Adding the output of GParser itself ("Unlabeled ← B+Z+G") leads to accuracy drop, although the oracle score is higher (96.95% on English and 91.50% on Chinese) than "Unlabeled ← B+Z". We suspect the reason is that the model is likely to distribute the probability mass to these parse trees produced by itself instead of those by Berkeley Parser or ZPar under this setting.

Table 4: UAS comparison on English test data.

In summary, we can conclude that *our proposed ambiguity-aware ensemble training is significantly better than both the supervised approaches and the semi-supervised approaches that use 1-best parse trees*. Appropriately composing the forest parse, our approach outperforms the best results of co-training or tri-training by 0.28% (93.78-93.50) on English and 0.92% (84.26-83.34) on Chinese.

4.3 Comparison with Previous Work

We adopt the best settings on development data for semi-supervised GParser with our proposed approach, and make comparison with previous results on test data. Table 4 shows the results.

The first major row lists several state-of-the-art supervised methods. McDonald and Pereira (2006) propose a second-order graph-based parser, but use a smaller feature set than our work. Koo and Collins (2010) propose a third-order graph-based parser. Zhang and McDonald (2012) explore higher-order features for graph-based dependency parsing, and adopt beam search for fast decoding. Zhang and Nivre (2011) propose a feature-rich transition-based parser. All work in the second major row adopts semi-supervised methods. The results show that our approach achieves comparable accuracy with most previous semi-supervised methods. Both Suzuki et al. (2009) and Chen et al. (2013) adopt the higher-order parsing model of Carreras (2007), and Suzuki et al. (2009) also incorporate word cluster features proposed by Koo et al. (2008) in their system. We expect our approach may achieve higher performance with such enhancements, which we leave for future work. Moreover, our method may be combined with other semi-supervised approaches, since they are orthogonal in methodology and utilize unlabeled data from different perspectives.

Table 5 make comparisons with previous results on Chinese test data. Li et al. (2012) and Bohnet and Nivre (2012) use joint models for POS tagging and dependency parsing, significantly outperforming their pipeline counterparts. Our approach can be combined with their work to utilize unlabeled data to improve both POS tagging and parsing simultaneously. Our work achieves comparable accuracy with Chen et al. (2013), although they adopt the higher-order model of Carreras (2007). Again, our method may be combined with their work to achieve higher performance.

4.4 Analysis

To better understand the effectiveness of our proposed approach, we make detailed analysis using the semi-supervised GParser with "Unlabeled ← B+Z" on English datasets.

Contribution of unlabeled data with regard to syntactic divergence: We divide the unlabeled data into three sets according to the divergence of the 1-best outputs of Berkeley Parser and ZPar. The first set contains those sentences that the two parsers produce identical parse trees, denoted by "consistent", which corresponds to the setting for tri-training. Other sentences are split into two sets according to averaged number of heads per word in parse forests, denoted by "low divergence" and "high divergence" respectively. Then we train semi-supervised GParser using the three sets of unlabeled data. Table 6 illustrates the results and statistics. We can see that unlabeled data with identical outputs from Berkeley Parser and ZPar tends to be short sentences (18.25 words per sen-

tence on average). Results show all the three sets of unlabeled data can help the parser. Especially, the unlabeled data with highly divergent structures leads to slightly higher improvement. This demonstrates that *our approach can better exploit unlabeled data on which parsers of different views produce divergent structures*.

Impact of unlabeled data size: To understand how our approach performs with regards to the unlabeled data size, we train semi-supervised GParser with different sizes of unlabeled data. Fig. 3 shows the accuracy curve on the test set. We can see that the parser consistently achieves higher accuracy with more unlabeled data, demonstrating the effectiveness of our approach. We expect that our approach has potential to achieve higher accuracy with more additional data.

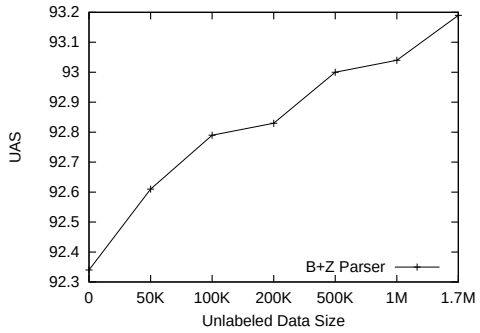

Figure 3: Performance of GParser with different sizes of "Unlabeled ← B+Z" on English test set.

5 Related Work

Our work is originally inspired by the work of Täckström et al. (2013). They first apply the idea of ambiguous labelings to multilingual parser transfer in the unsupervised parsing field, which aims to build a dependency parser for a resource-poor target language by making use of source-language treebanks. Different from their work, we explore the idea for semi-supervised dependency parsing where a certain amount of labeled training data is available. Moreover, we for the first time build a state-of-the-art CRF-based dependency parser and conduct in-depth comparisons with previous methods. Similar ideas of learning with ambiguous labelings are previously explored for classification (Jin and Ghahramani, 2002) and sequence labeling problems (Dredze et al., 2009).

Our work is also related with the parser ensemble approaches such as stacked learning and re-parsing in the supervised track. Stacked learning uses one parser's outputs as guide features for another parser, leading to improved performance (Nivre and McDonald, 2008; Torres Martins et al., 2008). Re-parsing merges the outputs of several parsers into a dependency graph, and then apply Viterbi decoding to find a better tree (Sagae and Lavie, 2006; Surdeanu and Manning, 2010). One possible drawback of parser ensemble is that several parsers are required to parse the same sentence during the test phase. Moreover, our approach can benefit from these methods in that we can get parse forests of higher quality on unlabeled data (Zhou, 2009).

6 Conclusions

This paper proposes a generalized training framework of semi-supervised dependency parsing based on ambiguous labelings. For each unlabeled sentence, we combine the 1-best parse trees of several diverse parsers to compose ambiguous labelings, represented by a parse forest. The training objective is to maximize the mixed likelihood of both the labeled data and the auto-parsed unlabeled data with ambiguous labelings. Experiments show that our framework can make better use of the unlabeled data, especially those with divergent outputs from different parsers, than traditional tri-training. Detailed analysis demonstrates the effectiveness of our approach. Specifically, we find that our approach is very effective when using divergent parsers such as the generative parser, and it is also helpful to properly balance the size and oracle accuracy of the parse forest of the unlabeled data.

For future work, among other possible extensions, we would like to see how our approach performs when employing more diverse parsers to compose the parse forest of higher quality for the unlabeled data, such as the easy-first non-directional dependency parser (Goldberg and Elhadad, 2010) and other constituent parsers (Collins and Koo, 2005; Charniak and Johnson, 2005; Finkel et al., 2008).

A Robust Approach to Aligning Heterogeneous Lexical Resources

Mohammad Taher Pilehvar and **Roberto Navigli**
Department of Computer Science
Sapienza University of Rome
{pilehvar,navigli}@di.uniroma1.it

Abstract

Lexical resource alignment has been an active field of research over the last decade. However, prior methods for aligning lexical resources have been either specific to a particular pair of resources, or heavily dependent on the availability of hand-crafted alignment data for the pair of resources to be aligned. Here we present a unified approach that can be applied to an arbitrary pair of lexical resources, including machine-readable dictionaries with no network structure. Our approach leverages a similarity measure that enables the structural comparison of senses across lexical resources, achieving state-of-the-art performance on the task of aligning WordNet to three different collaborative resources: Wikipedia, Wiktionary and OmegaWiki.

1 Introduction

Lexical resources are repositories of machine-readable knowledge that can be used in virtually any Natural Language Processing task. Notable examples are WordNet, Wikipedia and, more recently, collaboratively-curated resources such as OmegaWiki and Wiktionary (Hovy et al., 2013). On the one hand, these resources are heterogeneous in design, structure and content, but, on the other hand, they often provide complementary knowledge which we would like to see integrated. Given the large scale this intrinsic issue can only be addressed automatically, by means of lexical resource alignment algorithms. Owing to its ability to bring together features like multilinguality and increasing coverage, over the past few years resource alignment has proven beneficial to a wide spectrum of tasks, such as Semantic Parsing (Shi and Mihalcea, 2005), Semantic Role Labeling (Palmer et al., 2010), and Word Sense Disambiguation (Navigli and Ponzetto, 2012).

Nevertheless, when it comes to aligning textual definitions in different resources, the lexical approach (Ruiz-Casado et al., 2005; de Melo and Weikum, 2010; Henrich et al., 2011) falls short because of the potential use of totally different wordings to define the same concept. Deeper approaches leverage semantic similarity to go beyond the surface realization of definitions (Navigli, 2006; Meyer and Gurevych, 2011; Niemann and Gurevych, 2011). While providing good results in general, these approaches fail when the definitions of a given word are not of adequate quality and expressiveness to be distinguishable from one another. When a lexical resource can be viewed as a semantic graph, as with WordNet or Wikipedia, this limit can be overcome by means of alignment algorithms that exploit the network structure to determine the similarity of concept pairs. However, not all lexical resources provide explicit semantic relations between concepts and, hence, machine-readable dictionaries like Wiktionary have first to be transformed into semantic graphs before such graph-based approaches can be applied to them. To do this, recent work has proposed graph construction by monosemous linking, where a concept is linked to all the concepts associated with the monosemous words in its definition (Matuschek and Gurevych, 2013). However, this alignment method still involves tuning of parameters which are highly dependent on the characteristics of the generated graphs and, hence, requires hand-crafted sense alignments for the specific pair of resources to be aligned, a task which has to be replicated every time the resources are updated.

In this paper we propose a unified approach to aligning arbitrary pairs of lexical resources which is independent of their specific structure. Thanks to a novel modeling of the sense entries and an effective ontologization algorithm, our approach also fares well when resources lack relational structure or pair-specific training data is absent, meaning that it is applicable to arbitrary pairs

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 468–478,
Baltimore, Maryland, USA, June 23-25 2014.

without adaptation. We report state-of-the-art performance when aligning WordNet to Wikipedia, OmegaWiki and Wiktionary.

2 Resource Alignment

Preliminaries. Our approach for aligning lexical resources exploits the graph structure of each resource. Therefore, we assume that a lexical resource L can be represented as an undirected graph $G = (V, E)$ where V is the set of nodes, i.e., the concepts defined in the resource, and E is the set of undirected edges, i.e., semantic relations between concepts. Each concept $c \in V$ is associated with a set of lexicalizations $\mathcal{L}_G(c) = \{w_1, w_2, ..., w_n\}$. For instance, WordNet can be readily represented as an undirected graph G whose nodes are synsets and edges are modeled after the relations between synsets defined in WordNet (e.g., hypernymy, meronymy, etc.), and $\mathcal{L}_G$ is the mapping between each synset node and the set of synonyms which express the concept. However, other resources such as Wiktionary do not provide semantic relations between concepts and, therefore, have first to be transformed into semantic networks before they can be aligned using our alignment algorithm. We explain in Section 3 how a semi-structured resource which does not exhibit a graph structure can be transformed into a semantic network.

Alignment algorithm. Given a pair of lexical resources L_1 and L_2, we align each concept in L_1 by mapping it to its corresponding concept(s) in the target lexicon L_2. Algorithm 1 formalizes the alignment process: the algorithm takes as input the semantic graphs G_1 and G_2 corresponding to the two resources, as explained above, and produces as output an alignment in the form of a set A of concept pairs. The algorithm iterates over all concepts $c_1 \in V_1$ and, for each of them, obtains the set of concepts $C \subset V_2$, which can be considered as alignment candidates for c_1 (line 3). For a concept c_1, alignment candidates in G_2 usually consist of every concept $c_2 \in V_2$ that shares at least one lexicalization with c_1 in the same part of speech tag, i.e., $\mathcal{L}_{G_1}(c_1) \cap \mathcal{L}_{G_2}(c_2) \neq \emptyset$ (Reiter et al., 2008; Meyer and Gurevych, 2011). Once the set of target candidates C for a source concept c_1 is obtained, the alignment task can be cast as that of identifying those concepts in C to which c_1 should be aligned. To do this, the algorithm calculates the similarity between c_1 and each $c_2 \in C$ (line 5). If their similarity score exceeds a certain value denoted by θ

Algorithm 1 Lexical Resource Aligner

Input: graphs $H = (V_H, E_H)$, $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$, the similarity threshold θ, and the combination parameter β
Output: A, the set of all aligned concept pairs

```
1: A ← ∅
2: for each concept c1 ∈ V1
3:     C ← getCandidates(c1, V2)
4:     for each concept c2 ∈ C
5:         sim ← calculateSimilarity(H, G1, G2, c1, c2, β)
6:         if sim > θ then
7:             A ← A ∪ {(c1, c2)}
8: return A
```

(line 6), the two concepts c_1 and c_2 are aligned and the pair (c_1, c_2) is added to A (line 7).

Different resource alignment techniques usually vary in the way they compute the similarity of a pair of concepts across two resources (line 5 in Algorithm 1). In the following, we present our novel approach for measuring the similarity of concept pairs.

2.1 Measuring the Similarity of Concepts

Figure 1 illustrates the procedure underlying our cross-resource concept similarity measurement technique. As can be seen, the approach consists of two main components: *definitional similarity* and *structural similarity*. Each of these components gets, as its input, a pair of concepts belonging to two different semantic networks and produces a similarity score. These two scores are then combined into an overall score (part (e) of Figure 1) which quantifies the semantic similarity of the two input concepts c_1 and c_2.

The definitional similarity component computes the similarity of two concepts in terms of the similarity of their definitions, a method that has also been used in previous work for aligning lexical resources (Niemann and Gurevych, 2011; Henrich et al., 2012). In spite of its simplicity, the mere calculation of the similarity of concept definitions provides a strong baseline, especially for cases where the definitional texts for a pair of concepts to be aligned are lexically similar, yet distinguishable from the other definitions. However, as mentioned in the introduction, definition similarity-based techniques fail at identifying the correct alignments in cases where different wordings are used or definitions are not of high quality. The structural similarity component, instead, is a novel graph-based similarity measurement technique which calculates the similarity between a pair of concepts across the semantic networks of the two resources by leveraging the semantic

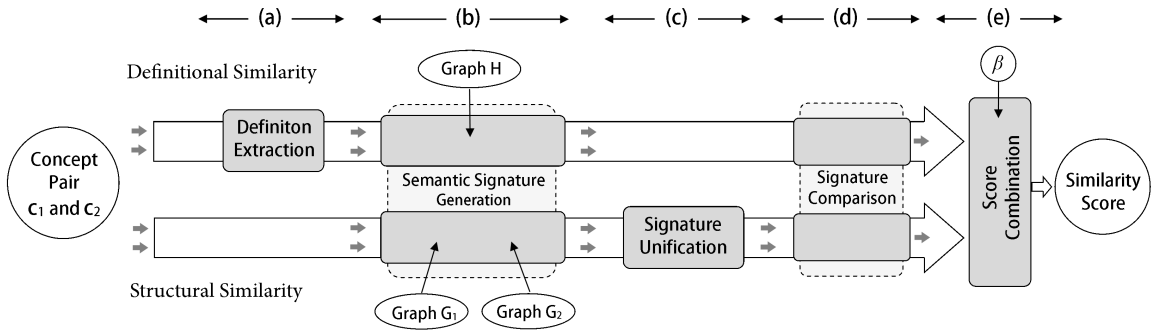

Figure 1: The process of measuring the similarity of a pair of concepts across two resources. The method consists of two components: definitional and structural similarities, each measuring a similarity score for the given concept pair. The two scores are combined by means of parameter β in the last stage.

structure of those networks. This component goes beyond the surface realization of concepts, thus providing a deeper measure of concept similarity.

The two components share the same backbone (parts (b) and (d) of Figure 1), but differ in some stages (parts (a) and (c) in Figure 1). In the following, we explain all the stages involved in the two components (gray blocks in the figure).

2.1.1 Semantic signature generation

The aim of this stage is to model a given concept or set of concepts through a vectorial semantic representation, which we refer to as the **semantic signature** of the input. We utilized Personalized PageRank (Haveliwala, 2002, PPR), a random walk graph algorithm, for calculating semantic signatures. The original PageRank (PR) algorithm (Brin and Page, 1998) computes, for a given graph, a single vector wherein each node is associated with a weight denoting its structural importance in that graph. PPR is a variation of PR where the computation is biased towards a set of initial nodes in order to capture the notion of importance with respect to those particular nodes. PPR has been previously used in a wide variety of tasks such as definition similarity-based resource alignment (Niemann and Gurevych, 2011), textual semantic similarity (Hughes and Ramage, 2007; Pilehvar et al., 2013), Word Sense Disambiguation (Agirre and Soroa, 2009; Faralli and Navigli, 2012) and semantic text categorization (Navigli et al., 2011). When applied to a semantic graph by initializing the random walks from a set of concepts (nodes), PPR yields a vector in which each concept is associated with a weight denoting its semantic relevance to the initial concepts.

Formally, we first represent a semantic network consisting of N concepts as a row-stochastic transition matrix $\mathbf{M} \in \mathbb{R}^{N \times N}$. The cell (i, j) in the matrix denotes the probability of moving from a concept i to j in the graph: 0 if no edge exists from i to j and $1/degree(i)$ otherwise. Then the PPR vector, hence the semantic signature $\mathcal{S}_{\mathbf{v}}$ of vector $\mathbf{v}$ is the unique solution to the linear system: $\mathcal{S}_{\mathbf{v}} = (1 - \alpha)\,\mathbf{v} + \alpha\,\mathbf{M}\,\mathcal{S}_{\mathbf{v}}$, where $\mathbf{v}$ is the personalization vector of size N in which all the probability mass is put on the concepts for which a semantic signature is to be computed and α is the damping factor, which is usually set to 0.85 (Brin and Page, 1998). We used the UKB[1] off-the-shelf implementation of PPR.

Definitional similarity signature. In the definitional similarity component, the two concepts c_1 and c_2 are first represented by their corresponding definitions d_1 and d_2 in the respective resources L_1 and L_2 (Figure 1(a), top). To improve expressiveness, we follow Niemann and Gurevych (2011) and further extend d_i with all the word forms associated with concept c_i and its neighbours, i.e., the union of all lexicalizations $\mathcal{L}_{G_i}(x)$ for all concepts $x \in \{c' \in V_i : (c, c') \in E_i\} \cup \{c\}$, where E_i is the set of edges in G_i. In this component the personalization vector $\mathbf{v}_i$ is set by uniformly distributing the probability mass over the nodes corresponding to the senses of all the content words in the extended definition of d_i according to the sense inventory of a semantic network H. We use the same semantic graph H for computing the semantic signatures of both definitions. Any semantic network with a dense relational structure, providing good coverage of the words appearing in the definitions, is a suitable candidate for H. For this purpose we used the WordNet (Fellbaum, 1998) graph which was further enriched by connecting

[1] http://ixa2.si.ehu.es/ukb/

each concept to all the concepts appearing in its disambiguated gloss.[2]

Structural similarity signature. In the structural similarity component (Figure 1(b), bottom), the semantic signature for each concept c_i is computed by running the PPR algorithm on its corresponding graph G_i, hence a different $\mathbf{M}_i$ is built for each of the two concepts.

2.1.2 Signature unification

As mentioned earlier, semantic signatures are vectors with dimension equal to the number of nodes in the semantic graph. Since the structural similarity signatures $\mathcal{S}_{\mathbf{v}_1}$ and $\mathcal{S}_{\mathbf{v}_2}$ are calculated on different graphs and thus have different dimensions, we need to make them comparable by unifying them. We therefore propose an approach (part (c) of Figure 1) that finds a common ground between the two signatures: to this end we consider all the concepts associated with monosemous words in the two signatures as landmarks and restrict the two signatures exclusively to those common concepts. Leveraging monosemous words as bridges between two signatures is a particularly reliable technique as typically a significant portion of all words in a lexicon are monosemous.[3]

Formally, let $\mathcal{I}_G(w)$ be an inventory mapping function that maps a term w to the set of concepts which are expressed by w in graph G. Then, given two signatures $\mathcal{S}_{\mathbf{v}_1}$ and $\mathcal{S}_{\mathbf{v}_2}$, computed on the respective graphs G_1 and G_2, we first obtain the set $\mathcal{M}$ of words that are monosemous according to both semantic networks, i.e., $\mathcal{M} = \{w : |\mathcal{I}_{G_1}(w)|=1 \wedge |\mathcal{I}_{G_2}(w)|=1\}$. We then transform each of the two signatures $\mathcal{S}_{\mathbf{v}_i}$ into a new sub-signature $\mathcal{S}'_{\mathbf{v}_i}$ whose dimension is $|\mathcal{M}|$: the k^{th} component of $\mathcal{S}'_{\mathbf{v}_i}$ corresponds to the weight in $\mathcal{S}_{\mathbf{v}_i}$ of the only concept of w_k in $\mathcal{I}_{G_i}(w_k)$. As an example, assume we are given two semantic signatures computed for two concepts in WordNet and Wiktionary. Also, consider the noun *tradeoff* which is monosemous according to both these resources. Then, each of the two unified sub-signatures will contain a component whose weight is determined by the weight of the only concept associated with *tradeoff*$_n$ in the corresponding semantic signature. As a result of the unification process, we obtain a pair of equally-sized semantic signatures with comparable components.

