We evaluate our model on the test set used by Zhu et al. (2010) namely, an aligned corpus of $100/131$ EWKP/SWKP sentences. Boxer produces a DRS for 96 of the 100 input sentences. These input are simplified using our simplification system namely, the DRS-SM model and the phrase-based machine translation system (Section 3.2). For the remaining four complex sentences, Boxer fails to produce DRSs. These four sentences are directly sent to the phrase-based machine translation system to produce simplified sentences.

4.2 Automatic Evaluation Metrics

To assess and compare simplification systems, two main automatic metrics have been used in previous work namely, BLEU and the Flesch-Kincaid Grade Level Index (FKG).

The FKG index is a readability metric taking into account the average sentence length in words and the average word length in syllables. In its original context (language learning), it was applied to well formed text and thus measured the simplicity of a well formed sentence. In the context of the simplification task however, the automatically generated sentences are not necessarily well formed so that the FKG index reduces to a measure of the sentence length (in terms of words and syllables) approximating the simplicity level of an output sentence irrespective of the length of the corresponding input. To assess simplification, we instead use metrics that are directly related to the simplification task namely, the number of splits in the overall (test and training) data and in average per sentences; the number of generated sentences with no edits i.e., which are identical to the original, complex one; and the average Levenshtein distance between the system's output and both the complex and the simple reference sentences.

BLEU gives a measure of how close a system's output is to the gold standard simple sentence. Because there are many possible ways of simplifying a sentence, BLEU alone fails to correctly assess the appropriateness of a simplification. Moreover BLEU does not capture the degree to which the system's output differs from the complex sentence input. We therefore use BLEU as a means to evaluate how close the systems output are to the reference corpus but complement it with further manual metrics capturing other important factors when

evaluating simplifications such as the fluency and the adequacy of the output sentences and the degree to which the output sentence simplifies the input.

4.3 Results and Discussion

Number of Splits Table 3 shows the proportion of input whose simplification involved a splitting operation. While our system splits in proportion similar to that observed in the training data, the other systems either split very often (80% of the time for Zhu and 63% of the time for Woodsend) or not at all (Wubben). In other words, when compared to the other systems, our system performs splits in proportion closest to the reference both in terms of total number of splits and of average number of splits per sentence.

Data	Total number of sentences	% split	average split / sentence
PWKP	108,016	6.1	1.06
GOLD	100	28	1.30
Zhu	100	80	1.80
Woodsend	100	63	2.05
Wubben	100	1	1.01
Hybrid	100	10	1.10

Table 3: Proportion of Split Sentences (% split) in the training/test data and in average per sentence (average split / sentence). GOLD is the test data with the gold standard SWKP sentences; Zhu, Woodsend, Wubben are the best output of the models of Zhu et al. (2010), Woodsend and Lapata (2011) and Wubben et al. (2012) respectively; Hybrid is our model.

Number of Edits Table 4 indicates the edit distance of the output sentences w.r.t. both the complex and the simple reference sentences as well as the number of input for which no simplification occur. The right part of the table shows that our system generate simplifications which are closest to the reference sentence (in terms of edits) compared to those output by the other systems. It also produces the highest number of simplifications which are identical to the reference. Conversely our system only ranks third in terms of dissimilarity with the input complex sentences (6.32 edits away from the input sentence) behind the Woodsend (8.63 edits) and the Zhu (7.87 edits) system. This is in part due to the difference in splitting strategies noted above : the many splits applied by these latter two systems correlate with a high number of edits.

System	BLEU	Edits (Complex to System)		Edits (System to Simple)	
		LD	No edit	LD	No edit
GOLD	100	12.24	3	0	100
Zhu	37.4	7.87	2	14.64	0
Woodsend	42	8.63	24	16.03	2
Wubben	41.4	3.33	6	13.57	2
Hybrid	53.6	6.32	4	11.53	3

Table 4: Automated Metrics for Simplification: average Levenshtein distance (LD) to complex and simple reference sentences per system ; number of input sentences for which no simplification occur (No edit).

BLEU score We used Moses support tools: multi-bleu[10] to calculate BLEU scores. The BLEU scores shown in Table 4 show that our system produces simplifications that are closest to the reference.

In sum, the automatic metrics indicate that our system produces simplification that are consistently closest to the reference in terms of edit distance, number of splits and BLEU score.

4.4 Human Evaluation

The human evaluation was done online using the LG-Eval toolkit (Kow and Belz, 2012)[11]. The evaluators were allocated a trial set using a Latin Square Experimental Design (LSED) such that each evaluator sees the same number of output from each system and for each test set item. During the experiment, the evaluators were presented with a pair of a complex and a simple sentence(s) and asked to rate this pair w.r.t. to adequacy (Does the simplified sentence(s) preserve the meaning of the input?) and simplification (Does the generated sentence(s) simplify the complex input?). They were also asked to rate the second (simplified) sentence(s) of the pair w.r.t. to fluency (Is the simplified output fluent and grammatical?). Similar to the Wubben's human evaluation setup, we randomly selected 20 complex sentences from Zhu's test corpus and included in the evaluation corpus: the corresponding simple (Gold) sentence from Zhu's test corpus, the output of our system (Hybrid) and the output of the other three systems (Zhu, Woodsend and Wubben) which were provided to us by the system authors. The evaluation data thus consisted of 100 complex/simple pairs. We collected ratings from 27 participants.

[10] http://www.statmt.org/moses/?n=Moses.SupportTools
[11] http://www.nltg.brighton.ac.uk/research/lg-eval/

All were either native speakers or proficient in English, having taken part in a Master taught in English or lived in an English speaking country for an extended period of time.

Systems	Simplification	Fluency	Adequacy
GOLD	3.57	3.93	3.66
Zhu	2.84	2.34	2.34
Woodsend	1.73	2.94	3.04
Wubben	1.81	3.65	3.84
Hybrid	3.37	3.55	3.50

Table 5: Average Human Ratings for simplicity, fluency and adequacy

Table 5 shows the average ratings of the human evaluation on a slider scale from 0 to 5. Pairwise comparisons between all models and their statistical significance were carried out using a one-way ANOVA with post-hoc Tukey HSD tests and are shown in Table 6.

Systems	GOLD	Zhu	Woodsend	Wubben
Zhu	◊□△			
Woodsend	◊□△	◊□△		
Wubben	◊■▲	◊□△	♦□△	
Hybrid	♦■▲	♦□△	◊□▲	◊■▲

Table 6: ◊/♦ is/not significantly different (sig. diff.) wrt simplicity. □/■ is/not sig. diff. wrt fluency. △/▲ is/not sig. diff. wrt adequacy. (significance level: $p < 0.05$)

With regard to simplification, our system ranks first and is very close to the manually simplified input (the difference is not statistically significant). The low rating for Woodsend reflects the high number of unsimplified sentences (24/100 in the test data used for the automatic evaluation and 6/20 in the evaluation data used for human judgments). Our system data is not significantly different from the manually simplified data for simplicity whereas all other systems are.

For fluency, our system rates second behind Wubben and before Woodsend and Zhu. The difference between our system and both Zhu and Woodsend system is significant. In particular, Zhu's output is judged less fluent probably because of the many incorrect splits it licenses. Manual examination of the data shows that Woodsend's system also produces incorrect splits. For this system however, the high proportion of non simplified sentences probably counterbalances these incorrect splits, allowing for a good fluency score overall.

Regarding adequacy, our system is against closest to the reference (3.50 for our system vs. 3.66 for manual simplification). Our system, the Wubben system and the manual simplifications are in the same group (the differences between these systems are not significant). The Woodsend system comes second and the Zhu system third (the difference between the two is significant). Wubben's high fluency, high adequacy but low simplicity could be explained with their minimal number of edit (3.33 edits) from the source sentence.

In sum, if we group together systems for which there is no significant difference, our system ranks first (together with GOLD) for simplicity; first for fluency (together with GOLD and Wubben); and first for adequacy (together with GOLD and Wubben).

5 Conclusion

A key feature of our approach is that it is semantically based. Typically, discourse level simplification operations such as sentence splitting, sentence reordering, cue word selection, referring expression generation and determiner choice are semantically constrained. As argued by Siddharthan (2006), correctly capturing the interactions between these phenomena is essential to ensuring text cohesion. In the future, we would like to investigate how our framework deals with such discourse level simplifications i.e., simplifications which involves manipulation of the coreference and of the discourse structure. In the PWKP data, the proportion of split sentences is rather low (6.1 %) and many of the split sentences are simple sentence coordination splits. A more adequate but small corpus is that used in (Siddharthan, 2006) which consists of 95 cases of discourse simplification. Using data from the language learning or the children reading community, it would be interesting to first construct a similar, larger scale corpus; and to then train and test our approach on more complex cases of sentence splitting.

Acknowledgments

We are grateful to Zhemin Zhu, Kristian Woodsend and Sander Wubben for sharing their data. We would like to thank our annotators for participating in our human evaluation experiments and to anonymous reviewers for their insightful comments.

Grammatical Relations in Chinese: GB-Ground Extraction and Data-Driven Parsing

Weiwei Sun, Yantao Du, Xin Kou, Shuoyang Ding, Xiaojun Wan*
Institute of Computer Science and Technology, Peking University

{ws,duyantao,kouxin,wanxiaojun}@pku.edu.cn, dsy100@gmail.com

Abstract

This paper is concerned with building linguistic resources and statistical parsers for deep grammatical relation (GR) analysis of Chinese texts. A set of linguistic rules is defined to explore implicit phrase structural information and thus build high-quality GR annotations that are represented as general directed dependency graphs. The reliability of this linguistically-motivated GR extraction procedure is highlighted by manual evaluation. Based on the converted corpus, we study transition-based, data-driven models for GR parsing. We present a novel transition system which suits GR graphs better than existing systems. The key idea is to introduce a new type of transition that reorders top k elements in the memory module. Evaluation gauges how successful GR parsing for Chinese can be by applying data-driven models.

1 Introduction

Grammatical relations (GRs) represent functional relationships between language units in a sentence. They are exemplified in traditional grammars by the notions of subject, direct/indirect object, etc. GRs have assumed an important role in linguistic theorizing, within a variety of approaches ranging from generative grammar to functional theories. For example, several computational grammar formalisms, such as Lexical Function Grammar (LFG; Bresnan and Kaplan, 1982; Dalrymple, 2001) and Head-driven Phrase Structure Grammar (HPSG; Pollard and Sag, 1994) encode grammatical functions directly. In particular, GRs can be viewed as the dependency backbone of an LFG analysis that provide general linguistic insights, and have great potential advantages for NLP applications, (Kaplan et al., 2004; Briscoe and Carroll, 2006; Clark and Curran, 2007a; Miyao et al., 2007).

In this paper, we address the question of analyzing Chinese sentences with deep GRs. To acquire high-quality GR corpus, we propose a linguistically-motivated algorithm to translate a Government and Binding (GB; Chomsky, 1981; Carnie, 2007) grounded phrase structure treebank, i.e. Chinese Treebank (CTB; Xue et al., 2005) to a deep dependency bank where GRs are explicitly represented. Different from popular *shallow* dependency parsing that focus on tree-shaped structures, our GR annotations are represented as general directed graphs that express not only local but also various long-distance dependencies, such as coordinations, control/raising constructions, topicalization, relative clauses and many other complicated linguistic phenomena that goes beyond shallow syntax (see Fig. 1 for example.). Manual evaluation highlights the reliability of our linguistically-motivated GR extraction algorithm: The overall dependency-based precision and recall are 99.17 and 98.87. The automatically-converted corpus would be of use for a wide variety of NLP tasks.

Recent years have seen the introduction of a number of treebank-guided statistical parsers capable of generating considerably accurate parses for Chinese. With the high-quality GR resource at hand, we study data-driven GR parsing. Previous work on dependency parsing mainly focused on structures that can be represented in terms of directed trees. We notice two exceptions. Sagae and Tsujii (2008) and Titov et al. (2009) individually studied two transition systems that can generate more general graphs rather than trees. Inspired by their work, we study transition-based models for building deep dependency structures. The existence of a large number of crossing arcs in GR graphs makes left-to-right, incremental graph spanning computationally hard. Applied to our data, the two existing systems cover only 51.0% and 76.5% GR graphs respectively. To better suit

Baltimore, Maryland, USA, June 23-25 2014.

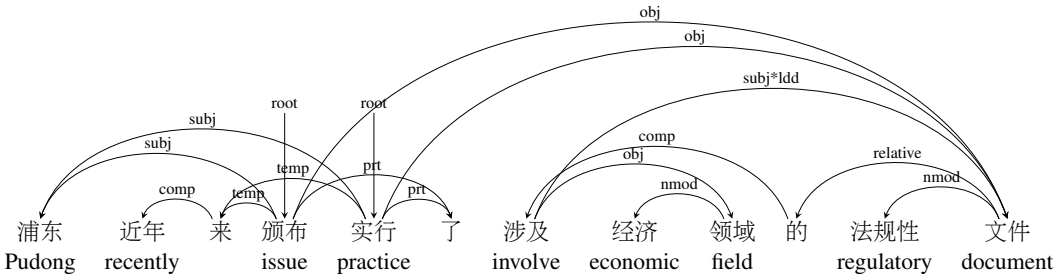

Figure 1: An example: *Pudong recently enacted regulatory documents involving the economic field*. The symbol "*ldd" indicates long-distance dependencies; "subj*ldd" between the word "涉及/involve" and the word "文件/documents" represents a long-range subject-predicate relation. The arguments and adjuncts of the coordinated verbs, namely "颁布/issue" and "实行/practice," are separately yet distributively linked the two heads.

our problem, we extend Titov et al.'s work and study what we call K-permutation transition system. The key idea is to introduce a new type of transition that reorders top k ($2 \leq k \leq K$) elements in the memory module of a stack-based transition system. With the increase of K, the expressiveness of the corresponding system strictly increases. We propose an oracle deriving method which is guaranteed to find a sound transition sequence if one exits. Moreover, we introduce an effective approximation of that oracle, which decreases decoding ambiguity but practically covers almost exactly the same graphs for our data.

Based on the stronger transition system, we build a GR parser with a discriminative model for disambiguation and a beam decoder for inference. We conduct experiments on CTB 6.0 to profile this parser. With the increase of the K, the parser is able to utilize more GR graphs for training and the numeric performance is improved. Evaluation gauges how successful GR parsing for Chinese can be by applying data-driven models. Detailed analysis reveal some important factors that may possibly boost the performance. To our knowledge, this work provides the first result of extensive experiments of parsing Chinese with GRs.

We release our GR processing kit and gold-standard annotations for research purposes. These resources can be downloaded at http://www.icst.pku.edu.cn/lcwm/omg.

2 GB-grounded GR Extraction

In this section, we discuss the construction of the GR annotations. Basically, the annotations are automatically converted from a GB-grounded phrase-structure treebank, namely CTB. Conceptually, this conversion is similar to the conversions from CTB structures to representations in deep grammar formalisms (Tse and Curran, 2010; Yu et al., 2010; Guo et al., 2007; Xia, 2001). However, our work is grounded in GB, which is the linguistic basis of the construction of CTB. We argue that this theoretical choice makes the conversion process more compatible with the original annotations and therefore more accurate. We use directed graphs to explicitly encode bi-lexical dependencies involved in coordination, raising/control constructions, extraction, topicalization, and many other complicated phenomena. Fig. 1 shows an example of such a GR graph and its original CTB annotation.

2.1 Linguistic Basis

GRs are encoded in different ways in different languages. In some languages, e.g. Turkish, grammatical function is encoded by means of morphological marking, while in highly *configurational* languages, e.g. Chinese, the grammatical function of a phrase is heavily determined by its constituent structure position. Dominant Chomskyan theories, including GB, have defined GRs as configurations at phrase structures. Following this principle, CTB groups words into constituents through the use of a limited set of fundamental grammatical functions. Transformational grammar utilizes empty categories (ECs) to represent long-distance dependencies. In CTB, traces are provided by relating displaced linguistic material to where it should be interpreted semantically. By exploiting configurational information, traces and functional tag annotations, GR information can be hopefully

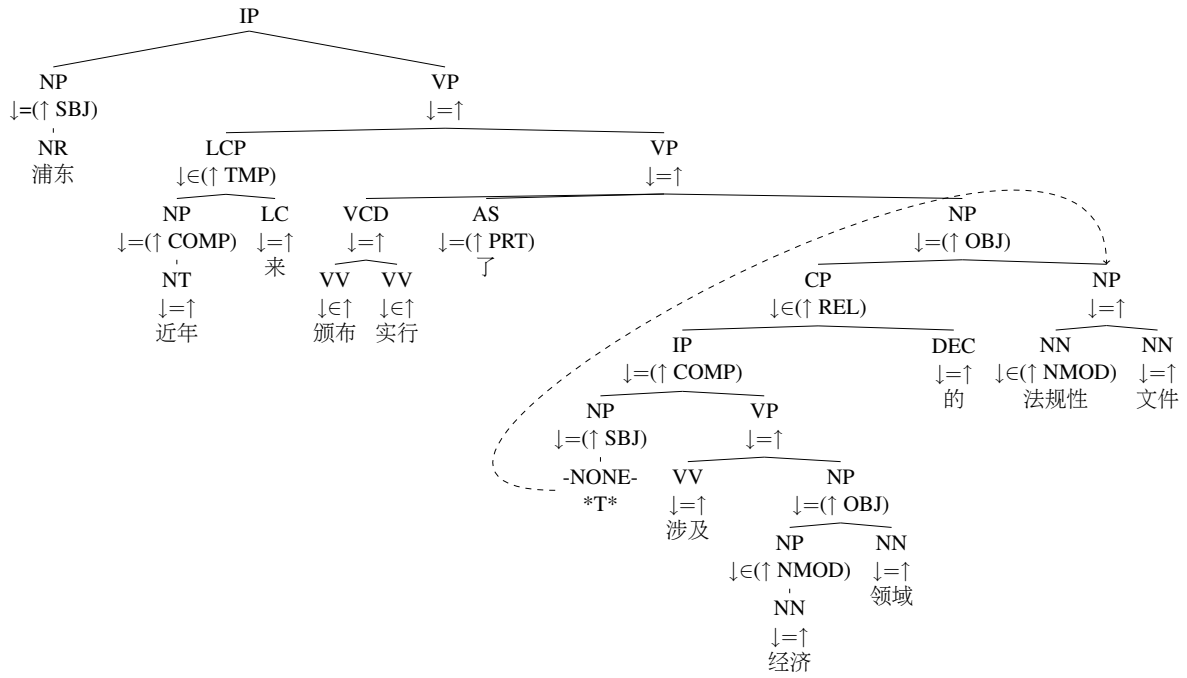

Figure 2: The original CTB annotation augmented with LFG-like f-structure annotations of the running example.

derived from CTB trees with high accuracy.