[2] http://wordnet.princeton.edu

[3] For instance, we calculated that more than 80% of the words in WordNet are monosemous, with over 60% of all the synsets containing at least one of them.

2.1.3 Signature comparison

Having at hand the semantic signatures for the two input concepts, we proceed to comparing them (part (d) in Figure 1). We leverage a non-parametric measure proposed by Pilehvar et al. (2013) which first transforms each signature into a list of sorted elements and then calculates the similarity on the basis of the average ranking of elements across the two lists:

$$Sim(\mathcal{S}_{\mathbf{v}_1}, \mathcal{S}_{\mathbf{v}_2}) = \frac{\sum_{i=1}^{|T|}(r_i^1 + r_i^2)^{-1}}{\sum_{i=1}^{|T|}(2i)^{-1}} \quad (1)$$

where T is the intersection of all concepts with non-zero probability in the two signatures and r_i^j is the rank of the i^{th} entry in the j^{th} sorted list. The denominator is a normalization factor to guarantee a maximum value of one. The method penalizes the differences in the higher rankings more than it does for the lower ones. The measure was shown to outperform the conventional cosine distance when comparing different semantic signatures in multiple textual similarity tasks (Pilehvar et al., 2013).

2.1.4 Score combination

Finally (part (e) of Figure 1), we calculate the overall similarity between two concepts as a linear combination of their definitional and structural similarities: $\beta\, Sim_{def}(\mathcal{S}_{\mathbf{v}_1}, \mathcal{S}_{\mathbf{v}_2}) + (1 - \beta)\, Sim_{str}(\mathcal{S}_{\mathbf{v}_1}, \mathcal{S}_{\mathbf{v}_2})$. In Section 4.2.1, we explain how we set, in our experiments, the values of β and the similarity threshold θ (cf. alignment algorithm in Section 2).

3 Lexical Resource Ontologization

In Section 2, we presented our approach for aligning lexical resources. However, the approach assumes that the input resources can be viewed as semantic networks, which seems to limit its applicability to structured resources only. In order to address this issue and hence generalize our alignment approach to any given lexical resource, we propose a method for transforming a given machine-readable dictionary into a semantic network, a process we refer to as *ontologization*.

Our ontologization algorithm takes as input a lexicon L and outputs a semantic graph $G = (V, E)$ where, as already defined in Section 2, V is the set of concepts in L and E is the set of semantic relations between these concepts. Introducing relational links into a lexicon can be achieved in different ways. A first option is to extract binary

relations between pairs of words from raw text. Both words in these relations, however, should be disambiguated according to the given lexicon (Pantel and Pennacchiotti, 2008), making the task particularly prone to mistakes due to the high number of possible sense pairings.

Here, we take an alternative approach which requires disambiguation on the target side only, hence reducing the size of the search space significantly. We first create the empty undirected graph $G_L = (V, E)$ such that V is the set of concepts in L and $E = \emptyset$. For each source concept $c \in V$ we create a bag of content words $W = \{w_1, \ldots, w_n\}$ which includes all the content words in its definition d and, if available, additional related words obtained from lexicon relations (e.g., synonyms in Wiktionary). The problem is then cast as a disambiguation task whose goal is to identify the intended sense of each word $w_i \in W$ according to the sense inventory of L: if w_i is monosemous, i.e., $|\{\mathcal{I}_{G_L}(w_i)\}| = 1$, we connect our source concept c to the only sense c_{w_i} of w_i and set $E := E \cup \{\{c, c_{w_i}\}\}$; else, w_i has multiple senses in L. In this latter case, we choose the most appropriate concept $c_i \in \mathcal{I}_{G_L}(w_i)$ by finding the maximal similarity between the definition of c and the definitions of each sense of w_i. To do this, we apply our definitional similarity measure introduced in Section 2.1. Having found the intended sense $\hat{c}_{w_i}$ of w_i, we add the edge $\{c, \hat{c}_{w_i}\}$ to E. As a result of this procedure, we obtain a semantic graph representation G for the lexicon L.

As an example, consider the 4^{th} sense of the noun *cone* in Wiktionary (i.e., $cone_n^4$) which is defined as *"The fruit of a conifer"*. The definition contains two content words: $fruit_n$ and $conifer_n$. The latter word is monosemous in Wiktionary, hence we directly connect $cone_n^4$ to the only sense of $conifer_n$. The noun *fruit*, however, has 5 senses in Wiktionary. We therefore measure the similarity between the definition of $cone_n^4$ and all the 5 definitions of *fruit* and introduce a link from $cone_n^4$ to the sense of fruit which yields the maximal similarity value (defined as *"(botany) The seed-bearing part of a plant..."*).

4 Experiments

Lexical resources. To enable a comparison with the state of the art, we followed Matuschek and Gurevych (2013) and performed an alignment of WordNet synsets (WN) to three different collaboratively-constructed resources: Wikipedia (WP), Wiktionary (WT), and OmegaWiki (OW). We utilized the DKPro software (Zesch et al., 2008; Gurevych et al., 2012) to access the information in the foregoing three resources. For WP, WT, OW we used the dump versions 20090822, 20131002, and 20131115, respectively.

Evaluation measures. We followed previous work (Navigli and Ponzetto, 2012; Matuschek and Gurevych, 2013) and evaluated the alignment performance in terms of four measures: precision, recall, F1, and accuracy. Precision is the fraction of correct alignment judgments returned by the system and recall is the fraction of alignment judgments in the gold standard dataset that are correctly returned by the system. F1 is the harmonic mean of precision and recall. We also report results for accuracy which, in addition to true positives, takes into account true negatives, i.e., pairs which are correctly judged as unaligned.

Lexicons and semantic graphs. Here, we describe how the four semantic graphs for our four lexical resources (i.e., WN, WP, WT, OW) were constructed. As mentioned in Section 2.1.1, we build the WN graph by including all the synsets and semantic relations defined in WordNet (e.g., hypernymy and meronymy) and further populate the relation set by connecting a synset to all the other synsets that appear in its disambiguated gloss. For WP, we used the graph provided by Matuschek and Gurevych (2013), constructed by directly connecting an article (concept) to all the hyperlinks in its first paragraph, together with the category links. Our WN and WP graphs have 118K and 2.8M nodes, respectively, with the average node degree being roughly 9 in both resources.

The other two resources, i.e., WT and OW, do not provide a reliable network of semantic relations, therefore we used our ontologization approach to construct their corresponding semantic graphs. We report, in the following subsection, the experiments carried out to assess the accuracy of our ontologization method, together with the statistics of the obtained graphs for WT and OW.

4.1 Ontologization Experiments

For ontologizing WT and OW, the bag of content words W is given by the content words in sense definitions and, if available, additional related words obtained from lexicon relations (see Section 3). In WT, both of these are in word surface form and hence had to be disambiguated. For OW, however, the encoded relations, though rela-

Source	Type	WT	OW
Definition	Ambiguous	76.6%	50.7%
	Unambiguous	18.3%	32.9%
Relation	Ambiguous	2.8%	-
	Unambiguous	2.3%	16.4%
Total number of edges		2.1M	255K

Table 1: The statistics of the generated graphs for WT and OW. We report the distribution of the edges across types (i.e., ambiguous and unambiguous) and sources (i.e., definitions and relations) from which candidate words were obtained.

tively small in number, are already disambiguated and, therefore, the ontologization was just performed on the definition's content words.

The resulting graphs for WT and OW contain 430K and 48K nodes, respectively, each providing more than 95% coverage of concepts, with the average node degree being around 10 for both resources. We present in Table 1, for WT and OW, the total number of edges together with their distribution across types (i.e., ambiguous and unambiguous) and sources (i.e., definitions and relations) from which candidate words were obtained.

The edges obtained from unambiguous entries are essentially sense disambiguated on both sides whereas those obtained from ambiguous terms are a result of our similarity-based disambiguation. Hence, given that a large portion of edges came from ambiguous words (see Table 1), we carried out an experiment to evaluate the accuracy of our disambiguation method. To this end, we took as our benchmark the dataset provided by Meyer and Gurevych (2010) for evaluating relation disambiguation in WT. The dataset contains 394 manually-disambiguated relations. We compared our similarity-based disambiguation approach against the state of the art on this dataset, i.e., the WKTWSD system, which is a WT relation disambiguation algorithm based on a series of rules (Meyer and Gurevych, 2012b).

Table 2 shows the performance of our disambiguation method, together with that of WKTWSD, in terms of Precision (P), Recall (R), F1, and accuracy. The "Human" row corresponds to the inter-rater F1 and accuracy scores, i.e., the upper-bound performance on this dataset, as calculated by Meyer and Gurevych (2010). As can be seen, our method proves to be very accurate, surpassing the performance of the WKTWSD system in terms of precision, F1, and accuracy. This is particularly

Approach	P	R	F1	A
WKTWSD	0.780	**0.800**	0.790	0.840
Our method	**0.852**	0.767	**0.807**	**0.857**
Human	-	-	0.890	0.910

Table 2: The performance of relation disambiguation for our similarity-based disambiguation method, as well as for the WKTWSD system.

interesting as the WKTWSD system uses a rule-based technique specific to relation disambiguation in WT, whereas our method is resource independent and can be applied to arbitrary words in the definition of any concept. We also note that the graph constructed by Meyer and Gurevych (2010) had an average node degree of around 1.

More recently, Matuschek and Gurevych (2013) leveraged monosemous linking (cf. Section 5) in order to create denser semantic graphs for OW and WT. Our approach, however, thanks to the connections obtained through ambiguous words, can provide graphs with significantly higher coverage. As an example, for WT, Matuschek and Gurevych (2013) generated a graph where around 30% of the nodes were in isolation, whereas this number drops to around 5% in our corresponding graph.

These results show that our ontologization approach can be used to obtain dense semantic graph representations of lexical resources, while at the same time preserving a high level of accuracy. Now that all the four resources are transformed into semantic graphs, we move to our alignment experiments.

4.2 Alignment Experiments

4.2.1 Experimental setup

Datasets. As our benchmark we tested on the gold standard datasets used in Matuschek and Gurevych (2013) for three alignment tasks: WordNet-Wikipedia (WN-WP), WordNet-Wiktionary (WN-WT), and WordNet-OmegaWiki (WN-OW). However, the dataset for WN-OW was originally built for the German language and, hence, was missing many English OW concepts that could be considered as candidate target alignments. We therefore fixed the dataset for the English language and reproduced the performance of previous work on the new dataset. The three datasets contained 320, 484, and 315 WN concepts that were manually mapped to their corresponding concepts in WP, WT, and OW, respectively.

Approach	Training type	WN-WP				WN-WT				WN-OW			
		P	R	F1	A	P	R	F1	A	P	R	F1	A

Table 3: The performance of different systems on the task of aligning WordNet to Wikipedia (WN-WP), Wiktionary (WN-WT), and OmegaWiki (WN-OW) in terms of Precision (P), Recall (R), F1, and Accuracy (A). We present results for different configurations of our system (SemAlign), together with the state of the art in definition similarity-based alignment approaches (SB) and the best configuration of the state-of-the-art graph-based system, Dijkstra-WSA (Matuschek and Gurevych, 2013, DWSA).

Configurations. Recall from Section 2 that our resource alignment technique has two parameters: the similarity threshold θ and the combination parameter β, both defined in [0, 1]. We performed experiments with three different configurations:

- *Unsupervised*, where the two parameters are set to their middle values (i.e., 0.5), hence, no tuning is performed for either of the parameters. In this case, both the definitional and structural similarity scores are treated as equally important and two concepts are aligned if their overall similarity exceeds the middle point of the similarity scale.
- *Tuning*, where we follow Matuschek and Gurevych (2013) and tune the parameters on a subset of the dataset comprising 100 items.
- *Cross-validation*, where a 5-fold cross validation is carried out to find the optimal values for the parameters, a technique used in most of the recent alignment methods (Niemann and Gurevych, 2011; Meyer and Gurevych, 2012a; Matuschek and Gurevych, 2013).

4.2.2 Results

We show in Table 3 the alignment performance of different systems on the task of aligning WN-WP, WN-WT, and WN-OW in terms of Precision (P), Recall (R), F1, and Accuracy. The SB system corresponds to the state-of-the-art definition similarity approaches for WN-WP (Niemann and Gurevych, 2011), WN-WT (Meyer and Gurevych, 2011), and WN-OW (Gurevych et al., 2012). DWSA stands for Dijkstra-WSA, the state-of-the-art graph-based alignment approach of Matuschek and Gurevych (2013). The authors also provided results for SB+Dijkstra-WSA, a hybrid system where DWSA was tuned for high precision and, in the case when no alignment target could be found, the algorithm fell back on SB judgments. We also show the results for this system as SB+DWSA in the table.

For our approach (SemAlign) we show the results of six different runs each corresponding to a different setting. The first three (middle part of the table) correspond to the results obtained with the three configurations of SemAlign: unsupervised, with tuning on subset, and cross-validation (see Section 4.2.1). In addition to these, we performed experiments where the two parameters of SemAlign were tuned on pair-independent training data, i.e., a training dataset for a pair of resources different from the one being aligned. For this setting, we used the whole dataset of the corresponding resource pair to tune the two parameters of our system. We show the results for this setting in the bottom part of the table (last three lines).

The main feature worth remarking upon is the consistency in the results across different resource pairs: the unsupervised system gains the best recall among the three configurations (with the improvement over SB+DWSA being always statistically significant[4]) whereas tuning, both on a subset or through cross-validation, consistently leads to the best performance in terms of F1 and accuracy (with the latter being statistically significant with respect to SB+DWSA on WN-WP and WN-WT).

Moreover, the unsupervised system proves to be very robust inasmuch as it provides competitive results on all the three datasets, while it surpasses the performance of SB+DWSA on WN-WT. This

[4] All significance tests are done using z-test at $p < 0.05$.

Approach	WN-WP				WN-WT				WN-OW			
	P	**R**	**F1**	**A**	**P**	**R**	**F1**	**A**	**P**	**R**	**F1**	**A**
Dijkstra-WSA	0.750	0.670	0.710	0.930	**0.680**	0.270	0.390	0.890	0.651	0.372	0.473	0.830
SemAlign$_{str}$	**0.877**	**0.788**	**0.830**	**0.959**	0.604	**0.643**	**0.623**	**0.907**	**0.654**	**0.602**	**0.627**	**0.853**

Table 4: Performance of SemAlign when using only the structural similarity component (SemAlign$_{str}$) compared to the state-of-the-art graph-based alignment approach, Dijkstra-WSA (Matuschek and Gurevych, 2013) for our three resource pairs: WordNet to Wikipedia (WN-WP), Wiktionary (WN-WT), and OmegaWiki (WN-OW).

is particularly interesting as the latter system involves tuning of several parameters, whereas SemAlign, in its unsupervised configuration, does not need any training data nor does it involve any tuning. In addition, as can be seen in the table, SemAlign benefits from pair-independent training data in most cases across the three resource pairs with performance surpassing that of SB+DWSA, a system which is dependent on pair-specific training data. The consistency in the performance of SemAlign in its different configurations and across different resource pairs indicates its robustness and shows that our system can be utilized effectively for aligning any pair of lexical resources, irrespective of their structure or availability of training data.

The system performance is generally higher on the alignment task for WP compared to WT and OW. We attribute this difference to the dictionary nature of the latter two, where sense distinctions are more fine-grained, as opposed to the relatively concrete concepts in the WP encyclopedia.

4.3 Similarity Measure Analysis

We explained in Section 2.1 that our concept similarity measure consists of two components: the definitional and the structural similarities. Measuring the similarity of two concepts in terms of their definitions has been investigated in previous work (Niemann and Gurevych, 2011; Henrich et al., 2012). The structural similarity component of our approach, however, is novel, but at the same time one of the very few measures which enables the computation of the similarity of concepts across two resources directly and independently of the similarity of their definitions. A comparable approach is the Dijkstra-WSA proposed by Matuschek and Gurevych (2013) which, as also mentioned earlier in the Introduction, first connects the two resources' graphs by leveraging monosemous linking and then aligns two concepts across the two graphs on the basis of their shortest distance. To gain more insight into the effectiveness of our structural similarity measure in comparison to the Dijkstra-WSA method, we carried out an experiment where our alignment system used only the structural similarity component, a variant of our system we refer to as SemAlign$_{str}$. Both systems (i.e., SemAlign$_{str}$ and Dijkstra-WSA) were tuned on 100-item subsets of the corresponding datasets.

We show in Table 4 the performance of the two systems on our three datasets. As can be seen in the table, SemAlign$_{str}$ consistently improves over Dijkstra-WSA according to recall, F1 and accuracy with all the differences in recall and accuracy being statistically significant ($p < 0.05$). The improvement is especially noticeable for pairs involving either WT or OW where, thanks to the relatively denser semantic graphs obtained by means of our ontologization technique, the gap in F1 is about 0.23 (WN-WT) and 0.15 (WN-OW).

In addition, as we mentioned earlier, for WN-WP we used the same graph as that of Dijkstra-WSA, since both WN and WP provide a full-fledged semantic network and thus neither needed to be ontologized. Therefore, the considerable performance improvement over Dijkstra-WSA on this resource pair shows the effectiveness of our novel concept similarity measure independently of the underlying semantic network.

5 Related Work

Resource ontologization. Having lexical resources represented as semantic networks is highly beneficial. A good example is WordNet, which has been exploited as a semantic network in dozens of NLP tasks (Fellbaum, 1998). A recent prominent case is Wikipedia (Medelyan et al., 2009; Hovy et al., 2013) which, thanks to its inter-article hyperlink structure, provides a rich backbone for structuring additional information (Auer et al., 2007; Suchanek et al., 2008; Moro and Navigli, 2013; Flati et al., 2014). However, there are many large-scale resources, such as Wiktionary for instance, which by their very nature are not in the form of a graph. This is

usually the case with machine-readable dictionaries, where structuring the resource involves the arduous task of connecting lexicographic senses by means of semantic relations. Surprisingly, despite their vast potential, little research has been conducted on the automatic ontologization of collaboratively-constructed dictionaries like Wiktionary and OmegaWiki. Meyer and Gurevych (2012a) and Matuschek and Gurevych (2013) provided approaches for building graph representations of Wiktionary and OmegaWiki. The resulting graphs, however, were either sparse or had a considerable portion of the nodes left in isolation. Our approach, in contrast, aims at transforming a lexical resource into a full-fledged semantic network, hence providing a denser graph with most of its nodes connected.

Resource alignment. Aligning lexical resources has been a very active field of research in the last decade. One of the main objectives in this area has been to enrich existing ontologies by means of complementary information from other resources. As a matter of fact, most efforts have been concentrated on aligning the *de facto* community standard sense inventory, i.e. WordNet, to other resources. These include: the Roget's thesaurus and Longman Dictionary of Contemporary English (Kwong, 1998), FrameNet (Laparra and Rigau, 2009), VerbNet (Shi and Mihalcea, 2005) or domain-specific terminologies such as the Unified Medical Language System (Burgun and Bodenreider, 2001). More recently, the growth of collaboratively-constructed resources has seen the development of alignment approaches with Wikipedia (Ruiz-Casado et al., 2005; Auer et al., 2007; Suchanek et al., 2008; Reiter et al., 2008; Navigli and Ponzetto, 2012), Wiktionary (Meyer and Gurevych, 2011) and OmegaWiki (Gurevych et al., 2012). Last year Matuschek and Gurevych (2013) proposed Dijkstra-WSA, a graph-based approach relying on shortest paths between two concepts when the two corresponding resources graphs were combined by leveraging monosemous linking. Their method when backed off with other definition similarity based approaches (Niemann and Gurevych, 2011; Meyer and Gurevych, 2011), achieved state-of-the-art results on the mapping of WordNet to different collaboratively-constructed resources. This approach, however, in addition to setting the threshold for the definition similarity component by means of cross validation, also required other parameters to be tuned, such as the allowed path length (λ) and the maximum number of edges in a graph. The optimal value for the λ parameter varied from one resource pair to another, and even for a specific resource pair it had to be tuned for each configuration. This made the approach dependent on the training data for the specific pair of resources that were to be aligned. Instead of measuring the similarity of two concepts on the basis of their distance in the combined graph, our approach models each concept through a rich vectorial representation we refer to as semantic signature and compares the two concepts in terms of the similarity of their semantic signatures. This rich representation leads to our approach having a good degree of robustness such that it can achieve competitive results even in the absence of training data. This enables our system to be applied effectively for aligning new pairs of resources for which no training data is available, with state-of-the-art performance.

6 Conclusions

This paper presents a unified approach for aligning lexical resources. Our method leverages a novel similarity measure which enables a direct structural comparison of concepts across different lexical resources. Thanks to an effective ontologization method, our alignment approach can be applied to any pair of lexical resources independently of whether they provide a full-fledged network structure. We demonstrate that our approach achieves state-of-the-art performance on aligning WordNet to three collaboratively-constructed resources with different characteristics, i.e., Wikipedia, Wiktionary, and OmegaWiki. We also show that our approach is robust across its different configurations, even when the training data is absent, enabling it to be used effectively for aligning new pairs of lexical resources for which no resource-specific training data is available. In future work, we plan to extend our concept similarity measure across different natural languages. We release all our data at `http://lcl.uniroma1.it/semalign`.