2.2 The Extraction Algorithm

Our treebank conversion algorithm borrows key insights from Lexical Functional Grammar (LFG; Bresnan and Kaplan, 1982; Dalrymple, 2001). LFG posits two levels of representation: c(onstituent)-structure and f(unctional)-structure minimally. C-structure is represented by phrase-structure trees, and captures surface syntactic configurations such as word order, while f-structure encodes grammatical functions. It is easy to extract a dependency backbone which approximates basic predicate-argument-adjunct structures from f-structures. The construction of the widely used PARC DepBank (King et al., 2003) is a good example.

LFG relates c-structure and f-structure through f-structure annotations, which compositionally map every constituent to a corresponding f-structure. Borrowing this key idea, we translate CTB trees to dependency graphs by first augmenting each constituency with f-structure annotations, then propagating the head words of the head or conjunct daughter(s) upwards to their parents, and finally creating a dependency graph. The following presents details step-by-step.

Tapping implicit information. Xue (2007) introduced a systematic study to tap the implicit functional information of CTB. This gives us a very good start to extract GRs. We slightly modify their method to enrich a CTB tree with f-structure annotations: Each node in a resulting tree is annotated with one and only one corresponding equation. See Fig. 2 for example. Comparing the original annotation and enriched one, we can see that the functionality of this step is to explicitly represent and regulate grammatical functions.

Beyond CTB annotations: tracing more. Natural languages do not always interpret linguistic material locally. In order to obtain accurate and complete GR, predicate-argument, or logical form representations, a hallmark of deep grammars is that they usually involve a non-local dependency resolution mechanism. CTB trees utilize ECs and coindexed materials to represent long-distance dependencies. An EC is a nominal element that does not have any phonological content and is therefore unpronounced. Two kinds of anaphoric ECs, i.e. big PRO and trace, are annotated in CTB. Theoretically speaking, only trace is generated as the result of *movement* and therefore annotated with antecedents in CTB. We carefully check the annotation and find that a considerable amount of antecedents are not labeled, and hence a lot of impor-

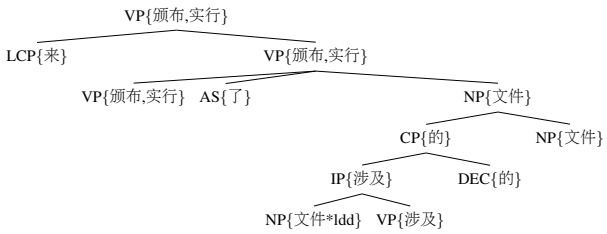

Figure 3: An example of lexicalized tree after head word upward passing. Only partial result is shown. The long-distance dependency between "涉及/involve" and "文件/document" is created through copying the dependent to a coindexed anaphoric EC position.

tant non-local information is missing. In addition, since the big PRO is also anaphoric, it is possible to find coindexed components sometimes. Such non-local information is also very valuable.

Beyond CTB annotations, we introduce a number of phrase-structure patterns to extract more non-local dependencies. The method heavily leverages linguistic rules to exploit structural information. We take into account both theoretical assumptions and analyzing practices to enrich coindexation information according to phrase-structure patterns. In particular, we try to link an anaphoric EC e with its c-commonders if no non-empty antecedent has already been coindexed with e. Because the CTB is influenced deeply by the X-bar syntax, which regulates constituent analysis much, the number of our linguistic rules is quite modest. For the development of conversion rules, we used the first 9 files of CTB, which contains about 100 sentences. Readers can refer to the well-documented Perl script for details. See Fig. 2 for example. The noun phrase "法规性文件/regulatory documents" is related to the trace "*T*." This coindexation is not labeled by the original annotation.

Passing head words and linking ECs. Based on an enriched tree, our algorithm propagates the head word of the head daughter upwards to their parents, linking coindexed units, and finally creating a GR graph. The partial result after head word passing of the running example is shown in Fig. 3. There are two differences of the head word passing between our GR extraction and a "normal" dependency tree extraction. First, the GR extraction procedure may pass multiple head words to its parent, especially in a coordination construction. Second, long-distance dependencies are created by linking ECs and their coindexed phrases.

	Precision	Recall	F-score
Unlabeled	99.48	99.17	99.32
Labeled	99.17	98.87	99.02

Table 1: Manual evaluation of 209 sentences.

2.3 Manual Evaluation

To have a precise understanding of whether our extraction algorithm works well, we have selected 20 files that contains 209 sentences in total for manual evaluation. Linguistic experts carefully examine the corresponding GR graphs derived by our extraction algorithm and correct all errors. In other words, a *gold standard* GR annotation set is created. The measure for comparing two dependency graphs is precision/recall of GR tokens which are defined as $\langle w_h, w_d, l \rangle$ tuples, where w_h is the head, w_d is the dependent and l is the relation. Labeled precision/recall (LP/LR) is the ratio of tuples correctly identified by the automatic generator, while unlabeled precision/recall (UP/UR) is the ratio regardless of l. F-score is a harmonic mean of precision and recall. These measures correspond to attachment scores (LAS/UAS) in dependency tree parsing. To evaluate our GR parsing models that will be introduced later, we also report these metrics.

The overall performance is summarized in Tab. 1. We can see that the automatical GR extraction achieves relatively high performance. There are two sources of errors in treebank conversion: (1) inadequate conversion rules and (2) wrong or inconsistent original annotations. During the creation of the gold standard corpus, we find that the former is mainly caused by complicated unbounded dependencies and the lack of internal structure for some kinds of phrases. Such problems are very hard to solve through rules only, if not possible, since original annotations do not provide sufficient information. The latter problem is more scattered and unpredictable.

2.4 Statistics

Allowing non-projective dependencies generally makes parsing either by graph-based or transition-based dependency parsing harder. Substantial research effort has been devoted in recent years to the design of elegant solutions for this problem. There are much more crossing arcs in the GR

graphs than syntactic dependency trees. In the training data (defined in Section 4.1), there are 558132 arcs and 86534 crossing pairs, About half of the sentences have crossing arcs (10930 out of 22277). The wide existence of crossing arcs poses an essential challenge for GR parsing, namely, to find methods for handling crossing arcs without a significant loss in accuracy and efficiency.

3 Transition-based GR Parsing

The availability of large-scale treebanks has contributed to the blossoming of statistical approaches to build accurate *shallow* constituency and dependency parsers. With high-quality GR resources at hand, it is possible to study statistical approaches to automatically parse GR graphs. In this section, we investigate the feasibility of applying a data-driven, grammar-free approach to build GRs directly. In particular, transition-based dependency parsing method is studied.

3.1 Data-Driven Dependency Parsing

Data-driven, grammar-free dependency parsing has received an increasing amount of attention in the past decade. Such approaches, e.g. transition-based (Yamada and Matsumoto, 2003; Nivre, 2008) and graph-based (McDonald, 2006; Torres Martins et al., 2009) models have attracted the most attention of dependency parsing in recent years. Transition-based parsers utilize transition systems to derive dependency trees together with treebank-induced statistical models for predicting transitions. This approach was pioneered by (Yamada and Matsumoto, 2003) and (Nivre et al., 2004). Most research concentrated on surface syntactic structures, and the majority of existing approaches are limited to producing only trees. We notice two exceptions. Sagae and Tsujii (2008) and Titov et al. (2009) individually introduced two transition systems that can generate specific graphs rather than trees. Inspired by their work, we study transition-based approach to build GR graphs.

3.2 Transition Systems

Following (Nivre, 2008), we define a transition system for dependency parsing as a quadruple $S = (\mathcal{C}, T, c_s, \mathcal{C}_t)$, where

1. $\mathcal{C}$ is a set of configurations, each of which contains a buffer β of (remaining) words and a set A of dependency arcs,

Transitions	
SHIFT	$(\sigma, j\|\beta, A) \Rightarrow (\sigma\|j, \beta, A)$
LEFT-ARC$_l$	$(\sigma\|i, j\|\beta, A) \Rightarrow (\sigma\|i, j\|\beta, A \cup \{(j, l, i)\})$
RIGHT-ARC$_l$	$(\sigma\|i, j\|\beta, A) \Rightarrow (\sigma\|i, j\|\beta, A \cup \{(i, l, j)\})$
POP	$(\sigma\|i, \beta, A) \Rightarrow (\sigma, \beta, A)$
ROTATE$_k$	$(\sigma\|i_k]\dots\|i_2\|i_1, \beta, A) \Rightarrow (\sigma\|i_1\|i_k]\dots\|i_2, \beta, A)$

Table 2: K-permutation System.

2. T is a set of transitions, each of which is a (partial) function $t : \mathcal{C} \mapsto \mathcal{C}$,

3. c_s is an initialization function, mapping a sentence x to a configuration, with $\beta = [1, \dots, n]$,

4. $\mathcal{C}_t \subseteq \mathcal{C}$ is a set of terminal configurations.

Given a sentence $x = w_1, \dots, w_n$ and a graph $G = (V, A)$ on it, if there is a sequence of transitions $t_1, \dots, t_m$ and a sequence of configurations $c_0, \dots, c_m$ such that $c_0 = c_s(x)$, $t_i(c_{i-1}) = c_i (i = 1, \dots, m)$, $c_m \in \mathcal{C}_t$, and $A_{c_m} = A$, we say the sequence of transitions is an *oracle* sequence. And we define $\bar{A}_{c_i} = A - A_{c_i}$ for the arcs to be built in c_i. In a typical transition-based parsing process, the input words are put into a queue and partially built structures are organized by a stack. A set of SHIFT/REDUCE actions are performed sequentially to consume words from the queue and update the partial parsing results.

3.3 Online Reordering

Among existing systems, Sagae and Tsujii's is designed for projective graphs (denoted by $\mathcal{G}_1$ in Definition 1), and Titov et al.'s handles only a specific subset of non-projective graphs as well as projective graphs ($\mathcal{G}_2$). Applied to our data, only 51.0% and 76.5% of the extracted graphs are parsable with their systems. Obviously, it is necessary to investigate new transition systems for the parsing task in our study. To deal with crossing arcs, Titov et al. (2009) and Nivre (2009) designed a SWAP transition that switches the position of the two topmost nodes on the stack. Inspired by their work, we extend this approach to parse more general graphs. The basic idea is to provide our new system with an ability to reorder more nodes during decoding in an online fashion, which we refer to as online reordering.

3.4 K-Permutation System

We define a K-permutation transition system $S_K = (\mathcal{C}, T, c_s, \mathcal{C}_t)$, where a configuration $c =$

$(\sigma, \beta, A) \in \mathcal{C}$ contains a stack σ of nodes besides β and A. We set the initial configuration for a sentence $x = w_1, \ldots, w_n$ to be $c_s(x) = ([], [1, \ldots, n], \{\})$, and take $\mathcal{C}_t$ to be the set of all configurations of the form $c_t = (\sigma, [], A)$ (for any arc set A). The set of transitions T contains five types of actions, as shown in Tab. 2:

1. SHIFT removes the front element from β and pushes it onto σ.
2. LEFT-ARC$_l$/RIGHT-ARC$_l$ updates a configuration by adding (i, l, j)/(j, l, i) to A where i is the top of σ, and j is the front of β.
3. POP deletes the top element of σ.
4. ROTATE$_k$ updates a configuration with stack $\sigma|i_k|\ldots|i_2|i_1$ by rotating the top k nodes in stack left by one index, obtaining $\sigma|i_1|i_k|\ldots|i_2$, with constraint $2 \leq k \leq K$.

We refer to this system as K-permutation because by rotating the top k $(2 \leq k \leq K)$ nodes in the stack, we can obtain all the permutations of the top K nodes. Note that S_2 is identical to Titov et al.'s; S_∞ is complete with respect to the class of all directed graphs without self-loop, since we can arbitrarily permute the nodes in the stack. The K-permutation system exhibits a nice property: The sets of corresponding graphs are strictly monotonic with respect to the $\subset$ operation.

Definition 1. If a graph G can be parsed with transition system S_K, we say G is a *K-perm graph*. We use $\mathcal{G}_K$ to denote the set of all k-perm graphs. Specially, $\mathcal{G}_0 = \emptyset$, $\mathcal{G}_1$ is the set of all projective graphs, and $\mathcal{G}_\infty = \bigcup_{k=0}^{\infty} \mathcal{G}_k$.

Theorem 1. $\mathcal{G}_i \subsetneq \mathcal{G}_{i+1}, \forall i \geq 0$.

Proof. It is obvious that $\mathcal{G}_i \subseteq \mathcal{G}_{i+1}$ and $\mathcal{G}_0 \subsetneq \mathcal{G}_1$. Fig. 4 gives an example which is in $\mathcal{G}_{i+1}$ but not in $\mathcal{G}_i$ for all $i > 0$, indicating $\mathcal{G}_i \neq \mathcal{G}_{i+1}$. □

Theorem 2. $\mathcal{G}_\infty$ is the set of all graphs without self-loop.

Proof. It follows immediately from the fact that $G \in \mathcal{G}_{|V|}, \forall G = \langle V, E \rangle$. □

The transition systems introduced in (Sagae and Tsujii, 2008) and (Titov et al., 2009) can be viewed as S_1[1] and S_2.

[1]Though Sagae and Tsujii (2008) introduced additional constraints to exclude cyclic path, the fundamental transition mechanism of their system is the same to S_1.

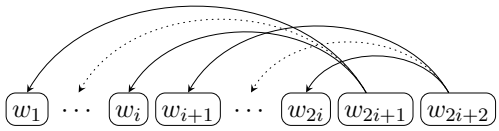

Figure 4: A graph which is in $\mathcal{G}_{i+1}$, but not in $\mathcal{G}_i$.

3.5 Normal Form Oracle

The K-permutation transition system may allow multiple oracle transition sequences on one graph, but trying to sum all the possible oracles is usually computational expensive. Here we give a construction procedure which is guaranteed to find an oracle sequence if one exits. We refer it as normal form oracle (NFO).

Let $L(j)$ be the ordered list of nodes connected to j in $\bar{A}_{c_{i-1}}$ for $j \in \sigma_{c_{i-1}}$, and let $\mathcal{L}_K(\sigma_{c_{i-1}}) = [L(j_1), \ldots, L(j_{\max\{l,K\}})]$. If $\sigma_{c_{i-1}}$ is empty, then we set t_i to SHIFT; if there is no arc linked to j_1 in $\bar{A}_{c_{i-1}}$, then we set t_i to POP; if there exits $a \in \bar{A}_{c_{i-1}}$ linking j_1 and b, then we set t_i to LEFT-ARC or RIGHT-ARC correspondingly. When there are only SHIFT and ROTATE left, we first apply a sequence of ROTATE's to make $\mathcal{L}_K(\sigma)$ complete ordered by lexicographical order, then apply a SHIFT. Let $c_i = t_i(c_{i-1})$, we continue to compute t_{i+1}, until β_{c_i} is empty.

Theorem 3. If a graph is parsable with the transition system S_K then the construction procedure is guaranteed to find an oracle transition sequence.

Proof. During the construction, all the arcs are built by LEFT-ARC or RIGHT-ARC, which links the top of the stack and the front of the buffer. Therefore, we prefer $\mathcal{L}(\sigma)$ to be as orderly as possible, to make the words to be linked sooner on the top of the stack. the construction procedure above does best within the power of the system S_K. □

3.6 An Approximation for NFO

In the construction of NFO transitions, we exhaustively use the ROTATE's to make $\mathcal{L}(\sigma)$ complete ordered. We also observed that the transition LEFT-ARC, RIGHT-ARC and SHIFT only change the relative order between the first element of $\mathcal{L}(\sigma)$ and the rest elements. Therefore we explored an approximate procedure to determine the ROTATE's, based on the observation. We call it approximate NFO (ANFO). Using notation defined in Section 3.5, the approximate procedure goes as follows. When it comes to the determination of

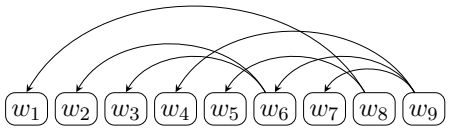

Figure 5: A graph that can be parsed with S_3 with a transition sequence $\text{SSSSR}_3\text{SR}_3\text{APAP}\mathbf{R}_2\mathbf{R}_3\text{SR}_3\text{SR}_3\text{APAPAPAPAP}$, where S stands for SHIFT, R for ROTATE, A for LEFT-ARC, and P for POP. But the approximate procedure fails to find the oracle, since $\mathbf{R}_2\mathbf{R}_3$ in bold in the sequence are not to be applied.

the ROTATE sequence, let k be the largest m such that $0 \leq m \leq \min\{K, l\}$ and $L(j_m)$ strictly precedes $L(j_1)$ by the lexicographical order (here we assume $L(j_0)$ strictly precedes any $L(j), j \in \sigma$). If $k > 0$, we set t_i to ROTATE_k; else we set t_i to SHIFT. The approximation assumes $\mathcal{L}(\sigma)$ is completely ordered except the first element, and insert the first element to its proper place each time.

Definition 2. We define $\hat{\mathcal{G}}_K$ as the graphs the oracle of which can be extracted by S_K with the approximation procedure.

It can be inferred similarly that Theorem 1 and Theorem 2 also hold for $\hat{\mathcal{G}}$'s. However, the $\hat{\mathcal{G}}_K$ is not equal to $\mathcal{G}_K$ in non-trivial cases.

Theorem 4. $\hat{\mathcal{G}}_i \subsetneq \mathcal{G}_i, \forall i \geq 3$.

Proof. It is trivial that $\hat{\mathcal{G}}_i \subseteq \mathcal{G}_i$. An example graph that is in $\mathcal{G}_3$ but not in $\hat{\mathcal{G}}_3$ is shown in Figure 5, examples for arbitrary $i > 3$ can be constructed similarly. □

The above theorem indicates the inadequacy of the ANFO deriving procedure. Nevertheless, empirical evaluation (Section 4.2) shows that the coverage of AFO and ANFO deriving procedures are almost identical when applying to linguistic data.

3.7 Statistical Parsing

When we parse a sentence $w_1 w_2 \cdots w_n$, we start with the initial configuration $c_0 = c_s(x)$, and choose next transition $t_i = C(c_{i-1})$ iteratively according to a discriminative classifier trained on oracle sequences. To build a parser, we use a structured classifier to approximate the oracle, and apply the Passive-Aggressive (PA) algorithm (Crammer et al., 2006) for parameter estimation. The PA algorithm is similar to the Perceptron algorithm, the difference from which is the update of weight vector. We also use parameter averaging and early update to achieve better training. Developing features has been shown crucial to advancing the state-of-the-art in dependency tree parsing (Koo and Collins, 2010; Zhang and Nivre, 2011). To build accurate deep dependency parsers, we utilize a large set of features for disambiguation. See the notes included in the supplymentary material for details. To improve the performance, we also apply the technique of beam search, which keep a beam of transition sequences with highest scores when parsing.

4 Experiments

4.1 Experimental setup

CTB is a segmented, part-of-speech (POS) tagged, and fully bracketed corpus in the constituency formalism, and very popular to evaluate fundamental NLP tasks, including word segmentation (Sun and Xu, 2011), POS tagging (Sun and Uszkoreit, 2012), and syntactic parsing (Zhang and Clark, 2009; Sun and Wan, 2013). We use CTB 6.0 and define the training, development and test sets according to the CoNLL 2009 shared task. We use gold-standard word segmentation and POS tagging results as inputs. All transition-based parsing models are trained with beam 16 and iteration 30. Overall precision/recall/f-score with respect to dependency tokens is reported. To evaluate the ability to recover non-local dependencies, the recall of such dependencies are reported too.