Abstract

Using distributional analysis methods to compute semantic proximity links between words has become commonplace in NLP. The resulting relations are often noisy or difficult to interpret in general. This paper focuses on the issues of evaluating a distributional resource and filtering the relations it contains, but instead of considering it in abstracto, we focus on pairs of words in context. In a discourse, we are interested in knowing if the semantic link between two items is a by-product of textual coherence or is irrelevant. We first set up a human annotation of semantic links with or without contextual information to show the importance of the textual context in evaluating the relevance of semantic similarity, and to assess the prevalence of actual semantic relations between word tokens. We then built an experiment to automatically predict this relevance, evaluated on the reliable reference data set which was the outcome of the first annotation. We show that in-document information greatly improve the prediction made by the similarity level alone.

1 Introduction

The goal of the work presented in this paper is to improve distributional thesauri, and to help evaluate the content of such resources. A distributional thesaurus is a lexical network that lists semantic neighbours, computed from a corpus and a similarity measure between lexical items, which generally captures the similarity of contexts in which the items occur. This way of building a semantic network has been very popular since (Grefenstette, 1994; Lin, 1998), even though the nature of the information it contains is hard to define, and its evaluation is far from obvious. A distributional thesaurus includes a lot of "noise" from a semantic point of view, but also lists relevant lexical pairs that escape classical lexical relations such as synonymy or hypernymy.

There is a classical dichotomy when evaluating NLP components between extrinsic and intrinsic evaluations (Jones, 1994), and this applies to distributional thesauri (Curran, 2004; Poibeau and Messiant, 2008). Extrinsic evaluations measure the capacity of a system in which a resource or a component to evaluate has been used, for instance in this case information retrieval (van der Plas, 2008) or word sense disambiguation (Weeds and Weir, 2005). Intrinsic evaluations try to measure the resource itself with respect to some human standard or judgment, for instance by comparing a distributional resource with respect to an existing synonym dictionary or similarity judgment produced by human subjects (Pado and Lapata, 2007; Baroni and Lenci, 2010). The shortcomings of these methods have been underlined in (Baroni and Lenci, 2011). Lexical resources designed for other objectives put the spotlight on specific areas of the distributional thesaurus. They are not suitable for the evaluation of the whole range of semantic relatedness that is exhibited by distributional similarities, which exceeds the limits of classical lexical relations, even though researchers have tried to collect equivalent resources manually, to be used as a gold standard (Weeds, 2003; Bordag, 2008; Anguiano et al., 2011). One advantage of distributional similarities is to exhibit a lot of different semantic relations, not necessarily standard lexical relations. Even with respect to established lexical resources, distributional approaches may improve coverage, complicating the evaluation even more.

The method we propose here has been designed as an intrinsic evaluation with a view to validate semantic proximity links in a broad per-

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 479–488,
Baltimore, Maryland, USA, June 23-25 2014.

spective, to cover what (Morris and Hirst, 2004) call "non classical lexical semantic relations". For instance, agentive relations (author/publish, author/publication) or associative relations (actor/cinema) should be considered. At the same time, we want to filter associations that can be considered as accidental in a semantic perspective (e.g. flag and composer are similar because they appear a lot with nationality names). We do this by judging the relevance of a lexical relation in a context where both elements of a lexical pair occur. We show not only that this improves the reliability of human judgments, but also that it gives a framework where this relevance can be predicted automatically. We hypothetize that evaluating and filtering semantic relations in texts where lexical items occur would help tasks that naturally make use of semantic similarity relations, but assessing this goes beyond the present work.

In the rest of this paper, we describe the resource we used as a case study, and the data we collected to evaluate its content (section 2). We present the experiments we set up to automatically filter semantic relations in context, with various groups of features that take into account information from the corpus used to build the thesaurus and contextual information related to occurrences of semantic neighbours 3). Finally we discuss some related work on the evaluation and improvement of distributional resources (section 4).

2 Evaluation of lexical similarity in context

2.1 Data

We use a distributional resource for French, built on a 200M word corpus extracted from the French Wikipedia, following principles laid out in (Bourigault, 2002) from a structured model (Baroni and Lenci, 2010), i.e. using syntactic contexts. In this approach, contexts are triples (governor,relation,dependent) derived from syntactic dependency structures. Governors and dependents are verbs, adjectives and nouns. Multiword units are available, but they form a very small subset of the resulting neighbours. Base elements in the thesaurus are of two types: arguments (dependents' lemma) and predicates (governor+relation). This is to keep the predicate/argument distinction since similarities will be computed between predicate pairs or argument pairs, and a lexical item can appear in many predicates and as an argument (e.g. *interest* as argument, *interest_for* as one predicate). The similarity of distributions was computed with Lin's score (Lin, 1998).

We will talk of lexical neighbours or distributional neighbours to label pairs of predicates or arguments, and in the rest of the paper we consider only lexical pairs with a Lin score of at least 0.1, which means about 1.4M pairs. This somewhat arbitrary level is an *a priori* threshold to limit the resulting database, and it is conservative enough not to exclude potential interesting relations. The distribution of scores is given figure 1; 97% of the selected pairs have a score between 0.1 and 0.29.

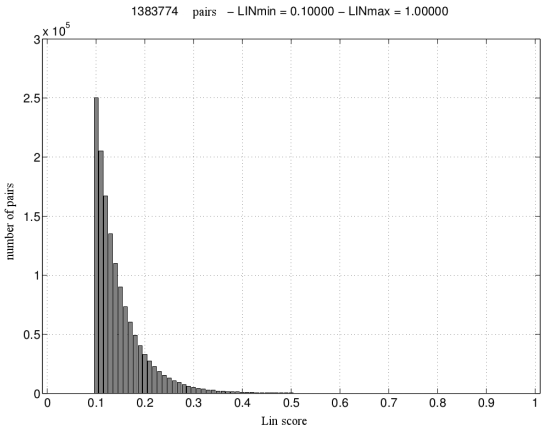

Figure 1: Histogram of Lin scores for pairs considered.

To ease the use of lexical neighbours in our experiments, we merged together predicates that include the same lexical unit, *a posteriori*. Thus there is no need for a syntactic analysis of the context considered when exploiting the resource, and sparsity is less of an issue[1].

2.2 Annotation

In order to evaluate the resource, we set up an annotation in context: pairs of lexical items are to be judged in their context of use, in texts where they occur together. To verify that this methodology is useful, we did a preliminary annotation to contrast judgment on lexical pairs with or without this contextual information. Then we made a larger annotation in context once we were assured of the reliability of the methodology.

For the preliminary test, we asked three annotators to judge the similarity of pairs of lexical items without any context (no-context), and to judge the

[1]Whenever two predicates with the same lemma have common neighbours, we average the score of the pairs.

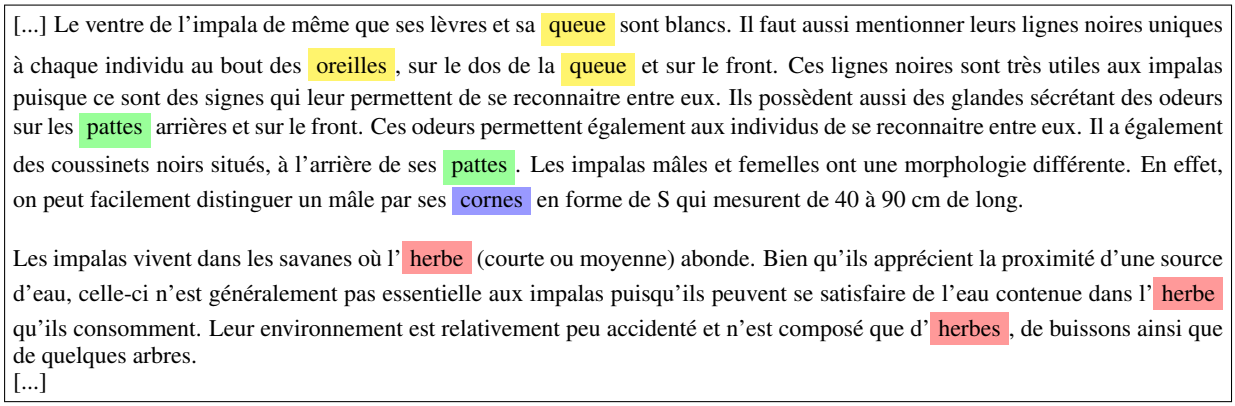

Figure 2: Example excerpt during the annotation of lexical pairs: annotators focus on a target item (here *corne*, horn, in blue) and must judge yellow words (pending: *oreille/queue*, ear/tail), either validating their relevance (green words: *pattes*, legs) or rejecting them (red words: *herbe*, grass). The text describes the morphology of the impala, and its habitat.

similarity of pairs presented within a paragraph where they both occur (in context). The three annotators were linguists, and two of them (1 and 3) knew about the resource and how it was built. For each annotation, 100 pairs were randomly selected, with the following constraints:

- for the no-context annotation, candidate pairs had a Lin score above 0.2, which placed them in the top 14% of lexical neighbours with respect to the similarity level.
- for the in context annotation, the only constraint was that the pairs occur in the same paragraph somewhere in the corpus used to build the resource. The example paragraph was chosen at random.

The guidelines given in both cases were the same: "Do you think the two words are semantically close ? In other words, is there a semantic relation between them, either classical (synonymy, hypernymy, co-hyponymy, meronymy, co-meronymy) or not (the relation can be paraphrased but does not belong to the previous cases) ?"

For the pre-test, agreement was rather moderate without context (the average of pairwise kappas was .46), and much better with a context (average = .68), with agreement rates above 90%. This seems to validate the feasability of a reliable annotation of relatedness in context, so we went on for a larger annotation with two of the previous annotators.

For the larger annotation, the protocol was slightly changed: two annotators were given 42 full texts from the original corpus where lexical neighbours occurred. They were asked to judge the relation between two items types, regardless of the number of occurrences in the text. This time there was no filtering of the lexical pairs beyond the 0.1 threshold of the original resource. We followed the well-known postulate (Gale et al., 1992) that all occurrences of a word in the same discourse tend to have the same sense ("one sense per discourse"), in order to decrease the annotator workload. We also assumed that the relation between these items remain stable within the document, an arguably strong hypothesis that needed to be checked against inter-annotator agreement before beginning the final annotation . It turns out that the kappa score (0.80) shows a better inter-annotator agreement than during the preliminary test, which can be explained by the larger context given to the annotator (the whole text), and thus more occurrences of each element in the pair to judge, and also because the annotators were more experienced after the preliminary test. Agreement measures are summed-up table 1. An excerpt of an example text, as it was presented to the annotators, is shown figure 2.

Overall, it took only a few days to annotate 9885 pairs of lexical items. Among the pairs that were presented to the annotators, about 11% were judged as relevant by the annotators. It is not easy to decide if the non-relevant pairs are just noise, or context-dependent associations that were not present in the actual text considered (for polysemy reasons for instance), or just low-level associations. An important aspect is thus to guarantee that there is a correlation between the sim-

Annotators	Non-contextual		Contextual	
	Agreement rate	Kappa	Agreement rate	Kappa
N1+N2	77%	0.52	91%	0.66
N1+N3	70%	0.36	92%	0.69
N2+N3	79%	0.50	92%	0.69
Average	75,3%	0,46	91,7%	0,68
Experts	NA	NA	90.8%	0.80

Table 1: Inter-annotator agreements with Cohen's Kappa for contextual and non-contextual annotations. N1, N2, N3 were annotators during the pre-test; expert annotation was made on a different dataset from the same corpus, only with the full discourse context.

ilarity score (Lin's score here), and the evaluated relevance of the neighbour pairs. Pearson correlation factor shows that Lin score is indeed significantly correlated to the annotated relevance of lexical pairs, albeit not strongly ($r = 0.159$).

The produced annotation[2] can be used as a reference to explore various aspects of distributional resources, with the caveat that it is as such a bit dependent on the particular resource used. We nonetheless assume that some of the relevant pairs would appear in other thesauri, or would be of interest in an evaluation of another resource.

The first thing we can analyse from the annotated data is the impact of a threshold on Lin's score to select relevant lexical pairs. The resource itself is built by choosing a cut-off which is supposed to keep pairs with a satisfactory similarity, but this threshold is rather arbitrary. Figure 3 shows the influence of the threshold value to select relevant pairs, when considering precision and recall of the pairs that are kept when choosing the threshold, evaluated against the human annotation of relevance in context. In case one wants to optimize the F-score (the harmonic mean of precision and recall) when extracting relevant pairs, we can see that the optimal point is at .24 for a threshold of .22 on Lin's score. This can be considered as a baseline for extraction of relevant lexical pairs, to which we turn in the following section.

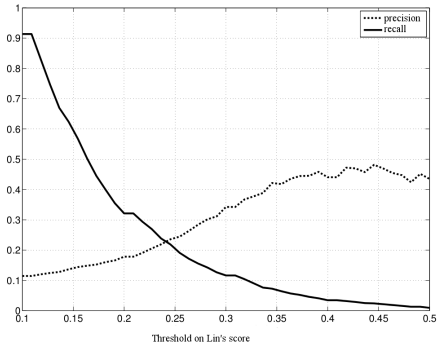

Figure 3: Precision and recall on relevant links with respect to a threshold on the similarity measure (Lin's score)

3 Experiments: predicting relevance in context

The outcome of the contextual annotation presented above is a rather sizeable dataset of validated semantic links, and we showed these linguistic judgments to be reliable. We used this dataset to set up a supervised classification experiment in order to automatically predict the relevance of a semantic link in a given discourse. We present now the list of features that were used for the model. They can be divided in three groups, according to their origin: they are computed from the whole corpus, gathered from the distributional resource, or extracted from the considered text which contains the semantic pair to be evaluated.

3.1 Features

For each pair *neighbour*$_a$/*neighbour*$_b$, we computed a set of features from Wikipedia (the corpus used to derive the distributional similarity): We first computed the frequencies of each item in the corpus, $freq_a$ and $freq_b$, from which we derive

- $freq_{min}$, $freq_{max}$: the min and max of $freq_a$ and $freq_b$;
- $freq_{\times}$: the combination of the two, or $\log(freq_a \times freq_b)$

[2]Freely available here `http://www.irit.fr/~Philippe.Muller/resources.html`.

We also measured the syntagmatic association of *neighbour*$_a$ and *neighbour*$_b$, with a mutual information measure (Church and Hanks, 1990), computed from the cooccurrence of two tokens within the same paragraph in Wikipedia. This is a rather large window, and thus gives a good coverage with respect to the neighbour database (70% of all pairs).

A straightforward parameter to include to predict the relevance of a link is of course the similarity measure itself, here Lin's information measure. But this can be complemented by additional information on the similarity of the neighbours, namely:

- each neighbour productivity : $prod_a$ and $prod_b$ are defined as the numbers of neighbours of respectively *neighbour*$_a$ and *neighbour*$_b$ in the database (thus related tokens with a similarity above the threshold), from which we derive three features as for frequencies: the min, the max, and the log of the product. The idea is that neighbours whith very high productivity give rise to less reliable relations.

- the ranks of tokens in other related items neighbours: $rank_{a-b}$ is defined as the rank of *neighbour*$_a$ among neighbours of *neighbour*$_b$ ordered with respect to Lin's score; $rang_{b-a}$ is defined similarly and again we consider as features the min, max and log-product of these ranks.

We add two categorial features, of a more linguistic nature:

- $cats$ is the pair of part-of-speech for the related items, e.g. to distinguish the relevance of NN or VV pairs.

- $predarg$ is related to the predicate/argument distinction: are the related items predicates or arguments ?

The last set of features derive from the occurrences of related tokens in the considered discourses:

First, we take into account the frequencies of items within the text, with three features as before: the min of the frequencies of the two related items, the max, and the log-product. Then we consider a *tf·idf* (Salton et al., 1975) measure, to evaluate the specificity and arguably the importance of a word

Feature	Description
$freq_{\min}$	$\min(freq_a, freq_b)$
$freq_{\max}$	$\max(freq_a, freq_b)$
$freq_{\times}$	$\log(freq_a \times freq_b)$
im	$im = \log \frac{P(a,b)}{P(a) \cdot P(b)}$
lin	Lin's score
$rank_{\min}$	$\min(rank_{a-b}, rank_{b-a})$
$rank_{\max}$	$\max(rank_{a-b}, rank_{b-a})$
$rank_{\times}$	$\log(rank_{a-b} \times rank_{b-a})$
$prod_{\min}$	$\min(prod_a, prod_b)$
$prod_{\max}$	$\max(prod_a, prod_b)$
$prod_{\times}$	$\log(prod_a \times prod_b)$
$cats$	neighbour pos pair
$predarg$	predicate or argument
$freqtxt_{\min}$	$\min(freqtxt_a, freqtxt_b)$
$freqtxt_{\max}$	$\max(freqtxt_a, freqtxt_b)$
$freqtxt_{\times}$	$\log(freqtxt_a \times freqstxt_b)$
tf·ipf	*tf·ipf*(*neighbour*$_a$)×*tf·ipf*(*neighbour*$_b$)
$copr_{ph}$	copresence in a sentence
$copr_{para}$	copresence in a paragraph
sd	smallest distance between *neighbour*$_a$ and *neighbour*$_b$
gd	highest distance between *neighbour*$_a$ and *neighbour*$_b$
ad	average distance between *neighbour*$_a$ and *neighbour*$_b$
$prodtxt_{\min}$	$\min(prod_a, prod_b)$
$prodtxt_{\max}$	$\max(prod_a, prod_b)$
$prodtxt_{\times}$	$\log(prod_a \times prod_b)$
cc	belong to the same lexical connected component

Table 2: Summary of features used in the supervised model, with respect to two lexical items a and b. The first group is corpus related, the second group is related to the distributional database, the third group is related to the textual context. Freq is related to the frequencies in the corpus, Freqtext the frequencies in the considered text.

in a document or within a document. Several variants of *tf·idf* have been proposed to adapt the measure to more local areas in a text with respect to the whole document. For instance (Dias et al., 2007) propose a *tf·isf*(*term frequency · inverse sentence frequency*), for topic segmentation. We similarly defined a *tf·ipf* measure based on the frequency of a word within a paragraph with respect to its frequency within the text. The resulting feature we used is the product of this measure for $neighbour_a$ and $neighbour_b$.

A few other contextual features are included in the model: the distances between pairs of related items, instantiated as:

- distance in words between occurrences of related word types:
  - minimal distance between two occurrences (sd)
  - maximal distance between two occurrences (gd)
  - average distance (ad) ;
- boolean features indicating whether $neighbour_a$ and $neighbour_b$ appear in the same sentence ($copr_s$) or the same paragraph ($copr_{para}$).

Finally, we took into account the network of related lexical items, by considering the largest sets of words present in the text and connected in the database (self-connected components), by adding the following features:

- the degree of each lemma, seen as a node in this similarity graph, combined as above in minimal degree of the pair, maximal degree, and product of degrees ($prodtxt_{\min}$, $prodtxt_{\max}$, $prodtxt_{\times}$). This is the number of pairs (present in the text) where a lemma appears in.
- a boolean feature cc saying whether a lexical pair belongs to a connected component of the text, except the largest. This reflects the fact that a small component may concern a lexical field which is more specific and thus more relevant to the text.

  Figure 4 shows examples of self-connected components in an excerpt of the page on *Gorille* (gorilla), e.g. the set {*pelage, dos, fourrure*} (coat, back, fur).

The last feature is probably not entirely independent from the productivity of an item, or from the tf.ipf measure.

Table 2 sums up the features used in our model.

3.2 Model

Our task is to identify relevant similarities between lexical items, between all possible related pairs, and we want to train an inductive model, a classifier, to extract the relevant links. We have seen that the relevant/not relevant classification is very imbalanced, biased towards the "not relevant" category (about 11%/89%), so we applied methods dedicated to counter-balance this, and will focus on the precision and recall of the predicted relevant links.

Following a classical methodology, we made a 10-fold cross-validation to evaluate robustly the performance of the classifiers. We tested a few popular machine learning methods, and report on two of them, a naive bayes model and the best method on our dataset, the Random Forest classifier (Breiman, 2001). Other popular methods (maximum entropy, SVM) have shown slightly inferior combined F-score, even though precision and recall might yield more important variations. As a baseline, we can also consider a simple threshold on the lexical similarity score, in our case Lin's measure, which we have shown to yield the best F-score of 24% when set at 0.22.