4.2 Coverage and Accuracy

There is a dual effect of the increase of the parameter k to our transition-based dependency parser. On one hand, the higher k is, the more expressivity the corresponding transition system has. A system with higher k covers more structures and allows to use more data for training. On the other hand, higher k brings more ambiguities to the corresponding parser, and the parsing performance may thus suffer. Note that the ambiguity exists not only in each step for transition decision, but also in selecting the training oracle.

The left-most columns of Tab. 3 shows the coverage of K-permutation transition system with respect to different K and different oracle deriving algorithms. Readers may be surprised that the coverage of NFO and ANFO deriving procedures is the same. Actually, all the covered graphs by the two oracle deriving procedures are exactly the

System	NFO	ANFO	UP	UR	UF	LP	LR	LF	UR_L	LR_L	UR_{NL}	LR_{NL}
S_2	76.5	76.5	85.88	81.00	83.37	83.98	79.21	81.53	81.93	80.34	58.88	52.17
S_3	89.0	89.0	86.02	81.72	83.82	84.07	79.86	81.91	82.61	80.94	60.46	54.28
S_4	95.6	95.6	86.28	82.06	84.12	84.35	80.22	82.23	82.92	81.29	61.48	54.77
S_5	98.4	98.4	86.44	82.21	84.27	84.51	80.37	82.39	83.15	81.51	59.80	53.30

Table 3: Coverage and accuracy of the GR parser on the development data.

same, except for S_3. Only 1 from 22277 sentences can find a NFO but not an ANFO. This number demonstrates the effectiveness of ANFO. In the following experiments, we use the ANFO's to train our parser.

Applied to our data, S_2, i.e. the exact system introduced by Titov et al. (2009), only covers 76.5% GR graphs. This is very different from the result obtained on the CoNLL shared task data for English semantic role labeling (SRL). According to (Titov et al., 2009), 99% semantic-role-labelled graphs can be generated by S_2. We think there are two main reasons accounting for the differences, and highlight the importance of the expressiveness of transition systems to solve deep dependency parsing problems. First, the SRL task only focuses on finding arguments and adjuncts of verbal (and nominal) predicates, while dependencies headed by other words are not contained in its graph representation. On contrast, a deep dependency structure, like GR graph, approximates deep syntactic or semantic information of a sentence as a whole, and therefore is more dense. As a result, permutation system with a very low k is incapable to handle more cases. Another reason is about the Chinese language. Some language-specific properties result in complex crossing arcs. For example, serial verb constructions are widely used in Chinese to describe several separate events without conjunctions. The verbal heads in such constructions share subjects and adjuncts, both of which are before the heads. The distributive dependencies between verbal heads and subjects/adjuncts usually produce crossing arcs (see Fig. 6). To test our assumption, we evaluate the coverage of S_2 over the functor-argument dependency graphs provided by the English and Chinese CCGBank (Hockenmaier and Steedman, 2007; Tse and Curran, 2010). The result is **96.9%** vs. **89.0%**, which confirms our linguistic intuition under another grammar formalism.

Tab. 3 summarizes the performance of the transition-based parser with different configurations to reveal how well data-driven parsing can

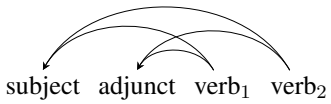

Figure 6: A simplified example to illustrate crossing arcs in serial verbal constructions.

be performed in realistic situations. We can see that with the increase of K, the overall parsing accuracy incrementally goes up. The high complexity of Chinese deep dependency structures demonstrates the importance of the expressiveness of a transition system, while the improved numeric accuracies practically certify the benefits. The two points merit further exploration to more expressive transition systems for deep dependency parsing, at least for Chinese. The labeled evaluation scores on the final test data are presented in Tab. 4.

Test	UP	UR	UF	LR_L	LR_{NL}
S_5	83.93	79.82	81.82	80.94	54.38

Table 4: Performance on the test data.

4.3 Precision vs. Recall

A noteworthy thing about the overall performance is that the precision is promising but the recall is too low behind. This difference is consistent with the result obtained by a shift-reduce CCG parser (Zhang and Clark, 2011). The functor-argument dependencies generated by that parser also has a relatively high precision but considerably low recall. There are two similarities between our parser and theirs: 1) both parsers produce dependency graphs rather trees; 2) both parser employ a beam decoder that does not guarantee global optimality. To build NLP application, e.g. information extraction, systems upon GR parsing, such property merits attention. A good trade-off between the precision and the recall may have a great impact on final results.

4.4 Local vs. Non-local

Although the micro accuracy of all dependencies are considerably good, the ability of current state-of-the-art statistical parsers to find difficult non-local materials is far from satisfactory, even for English (Rimell et al., 2009; Bender et al., 2011). We report the accuracy in terms of local and non-local dependencies respectively to show the difficulty of the recovery of non-local dependencies. The last four columns of Tab. 3 demonstrates the labeled/unlabeled recall of local (UR_L/LR_L) and non-local dependencies (UR_{NL}/LR_{NL}). We can clearly see that non-local dependency recovery is extremely difficult for Chinese parsing.

4.5 Deep vs. Deep

CCG and HPSG parsers also favor the dependency-based metrics for evaluation (Clark and Curran, 2007b; Miyao and Tsujii, 2008). Previous work on Chinese CCG and HPSG parsing unanimously agrees that obtaining the deep analysis of Chinese is more challenging (Yu et al., 2011; Tse and Curran, 2012). The successful C&C and Enju parsers provide very inaccurate results for Chinese texts. Though the numbers profiling the qualities of deep dependency structures under different formalisms are not directly comparable, all empirical evaluation indicates that the state-of-the-art of deep linguistic processing for Chinese lag behind very much.

5 Related Work

Wide-coverage in-depth and accurate linguistic processing is desirable for many practical NLP applications, such as machine translation (Wu et al., 2010) and information extraction (Miyao et al., 2008). Parsing in deep formalisms, e.g. CCG, HPSG, LFG and TAG, provides valuable, richer linguistic information, and researchers thus draw more and more attention to it. Very recently, study on deep linguistic processing for Chinese has been initialized. Our work is one of them.

To quickly construct deep annotations, corpus-driven grammar engineering has been studied. Phrase structure trees in CTB have been semi-automatically converted to deep derivations in the CCG (Tse and Curran, 2010), LFG (Guo et al., 2007), TAG (Xia, 2001) and HPSG (Yu et al., 2010) formalisms. Our GR extraction work is similar, but grounded in GB, which is more consistent with the construction of the original annotations.

Based on converted fine-grained linguistic annotations, successful English deep parsers, such as C&C (Clark and Curran, 2007b) and Enju (Miyao and Tsujii, 2008), have been evaluated (Yu et al., 2011; Tse and Curran, 2012). We also borrow many ideas from recent advances in deep syntactic or semantic parsing for English. In particular, Sagae and Tsujii (2008)'s and Titov et al. (2009)'s studies on transition-based deep dependency parsing motivated our work very much. However, simple adoption of their systems does not resolve Chinese GR parsing well because the GR graphs are much more complicated. Our investigation on the K-permutation transition system advances the capacity of existing methods.

6 Conclusion

Recent years witnessed rapid progress made on deep linguistic processing for English, and initial attempts for Chinese. Our work stands in between traditional dependency tree parsing and deep linguistic processing. We introduced a system for automatically extracting grammatical relations of Chinese sentences from GB phrase structure trees. The present work remedies the resource gap by facilitating the accurate extraction of GR annotations from GB trees. Manual evaluation demonstrate the effectiveness of our method. With the availability of high-quality GR resources, transition-based methods for GR parsing was studied. A new formal system, namely K-permutation system, is well theoretically discussed and practically implemented as the core module of a deep dependency parser. Empirical evaluation and analysis were presented to give better understanding of the Chinese GR parsing problem. Detailed analysis reveals some important directions for future investigation.

Ambiguity-aware Ensemble Training for Semi-supervised Dependency Parsing

Zhenghua Li , Min Zhang*, Wenliang Chen

Abstract

This paper proposes a simple yet effective framework for semi-supervised dependency parsing at entire tree level, referred to as *ambiguity-aware ensemble training*. Instead of only using 1-best parse trees in previous work, our core idea is to utilize parse forest (*ambiguous labelings*) to combine multiple 1-best parse trees generated from diverse parsers on unlabeled data. With a conditional random field based probabilistic dependency parser, our training objective is to maximize mixed likelihood of labeled data and auto-parsed unlabeled data with ambiguous labelings. This framework offers two promising advantages. 1) ambiguity encoded in parse forests compromises noise in 1-best parse trees. During training, the parser is aware of these ambiguous structures, and has the flexibility to distribute probability mass to its preferred parse trees as long as the likelihood improves. 2) diverse syntactic structures produced by different parsers can be naturally compiled into forest, offering complementary strength to our single-view parser. Experimental results on benchmark data show that our method significantly outperforms the baseline supervised parser and other entire-tree based semi-supervised methods, such as self-training, co-training and tri-training.

1 Introduction

Supervised dependency parsing has made great progress during the past decade. However, it is very difficult to further improve performance of supervised parsers. For example, Koo and Collins (2010) and Zhang and McDonald (2012) show that incorporating higher-order features into a graph-based parser only leads to modest increase in parsing accuracy. In contrast, semi-supervised approaches, which can make use of large-scale unlabeled data, have attracted more and more interest. Previously, unlabeled data is explored to derive useful local-context features such as word clusters (Koo et al., 2008), subtree frequencies (Chen et al., 2009; Chen et al., 2013), and word co-occurrence counts (Zhou et al., 2011; Bansal and Klein, 2011). A few effective learning methods are also proposed for dependency parsing to implicitly utilize distributions on unlabeled data (Smith and Eisner, 2007; Wang et al., 2008; Suzuki et al., 2009). All above work leads to significant improvement on parsing accuracy.

Another line of research is to pick up some high-quality auto-parsed training instances from unlabeled data using bootstrapping methods, such as self-training (Yarowsky, 1995), co-training (Blum and Mitchell, 1998), and tri-training (Zhou and Li, 2005). However, these methods gain limited success in dependency parsing. Although working well on constituent parsing (McClosky et al., 2006; Huang and Harper, 2009), self-training is shown unsuccessful for dependency parsing (Spreyer and Kuhn, 2009). The reason may be that dependency parsing models are prone to amplify previous mistakes during training on self-parsed unlabeled data. Sagae and Tsujii (2007) apply a variant of co-training to dependency parsing and report positive results on out-of-domain text. Søgaard and Rishøj (2010) combine tri-training and parser ensemble to boost parsing accuracy. Both work employs two parsers to process the unlabeled data, and only select as extra training data sentences on which the 1-best parse trees of the two parsers are identical. In this way, the auto-parsed unlabeled data becomes more reliable.

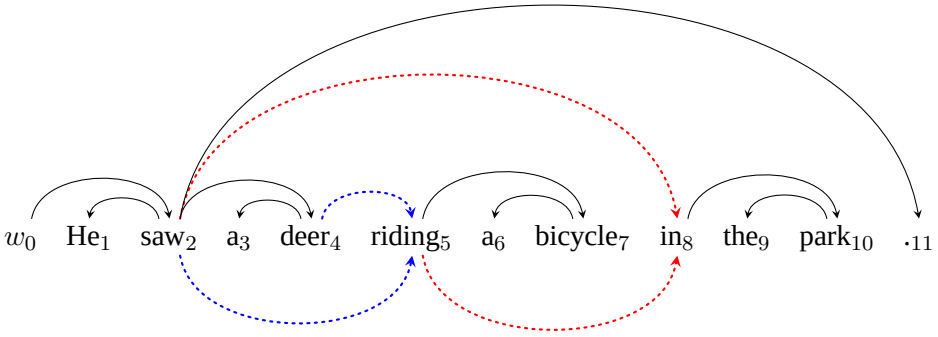

Figure 1: An example sentence with an ambiguous parse forest.

However, one obvious drawback of these methods is that they are unable to exploit unlabeled data with divergent outputs from different parsers. Our experiments show that unlabeled data with identical outputs from different parsers tends to be short (18.25 words per sentence on average), and only has a small proportion of 40% (see Table 6). More importantly, we believe that unlabeled data with divergent outputs is equally (if not more) useful. Intuitively, an unlabeled sentence with divergent outputs should contain some ambiguous syntactic structures (such as preposition phrase attachment) that are very hard to resolve and lead to the disagreement of different parsers. Such sentences can provide more discriminative instances for training which may be unavailable in labeled data.

To solve above issues, this paper proposes a more general and effective framework for semi-supervised dependency parsing, referred to as *ambiguity-aware ensemble training*. Different from traditional self/co/tri-training which only use 1-best parse trees on unlabeled data, our approach adopts ambiguous labelings, represented by parse forest, as gold-standard for unlabeled sentences. Figure 1 shows an example sentence with an ambiguous parse forest. The forest is formed by two parse trees, respectively shown at the upper and lower sides of the sentence. The differences between the two parse trees are highlighted using dashed arcs. The upper tree take *"deer"* as the subject of *"riding"*, whereas the lower one indicates that *"he"* rides the bicycle. The other difference is where the preposition phrase (PP) *"in the park"* should be attached, which is also known as the PP attachment problem, a notorious challenge for parsing. Reserving such uncertainty has three potential advantages. First, noise in unlabeled data is largely alleviated, since parse forest encodes only a few highly possible parse trees with high oracle score. Please note that the parse forest in Figure 1 contains four parse trees after combination of the two different choices. Second, the parser is able to learn useful features from the unambiguous parts of the parse forest. Finally, with sufficient unlabeled data, it is possible that the parser can learn to resolve such uncertainty by biasing to more reasonable parse trees.

To construct parse forest on unlabeled data, we employ three supervised parsers based on different paradigms, including our baseline graph-based dependency parser, a transition-based dependency parser (Zhang and Nivre, 2011), and a generative constituent parser (Petrov and Klein, 2007). The 1-best parse trees of these three parsers are aggregated in different ways. Evaluation on labeled data shows the oracle accuracy of parse forest is much higher than that of 1-best outputs of single parsers (see Table 3). Finally, using a conditional random field (CRF) based probabilistic parser, we train a better model by maximizing mixed likelihood of labeled data and auto-parsed unlabeled data with ambiguous labelings. Experimental results on both English and Chinese datasets demonstrate that the proposed ambiguity-aware ensemble training outperforms other entire-tree based methods such as self/co/tri-training. In summary, we make following contributions.

1. We propose a generalized ambiguity-aware ensemble training framework for semi-supervised dependency parsing, which can

make better use of unlabeled data, especially when parsers from different views produce divergent syntactic structures.

2. We first employ a generative constituent parser for semi-supervised dependency parsing. Experiments show that the constituent parser is very helpful since it produces more divergent structures for our semi-supervised parser than discriminative dependency parsers.

3. We build the first state-of-the-art CRF-based dependency parser. Using the probabilistic parser, we benchmark and conduct systematic comparisons among ours and all previous bootstrapping methods, including self/co/tri-training.

2 Supervised Dependency Parsing

Given an input sentence $\mathbf{x} = w_0 w_1 ... w_n$, the goal of dependency parsing is to build a dependency tree as depicted in Figure 1, denoted by $\mathbf{d} = \{(h, m) : 0 \leq h \leq n, 0 < m \leq n\}$, where (h, m) indicates a directed arc from the *head* word w_h to the *modifier* w_m, and w_0 is an artificial node linking to the root of the sentence.

In parsing community, two mainstream methods tackle the dependency parsing problem from different perspectives but achieve comparable accuracy on a variety of languages. The graph-based method views the problem as finding an optimal tree from a fully-connected directed graph (McDonald et al., 2005; McDonald and Pereira, 2006; Carreras, 2007; Koo and Collins, 2010), while the transition-based method tries to find a highest-scoring transition sequence that leads to a legal dependency tree (Yamada and Matsumoto, 2003; Nivre, 2003; Zhang and Nivre, 2011).

2.1 Graph-based Dependency Parser (GParser)

In this work, we adopt the graph-based paradigm because it allows us to naturally derive conditional probability of a dependency tree $\mathbf{d}$ given a sentence $\mathbf{x}$, which is required to compute likelihood of both labeled and unlabeled data. Under the graph-based model, the score of a dependency tree is factored into the scores of small subtrees $\mathbf{p}$.

$$\begin{aligned} Score(\mathbf{x}, \mathbf{d}; \mathbf{w}) &= \mathbf{w} \cdot \mathbf{f}(\mathbf{x}, \mathbf{d}) \\ &= \sum_{\mathbf{p} \subseteq \mathbf{d}} Score(\mathbf{x}, \mathbf{p}; \mathbf{w}) \end{aligned}$$

(a) *single dependency* (b) *adjacent sibling*

Figure 2: Two types of scoring subtrees in our second-order graph-based parsers.

Dependency features $\mathbf{f}_{dep}(\mathbf{x}, h, m)$:
w_h, w_m, t_h, t_m, $t_{h\pm1}$, $t_{m\pm1}$, t_b, $dir(h,m)$, $dist(h,m)$
Sibling features $\mathbf{f}_{sib}(\mathbf{x}, h, m, s)$:
w_h, w_s, w_m, t_h, t_m, t_s, $t_{h\pm1}$, $t_{m\pm1}$, $t_{s\pm1}$
$dir(h,m)$, $dist(h,m)$

Table 1: Brief illustration of the syntactic features. t_i denotes the POS tag of w_i. b is an index between h and m. $dir(i,j)$ and $dist(i,j)$ denote the direction and distance of the dependency (i,j).

We adopt the second-order graph-based dependency parsing model of McDonald and Pereira (2006) as our core parser, which incorporates features from the two kinds of subtrees in Fig. 2.[1] Then the score of a dependency tree is:

$$\begin{aligned} Score(\mathbf{x}, \mathbf{d}; \mathbf{w}) = &\sum_{\{(h,m)\} \subseteq \mathbf{d}} \mathbf{w}_{dep} \cdot \mathbf{f}_{dep}(\mathbf{x}, h, m) \\ &+ \sum_{\{(h,s),(h,m)\} \subseteq \mathbf{d}} \mathbf{w}_{sib} \cdot \mathbf{f}_{sib}(\mathbf{x}, h, s, m) \end{aligned}$$

where $\mathbf{f}_{dep}(\mathbf{x}, h, m)$ and $\mathbf{f}_{sib}(\mathbf{x}, h, s, m)$ are the feature vectors of the two subtree in Fig. 2; $\mathbf{w}_{dep/sib}$ are feature weight vectors; the dot product gives scores contributed by corresponding subtrees.

For syntactic features, we adopt those of Bohnet (2010) which include two categories corresponding to the two types of scoring subtrees in Fig. 2. We summarize the atomic features used in each feature category in Table 1. These atomic features are concatenated in different combinations to compose rich feature sets. Please refer to Table 4 of Bohnet (2010) for the complete feature list.