To address class imbalance, two broad types of methods can be applied to help the model focus on the minority class. The first one is to resample the training data to balance the two classes, the second one is to penalize differently the two classes during training when the model makes a mistake (a mistake on the minority class being made more costly than on the majority class). We tested the two strategies, by applying the classical Smote method of (Chawla et al., 2002) as a kind of resampling, and the ensemble method MetaCost of (Domingos, 1999) as a cost-aware learning method. Smote synthetizes and adds new instances similar to the minority class instances and is more efficient than a mere resampling. MetaCost is an interesting meta-learner that can use any classifier as a base classifier. We used Weka's implementations of these methods (Frank et al., 2004), and our experiments and comparisons are thus easily replicated on our dataset, provided with this paper, even though they can be improved by

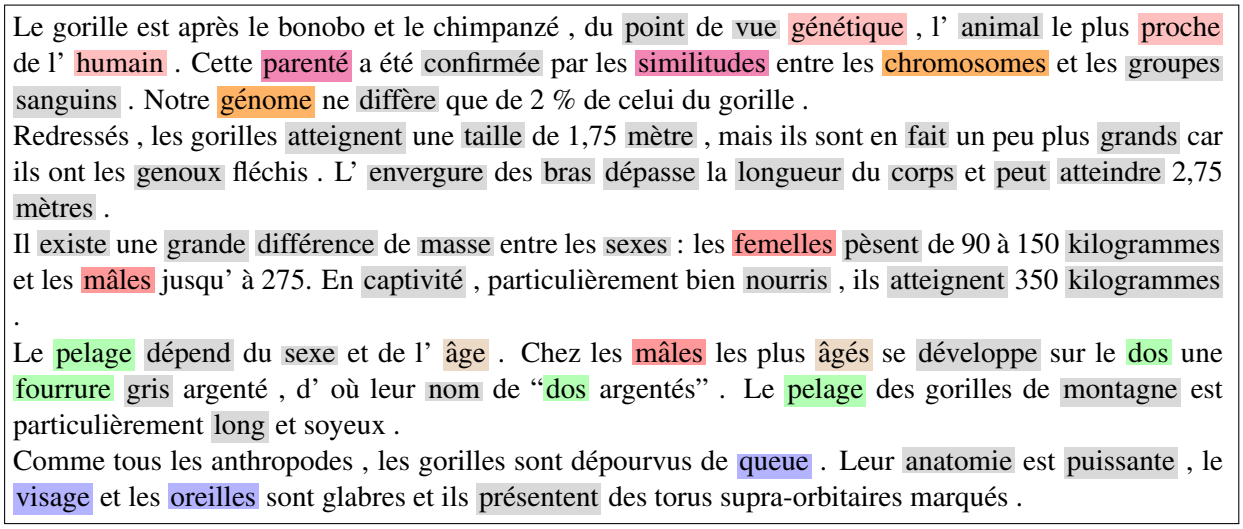

Figure 4: A few connected lexical components of the similarity graph, projected on a text, each in a different color. The groups are, in order of appearance of the first element: {genetic, close, human}, {similarity, kinship}, {chromosome, genome}, {male, female}, {coat, back, fur}, {age/N, aged/A}, {ear, tail, face}. The text describes the gorilla species, more particularly its morphology. Gray words are other lexical elements in the neighbour database.

refinements of these techniques. We chose the following settings for the different models: naive bayes uses a kernel density estimation for numerical features, as this generally improves performance. For Random Forests, we chose to have ten trees, and each decision is taken on a randomly chosen set of five features. For resampling, Smote advises to double the number of instances of the minority class, and we observed that a bigger resampling degrades performances. For cost-aware learning, a sensible choice is to invert the class ratio for the cost ratio, i.e. here the cost of a mistake on a relevant link (false negative) is exactly 8.5 times higher than the cost on a non-relevant link (false positive), as non-relevant instances are 8.5 times more present than relevant ones.

3.3 Results

We are interested in the precision and recall for the "relevant" class. If we take the best simple classifier (random forests), the precision and recall are 68.1% and 24.2% for an F-score of 35.7%, and this is significantly beaten by the Naive Bayes method as precision and recall are more even (F-score of 41.5%). This is already a big improvement on the use of the similarity measure alone (24%). Also note that predicting every link as relevant would result in a 2.6% precision, and thus a 5% F-score. The random forest model is significantly improved by the balancing techniques: the overall best F-score of 46.3% is reached with Random Forests and the cost-aware learning method. Table 3 sums up the scores for the different configurations, with precision, recall, F-score and the confidence interval on the F-score. We analysed the learning curve by doing a cross-validation on reduced set of instances (from 10% to 90%); F1-scores range from 37.3% with 10% of instances and stabilize at 80%, with small increment in every case.

The filtering approach we propose seems to yield good results, by augmenting the similarity built on the whole corpus with signals from the local contexts and documents where related lexical items appear together.

To try to analyse the role of each set of features, we repeated the experiment but changed the set of features used during training, and results are shown table 4 for the best method (RF with cost-aware learning).

We can see that similarity-related features (measures, ranks) have the biggest impact, but the other ones also seem to play a significant role. We can draw the tentative conclusion that the quality of distributional relations depends on the contextualizing of the related lexical items, beyond just the similarity score and the ranks of items as neighbours of other items.

Method	Precision	Recall	F-score	CI
Baseline (Lin threshold)	24.0	24.0	24.0	
RF	**68.1**	24.2	35.7	± 3.4
NB	34.8	51.3	41.5	± 2.6
RF+resampling	56.6	32.0	40.9	± 3.3
NB+resampling	32.8	54.0	40.7	± 2.5
RF+cost aware learning	40.4	54.3	**46.3**	± 2.7
NB+cost aware learning	27.3	**61.5**	37.8	± 2.2

Table 3: Classification scores (%) on the relevant class. CI is the confidence interval on the F-score (RF = Random Forest, NB= naive bayes).

Features	Prec.	Recall	F-score
all	40.4	54.3	46.3
all − corpus feat.	37.4	52.8	43.8
all − similarity feat.	36.1	49.5	41.8
all − contextual feat.	36.5	54.8	43.8

Table 4: Impact of each group of features on the best scores (%) : the lowest the results, the bigger the impact of the removed group of features.

4 Related work

Our work is related to two issues: evaluating distributional resources, and improving them. Evaluating distributional resources is the subject of a lot of methodological reflection (Sahlgren, 2006), and as we said in the introduction, evaluations can be divided between extrinsic and intrinsic evaluations. In extrinsic evaluations, models are evaluated against benchmarks focusing on a single task or a single aspect of a resource: either discriminative, TOEFL-like tests (Freitag et al., 2005), analogy production (Turney, 2008), or synonym selection (Weeds, 2003; Anguiano et al., 2011; Ferret, 2013; Curran and Moens, 2002). In intrinsic evaluations, associations norms are used, such as the 353 word-similarity dataset (Finkelstein et al., 2002), e.g. (Pado and Lapata, 2007; Agirre et al., 2009), or specifically designed test cases, as in (Baroni and Lenci, 2011). We differ from all these evaluation procedures as we do not focus on an *essential* view of the relatedness of two lexical items, but evaluate the link in a context where the relevance of the link is in question, an "existential" view of semantic relatedness.

As for improving distributional thesauri, outside of numerous alternate approaches to the construction, there is a body of work focusing on improving an existing resource, for instance reweighting context features once an initial thesaurus is built (Zhitomirsky-Geffet and Dagan, 2009), or post-processing the resource to filter bad neighbours or re-ranking neighbours of a given target (Ferret, 2013). They still use "essential" evaluation measures (mostly synonym extraction), although the latter comes close to our work since it also trains a model to detect (intrinsically) bad neighbours by using example sentences with the words to discriminate. We are not aware of any work that would try to evaluate differently semantic neighbours according to the context they appear in.

5 Conclusion

We proposed a method to reliably evaluate distributional semantic similarity in a broad sense by considering the validation of lexical pairs in contexts where they both appear. This helps cover non classical semantic relations which are hard to evaluate with classical resources. We also presented a supervised learning model which combines global features from the corpus used to built a distributional thesaurus and local features from the text where similarities are to be judged as relevant or not to the coherence of a document. It seems from these experiments that the quality of distributional relations depends on the contextualizing of the related lexical items, beyond just the simi-

larity score and the ranks of items as neighbours of other items. This can hopefully help filter out lexical pairs when word lexical similarity is used as an information source where context is important: lexical disambiguation (Miller et al., 2012), topic segmentation (Guinaudeau et al., 2012). This can also be a preprocessing step when looking for similarities at higher levels, for instance at the sentence level (Mihalcea et al., 2006) or other macrotextual level (Agirre et al., 2013), since these are always aggregation functions of word similarities. There are limits to what is presented here: we need to evaluate the importance of the level of noise in the distributional neighbours database, or at least the quantity of non-semantic relations present, and this depends on the way the database is built. Our starting corpus is relatively small compared to current efforts in this framework. We are confident that the same methodology can be followed, even though the quantitative results may vary, since it is independent of the particular distributional thesaurus we used, and the way the similarities are computed.

Abstract

Vector space models (VSMs) represent word meanings as points in a high dimensional space. VSMs are typically created using a large text corpora, and so represent word semantics as observed in text. We present a new algorithm (JNNSE) that can incorporate a measure of semantics not previously used to create VSMs: brain activation data recorded while people read words. The resulting model takes advantage of the complementary strengths and weaknesses of corpus and brain activation data to give a more complete representation of semantics. Evaluations show that the model 1) matches a behavioral measure of semantics more closely, 2) can be used to predict corpus data for unseen words and 3) has predictive power that generalizes across brain imaging technologies and across subjects. We believe that the model is thus a more faithful representation of mental vocabularies.

1 Introduction

Vector Space Models (VSMs) represent lexical meaning by assigning each word a point in high dimensional space. Beyond their use in NLP applications, they are of interest to cognitive scientists as an objective and data-driven method to discover word meanings (Landauer and Dumais, 1997).

Typically, VSMs are created by collecting word usage statistics from large amounts of text data and applying some dimensionality reduction technique like Singular Value Decomposition (SVD). The basic assumption is that semantics drives a person's language production behavior, and as a result co-occurrence patterns in written text indirectly encode word meaning. The raw co-occurrence statistics are unwieldy, but in the compressed VSM the distance between any two words is conceived to represent their mutual semantic similarity (Sahlgren, 2006; Turney and Pantel, 2010), as perceived and judged by speakers. This space then reflects the "semantic ground truth" of shared lexical meanings in a language community's vocabulary. However corpus-based VSMs have been criticized as being noisy or incomplete representations of meaning (Glenberg and Robertson, 2000). For example, multiple word senses collide in the same vector, and noise from mis-parsed sentences or spam documents can interfere with the final semantic representation.

When a person is reading or writing, the semantic content of each word will be necessarily activated in the mind, and so in patterns of activity over individual neurons. In principle then, brain activity could replace corpus data as input to a VSM, and contemporary imaging techniques allow us to attempt this. Functional Magnetic Resonance Imaging (fMRI) and Magnetoencephalography (MEG) are two brain activation recording technologies that measure neuronal activation in aggregate, and have been shown to have a predictive relationship with models of word meaning (Mitchell et al., 2008; Palatucci et al., 2009; Sudre et al., 2012; Murphy et al., 2012b).[1]

If brain activation data encodes semantics, we theorized that including brain data in a model of semantics could result in a model more consistent with semantic ground truth. However, the inclusion of brain data will only improve a text-based model if brain data contains semantic information not readily available in the corpus. In addition, if a semantic test involves another subject's brain activation data, performance can improve only if the additional semantic information is consistent across brains. Of course, brains differ in shape, size and in connectivity, so additional information encoded in one brain might not translate to an-

[1]For more details on fMRI and MEG, see Section 4.2

Baltimore, Maryland, USA, June 23-25 2014.

other. Furthermore, different brain imaging technologies measure very different correlates of neuronal activity. Due to these differences, it is possible that one subject's brain activation data cannot improve a model's performance on another subject's brain data, or for brain data collected using a different recording technology. Indeed, inter-subject models of brain activation is an open research area (Conroy et al., 2013), as is learning the relationship between recording technologies (Engell et al., 2012; Hall et al., 2013). Brain data can also be corrupted by many types of noise (e.g. recording room interference, movement artifacts), another possible hindrance to the use of brain data in VSMs.

VSMs are interesting from both engineering and scientific standpoints. In this work we focus on the scientific question: Can the inclusion of brain data improve semantic representations learned from corpus data? What can we learn from such a model? From an engineering perspective, brain activation data will likely never replace text data. Brain activation recordings are both expensive and time consuming to collect, whereas textual data is vast and much of it is free to download. However, from a scientific perspective, combining text and brain data could lead to more consistent semantic models, in turn leading to a better understanding of semantics and semantic modeling generally.

In this paper, we leverage both kinds of data to build a hybrid VSM using a new matrix factorization method (JNNSE). Our hypothesis is that the noise of brain and corpus derived statistics will be largely orthogonal, and so the two data sources will have complementary strengths as input to VSMs. If this hypothesis is correct, we should find that the resulting VSM is more successful in modeling word semantics as encoded in human judgements, as well as separate corpus and brain data that was not used in the derivation of the model. We will show that our method:

1. creates a VSM that is more correlated to an independent measure of word semantics.
2. produces word vectors that are more predictable from the brain activity of different people, even when brain data is collected with a different recording technology.
3. predicts corpus representations of withheld words more accurately than a model that does not combine data sources.
4. directly maps semantic concepts onto the brain by jointly learning neural representations.

Together, these results suggest that corpus and brain activation data measure semantics in compatible and complimentary ways. Our results are evidence that a joint model of brain- and text-based semantics may be closer to semantic ground truth than text-only models. Our findings also indicate that there is additional semantic information available in brain activation data that is not present in corpus data, and that there are elements of semantics currently lacking in text-based VSMs. We have made available the top performing VSMs created with brain and text data (`http://www.cs.cmu.edu/~afyshe/papers/acl2014/`).

In the following sections we will review NNSE, and our extension, JNNSE. We will describe the data used and the experiments to support our position that brain data is a valuable source of semantic information that compliments text data.

2 Non-Negative Sparse Embedding

Non-Negative Sparse Embedding (NNSE) (Murphy et al., 2012a) is an algorithm that produces a latent representation using matrix factorization. Standard NNSE begins with a matrix $X \in \mathbb{R}^{w \times c}$ made of c corpus statistics for w words. NNSE solves the following objective function:

$$\underset{A,D}{\operatorname{argmin}} \sum_{i=1}^{w} \left\| X_{i,:} - A_{i,:} \times D \right\|^2 + \lambda \left\| A \right\|_1 \quad (1)$$

$$\text{subject to: } D_{i,:} D_{i,:}^T \leq 1, \forall\, 1 \leq i \leq \ell \quad (2)$$

$$A_{i,j} \geq 0,\ 1 \leq i \leq w,\ 1 \leq j \leq \ell \quad (3)$$

The solution will find a matrix $A \in \mathbb{R}^{w \times \ell}$ that is sparse, non-negative, and represents word semantics in an ℓ-dimensional latent space. $D \in \mathbb{R}^{\ell \times c}$ gives the encoding of corpus statistics in the latent space. Together, they factor the original corpus statistics matrix X in a way that minimizes the reconstruction error. The L_1 constraint encourages sparsity in A; λ is a hyperparameter. Equation 2 constrains D to eliminate solutions where A is made arbitrarily small by making D arbitrarily large. Equation 3 ensures that A is non-negative. We may increase ℓ to give more dimensional space to represent word semantics, or decrease ℓ for more compact representations.

The sparse and non-negative representation in A produces a more interpretable semantic space, where interpretability is quantified with a behavioral task (Chang et al., 2009; Murphy et al., 2012a). To illustrate the interpretability of NNSE, we describe a word by selecting the word's top scoring dimensions, and selecting the top scoring words in those dimensions. For example, the word chair has the following top scoring dimensions:

1. chairs, seating, couches;
2. mattress, futon, mattresses;
3. supervisor, coordinator, advisor.

These dimensions cover two of the distinct meanings of the word chair (furniture and person of power).

NNSE's sparsity constraint dictates that each word can have a non-zero score in only a few dimensions, which aligns well to previous feature elicitation experiments in psychology. In feature elicitation, participants are asked to name the characteristics (features) of an object. The number of characteristics named is usually small (McRae et al., 2005), which supports the requirement of sparsity in the learned latent space.

3 Joint Non-Negative Sparse Embedding

We extend NNSEs to incorporate an additional source of data for a subset of the words in X, and call the approach Joint Non-Negative Sparse Embeddings (JNNSEs). The JNNSE algorithm is general enough to incorporate any new information about the a word w, but for this study we will focus on brain activation recordings of a human subject reading single words. We will incorporate either fMRI or MEG data, and call the resulting models JNNSE(fMRI+Text) and JNNSE(MEG+Text) and refer to them generally as JNNSE(Brain+Text). For clarity, from here on, we will refer to NNSE as NNSE(Text), or NNSE(Brain) depending on the single source of input data used.

Let us order the rows of the corpus data X so that the first $1 \dots w'$ rows have both corpus statistics and brain activation recordings. Each brain activation recording is a row in the brain data matrix $Y \in \mathbb{R}^{w' \times v}$ where v is the number of features derived from the recording. For MEG recordings, $v =$sensors $\times$ time points$= 306 \times 150$. For fMRI $v =$ grey-matter voxels $=\simeq 20,000$ depending on the brain anatomy of each individual subject. The new objective function is:

$$\underset{A, D^{(c)}, D^{(b)}}{\operatorname{argmin}} \sum_{i=1}^{w} \left\| X_{i,:} - A_{i,:} \times D^{(c)} \right\|^2 + \sum_{i=1}^{w'} \left\| Y_{i,:} - A_{i,:} \times D^{(b)} \right\|^2 + \lambda \left\| A \right\|_1 \quad (4)$$

$$\text{subject to:} \quad D^{(c)}_{i,:} D^{(c)T}_{i,:} \leq 1, \forall\, 1 \leq i \leq \ell \quad (5)$$

$$D^{(b)}_{i,:} D^{(b)T}_{i,:} \leq 1, \forall\, 1 \leq i \leq \ell \quad (6)$$

$$A_{i,j} \geq 0,\ 1 \leq i \leq w,\ 1 \leq j \leq \ell \quad (7)$$

We have introduced an additional constraint on the rows $1 \dots w'$, requiring that some of the learned representations in A also reconstruct the brain activation recordings (Y) through representations in $D^{(b)} \in \mathbb{R}^{\ell \times v}$. Let us use A' to refer to the brain-constrained rows of A. Words that are close in "brain space" must have similar representations in A', which can further percolate to affect the representations of other words in A via closeness in "corpus space".

With A or D fixed, the objective function for NNSE(Text) and JNNSE(Brain+Text) is convex. However, we are solving for A and D, so the problem is non-convex. To solve for this objective, we use the online algorithm of Section 3 from Mairal et al. (Mairal et al., 2010). This algorithm is guaranteed to converge, and in practice we found that JNNSE(Brain+Text) converged as quickly as NNSE(Text) for the same ℓ. We used the SPAMS package[2] to solve, and set $\lambda = 0.025$. This algorithm was a very easy extension to NNSE(Text) and required very little additional tuning.

We also consider learning shared representations in the case where data X and Y contain the effects of known *disjoint* features. For example, when a person reads a word, the recorded brain activation data Y will contain the physiological response to viewing the stimulus, which is unrelated to the semantics of the word. These signals can be attributed to, for example, the number of letters in the word and the number of white pixels on the screen (Sudre et al., 2012). To account for such effects in the data, we augment A' with a set of n fixed, manually defined features (e.g. word length) to create $A'_{percept} \in \mathbb{R}^{w \times (\ell+n)}$. $D^{(b)} \in \mathbb{R}^{(\ell+n) \times v}$ is used with $A'_{percept}$,

[2]SPAMS Package: http://spams-devel.gforge.inria.fr/

to reconstruct the brain data Y. More generally, one could instead allocate a certain number of latent features specific to X *or* Y, both of which could be learned, as explored in some related work (Gupta et al., 2013). We use 11 *perceptual* features that characterize the non-semantic features of the word stimulus (for a list, see supplementary material at `http://www.cs.cmu.edu/~afyshe/papers/acl2014/`).

The JNNSE algorithm is advantageous in that it can handle partially paired data. That is, the algorithm does not require that every row in X also have a row in Y. Fully paired data is a requirement of many other approaches (White et al., 2012; Jia and Darrell, 2010). Our approach allows us to leverage the semantic information in corpus data even for words without brain activation recordings.

JNNSE(Brain+Text) does not require brain data to be mapped to a common average brain, which is often the case when one wants to generalize between human subjects. Such mappings can blur and distort data, making it less useful for subsequent prediction steps. We avoid these mappings, and instead use the fact that similar words elicit similar brain activation *within* a subject. In the JNNSE algorithm, it is this closeness in "brain space" that guides the creation of the latent space A. Leveraging intra-subject distance measures to study inter-subject encodings has been studied previously (Kriegeskorte et al., 2008a; Raizada and Connolly, 2012), and has even been used across species (humans and primates) (Kriegeskorte et al., 2008b).

Though we restrict ourselves to using one subject per JNNSE(Brain+Text) model, the JNNSE algorithm could easily be extended to include data from multiple brain imaging experiments by adding a new squared loss term for additional brain data.

3.1 Related Work

Perhaps the most well known related approach to joining data sources is Canonical Correlation Analysis (CCA) (Hotelling, 1936), which has been applied to brain activation data in the past (Rustandi et al., 2009). CCA seeks two linear transformations that maximally correlate two data sets in the transformed form. CCA requires that the data sources be paired (all rows in the corpus data must have a corresponding brain data), as correlation between points is integral to the objective. To apply CCA to our data we would need to discard the vast majority of our corpus data, and use only the 60 rows of X with corresponding rows in Y. While CCA holds the input data fixed and maximally correlates the transformed form, we hold the transformed form fixed and seek a solution that maximally correlates the reconstruction ($AD^{(c)}$ or $A'D^{(b)}$) with the data (X and Y respectively). This shift in error compensation is what allows our data to be only partially paired. While a Bayesian formulation of CCA can handle missing data, our model has missing data for $> 97\%$ of the full $w \times (v + c)$ brain and corpus data matrix. To our knowledge, this extreme amount of missing data has not been explored with Bayesian CCA.