2.2 CRF-based GParser

Previous work on graph-based dependency parsing mostly adopts linear models and perceptron based training procedures, which lack probabilistic explanations of dependency trees and do not need to compute likelihood of labeled training

[1] Higher-order models of Carreras (2007) and Koo and Collins (2010) can achieve higher accuracy, but has much higher time cost ($O(n^4)$). Our approach is applicable to these higher-order models, which we leave for future work.

data. Instead, we build a log-linear CRF-based dependency parser, which is similar to the CRF-based constituent parser of Finkel et al. (2008). Assuming the feature weights $\mathbf{w}$ are known, the probability of a dependency tree $\mathbf{d}$ given an input sentence $\mathbf{x}$ is defined as:

$$p(\mathbf{d}|\mathbf{x};\mathbf{w}) = \frac{exp\{Score(\mathbf{x},\mathbf{d};\mathbf{w})\}}{Z(\mathbf{x};\mathbf{w})}$$
$$Z(\mathbf{x};\mathbf{w}) = \sum_{\mathbf{d}' \in \mathcal{Y}(\mathbf{x})} exp\{Score(\mathbf{x},\mathbf{d}';\mathbf{w})\} \quad (1)$$

where $Z(\mathbf{x})$ is the normalization factor and $\mathcal{Y}(\mathbf{x})$ is the set of all legal dependency trees for $\mathbf{x}$.

Suppose the labeled training data is $\mathcal{D} = \{(\mathbf{x}_i, \mathbf{d}_i)\}_{i=1}^{N}$. Then the log likelihood of $\mathcal{D}$ is:

$$\mathcal{L}(\mathcal{D};\mathbf{w}) = \sum_{i=1}^{N} \log p(\mathbf{d}_i|\mathbf{x}_i;\mathbf{w})$$

The training objective is to maximize the log likelihood of the training data $\mathcal{L}(\mathcal{D})$. The partial derivative with respect to the feature weights $\mathbf{w}$ is:

$$\frac{\partial \mathcal{L}(\mathcal{D};\mathbf{w})}{\partial \mathbf{w}} = \sum_{i=1}^{N} \left(\mathbf{f}(\mathbf{x}_i,\mathbf{d}_i) - \sum_{\mathbf{d}' \in \mathcal{Y}(\mathbf{x}_i)} p(\mathbf{d}'|\mathbf{x}_i;\mathbf{w}) \mathbf{f}(\mathbf{x}_i,\mathbf{d}') \right) \quad (2)$$

where the first term is the empirical counts and the second term is the model expectations. Since $\mathcal{Y}(\mathbf{x}_i)$ contains exponentially many dependency trees, direct calculation of the second term is prohibitive. Instead, we can use the classic inside-outside algorithm to efficiently compute the model expectations within $O(n^3)$ time complexity, where n is the input sentence length.

3 Ambiguity-aware Ensemble Training

In standard entire-tree based semi-supervised methods such as self/co/tri-training, automatically parsed unlabeled sentences are used as additional training data, and noisy 1-best parse trees are considered as gold-standard. To alleviate the noise, the tri-training method only uses unlabeled data on which multiple parsers from different views produce identical parse trees. However, unlabeled data with divergent syntactic structures should be more useful. Intuitively, if several parsers disagree on an unlabeled sentence, it implies that the unlabeled sentence contains some difficult syntactic phenomena which are not sufficiently covered in manually labeled data. Therefore, exploiting such unlabeled data may introduce more discriminative syntactic knowledge, largely compensating labeled training data.

To address above issues, we propose *ambiguity-aware ensemble training*, which can be interpreted as a *generalized tri-training* framework. The key idea is the use of *ambiguous labelings* for the purpose of aggregating multiple 1-best parse trees produced by several diverse parsers. Here, "ambiguous labelings" mean an unlabeled sentence may have multiple parse trees as gold-standard reference, represented by parse forest (see Figure 1). The training procedure aims to maximize mixed likelihood of both manually labeled and auto-parsed unlabeled data with ambiguous labelings. For an unlabeled instance, the model is updated to maximize the probability of its parse forest, instead of a single parse tree in traditional tri-training. In other words, the model is free to distribute probability mass among the trees in the parse forest to its liking, as long as the likelihood improves (Täckström et al., 2013).

3.1 Likelihood of the Unlabeled Data

The auto-parsed unlabeled data with ambiguous labelings is denoted as $\mathcal{D}' = \{(\mathbf{u}_i, \mathcal{V}_i)\}_{i=1}^{M}$, where $\mathbf{u}_i$ is an unlabeled sentence, and $\mathcal{V}_i$ is the corresponding parse forest. Then the log likelihood of $\mathcal{D}'$ is:

$$\mathcal{L}(\mathcal{D}';\mathbf{w}) = \sum_{i=1}^{M} \log \left(\sum_{\mathbf{d}' \in \mathcal{V}_i} p(\mathbf{d}'|\mathbf{u}_i;\mathbf{w}) \right)$$

where $p(\mathbf{d}'|\mathbf{u}_i;\mathbf{w})$ is the conditional probability of $\mathbf{d}'$ given $\mathbf{u}_i$, as defined in Eq. (1). For an unlabeled sentence $\mathbf{u}_i$, the probability of its parse forest $\mathcal{V}_i$ is the summation of the probabilities of all the parse trees contained in the forest.

Then we can derive the partial derivative of the log likelihood with respect to $\mathbf{w}$:

$$\frac{\partial \mathcal{L}(\mathcal{D}';\mathbf{w})}{\partial \mathbf{w}} = \sum_{i=1}^{M} \left(\sum_{\mathbf{d}' \in \mathcal{V}_i} \tilde{p}(\mathbf{d}'|\mathbf{u}_i,\mathcal{V}_i;\mathbf{w}) \mathbf{f}(\mathbf{u}_i,\mathbf{d}') - \sum_{\mathbf{d}' \in \mathcal{Y}(\mathbf{u}_i)} p(\mathbf{d}'|\mathbf{u}_i;\mathbf{w}) \mathbf{f}(\mathbf{u}_i,\mathbf{d}') \right) \quad (3)$$

where $\tilde{p}(\mathbf{d}'|\mathbf{u}_i,\mathcal{V}_i;\mathbf{w})$ is the probability of $\mathbf{d}'$ un-

der the space constrained by the parse forest $\mathcal{V}_i$.

$$\tilde{p}(\mathbf{d}'|\mathbf{u}_i, \mathcal{V}_i; \mathbf{w}) = \frac{\exp\{Score(\mathbf{u}_i, \mathbf{d}'; \mathbf{w})\}}{Z(\mathbf{u}_i, \mathcal{V}_i; \mathbf{w})}$$

$$Z(\mathbf{u}_i, \mathcal{V}_i; \mathbf{w}) = \sum_{\mathbf{d}' \in \mathcal{V}_i} \exp\{Score(\mathbf{u}_i, \mathbf{d}'; \mathbf{w})\}$$

The second term in Eq. (3) is the same with the second term in Eq. (2). The first term in Eq. (3) can be efficiently computed by running the inside-outside algorithm in the constrained search space $\mathcal{V}_i$.

3.2 Stochastic Gradient Descent (SGD) Training

We apply L2-norm regularized SGD training to iteratively learn feature weights $\mathbf{w}$ for our CRF-based baseline and semi-supervised parsers. We follow the implementation in CRFsuite.[2] At each step, the algorithm approximates a gradient with a small subset of the training examples, and then updates the feature weights. Finkel et al. (2008) show that SGD achieves optimal test performance with far fewer iterations than other optimization routines such as L-BFGS. Moreover, it is very convenient to parallel SGD since computations among examples in the same batch is mutually independent.

Training with the combined labeled and unlabeled data, the objective is to maximize the mixed likelihood:

$$\mathcal{L}(\mathcal{D}; \mathcal{D}') = \mathcal{L}(\mathcal{D}) + \mathcal{L}(\mathcal{D}')$$

Since $\mathcal{D}'$ contains much more instances than $\mathcal{D}$ (1.7M vs. 40K for English, and 4M vs. 16K for Chinese), it is likely that the unlabeled data may overwhelm the labeled data during SGD training. Therefore, we propose a simple corpus-weighting strategy, as shown in Algorithm 1, where $\mathcal{D}^b_{i,k}$ is the subset of training data used in k^{th} update and b is the batch size; η_k is the update step, which is adjusted following the simulated annealing procedure (Finkel et al., 2008). The idea is to use a fraction of training data ($\mathcal{D}_i$) at each iteration, and do corpus weighting by randomly sampling labeled and unlabeled instances in a certain proportion (N_1 vs. M_1).

Once the feature weights $\mathbf{w}$ are learnt, we can parse the test data to find the optimal parse tree.

$$\mathbf{d}^* = \arg\max_{\mathbf{d}' \in \mathcal{Y}(\mathbf{x})} p(\mathbf{d}'|\mathbf{x}; \mathbf{w}) = \arg\max_{\mathbf{d}' \in \mathcal{Y}(\mathbf{x})} Score(\mathbf{x}, \mathbf{d}'; \mathbf{w})$$

This can be done with the Viterbi decoding algorithm described in McDonald and Pereira (2006) in $O(n^3)$ parsing time.

Algorithm 1 SGD training with mixed labeled and unlabeled data.