One could also use a topic model style formulation to represent this semantic representation task. Supervised topic models (Blei and McAuliffe, 2007) use a latent topic to generate two observed outputs: words in a document and a categorical label for the document. The same idea could be applied here: the latent semantic representation generates the observed brain activity and corpus statistics. Generative and discriminative models both have their own strengths and weaknesses, generative models being particularly strong when data sources are limited (Ng and Jordan, 2002). Our task is an interesting blend of data-limited and data-rich problem scenarios.

In the past, various pieces of additional information have been incorporated into semantic models. For example, models with behavioral data (Silberer and Lapata, 2012) and models with visual information (Bruni et al., 2011; Silberer et al., 2013) have both shown to improve semantic representations. Other works have correlated VSMs built with text or images with brain activation data (Murphy et al., 2012b; Anderson et al., 2013). To our knowledge, this work is the first to integrate brain activation data into the construction of the VSM.

4 Data

4.1 Corpus Data

The corpus statistics used here are the downloadable vectors from Fyshe et al. (2013)[3]. They are compiled from a 16 billion word subset of ClueWeb09 (Callan and Hoy, 2009) and contain two types of corpus features: dependency and document features, found to be complimentary for

[3] `http://www.cs.cmu.edu/~afyshe/papers/conll2013/`

most tasks. Dependency statistics were derived by dependency parsing the corpus and compiling counts for all dependencies incident on the word. Document statistics are word-document co-occurrence counts. Count thresholding was applied to reduce noise, and positive pointwise-mutual-information (PPMI) (Church and Hanks, 1990) was applied to the counts. SVD was applied to the document and dependency statistics and the top 1000 dimensions of each type were retained. We selected the rows corresponding to noun-tagged words (approx. 17000 words).

4.2 Brain Activation Data

We have MEG and fMRI data at our disposal. MEG measures the magnetic field caused by many thousands of neurons firing together, and has good time resolution (1000 Hz) but poor spatial resolution. fMRI measures the change in blood oxygenation that results from differential neural activity, and has good spatial resolution but poor time resolution (0.5-1 Hz). We have fMRI data and MEG data for 18 subjects (9 in each imaging modality) viewing 60 concrete nouns (Mitchell et al., 2008; Sudre et al., 2012). The 60 words span 12 word categories (animals, buildings, tools, insects, body parts, furniture, building parts, utensils, vehicles, objects, clothing, food). Each of the 60 words was presented with a line drawing, so word ambiguity is not an issue. For both recording modalities, all trials for a particular word were averaged together to create one training instance per word, with 60 training instances in all for each subject and imaging modality. More preprocessing details appear in the supplementary material.

5 Experimental Results

Here we explore several variations of JNNSE and NNSE formulations. For a comparison of the models used, see Table 1.

5.1 Correlation to Behavioral Data

To test if our joint model of Brain+Text is closer to semantic ground truth we compared the latent representation A learned via JNNSE(Brain+Text) or NNSE(Text) to an independent behavioral measure of semantics. We collected behavioral data for the 60 nouns in the form of answers to 218 semantic questions. Answers were gathered with Mechanical Turk. The full list of questions appear in the supplementary material. Some example questions are:"Is it alive?", and "Can it bend?". Mechanical Turk users were asked to respond to each question for each word on a scale of 1-5. At least 3 respondents answered each question and the median score was used. This gives us a semantic representation of each of the 60 words in a 218-dimensional behavioral space. Because we required answers to each of the questions for all words, we do not have the problems of sparsity that exist for feature production norms from other studies (McRae et al., 2005). In addition, our answers are ratings, rather than binary yes/no answers.

For a given value of ℓ we solve the NNSE(Text) and JNNSE(Brain+Text) objective function as detailed in Equation 1 and 4 respectively. We compared JNNSE(Brain+Text) and NNSE(Text) models by measuring the correlation of all pairwise distances in JNNSE(Brain+Text) and NNSE(Text) space to the pairwise distances in the 218-dimensional semantic space. Distances were calculated using normalized Euclidean distance (equivalent in rank-ordering to cosine distance, but more suitable for sparse vectors). Figure 1 shows the results of this correlation test. The error bars for the JNNSE(Brain+Text) models represent a 95% confidence interval calculated using the standard error of the mean (SEM) over the 9 person-specific JNNSE(Brain+Text) models. Because there is only one NNSE(Text) model for each dimension setting, no SEM can be calculated, but it suffices to show that the NNSE(Text) correlation does not fall into the 95% confidence interval of the JNNSE(Brain+Text) models. The SVD matrix for the original corpus data has correlation 0.4279 to the behavioral data, also below the 95% confidence interval for all JNNSE models. The results show that a model that incorporates brain activation data is more faithful to a behavioral measure of semantics.

5.2 Word Prediction from Brain Activation

We now show that the JNNSE(Brain+Text) vectors are more consistent with independent samples of brain activity collected from different subjects, even when recorded using different recording technologies. As previously mentioned, because there is a large degree of variation between brains and because MEG and fMRI measure very different correlates of neuronal activity, this type of generalization has proven to be very challenging and is an open research question in the neuroscience community.

The output A of the JNNSE(Brain+Text) or

Table 1: A Comparison of the models explored in this paper, and the data upon which they operate.

Model Name	Section(s)	Text Data	Brain Data	Withheld Data
NNSE(Text)	2, 5	✓	x	-

JNNSE(Brain+Text)	3, 5	✓	✓	-
JNNSE(Brain+Text): Dropout task	5.2.2	✓	✓	subset of brain data
JNNSE(Brain+Text): Predict corpus	5.3	✓	✓	subset of text data

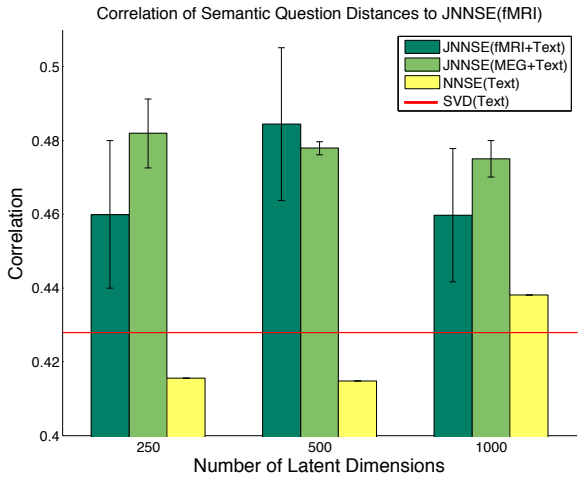

Figure 1: Correlation of JNNSE(Brain+Text) and NNSE(Text) models with the distances in a semantic space constructed from behavioral data. Error bars indicate SEM.

NNSE(Text) algorithm can be used as a VSM, which we use for the task of word prediction from fMRI or MEG recordings. A JNNSE(Brain+Text) created with a particular human subject's data is never used in the prediction framework with that same subject. For example, if we use fMRI data from subject 1 to create a JNNSE(fMRI+Text), we will test it with the remaining 8 fMRI subjects, but all 9 MEG subjects (fMRI and MEG subjects are disjoint).

Let us call the VSM learned with JNNSE(Brain+Text) or NNSE(Text) the *semantic vectors*. We can train a weight matrix W that predicts the semantic vector $\mathbf{a}$ of a word from that word's brain activation vector $\mathbf{x}$: $\mathbf{a} = W\mathbf{x}$. W can be learned with a variety of methods, we will use L_2 regularized regression. One can also train regressors that predict the brain activation data from the semantic vector: $\mathbf{x} = W\mathbf{a}$, but we have found this to give lower predictive accuracy. Note that we must *re-train* our weight matrix W for each subject (instead of re-using $D^{(b)}$ from Equation 4) because testing always occurs on a different subject, and the brain activation data is not inter-subject aligned.

We train ℓ independent L_2 regularized regressors to predict the ℓ-dimensional vectors $\mathbf{a} = \{a_1 \dots a_\ell\}$. The predictions are concatenated to produce a *predicted* semantic vector: $\hat{\mathbf{a}} = \{\hat{a}_1, \dots, \hat{a}_\ell\}$. We assess word prediction performance by testing if the model can differentiate between two unseen words, a task named *2 vs. 2 prediction* (Mitchell et al., 2008; Sudre et al., 2012). We choose the assignment of the two held out semantic vectors $(\mathbf{a}^{(1)}, \mathbf{a}^{(2)})$ to predicted semantic vectors $(\hat{\mathbf{a}}^{(1)}, \hat{\mathbf{a}}^{(2)})$ that minimizes the sum of the two normalized Euclidean distances. 2 vs. 2 accuracy is the percentage of tests where the correct assignment is chosen.

The 60 nouns fall into 12 word categories. Words in the same word category (e.g. screwdriver and hammer) are closer in semantic space than words in different word categories, which makes some 2 vs. 2 tests more difficult than others. We choose 150 random pairs of words (with each word represented equally) to estimate the difficulty of a typical word pair, without having to test all $\binom{60}{2}$ word pairs. The same 150 random pairs are used for all subjects and all VSMs. Expected chance performance on the 2 vs. 2 test is 50%.

Results for testing on fMRI data in the 2 vs. 2 framework appear in Figure 2. JNNSE(fMRI+Text) data performed on average 6% better than the best NNSE(Text), and exceeding even the original SVD corpus representations while maintaining interpretability. These results generalize across brain activity recording types; JNNSE(MEG+Text) performs as well as JNNSE(fMRI+Text) when tested on fMRI data. The results are consistent when testing on MEG data: JNNSE(MEG+Text) or JNNSE(fMRI+Text) outperforms NNSE(Text) (see Figure 3).

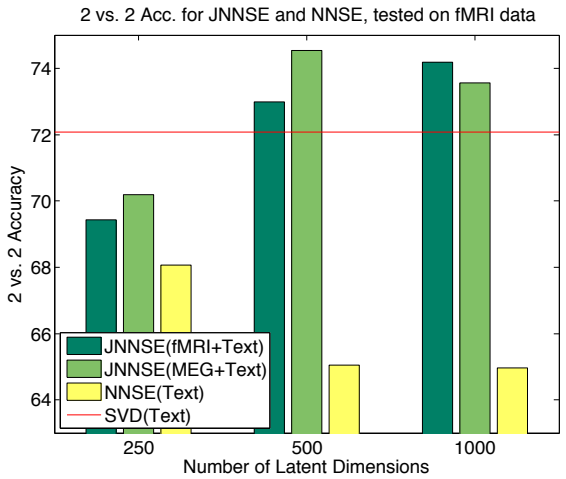

Figure 2: Average 2 vs. 2 accuracy for NNSE(Text) and JNNSE(Brain+Text), tested on fMRI data. Models created with one subject's fMRI data were not used to compute 2 vs. 2 accuracy for that same subject.

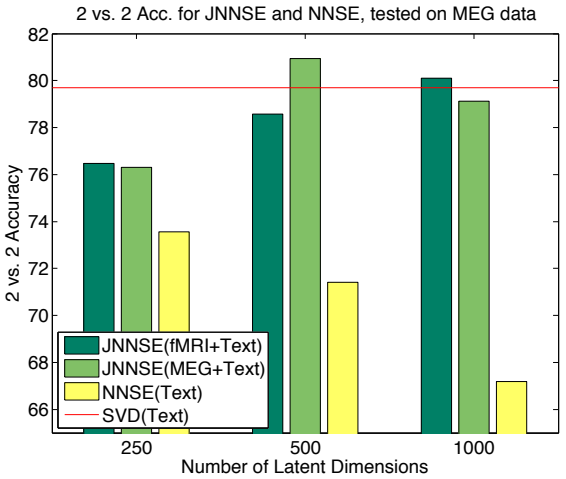

Figure 3: Average 2 vs. 2 accuracy for NNSE(Text) and JNNSE(Brain+Text), tested on MEG data. Models created with one subject's MEG data were not used to compute 2 vs. 2 accuracy for that same subject.

NNSE(Text) performance decreases as the number of latent dimension increases. This implies that without the regularizing effect of brain activation data, the extra NNSE(Text) dimensions are being used to overfit to the corpus data, or possibly to fit semantic properties not detectable with current brain imaging technologies. However, when brain activation data is included, increasing the number of latent dimensions strictly increases performance for JNNSE(fMRI+Text). JNNSE(MEG+Text) has peak performance with 500 latent dimensions, with $\sim$ 1% decrease in performance at 1000 latent dimensions. In previous work, the ability to decode words from brain activation data was found to improve with added latent dimensions (Murphy et al., 2012a). Our results may differ because our words are POS tagged, and we included only nouns for the final NNSE(Text) model. We found that with the original $\lambda = 0.05$ setting from Murphy et al. (Murphy et al., 2012a) produced vectors that were too sparse; four of the 60 test words had all-zero vectors (JNNSE(Brain+Text) models did have any all-zero vectors). To improve the NNSE(Text) vectors for a fair comparison, we reduced $\lambda = 0.025$, under which NNSE(Text) did not produce any all-zero vectors for the 60 words.

Our results show that brain activation data contributes additional information, which leads to an increase in performance for the task of word prediction from brain activation data. This suggests that corpus-only models may not capture all relevant semantic information. This conflicts with previous studies which found that semantic vectors culled from corpus statistics contain all of the semantic information required to predict brain activation (Bullinaria and Levy, 2013).

5.2.1 Prediction from a Brain-only Model

How much predictive power does the corpus data provide to this word prediction task? To test this, we calculated the 2 vs. 2 accuracy for a NNSE(Brain) model trained on brain activation data only. We train NNSE(Brain) with one subject's data and use the resulting vectors to calculate 2 vs. 2 accuracy for the remaining subjects. We have brain data for only 60 words, so using $\ell \geq 60$ latent dimensions leads to an under-constrained system and a degenerate solution wherein only one latent dimension is active for any word (and where the brain data can be perfectly reconstructed). The degenerate solution makes it impossible to generalize across words and leads to performance at chance levels. An NNSE(MEG) trained on MEG data gave maximum 2 vs. 2 accuracy of 67% when $\ell = 20$. The reduced performance may be due to the limited training data and the low SNR of the data, but could also be attributed to the lack of corpus information, which provides another piece of semantic information.

5.2.2 Effect on Rows Without Brain Data

It is possible that some JNNSE(Brain+Text) dimensions are being used exclusively to fit brain activation data, and not the semantics represented in both brain and corpus data. If a particular dimension j is solely used for brain data, the sparsity constraint will favor solutions that sets $A_{(i,j)} = 0$ for $i > w'$ (no brain data constraint), and $A_{(i,j)} > 0$ for some $0 \leq i \leq w'$ (brain data constrained). We found that there were no such dimensions in the JNNSE(Brain+Text). In fact for the $\ell = 1000$ JNNSE(Brain+Text), all latent dimensions had greater than $\sim 25\%$ non-zero entries, which implies that all dimensions are being shared between the two data inputs (corpus and brain activation), and are used to reconstruct both.

To test that the brain activation data is truly influencing rows of A not constrained by brain activation data, we performed a *dropout* test. We split the original 60 words into two 30 word groups (as evenly as possible across word categories). We trained JNNSE(fMRI+Text) with 30 words, and tested word prediction with the remaining 8 subjects and the other 30 words. Thus, the training and testing word sets are disjoint. Because of the reduced size of the training data, we did see a drop in performance, but JNNSE(fMRI+Text) vectors still gave word prediction performance 7% higher than NNSE(Text) vectors. Full results appear in the supplementary material.

5.3 Predicting Corpus Data

Here we ask: can an accurate latent representation of a word be constructed using only brain activation data? This task simulates the scenario where there is no reliable corpus representation of a word, but brain data is available. This scenario may occur for seldom-used words that fall below the thresholds used for the compilation of corpus statistics. It could also be useful for acronym tokens (lol, omg) found in social media contexts where the meaning of the token is actually a full sentence.

We trained a JNNSE(fMRI+Text) with brain data for all 60 words, but withhold the corpus data for 30 of the 60 words (as evenly distributed as possible amongst the 12 word categories). The brain activation data for the 30 withheld words will allow us to create latent representations in A for withheld words. Simultaneously, we will learn a mapping from the latent representation to the corpus data ($D^{(c)}$). This task cannot be performed with a NNSE(Text) model because one cannot learn a latent representation of a word without data of some kind. This further emphasizes the impact of brain imaging data, which will allow us to generalize to previously unseen words in corpus space.

Table 2: Mean rank accuracy over 30 words using corpus representations predicted by a JNNSE(MEG+Text) model trained with some rows of the corpus data withheld. Significance is calculated using Fisher's method to combine p-values for each of the subject-dependent models.

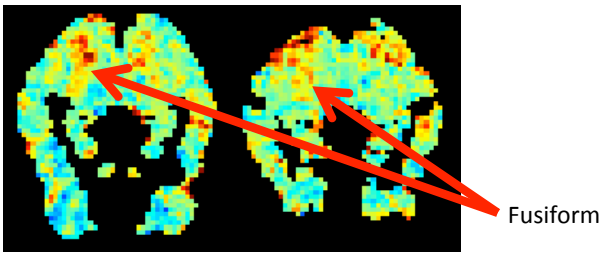
Latent Dim size	Rank Accuracy	p-value
250	65.30	$< 10^{-19}$
500	67.37	$< 10^{-24}$
1000	63.47	$< 10^{-15}$

We use the latent representations in A for each of the words without corpus data and the mapping to corpus space $D^{(c)}$ to predict the withheld corpus data in X. We then rank the withheld rows of X by their distance to the predicted row of X and calculate the mean rank accuracy of the held out words. Results in Table 2 show that we can recreate the withheld corpus data using brain activation data. Peak mean rank accuracy (67.37) is attained at $\ell = 500$ latent dimensions. This result shows that neural semantic representations can create a latent representation that is faithful to unseen corpus statistics, providing further evidence that the two data sources share a strong common element.

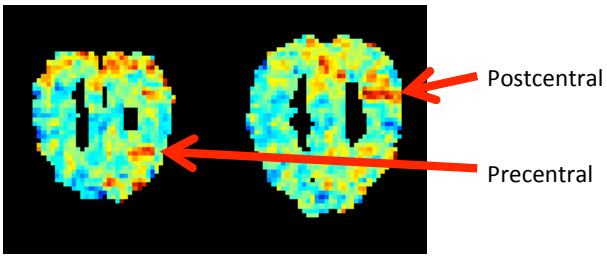
How much power is the remaining corpus data supplying in scenarios where we withhold corpus data? To answer this question, we trained an NNSE(Brain) model on 30 words of brain activation, and then trained a regressor to predict corpus data from those latent brain-only representations. We use the trained regressor to predict the corpus data for the remaining 30 words. Peak performance is attained at $\ell = 10$ latent dimensions, giving mean rank accuracy of 62.37, significantly worse than the model that includes both corpus and brain activation data (67.37).

5.4 Mapping Semantics onto the Brain

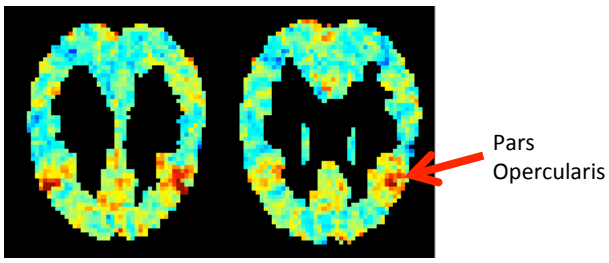
Because our method incorporates brain data into an interpretable semantic model, we can directly map semantic concepts onto the brain. To do this, we examined the mappings from the latent space to the brain space via $D^{(b)}$. We found that the most interpretable mappings come from mod-



(a) $D^{(b)}$ matrix, subject P3, dimension with top words bathroom, balcony, kitchen. MNI coordinates z=-12 (left) and z=-18 (right). Fusiform is associated with shelter words.



(b) $D^{(b)}$ matrix; subject P1; dimension with top words ankle, elbow, knee. MNI coordinates z=60 (left) and z=54 (right). Pre- and post-central areas are activated for body part words.



(c) $D^{(b)}$ matrix; subject P1; dimension with top scoring words buffet, brunch, lunch. MNI coordinates z=30 (left) and z=24 (right). Pars opercularis is believed to be part of the gustatory cortex, which responds to food related words.

Figure 4: The mappings ($D^{(b)}$) from latent semantic space (A) to brain space (Y) for fMRI and words from three semantic categories. Shown are representations of the fMRI slices such that the back of the head is at the top of the image, the front of the head is at the bottom.

els where the perceptual features had been scaled down (divided by a constant factor), which encourages more of the data to be explained by the semantic features in A. Figure 4 shows the mappings ($D^{(b)}$) for dimensions related to shelter, food and body parts. The red areas align with areas of the brain previously known to be activated by the corresponding concepts (Mitchell et al., 2008; Just et al., 2010). Our model has learned these mappings in an unsupervised setting by relating semantic knowledge gleaned from word usage to patterns of activation in the brain. This illustrates how the interpretability of JNNSE can allow one to explore semantics in the human brain. The mappings for one subject are available for download (`http://www.cs.cmu.edu/~afyshe/papers/acl2014/`).

6 Future Work and Conclusion

We are interested in pursuing many future projects inspired by the success of this model. We would like to extend the JNNSE algorithm to incorporate data from multiple subjects, multiple modalities and multiple experiments with non-overlapping words. Including behavioral data and image data is another possibility.

We have explored a model of semantics that incorporates text and brain activation data. Though the number of words for which we have brain activation data is comparatively small, we have shown that including even this small amount of data has a positive impact on the learned latent representations, including for words without brain data. We have provided evidence that the latent representations are closer to the neural representation of semantics, and possibly, closer to semantic ground truth. Our results reveal that there are aspects of semantics not currently represented in text-based VSMs, indicating that there may be room for improvement in either the data or algorithms used to create VSMs. Our findings also indicate that using the brain as a semantic test can separate models that capture this additional semantic information from those that do not. Thus, the brain is an important source of both training and testing data.

Single-Agent vs. Multi-Agent Techniques for Concurrent Reinforcement Learning of Negotiation Dialogue Policies

Kallirroi Georgila, Claire Nelson, David Traum

Abstract

We use single-agent and multi-agent Reinforcement Learning (RL) for learning dialogue policies in a resource allocation negotiation scenario. Two agents learn concurrently by interacting with each other without any need for simulated users (SUs) to train against or corpora to learn from. In particular, we compare the Q-learning, Policy Hill-Climbing (PHC) and Win or Learn Fast Policy Hill-Climbing (PHC-WoLF) algorithms, varying the scenario complexity (state space size), the number of training episodes, the learning rate, and the exploration rate. Our results show that generally Q-learning fails to converge whereas PHC and PHC-WoLF always converge and perform similarly. We also show that very high gradually decreasing exploration rates are required for convergence. We conclude that multi-agent RL of dialogue policies is a promising alternative to using single-agent RL and SUs or learning directly from corpora.

1 Introduction

The dialogue policy of a dialogue system decides on which actions the system should perform given a particular dialogue state (i.e., dialogue context). Building a dialogue policy can be a challenging task especially for complex applications. For this reason, recently much attention has been drawn to machine learning approaches to dialogue management and in particular Reinforcement Learning (RL) of dialogue policies (Williams and Young, 2007; Rieser et al., 2011; Jurčíček et al., 2012).

Typically there are three main approaches to the problem of learning dialogue policies using RL: (1) learn against a simulated user (SU), i.e., a model that simulates the behavior of a real user (Georgila et al., 2006; Schatzmann et al., 2006); (2) learn directly from a corpus (Henderson et al., 2008; Li et al., 2009); or (3) learn via live interaction with human users (Singh et al., 2002; Gašić et al., 2011; Gašić et al., 2013).

We propose a fourth approach: concurrent learning of the system policy and the SU policy using multi-agent RL techniques. Both agents are trained simultaneously and there is no need for building a SU separately or having access to a corpus.[1] As we discuss below, concurrent learning could potentially be used for learning via live interaction with human users. Moreover, for negotiation in particular there is one more reason in favor of concurrent learning as opposed to learning against a SU. Unlike slot-filling domains, in negotiation the behaviors of the system and the user are symmetric. They are both negotiators, thus building a good SU is as difficult as building a good system policy.

So far research on using RL for dialogue policy learning has focused on single-agent RL techniques. Single-agent RL methods make the assumption that the system learns by interacting with a stationary environment, i.e., an environment that does not change over time. Here the environment is the user. Generally the assumption that users do not significantly change their behavior over time holds for simple information providing tasks (e.g., reserving a flight). But this is not necessarily the case for other genres of dialogue, including negotiation. Imagine a situation where a negotiator is so uncooperative and arrogant that the other negotiators decide to completely change their negotiation strategy in order to punish her. Therefore it is important to investigate RL approaches that do not make such assumptions about the user/environment.

[1] Though corpora or SUs may still be useful for bootstrapping the policies and encoding real user behavior (see section 6).

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 500–510,
Baltimore, Maryland, USA, June 23-25 2014.

Multi-agent RL is designed to work for non-stationary environments. In this case the environment of a learning agent is one or more other agents that can also be learning at the same time. Therefore, unlike single-agent RL, multi-agent RL can handle changes in user behavior or in the behavior of other agents participating in the interaction, and thus potentially lead to more realistic dialogue policies in complex dialogue scenarios. This ability of multi-agent RL can also have important implications for learning via live interaction with human users. Imagine a system that learns to change its strategy as it realizes that a particular user is no longer a novice user, or that a user no longer cares about five star restaurants.

We apply multi-agent RL to a resource allocation negotiation scenario. Two agents with different preferences negotiate about how to share resources. We compare Q-learning (a single-agent RL algorithm) with two multi-agent RL algorithms: Policy Hill-Climbing (PHC) and Win or Learn Fast Policy Hill-Climbing (PHC-WoLF) (Bowling and Veloso, 2002). We vary the scenario complexity (i.e., the quantity of resources to be shared and consequently the state space size), the number of training episodes, the learning rate, and the exploration rate.

Our research contributions are as follows: (1) we propose concurrent learning using multi-agent RL as a way to deal with some of the issues of current approaches to dialogue policy learning (i.e., the need for SUs and corpora), which may also potentially prove useful for learning via live interaction with human users; (2) we show that concurrent learning can address changes in user behavior over time, and requires multi-agent RL techniques and variable exploration rates; (3) to our knowledge this is the first time that PHC and PHC-WoLF are used for learning dialogue policies; (4) for the first time, the above techniques are applied to a negotiation domain; and (5) this is the first study that compares Q-learning, PHC, and PHC-WoLF in such a variety of situations (varying a large number of parameters).

The paper is structured as follows. Section 2 presents related work. Section 3 provides a brief introduction to single-agent RL and multi-agent RL. Section 4 describes our negotiation domain and experimental setup. In section 5 we present our results. Finally, section 6 concludes and provides some ideas for future work.

2 Related Work

Most research in RL for dialogue management has been done in the framework of slot-filling applications such as restaurant recommendations (Lemon et al., 2006; Thomson and Young, 2010; Gašić et al., 2012; Daubigney et al., 2012), flight reservations (Henderson et al., 2008), sightseeing recommendations (Misu et al., 2010), appointment scheduling (Georgila et al., 2010), etc. RL has also been applied to question-answering (Misu et al., 2012), tutoring domains (Tetreault and Litman, 2008; Chi et al., 2011), and learning negotiation dialogue policies (Heeman, 2009; Georgila and Traum, 2011; Georgila, 2013).

As mentioned in section 1, there are three main approaches to the problem of learning dialogue policies using RL.

In the first approach, a SU is hand-crafted or learned from a small corpus of human-human or human-machine dialogues. Then the dialogue policy can be learned by having the system interact with the SU for a large number of dialogues (usually thousands of dialogues). Depending on the application, building a realistic SU can be just as difficult as building a good dialogue policy. Furthermore, it is not clear what constitutes a good SU for dialogue policy learning. Should the SU resemble real user behavior as closely as possible, or should it exhibit some degree of randomness to explore a variety of interaction patterns? Despite much research on the issue, these are still open questions (Schatzmann et al., 2006; Ai and Litman, 2008; Pietquin and Hastie, 2013).

In the second approach, no SUs are required. Instead the dialogue policy is learned directly from a corpus of human-human or human-machine dialogues. For example, Henderson et al. (2008) used a combination of RL and supervised learning to learn a dialogue policy in a flight reservation domain, whereas Li et al. (2009) used Least-Squares Policy Iteration (Lagoudakis and Parr, 2003), an RL-based technique that can learn directly from corpora, in a voice dialer application. However, collecting such corpora is not trivial, especially in new domains. Typically, data are collected in a Wizard-of-Oz setup where human users think that they interact with a system while in fact they interact with a human pretending to be the system, or by having human users interact with a preliminary version of the dialogue system. In both cases the resulting interactions are expected to be quite dif-

ferent from the interactions of human users with the final system. In practice this means that dialogue policies learned from such data could be far from optimal.

The first experiment on learning via live interaction with human users (third approach) was reported by Singh et al. (2002). They used RL to help the system with two choices: how much initiative it should allow the user, and whether or not to confirm information provided by the user. Recently, learning of "full" dialogue policies (not just choices at specific points in the dialogue) via live interaction with human users has become possible with the use of Gaussian processes (Engel et al., 2005; Rasmussen and Williams, 2006). Typically learning a dialogue policy is a slow process requiring thousands of dialogues, hence the need for SUs. Gaussian processes have been shown to speed up learning. This fact together with easy access to a large number of human users through crowd-sourcing has allowed dialogue policy learning via live interaction with human users (Gašić et al., 2011; Gašić et al., 2013).

Space constraints prevent us from providing an exhaustive list of previous work on using RL for dialogue management. Thus below we focus only on research that is directly related to our work, specifically research on concurrent learning of the policies of multiple agents, and the application of RL to negotiation domains.

So far research on RL in the dialogue community has focused on using single-agent RL techniques where the stationary environment is the user. Most approaches assume that the user goal is fixed and that the behavior of the user is rational. Other approaches account for changes in user goals (Ma, 2013). In either case, one can build a user simulation model that is the average of different user behaviors or learn a policy from a corpus that contains a variety of interaction patterns, and thus safely assume that single-agent RL techniques will work. However, in the latter case if the behavior of the user changes significantly over time then the assumption that the environment is stationary will no longer hold.

There has been a lot of research on multi-agent RL in the optimal control and robotics communities (Littman, 1994; Hu and Wellman, 1998; Busoniu et al., 2008). Here two or more agents learn simultaneously. Thus the environment of an agent is one or more other agents that continuously change their behavior because they are also learning at the same time. Therefore the environment is no longer stationary and single-agent RL techniques do not work well or do not work at all. We are particularly interested in the work of Bowling and Veloso (2002) who proposed the PHC and PHC-WoLF algorithms that we use in this paper. We chose these two algorithms because, unlike other multi-agent RL methods (Littman, 1994; Hu and Wellman, 1998), they do not make assumptions that do not always hold and do not require quadratic or linear programming that does not always scale.

English and Heeman (2005) were the first in the dialogue community to explore the idea of concurrent learning of dialogue policies. However, English and Heeman (2005) did not use multi-agent RL but only standard single-agent RL, in particular an on-policy Monte Carlo method (Sutton and Barto, 1998). But single-agent RL techniques are not well suited for concurrent learning where each agent is trained against a continuously changing environment. Indeed, English and Heeman (2005) reported problems with convergence. Chandramohan et al. (2012) proposed a framework for co-adaptation of the dialogue policy and the SU using single-agent RL. They applied Inverse Reinforcement Learning (IRL) (Abbeel and Ng, 2004) to a corpus in order to learn the reward functions of both the system and the SU. Furthermore, Cuayáhuitl and Dethlefs (2012) used hierarchical multi-agent RL for co-ordinating the verbal and non-verbal actions of a robot. Cuayáhuitl and Dethlefs (2012) did not use PHC or PHC-WoLF and did not compare against single-agent RL methods.

With regard to using RL for learning negotiation policies, the amount of research that has been performed is very limited compared to slot-filling. English and Heeman (2005) learned negotiation policies for a furniture layout task. Then Heeman (2009) extended this work by experimenting with different representations of the RL state in the same domain (this time learning against a hand-crafted SU). In both cases, to reduce the search space, the RL state included only information about e.g., whether there was a pending proposal rather than the actual value of this proposal. Paruchuri et al. (2009) performed a theoretical study on how Partially Observable Markov Decision Processes (POMDPs) can be applied to negotiation domains.

Georgila and Traum (2011) built argumentation dialogue policies for negotiation against users of different cultural norms in a one-issue negotiation scenario. To learn these policies they trained SUs on a spoken dialogue corpus in a florist-grocer negotiation domain, and then tweaked these SUs towards a particular cultural norm using hand-crafted rules. Georgila (2013) learned argumentation dialogue policies from a simulated corpus in a two-issue negotiation scenario (organizing a party). Finally, Nouri et al. (2012) used IRL to learn a model for cultural decision-making in a simple negotiation game (the Ultimatum Game).

3 Single-Agent vs. Multi-Agent Reinforcement Learning

Reinforcement Learning (RL) is a machine learning technique used to learn the policy of an agent, i.e., which action the agent should perform given its current state (Sutton and Barto, 1998). The goal of an RL-based agent is to maximize the reward it gets during an interaction. Because it is very difficult for the agent to know what will happen in the rest of the interaction, the agent must select an action based on the average reward it has previously observed after having performed that action in similar contexts. This average reward is called *expected future reward*. Single-agent RL is used in the framework of Markov Decision Processes (MDPs) (Sutton and Barto, 1998) or Partially Observable Markov Decision Processes (POMDPs) (Williams and Young, 2007). Here we focus on MDPs.

An MDP is defined as a tuple (S, A, T, R, γ) where S is the set of states (representing different contexts) which the agent may be in, A is the set of actions of the agent, T is the transition function $S \times A \times S \rightarrow$ [0, 1] which defines a set of transition probabilities between states after taking an action, R is the reward function $S \times A \rightarrow \Re$ which defines the reward received when taking an action from the given state, and γ is a factor that discounts future rewards. Solving the MDP means finding a policy $\pi : S \rightarrow A$. The quality of the policy π is measured by the expected discounted (with discount factor γ) future reward also called Q-value, $Q^{\pi} : S \times A \rightarrow \Re$.

A *stochastic game* is defined as a tuple (n, S, $A_{1...n}$, T, $R_{1...n}$, γ) where n is the number of agents, S is the set of states, A_i is the set of actions available for agent i (and A is the joint action space $A_1 \times A_2 \times ... \times A_n$), T is the transition function $S \times A \times S \rightarrow$ [0, 1] which defines a set of transition probabilities between states after taking a joint action, R_i is the reward function for the ith agent $S \times A \rightarrow \Re$, and γ is a factor that discounts future rewards. The goal is for each agent i to learn a mixed policy $\pi_i : S \times A_i \rightarrow$ [0, 1] that maps states to mixed strategies, which are probability distributions over the agent's actions, so that the agent's expected discounted (with discount factor γ) future reward is maximized.

Stochastic games are a generalization of MDPs for multi-agent RL. In stochastic games there are many agents that select actions and the next state and rewards depend on the joint action of all these agents. The agents can have different reward functions. Partially Observable Stochastic Games (POSGs) are the equivalent of POMDPs for multi-agent RL. In POSGs, the agents have different observations, and uncertainty about the state they are in and the beliefs of their interlocutors. POSGs are very hard to solve but new algorithms continuously emerge in the literature.

In this paper we use three algorithms: Q-learning, Policy Hill-Climbing (PHC), and Win or Learn Fast Policy Hill-Climbing (PHC-WoLF). PHC is an extension of Q-learning. For all three algorithms, Q-values are updated as follows:

$$Q(s,a) \leftarrow (1-\alpha)Q(s,a)+\alpha\left(r+\gamma \text{max}_{a'}Q(s^{'},a^{'})\right) \quad (1)$$

In Q-learning, for a given state s, the agent performs the action with the highest Q-value for that state. In addition to Q-values, PHC and PHC-WoLF also maintain the current mixed policy $\pi(s,a)$. In each step the mixed policy is updated by increasing the probability of selecting the highest valued action according to a learning rate δ (see equations (2), (3), and (4) below).

$$\pi(s,a) \leftarrow \pi(s,a) + \Delta_{sa} \quad (2)$$

$$\Delta_{sa} = \begin{cases} -\delta_{sa} & \text{if } a \neq \text{argmax}_{a'}Q(s,a^{'}) \\ \Sigma_{a' \neq a}\delta_{sa'} & \text{otherwise} \end{cases} \quad (3)$$

$$\delta_{sa} = \min\left(\pi(s,a), \frac{\delta}{|A_i|-1}\right) \quad (4)$$

The difference between PHC and PHC-WoLF is that PHC uses a constant learning rate δ whereas

PHC-WoLF uses a variable learning rate (see equation (5) below). The main idea is that when the agent is "winning" the learning rate δ_W should be low so that the opponents have more time to adapt to the agent's policy, which helps with convergence. On the other hand when the agent is "losing" the learning rate δ_{LF} should be high so that the agent has more time to adapt to the other agents' policies, which also facilitates convergence. Thus PHC-WoLF uses two learning rates δ_W and δ_{LF}. PHC-WoLF determines whether the agent is "winning" or "losing" by comparing the current policy's $\pi(s,a)$ expected payoff with that of the average policy $\tilde{\pi}(s,a)$ over time. If the current policy's expected payoff is greater then the agent is "winning", otherwise it is "losing".

$$\delta = \begin{cases} \delta_W & \text{if } \begin{cases} \Sigma_{\alpha'} \pi(s,\alpha') Q(s,\alpha') > \\ \Sigma_{\alpha'} \tilde{\pi}(s,\alpha') Q(s,\alpha') \end{cases} \\ \delta_{LF} & \text{otherwise} \end{cases} \quad (5)$$

More details about Q-learning, PHC, and PHC-WoLF can be found in (Sutton and Barto, 1998; Bowling and Veloso, 2002).

As discussed in sections 1 and 2, single-agent RL techniques, such as Q-learning, are not suitable for multi-agent RL. Nevertheless, despite its shortcomings Q-learning has been used successfully for multi-agent RL (Claus and Boutilier, 1998). Indeed, as we see in section 5, Q-learning can converge to the optimal policy for small state spaces. However, as the state space size increases the performance of Q-learning drops (compared to PHC and PHC-WoLF).

4 Domain and Experimental Setup

Our domain is a resource allocation negotiation scenario. Two agents negotiate about how to share resources. For the sake of readability from now on we will refer to apples and oranges.

The two agents have different goals. Also, they have human-like constraints of imperfect information about each other; they do not know each other's reward function or degree of rationality (during learning our agents can be irrational). Thus a Nash equilibrium (if there exists one) cannot be computed in advance. Agent 1 cares more about apples and Agent 2 cares more about oranges. Table 1 shows the points that Agents 1 and 2 earn for each apple and each orange that they have at the end of the negotiation.

	Agent 1	**Agent 2**
apple	300	200
orange	200	300

Table 1: Points earned by Agents 1 and 2 for each apple and each orange that they have at the end of the negotiation.

Agent 1: offer-2-2 (I offer you 2 A and 2 O)
Agent 2: offer-3-0 (I offer you 3 A and 0 O)
Agent 1: offer-0-3 (I offer you 0 A and 3 O)
Agent 2: offer-4-0 (I offer you 4 A and 0 O)
Agent 1: accept (I accept your offer)

Figure 1: Example interaction between Agents 1 and 2 (A: apples, O: oranges).

We use a simplified dialogue model with two types of speech acts: offers and acceptances. The dialogue proceeds as follows: one agent makes an offer, e.g., "I give you 3 apples and 1 orange", and the other agent may choose to accept it or make a new offer. The negotiation finishes when one of the agents accepts the other agent's offer or time runs out.

We compare Q-learning with PHC and PHC-WoLF. For all algorithms and experiments each agent is rewarded only at the end of the dialogue based on the negotiation outcome (see Table 1). Thus the two agents have different reward functions. There is also a penalty of -10 for each agent action to ensure that dialogues are not too long. Also, to avoid long dialogues, if none of the agents accepts the other agent's offers, the negotiation finishes after 20 pairs of exchanges between the two agents (20 offers from Agent 1 and 20 offers from Agent 2).

An example interaction between the two agents is shown in Figure 1. As we can see, each agent can offer any combination of apples and oranges. So if we have X apples and Y oranges for sharing, there can be $(X+1) \times (Y+1)$ possible offers. For example if we have 2 apples and 2 oranges for sharing, there can be 9 possible offers: "offer-0-0", "offer-0-1", ..., "offer-2-2". For our experiments we vary the number of fruits to be shared and choose to keep X equal to Y.

Table 2 shows our state representation, i.e., the state variables that we keep track of with all the possible values they can take, where X is the num-

Current offer: $(X + 1) \times (Y + 1)$ possible values
How many times the current offer has already been rejected: (0, 1, 2, 3, or 4)
Is the current offer accepted: yes, no

Table 2: State variables.

ber of apples and Y is the number of oranges to be shared. The third variable is always set to "no" until one of the agents accepts the other agent's offer.

Table 3 shows the state and action space sizes for different numbers of apples and oranges to be shared used in our experiments below. The number of actions includes the acceptance of an offer. Table 3 also shows the number of state-action pairs (Q-values). As we will see in section 5, even though the number of states for each agent is not large, it takes many iterations and high exploration rates for convergence due to the fact that both agents are learning at the same time and the assumption of interacting with a stationary environment no longer holds. For comparison, in (English and Heeman, 2005) the state specification for each agent included 5 binary variables resulting in 32 possible states. English and Heeman (2005) kept track of whether there was an offer on the table but not of the actual value of the offer. For our task it is essential to keep track of the offer values, which of course results in much larger state spaces. Also, in (English and Heeman, 2005) there were 5 possible actions resulting in 160 state-action pairs. Our state and action spaces are much larger and furthermore we explore the effect of different state and action space sizes on convergence.

During learning the two agents interact for 5 epochs. Each epoch contains N number of episodes. We vary N from 25,000 up to 400,000 with a step of 25,000 episodes. English and Heeman (2005) trained their agents for 200 epochs, where each epoch contained 200 episodes.