Input: Labeled data $\mathcal{D} = \{(\mathbf{x}_i, \mathbf{d}_i)\}_{i=1}^N$, and unlabeled data $\mathcal{D}' = \{(\mathbf{u}_i, \mathcal{V}_i)\}_{j=1}^M$; Parameters: I, N_1, M_1, b
Output: $\mathbf{w}$
Initialization: $\mathbf{w}^{(0)} = \mathbf{0}$, $k = 0$;
for $i = 1$ **to** I **do** {*iterations*}
  Randomly select N_1 instances from $\mathcal{D}$ and M_1 instances from $\mathcal{D}'$ to compose a new dataset $\mathcal{D}_i$, and shuffle it.
  Traverse $\mathcal{D}_i$: a small batch $\mathcal{D}^b_{i,k} \subseteq \mathcal{D}_i$ at one step.
    $\mathbf{w}_{k+1} = \mathbf{w}_k + \eta_k \frac{1}{b} \nabla \mathcal{L}(\mathcal{D}^b_{i,k}; \mathbf{w}_k)$
    $k = k + 1$
end for

3.3 Forest Construction with Diverse Parsers

To construct parse forests for unlabeled data, we employ three diverse parsers, i.e., our baseline GParser, a transition-based parser (ZPar[3]) (Zhang and Nivre, 2011), and a generative constituent parser (Berkeley Parser[4]) (Petrov and Klein, 2007). These three parsers are trained on labeled data and then used to parse each unlabeled sentence. We aggregate the three parsers' outputs on unlabeled data in different ways and evaluate the effectiveness through experiments.

4 Experiments and Analysis

To verify the effectiveness of our proposed approach, we conduct experiments on Penn Treebank (PTB) and Penn Chinese Treebank 5.1 (CTB5). For English, we follow the popular practice to split data into training (sections 2-21), development (section 22), and test (section 23). For CTB5, we adopt the data split of (Duan et al., 2007). We convert original bracketed structures into dependency structures using Penn2Malt with its default head-finding rules.

For unlabeled data, we follow Chen et al. (2013) and use the BLLIP WSJ corpus (Charniak et al., 2000) for English and Xinhua portion of Chinese

Gigaword Version 2.0 (LDC2009T14) (Huang, 2009) for Chinese. We build a CRF-based bigram part-of-speech (POS) tagger with the features described in (Li et al., 2012), and produce POS tags for all train/development/test/unlabeled sets (10-way jackknifing for training sets). The tagging accuracy on test sets is 97.3% on English and 94.0% on Chinese. Table 2 shows the data statistics.

We measure parsing performance using the standard unlabeled attachment score (UAS), excluding punctuation marks. For significance test, we adopt Dan Bikel's randomized parsing evaluation comparator (Noreen, 1989).[5]

4.1 Parameter Setting

When training our CRF-based parsers with SGD, we use the batch size $b = 100$ for all experiments. We run SGD for $I = 100$ iterations and choose the model that performs best on development data. For the semi-supervised parsers trained with Algorithm 1, we use $N_1 = 20$K and $M_1 = 50$K for English, and $N_1 = 15$K and $M_1 = 50$K for Chinese, based on a few preliminary experiments. To accelerate the training, we adopt parallelized implementation of SGD and employ 20 threads for each run. For semi-supervised cases, one iteration takes about 2 hours on an IBM server having 2.0 GHz Intel Xeon CPUs and 72G memory.

Default parameter settings are used for training ZPar and Berkeley Parser. We run ZPar for 50 iterations, and choose the model that achieves highest accuracy on the development data. For Berkeley Parser, we use the model after 5 split-merge iterations to avoid over-fitting the training data according to the manual. The phrase-structure outputs of Berkeley Parser are converted into dependency structures using the same head-finding rules.

4.2 Methodology Study on Development Data

Using three supervised parsers, we have many options to construct parse forest on unlabeled data. To examine the effect of different ways for forest construction, we conduct extensive methodology study on development data. Table 3 presents the results. We divide the systems into three types: 1) supervised single parsers; 2) CRF-based GParser with conventional self/co/tri-training; 3) CRF-based GParser with our approach. For the latter two cases, we also present the oracle accuracy and averaged head number per word ("Head/Word") of parse forest when applying different ways to construct forests on development datasets.

The first major row presents performance of the three supervised parsers. We can see that the three parsers achieve comparable performance on English, but the performance of ZPar is largely inferior on Chinese.

The second major row shows the results when we use single 1-best parse trees on unlabeled data. When using the outputs of GParser itself ("Unlabeled ← G"), the experiment reproduces traditional self-training. The results on both English and Chinese re-confirm that *self-training may not work for dependency parsing*, which is consistent with previous studies (Spreyer and Kuhn, 2009). The reason may be that dependency parsers are prone to amplify previous mistakes on unlabeled data during training.

The next two experiments in the second major row reimplement *co-training*, where another parser's 1-best results are projected into unlabeled data to help the core parser. Using unlabeled data with the results of ZPar ("Unlabeled ← Z") significantly outperforms the baseline GParser by 0.30% (93.15-82.85) on English. However, the improvement on Chinese is not significant. Using unlabeled data with the results of Berkeley Parser ("Unlabeled ← B") significantly improves parsing accuracy by 0.55% (93.40-92.85) on English and 1.06% (83.34-82.28) on Chinese. We believe the reason is that being a generative model designed for constituent parsing, Berkeley Parser is more different from discriminative dependency parsers, and therefore can provide more divergent syntactic structures. This kind of syntactic divergence is helpful because it can provide complementary knowledge from a different perspective. Surdeanu and Manning (2010) also show that the diversity of parsers is important for performance improvement when integrating different parsers in the supervised track. Therefore, we can conclude that *co-training helps dependency parsing, especially when using a more divergent parser*.

The last experiment in the second major row is known as *tri-training*, which only uses unla-

		English			Chinese		
		UAS	Oracle	Head/Word	UAS	Oracle	Head/Word
Supervised	GParser	**92.85**	—	—	82.28	—	—
	ZPar	92.50			81.04		
	Berkeley	92.70			**82.46**		
Semi-supervised GParser with Single 1-best Trees	Unlabeled ← G (self-train)	92.88	92.85	1.000	82.14	82.28	1.000
	Unlabeled ← Z (co-train)	93.15 †	92.50		82.54	81.04	
	Unlabeled ← B (co-train)	93.40 †	92.70		**83.34** †	82.46	
	Unlabeled ← B=Z (tri-train)	**93.50** †	97.52		83.10 †	95.05	
Semi-supervised GParser Ambiguity-aware Ensemble	Unlabeled ← Z+G	93.18 †	94.97	1.053	82.78	86.66	1.136
	Unlabeled ← B+G	93.35 †	96.37	1.080	83.24 †	89.72	1.188
	Unlabeled ← B+Z	**93.78** †‡	96.18	1.082	83.86 †‡	89.54	1.199
	Unlabeled ← B+(Z∩G)	93.77 †‡	95.60	1.050	**84.26** †‡	87.76	1.106
	Unlabeled ← B+Z+G	93.50 †	96.95	1.112	83.30 †	91.50	1.281

Table 3: Main results on development data. G is short for GParser, Z for ZPar, and B for Berkeley Parser. † means the corresponding parser significantly outperforms supervised parsers, and ‡ means the result significantly outperforms co/tri-training at confidence level of $p < 0.01$.

beled sentences on which Berkeley Parser and ZPar produce identical outputs ("Unlabeled ← B=Z"). We can see that with the verification of two views, the oracle accuracy is much higher than using single parsers (97.52% vs. 92.85% on English, and 95.06% vs. 82.46% on Chinese). Although using less unlabeled sentences (0.7M for English and 1.2M for Chinese), *tri-training achieves comparable performance to co-training* (slightly better on English and slightly worse on Chinese).

The third major row shows the results of the semi-supervised GParser with our proposed approach. We experiment with different combinations of the 1-best parse trees of the three supervised parsers. The first three experiments combine 1-best outputs of two parsers to compose parse forest on unlabeled data. "Unlabeled ← B+(Z∩G)" means that the parse forest is initialized with the Berkeley parse and augmented with the intersection of dependencies of the 1-best outputs of ZPar and GParser. In the last setting, the parse forest contains all three 1-best results.

When the parse forests of the unlabeled data are the union of the outputs of GParser and ZPar, denoted as "Unlabeled ← Z+G", each word has 1.053 candidate heads on English and 1.136 on Chinese, and the oracle accuracy is higher than using 1-best outputs of single parsers (94.97% vs. 92.85% on English, 86.66% vs. 82.46% on Chinese). However, we find that although the parser significantly outperforms the supervised GParser on English, it does not gain significant improvement over co-training with ZPar ("Unlabeled ← Z") on both English and Chinese.

Combining the outputs of Berkeley Parser and GParser ("Unlabeled ← B+G"), we get higher oracle score (96.37% on English and 89.72% on Chinese) and higher syntactic divergence (1.085 candidate heads per word on English, and 1.188 on Chinese) than "Unlabeled ← Z+G", which verifies our earlier discussion that Berkeley Parser produces more different structures than ZPar. However, it leads to slightly worse accuracy than co-training with Berkeley Parser ("Unlabeled ← B"). This indicates that adding the outputs of GParser itself does not help the model.

Combining the outputs of Berkeley Parser and ZPar ("Unlabeled ← B+Z"), we get the best performance on English, which is also significantly better than both co-training ("Unlabeled ← B") and tri-training ("Unlabeled ← B=Z") on both English and Chinese. This demonstrates that *our proposed approach can better exploit unlabeled data than traditional self/co/tri-training*. More analysis and discussions are in Section 4.4.

During experimental trials, we find that "Unlabeled ← B+(Z∩G)" can further boost performance on Chinese. A possible explanation is that by using the intersection of the outputs of GParser and ZPar, the size of the parse forest is better controlled, which is helpful considering that ZPar performs worse on this data than both Berkeley Parser and GParser.