We also vary the exploration rate per epoch. In particular, in the experiments reported in section 5.1 the exploration rate is set as follows: 0.95 for epoch 1, 0.8 for epoch 2, 0.5 for epoch 3, 0.3 for epoch 4, and 0.1 for epoch 5. Section 5.2 reports results again with 5 epochs of training but a constant exploration rate per epoch set to 0.3. An exploration rate of 0.3 means that 30% of the time the agent will select an action randomly.

Finally, we vary the learning rate. For PHC-WoLF we set δ_W = 0.05 and δ_{LF} = 0.2 (see section 3). These values were chosen with experimentation and the basic idea is that the agent should learn faster when "losing" and slower when "winning". For PHC we explore two cases. In the first case which from now on will be referred to as PHC-W, we set δ to be equal to δ_W (also used for PHC-WoLF). In the second case which from now on will be referred to as PHC-LF, we set δ to be equal to δ_{LF} (also used for PHC-WoLF). So unlike PHC-WoLF, PHC-W and PHC-LF do not use a variable learning rate. PHC-W always learns slowly and PHC-LF always learns fast.

	#States	**#Actions**	**#State-Action Pairs**
1 A & O	40	5	200
2 A & O	90	10	900
3 A & O	160	17	2720
4 A & O	250	26	6500
5 A & O	360	37	13320
6 A & O	490	50	24500
7 A & O	640	65	41600

Table 3: State space, action space, and state-action space sizes for different numbers of apples and oranges to be shared (A: apples, O: oranges).

In all the above cases, training stops after 5 epochs. Then we test the learned policies against each other for one more epoch the size of which is the same as the size of the epochs used for training. For example, if the policies were learned for 5 epochs with each epoch containing 25,000 episodes, then for testing the two policies will interact for another 25,000 episodes. For comparison, English and Heeman (2005) had their agents interact for 5,000 dialogues during testing. To ensure that the policies do not converge by chance, we run the training and test sessions 20 times each and we report averages. Thus all results presented in section 5 are averages of 20 runs.

5 Results

Given that Agent 1 is more interested in apples and Agent 2 cares more about oranges, the maximum total utility solution would be the case where each agent offers to get all the fruits it cares about and to give its interlocutor all the fruits it does not care about, and the other agent accepts this offer. Thus, when converging to the maximum total utility solution, in the case of 4 fruits (4 ap-

ples and 4 oranges), the average reward of the two agents should be 1200 minus 10 for making or accepting an offer. For 5 fruits the average reward should be 1500 minus 10, and so forth. We call 1200 (or 1500) the *convergence reward*, i.e., the reward after converging to the maximum total utility solution if we do not take into account the action penalty. For example, in the case of 4 fruits, if Agent 1 starts the negotiation, after converging to the maximum total utility solution the optimal interaction should be: Agent 1 makes an offer to Agent 2, namely 0 apples and 4 oranges, and Agent 2 accepts. Thus the reward for Agent 1 is 1190, the reward for Agent 2 is 1190, and the average reward of the two agents is also 1190. Also, the convergence reward for Agent 1 is 1200 and the convergence reward for Agent 2 is also 1200.

Below, in all the graphs that we provide, we show the average distance from the convergence reward. This is to make all graphs comparable because in all cases the optimal average distance from the convergence reward of the two agents should be equal to 10 (make the optimal offer or accept the optimal offer that the other agent makes). The formulas for calculating the average distance from the convergence reward are:

$$AD_1 = \frac{\sum_{j=1}^{n_r} |CR_1 - R_{1j}|}{n_r} \quad (6)$$

$$AD_2 = \frac{\sum_{j=1}^{n_r} |CR_2 - R_{2j}|}{n_r} \quad (7)$$

$$AD = \frac{AD_1 + AD_2}{2} \quad (8)$$

where CR_1 is the convergence reward for Agent 1, R_{1j} is the reward of Agent 1 for run j, CR_2 is the convergence reward for Agent 2, and R_{2j} is the reward of Agent 2 for run j. Moreover, AD_1 is the average distance from the convergence reward for Agent 1, AD_2 is the average distance from the convergence reward for Agent 2, and AD is the average of AD_1 and AD_2. All graphs of section 5 show AD values. Also, n_r is the number of runs (in our case always equal to 20). Thus in the case of 4 fruits, we will have CR_1=CR_2=1200, and if for all runs R_{1j}=R_{2j}=1190, then AD=10.

5.1 Variable Exploration Rate

In this section we report results with different exploration rates per training epoch (see section 4).

	Q-learning	**PHC-LF**	**PHC-W**	**PHC-WoLF**
1 A & O	10.5	10	10	10
2 A & O	10.3	10.3	10	10
3 A & O	11.7	10	10	10
4 A & O	15	11.8	11.7	11.7
5 A & O	45.4	29.5	26.5	22.9
6 A & O	60.8	33.4	46.1	33.9
7 A & O	95	56	187.8	88.6

Table 4: Average distance from convergence reward over 20 runs for 100,000 episodes per epoch and for different numbers of fruits to be shared (A: apples, O: oranges). The best possible value is 10.

Table 4 shows the average distance from the convergence reward over 20 runs for 100,000 episodes per epoch, for different numbers of fruits, and for all four methods (Q-learning, PHC-LF, PHC-W, and PHC-WoLF). It is clear that as the state space becomes larger 100,000 training episodes per epoch are not enough for convergence. Also, for 1, 2, and 3 fruits all algorithms converge and perform comparably. As the number of fruits increases, Q-learning starts performing worse than the multi-agent RL algorithms. For 7 fruits PHC-W appears to perform worse than Q-learning but this is because, as we can see in Figure 5, in this case more than 400,000 episodes per epoch are required for convergence. Thus after only 100,000 episodes per epoch all policies still behave somewhat randomly.

Figures 2, 3, 4, and 5 show the average distance from the convergence reward as a function of the number of episodes per epoch during training, for 4, 5, 6, and 7 fruits respectively. For 4 fruits it takes about 125,000 episodes per epoch and for 5 fruits it takes about 225,000 episodes per epoch for the policies to converge. This number rises to approximately 350,000 for 6 fruits and becomes even higher for 7 fruits. Q-learning consistently performs worse than the rest of the algorithms. The differences between PHC-LF, PHC-W, and PHC-WoLF are insignificant, which is a bit surprising given that Bowling and Veloso (2002) showed that PHC-WoLF performed better than PHC in a series of benchmark tasks. In Figures 2 and 3, PHC-LF appears to be reaching convergence slightly faster than PHC-W and PHC-WoLF but this is not statistically significant.

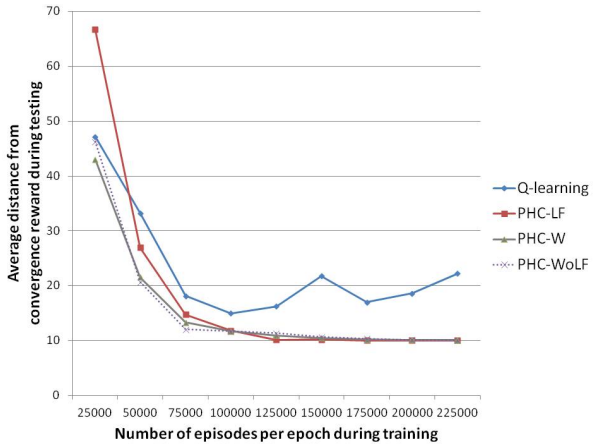

Figure 2: 4 fruits and variable exploration rate: Average distance from convergence reward during testing (20 runs). The best possible value is 10.

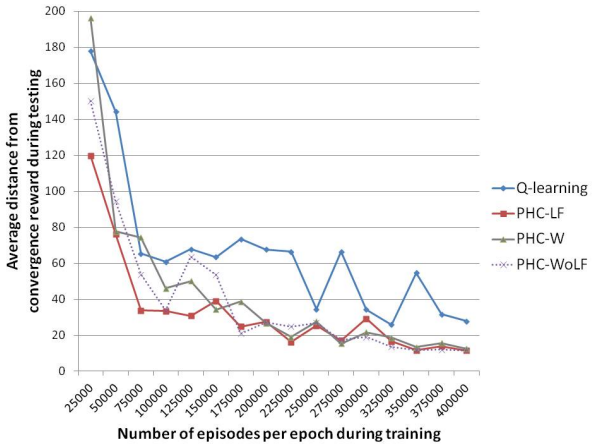

Figure 4: 6 fruits and variable exploration rate: Average distance from convergence reward during testing (20 runs). The best possible value is 10.

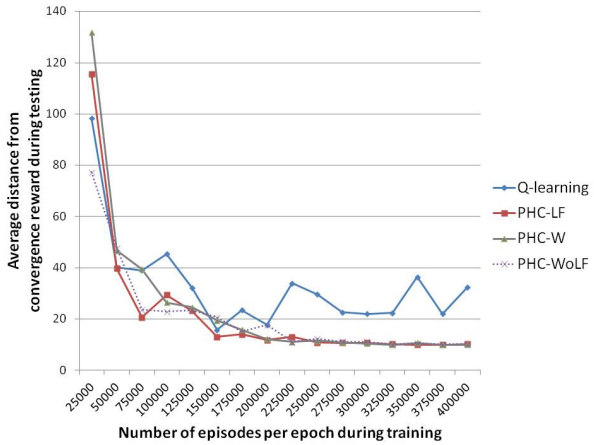

Figure 3: 5 fruits and variable exploration rate: Average distance from convergence reward during testing (20 runs). The best possible value is 10.

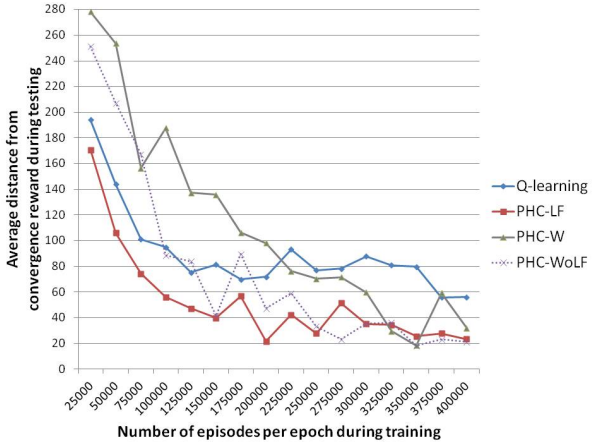

Figure 5: 7 fruits and variable exploration rate: Average distance from convergence reward during testing (20 runs). The best possible value is 10.

5.2 Constant Exploration Rate

In this section we report results with a constant exploration rate for all training epochs (see section 4). Figures 6 and 7 show the average distance from the convergence reward as a function of the number of episodes per epoch during training, for 4 and 5 fruits respectively. Clearly having a constant exploration rate in all epochs is problematic. For 4 fruits, after 225,000 episodes per epoch there is still no convergence. For comparison, with a variable exploration rate it took about 125,000 episodes per epoch for the policies to converge. Likewise for 5 fruits. After 400,000 episodes per epoch there is still no convergence. For comparison, with a variable exploration rate it took about 225,000 episodes per epoch for convergence.

The above results show that, unlike single-agent RL where having a constant exploration rate is perfectly acceptable, here a constant exploration rate does not work.

6 Conclusion and Future Work

We used single-agent RL and multi-agent RL for learning dialogue policies in a resource allocation negotiation scenario. Two agents interacted with each other and both learned at the same time. The advantage of this approach is that it does not require SUs to train against or corpora to learn from.

We compared a traditional single-agent RL algorithm (Q-learning) against two multi-agent RL algorithms (PHC and PHC-WoLF) varying the scenario complexity (state space size), the number

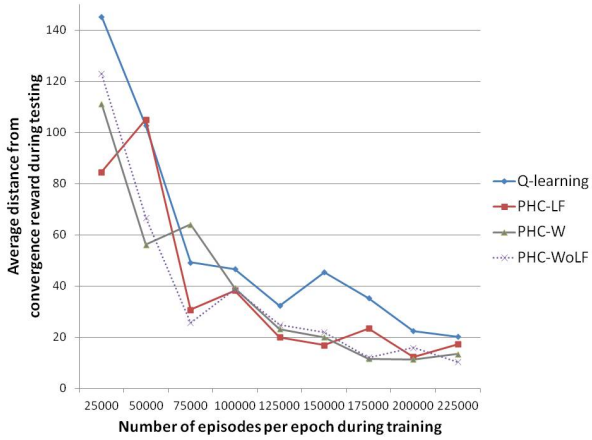

Figure 6: 4 fruits and constant exploration rate: Average distance from convergence reward during testing (20 runs). The best possible value is 10.

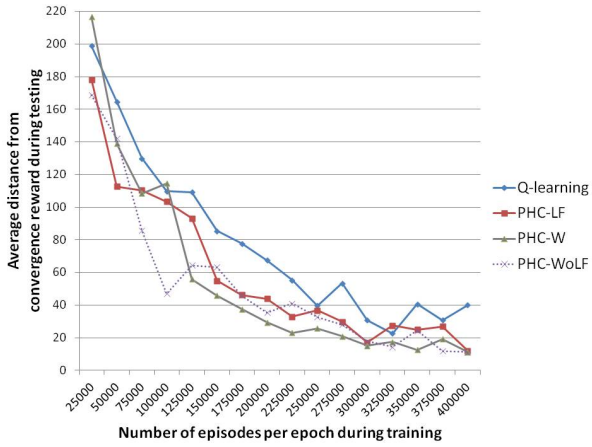

Figure 7: 5 fruits and constant exploration rate: Average distance from convergence reward during testing (20 runs). The best possible value is 10.

of training episodes, and the learning and exploration rates. Our results showed that Q-learning is not suitable for concurrent learning given that it is designed for learning against a stationary environment. Q-learning failed to converge in all cases, except for very small state space sizes. On the other hand, both PHC and PHC-WoLF always converged (or in the case of 7 fruits they needed more training episodes) and performed similarly. We also showed that in concurrent learning very high gradually decreasing exploration rates are required for convergence. We conclude that multi-agent RL of dialogue policies is a promising alternative to using single-agent RL and SUs or learning directly from corpora.

The focus of this paper is on comparing single-agent RL and multi-agent RL for concurrent learning, and studying the implications for convergence and exploration/learning rates. Our next step is testing with human users. We are particularly interested in users whose behavior changes during the interaction and continuous testing against expert repeat users, which has never been done before. Another interesting question is whether corpora or SUs may still be required for designing the state and action spaces and the reward functions of the interlocutors, bootstrapping the policies, and ensuring that information about the behavior of human users is encoded in the resulting learned policies. Gašić et al. (2013) showed that it is possible to learn "full" dialogue policies just via interaction with human users (without any bootstrapping using corpora or SUs). Similarly, concurrent learning could be used in an on-line fashion via live interaction with human users. Or alternatively concurrent learning could be used off-line to bootstrap the policies and then these policies could be improved via live interaction with human users (again using concurrent learning to address possible changes in user behavior). These are open research questions for future work.

Furthermore, we intend to apply multi-agent RL to more complex negotiation domains, e.g., experiment with more than two types of resources (not just apples and oranges) and more types of actions (not just offers and acceptances). We would also like to compare policies learned with multi-agent RL techniques with policies learned with SUs or from corpora both in simulation and with human users. Finally, we aim to experiment with different feature-based representations of the state and action spaces. Currently all possible deal combinations are listed as possible actions and as elements of the state, which can quickly lead to very large state and action spaces as the application becomes more complex (in our case as the number of fruits increases). However, abstraction is not trivial because the agents have no guarantee that the value of a deal is a simple function of the value of its parts, and values may differ for different agents.

Acknowledgments

Claire Nelson sadly died in May 2013. We continued and completed this work after her passing away. She is greatly missed. This work was funded by the NSF grant #1117313.

Abstract

Text-level discourse parsing remains a challenge. The current state-of-the-art overall accuracy in relation assignment is 55.73%, achieved by Joty et al. (2013). However, their model has a high order of time complexity, and thus cannot be applied in practice. In this work, we develop a much faster model whose time complexity is linear in the number of sentences. Our model adopts a greedy bottom-up approach, with two linear-chain CRFs applied in cascade as local classifiers. To enhance the accuracy of the pipeline, we add additional constraints in the Viterbi decoding of the first CRF. In addition to efficiency, our parser also significantly outperforms the state of the art. Moreover, our novel approach of post-editing, which modifies a fully-built tree by considering information from constituents on upper levels, can further improve the accuracy.

1 Introduction

Discourse parsing is the task of identifying the presence and the type of the discourse relations between discourse units. While research in discourse parsing can be partitioned into several directions according to different theories and frameworks, Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) is probably the most ambitious one, because it aims to identify not only the discourse relations in a small local context, but also the hierarchical tree structure for the **full text**: from the relations relating the smallest discourse units (called elementary discourse units, EDUs), to the ones connecting paragraphs.

For example, Figure 1 shows a text fragment consisting of two sentences with four EDUs in total (e_1-e_4). Its discourse tree representation is shown below the text, following the notation convention of RST: the two EDUs e_1 and e_2 are related by a mononuclear relation CONSEQUENCE, where e_2 is the more salient span (called *nucleus*, and e_1 is called *satellite*); e_3 and e_4 are related by another mononuclear relation CIRCUMSTANCE, with e_4 as the nucleus; the two spans $e_{1:2}$ and $e_{3:4}$ are further related by a multi-nuclear relation SEQUENCE, with both spans as the nucleus.

Conventionally, there are two major sub-tasks related to text-level discourse parsing: (1) **EDU segmentation**: to segment the raw text into EDUs, and (2) **tree-building**: to build a discourse tree from EDUs, representing the discourse relations in the text. Since the first sub-task is considered relatively easy, with the state-of-art accuracy at above 90% (Joty et al., 2012), the recent research focus is on the second sub-task, and often uses manual EDU segmentation.

The current state-of-the-art overall accuracy of the tree-building sub-task, evaluated on the RST Discourse Treebank (RST-DT, to be introduced in Section 8), is 55.73% by Joty et al. (2013). However, as an optimal discourse parser, Joty et al.'s model is highly inefficient in practice, with respect to both their DCRF-based local classifiers, and their CKY-like bottom-up parsing algorithm. DCRF (Dynamic Conditional Random Fields) is a generalization of linear-chain CRFs, in which each time slice contains a set of state variables and edges (Sutton et al., 2007). CKY parsing is a bottom-up parsing algorithm which searches all possible parsing paths by dynamic programming. Therefore, despite its superior performance, their model is infeasible in most realistic situations.

The main objective of this work is to develop a more efficient discourse parser, with similar or even better performance with respect to Joty et al.'s optimal parser, but able to produce parsing results in real time.

Our contribution is three-fold. First, with a

greedy bottom-up strategy, we develop a discourse parser with a time complexity linear in the total number of sentences in the document. As a result of successfully avoiding the expensive non-greedy parsing algorithms, our discourse parser is very efficient in practice. Second, by using two linear-chain CRFs to label a sequence of discourse constituents, we can incorporate contextual information in a more natural way, compared to using traditional discriminative classifiers, such as SVMs. Specifically, in the Viterbi decoding of the first CRF, we include additional constraints elicited from common sense, to make more effective local decisions. Third, after a discourse (sub)tree is fully built from bottom up, we perform a novel post-editing process by considering information from the constituents on upper levels. We show that this post-editing can further improve the overall parsing performance.

2 Related work

2.1 HILDA discourse parser

The HILDA discourse parser by Hernault et al. (2010) is the first attempt at RST-style text-level discourse parsing. It adopts a pipeline framework, and greedily builds the discourse tree from the bottom up. In particular, starting from EDUs, at each step of the tree-building, a binary SVM classifier is first applied to determine which pair of adjacent discourse constituents should be merged to form a larger span, and another multi-class SVM classifier is then applied to assign the type of discourse relation that holds between the chosen pair.

The strength of HILDA's greedy tree-building strategy is its efficiency in practice. Also, the employment of SVM classifiers allows the incorporation of rich features for better data representation (Feng and Hirst, 2012). However, HILDA's approach also has obvious weakness: the greedy algorithm may lead to poor performance due to local optima, and more importantly, the SVM classifiers are not well-suited for solving structural problems due to the difficulty of taking context into account.

2.2 Joty et al.'s joint model

Joty et al. (2013) approach the problem of text-level discourse parsing using a model trained by Conditional Random Fields (CRF). Their model has two distinct features.

First, they decomposed the problem of text-level discourse parsing into two stages: intra-sentential parsing to produce a discourse tree for each sentence, followed by multi-sentential parsing to combine the sentence-level discourse trees and produce the text-level discourse tree. Specifically, they employed two separate models for intra- and multi-sentential parsing. Their choice of two-stage parsing is well motivated for two reasons: (1) it has been shown that sentence boundaries correlate very well with discourse boundaries, and (2) the scalability issue of their CRF-based models can be overcome by this decomposition.

Second, they jointly modeled the structure and the relation for a given pair of discourse units. For example, Figure 2 shows their intra-sentential model, in which they use the bottom layer to represent discourse units; the middle layer of binary nodes to predict the connection of adjacent discourse units; and the top layer of multi-class nodes to predict the type of the relation between two units. Their model assigns a probability to each possible constituent, and a CKY-like parsing algorithm finds the globally optimal discourse tree, given the computed probabilities.

The strength of Joty et al.'s model is their joint modeling of the structure and the relation, such that information from each aspect can interact with the other. However, their model has a major defect in its inefficiency, or even infeasibility, for application in practice. The inefficiency lies in both their DCRF-based joint model, on which inference is usually slow, and their CKY-like parsing algorithm, whose issue is more prominent. Due to the $O(n^3)$ time complexity, where n is the number

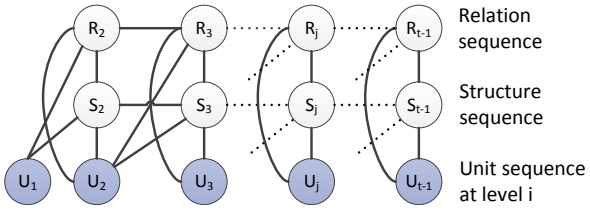

Figure 2: Joty et al. (2013)'s intra-sentential Condition Random Fields.

of input discourse units, for large documents, the parsing simply takes too long[1].

3 Overall work flow

Figure 3 demonstrates the overall work flow of our discourse parser. The general idea is that, similar to Joty et al. (2013), we perform a sentence-level parsing for each sentence first, followed by a text-level parsing to generate a full discourse tree for the whole document. However, in addition to efficiency (to be shown in Section 6), our discourse parser has a distinct feature, which is the post-editing component (to be introduced in Section 5), as outlined in dashes.

Our discourse parser works as follows. A document D is first segmented into a list of sentences. Each sentence S_i, after being segmented into EDUs (not shown in the figure), goes through an intra-sentential bottom-up tree-building model M_{intra}, to form a sentence-level discourse tree T_{S_i}, with the EDUs as leaf nodes. After that, we apply the intra-sentential post-editing model P_{intra} to modify the generated tree T_{S_i} to $T^p_{S_i}$, by considering upper-level information.

We then combine all sentence-level discourse tree $T^p_{S_i}$'s using our multi-sentential bottom-up tree-building model M_{multi} to generate the text-level discourse tree T_D. Similar to sentence-level parsing, we also post-edit T_D using P_{multi} to produce the final discourse tree T^p_D.

[1]The largest document in the RST-DT contains over 180 sentences, i.e., $n > 180$ for their multi-sentential CKY parsing. Intuitively, suppose the average time to compute the probability of each constituent is 0.01 second, then in total, the CKY-like parsing takes over 16 hours. It is possible to optimize Joty et al.'s CKY-like parsing by replacing their CRF-based computation for upper-level constituents with some local computation based on the probabilities of lower-level constituents. However, such optimization is beyond the scope of this paper.

4 Bottom-up tree-building

For both intra- and multi-sentential parsing, our bottom-up tree-building process adopts a similar greedy pipeline framework like the HILDA discourse parser (discussed in Section 2.1), to guarantee efficiency for large documents. In particular, starting from the constituents on the bottom level (EDUs for intra-sentential parsing and sentence-level discourse trees for multi-sentential parsing), at each step of the tree-building, we greedily merge a pair of adjacent discourse constituents such that the merged constituent has the highest probability as predicted by our *structure* model. The *relation* model is then applied to assign the relation to the new constituent.

4.1 Linear-chain CRFs as Local models

Now we describe the local models we use to make decisions for a given pair of adjacent discourse constituents in the bottom-up tree-building. There are two dimensions for our local models: (1) scope of the model: intra- or multi-sentential, and (2) purpose of the model: for determining structures or relations. So we have four local models, M^{struct}_{intra}, M^{rel}_{intra}, M^{struct}_{multi}, and M^{rel}_{multi}.

While our bottom-up tree-building shares the greedy framework with HILDA, unlike HILDA, our local models are implemented using CRFs. In this way, we are able to take into account the sequential information from contextual discourse constituents, which cannot be naturally represented in HILDA with SVMs as local classifiers. Therefore, our model incorporates the strengths of both HILDA and Joty et al.'s model, i.e., the efficiency of a greedy parsing algorithm, and the ability to incorporate sequential information with CRFs.

As shown by Feng and Hirst (2012), for a pair of discourse constituents of interest, the sequential information from contextual constituents is crucial for determining structures. Therefore, it is well motivated to use Conditional Random Fields (CRFs) (Lafferty et al., 2001), which is a discriminative probabilistic graphical model, to make predictions for a sequence of constituents surrounding the pair of interest.

In this sense, our local models appear similar to Joty et al.'s non-greedy parsing models. However, the major distinction between our models and theirs is that we do not jointly model the structure and the relation; rather, we use two linear-

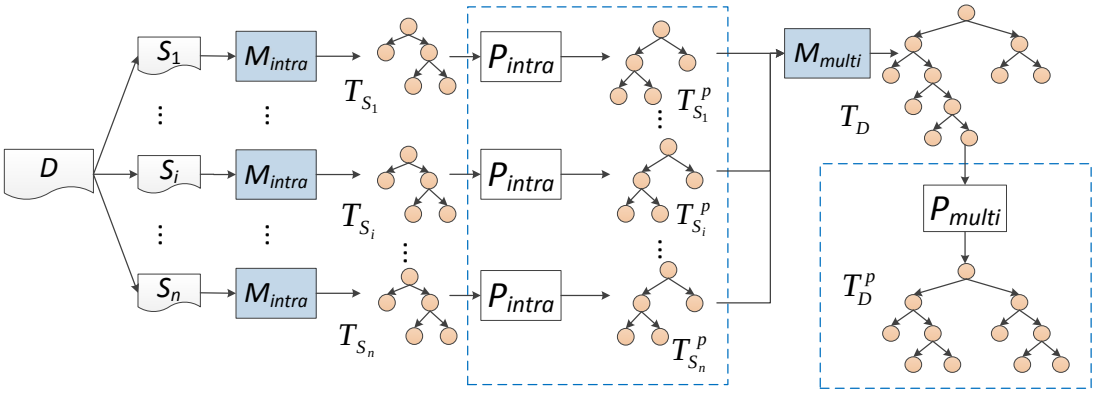

Figure 3: The work flow of our proposed discourse parser. In the figure, M_{intra} and M_{multi} stand for the intra- and multi-sentential bottom-up tree-building models, and P_{intra} and P_{multi} stand for the intra- and multi-sentential post-editing models.

chain CRFs to model the structure and the relation separately. Although joint modeling has shown to be effective in various NLP and computer vision applications (Sutton et al., 2007; Yang et al., 2009; Wojek and Schiele, 2008), our choice of using two separate models is for the following reasons:

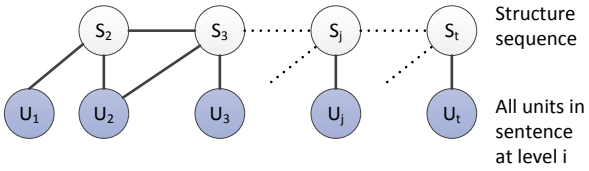
First, it is not entirely appropriate to model the structure and the relation at the same time. For example, with respect to Figure 2, it is unclear how the relation node R_j is represented for a training instance whose structure node $S_j = 0$, i.e., the units U_{j-1} and U_j are disjoint. Assume a special relation NO-REL is assigned for R_j. Then, in the tree-building process, we will have to deal with the situations where the joint model yields conflicting predictions: it is possible that the model predicts $S_j = 1$ and $R_j =$ NO-REL, or vice versa, and we will have to decide which node to trust (and thus in some sense, the structure and the relation is no longer jointly modeled).

Secondly, as a joint model, it is mandatory to use a dynamic CRF, for which exact inference is usually intractable or slow. In contrast, for linear-chain CRFs, efficient algorithms and implementations for exact inference exist.

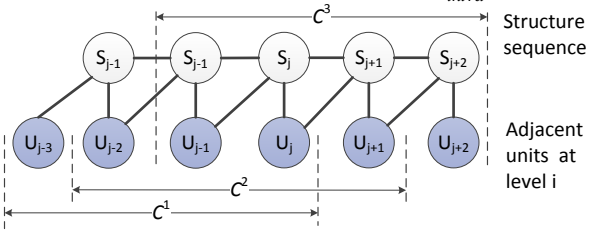
4.2 Structure models

4.2.1 Intra-sentential structure model

Figure 4a shows our intra-sentential structure model M^{struct}_{intra} in the form of a linear-chain CRF. Similar to Joty et al.'s intra-sentential model, the first layer of the chain is composed of discourse constituents U_j's, and the second layer is composed of binary nodes S_j's to indicate the probability of merging adjacent discourse constituents.



(a) Intra-sentential structure model M^{struct}_{intra}.



(b) Multi-sentential structure model M^{struct}_{multi}. C^1, C^2, and C^3 denote the three chains for predicting U_j and U_{j+1}.

Figure 4: Local structure models.

At each step in the bottom-up tree-building process, we generate a single sequence E, consisting of $U_1, U_2, \ldots, U_j, \ldots, U_t$, which are all the current discourse constituents in the sentence that need to be processed. For instance, initially, we have the sequence $E_1 = \{e_1, e_2, \ldots, e_m\}$, which are the EDUs of the sentence; after merging e_1 and e_2 on the second level, we have $E_2 = \{e_{1:2}, e_3, \ldots, e_m\}$; after merging e_4 and e_5 on the third level, we have $E_3 = \{e_{1:2}, e_3, e_{4:5}, \ldots, e_m\}$, and so on.

Because the structure model is the first component in our pipeline of local models, its accuracy is crucial. Therefore, to improve its accuracy, we enforce additional commonsense constraints in its Viterbi decoding. In particular, we disallow 1-1 transitions between adjacent labels (a discourse unit can be merged with at most one adjacent unit), and we disallow all-zero sequences (at least one

pair must be merged).

Since the computation of E_i **does not** depend on a particular pair of constituents, we can use the same sequence E_i to compute structural probabilities for **all** adjacent constituents. In contrast, Joty et al.'s computation of intra-sentential sequences depends on the particular pair of constituents: the sequence is composed of the pair in question, with other EDUs in the sentence, even if those EDUs have already been merged. Thus, different CRF chains have to be formed for different pairs of constituents. In addition to efficiency, our use of a single CRF chain for all constituents can better capture the sequential dependencies among context, by taking into account the information from partially built discourse constituents, rather than bottom-level EDUs only.

4.2.2 Multi-sentential structure model

For multi-sentential parsing, where the smallest discourse units are single sentences, as argued by Joty et al. (2013), it is not feasible to use a long chain to represent all constituents, due to the fact that it takes $O(TM^2)$ time to perform the forward-backward exact inference on a chain with T units and an output vocabulary size of M, thus the overall complexity for all possible sequences in their model is $O(M^2n^3)$[2].

Instead, we choose to take a sliding-window approach to form CRF chains for a particular pair of constituents, as shown in Figure 4b. For example, suppose we wish to compute the structural probability for the pair U_{j-1} and U_j, we form three chains, each of which contains two contextual constituents: $C^1 = \{U_{j-3}, U_{j-2}, U_{j-1}, U_j\}$, $C^2 = \{U_{j-2}, U_{j-1}, U_j, U_{j+1}\}$, and $C^3 = \{U_{j-1}, U_j, U_{j+1}, U_{j+2}\}$. We then find the chain $C^t, 1 \leq t \leq 3$, with the highest joint probability over the entire sequence, and assign its marginal probability $P(S_j^t = 1)$ to $P(S_j = 1)$.

Similar to M_{intra}^{struct}, for M_{multi}^{struct}, we also include additional constraints in the Viterbi decoding, by disallowing transitions between two ones, and disallowing the sequence to be all zeros if it contains all the remaining constituents in the document.

4.3 Relation models

4.3.1 Intra-sentential relation model

The intra-sentential relation model M_{intra}^{rel}, shown in Figure 5a, works in a similar way to M_{intra}^{struct}, as described in Section 4.2.1. The linear-chain CRF contains a first layer of all discourse constituents U_j's in the sentence on level i, and a second layer of relation nodes R_j's to represent the relation between a pair of discourse constituents.

However, unlike the structure model, adjacent relation nodes do not share discourse constituents on the first layer. Rather, each relation node R_j attempts to model the relation of one single constituent U_j, by taking U_j's left and right subtrees $U_{j,L}$ and $U_{j,R}$ as its first-layer nodes; if U_j is a single EDU, then the first-layer node of R_j is simply U_j, and R_j is a special relation symbol LEAF[3]. Since we know, a priori, that the constituents in the chains are either leaf nodes or the ones that have been merged by our structure model, we never need to worry about the NO-REL issue as outlined in Section 4.1.

In the bottom-up tree-building process, after merging a pair of adjacent constituents using M_{intra}^{struct} into a new constituent, say U_j, we form a chain consisting of all current constituents in the sentence to decide the relation label for U_j, i.e., the R_j node in the chain. In fact, by performing inference on this chain, we produce predictions not only for R_j, but also for all other R nodes in the chain, which correspond to all other constituents in the sentence. Since those non-leaf constituents are already labeled in previous steps in the tree-building, we can now **re-assign** their relations if the model predicts differently in this step. Therefore, this re-labeling procedure can compensate for the loss of accuracy caused by our greedy bottom-up strategy to some extent.

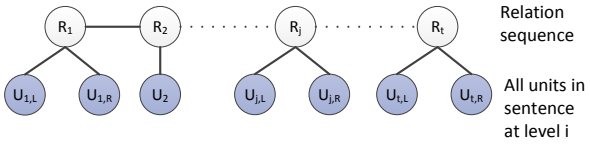
4.3.2 Multi-sentential relation model

Figure 5b shows our multi-sentential relation model. Like M_{intra}^{rel}, the first layer consists of adjacent discourse units, and the relation nodes on the second layer model the relation of each constituent separately.

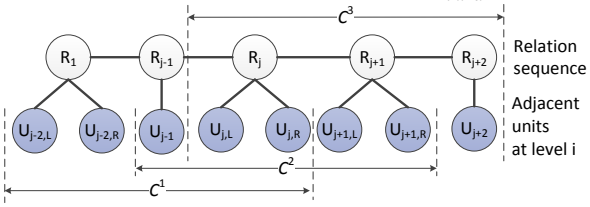
Similar to M_{multi}^{struct} introduced in Section 4.2.2, M_{multi}^{rel} also takes a sliding-window approach to predict labels for constituents in a local context. For a constituent U_j to be predicted, we form three chains, and use the chain with the highest joint probability to assign or re-assign relations to constituents in that chain.

[2]The time complexity will be reduced to $O(M^2n^2)$, if we use the same chain for all constituents as in our M_{intra}^{struct}.

[3]These leaf constituents are represented using a special feature vector `is_leaf = True`; thus the CRF never labels them with relations other than LEAF.



(a) Intra-sentential relation model M^{rel}_{intra}.



(b) Multi-sentential relation model M^{rel}_{multi}. C^1, C^2, and C^3 denote the three sliding windows for predicting $U_{j,L}$ and $U_{j,R}$.

Figure 5: Local relation models.

5 Post-editing

After an intra- or multi-sentential discourse tree is fully built, we perform a post-editing to consider possible modifications to the current tree, by considering useful information from the discourse constituents on upper levels, which is unavailable in the bottom-up tree-building process.

The motivation for post-editing is that, some particular discourse relations, such as TEXTUAL-ORGANIZATION, tend to occur on the top levels of the discourse tree; thus, information such as the depth of the discourse constituent can be quite indicative. However, the exact depth of a discourse constituent is usually unknown in the bottom-up tree-building process; therefore, it might be beneficial to modify the tree by including top-down information after the tree is fully built.

The process of post-editing is shown in Algorithm 1. For each input discourse tree T, which is already fully built by bottom-up tree-building models, we do the following:

Lines 3 – 9: Identify the lowest level of T on which the constituents can be modified according to the post-editing structure component, P^{struct}. To do so, we maintain a list L to store the discourse constituents that need to be examined. Initially, L consists of all the bottom-level constituents in T. At each step of the loop, we consider merging the pair of adjacent units in L with the highest probability predicted by P^{struct}. If the predicted pair is not merged in the original tree T, then a possible modification is located; otherwise, we merge the pair, and proceed to the next iteration.

Lines 10 – 12: If modifications have been proposed in the previous step, we build a new tree

Algorithm 1 Post-editing algorithm.

Input: A fully built discourse tree T.

1: **if** $|T| = 1$ **then**
2: **return** T ▷ Do nothing if it is a single EDU.
3: $L \leftarrow [U_1, U_2, \ldots, U_t]$ ▷ The bottom-level constituents in T.
4: **while** $|L| > 2$ **do**
5: $i \leftarrow \text{PREDICTMERGING}(L, P^{struct})$
6: $p \leftarrow \text{PARENT}(L[i], L[i+1], T)$
7: **if** p = NULL **then**
8: **break**
9: Replace $L[i]$ and $L[i+1]$ with p
10: **if** $|L| = 2$ **then**
11: $L \leftarrow [U_1, U_2, \ldots, U_t]$
12: $T^p \leftarrow \text{BUILDTREE}(L, P^{struct}, P^{rel}, T)$

Output: T^p

T^p using P^{struct} as the structure model, and P^{rel} as the relation model, from the constituents on which modifications are proposed. Otherwise, T^p is built from the bottom-level constituents of T. The upper-level information, such as the depth of a discourse constituent, is derived from the initial tree T.

5.1 Local models

The local models, $P^{\{struct|rel\}}_{\{intra|multi\}}$, for post-editing is almost identical to their counterparts of the bottom-up tree-building, except that the linear-chain CRFs in post-editing includes additional features to represent information from constituents on higher levels (to be introduced in Section 7).

6 Linear time complexity

Here we analyze the time complexity of each component in our discourse parser, to quantitatively demonstrate the time efficiency of our model. The following analysis is focused on the bottom-up tree-building process, but a similar analysis can be carried out for the post-editing process. Since the number of operations in the post-editing process is roughly the same (1.5 times in the worst case) as in the bottom-up tree-building, post-editing shares the same complexity as the tree-building.

6.1 Intra-sentential parsing

Suppose the input document is segmented into n sentences, and each sentence S_k contains m_k EDUs. For each sentence S_k with m_k EDUs, the

overall time complexity to perform intra-sentential parsing is $O(m_k^2)$. The reason is the following. On level i of the bottom-up tree-building, we generate a single chain to represent the structure or relation for all the $m_k - i$ constituents that are currently in the sentence. The time complexity for performing forward-backward inference on the single chain is $O((m_k - i) \times M^2) = O(m_k - i)$, where the constant M is the size of the output vocabulary. Starting from the EDUs on the bottom level, we need to perform inference for one chain on each level during the bottom-up tree-building, and thus the total time complexity is $\Sigma_{i=1}^{m_k} O(m_k - i) = O(m_k^2)$.

The total time to generate sentence-level discourse trees for n sentences is $\Sigma_{k=1}^{n} O(m_k^2)$. It is fairly safe to assume that each m_k is a constant, in the sense that m_k is independent of the total number of sentences in the document. Therefore, the total time complexity $\Sigma_{k=1}^{n} O(m_k^2) \leq n \times O(\max_{1 \leq j \leq n}(m_j^2)) = n \times O(1) = O(n)$, i.e., linear in the total number of sentences.

6.2 Multi-sentential parsing

For multi-sentential models, M_{multi}^{struct} and M_{multi}^{rel}, as shown in Figures 4b and 5b, for a pair of constituents of interest, we generate multiple chains to predict the structure or the relation.

By including a constant number k of discourse units in each chain, and considering a constant number l of such chains for computing each adjacent pair of discourse constituents ($k = 4$ for M_{multi}^{struct} and $k = 3$ for M_{multi}^{rel}; $l = 3$), we have an overall time complexity of $O(n)$. The reason is that it takes $l \times O(kM^2) = O(1)$ time, where l, k, M are all constants, to perform exact inference for a given pair of adjacent constituents, and we need to perform such computation for all $n - 1$ pairs of adjacent sentences on the first level of the tree-building. Adopting a greedy approach, on an arbitrary level during the tree-building, once we decide to merge a certain pair of constituents, say U_j and U_{j+1}, we only need to recompute a small number of chains, i.e., the chains which originally include U_j or U_{j+1}, and inference on each chain takes $O(1)$. Therefore, the total time complexity is $(n-1) \times O(1) + (n-1) \times O(1) = O(n)$, where the first term in the summation is the complexity of computing all chains on the bottom level, and the second term is the complexity of computing the constant number of chains on higher levels.

We have thus showed that the time complexity is *linear* in n, which is the number of sentences in the document. In fact, under the assumption that the number of EDUs in each sentence is independent of n, it can be shown that the time complexity is also linear in the total number of EDUs[4].

7 Features

In our local models, to encode two adjacent units, U_j and U_{j+1}, within a CRF chain, we use the following 10 sets of features, some of which are modified from Joty et al.'s model.

Organization features: Whether U_j (or U_{j+1}) is the first (or last) constituent in the sentence (for intra-sentential models) or in the document (for multi-sentential models); whether U_j (or U_{j+1}) is a bottom-level constituent.

Textual structure features: Whether U_j contains more sentences (or paragraphs) than U_{j+1}.

N-gram features: The beginning (or end) lexical n-grams in each unit; the beginning (or end) POS n-grams in each unit, where $n \in \{1, 2, 3\}$.

Dominance features: The PoS tags of the head node and the attachment node; the lexical heads of the head node and the attachment node; the dominance relationship between the two units.

Contextual features: The feature vector of the previous and the next constituent in the chain.

Substructure features: The root node of the left and right discourse subtrees of each unit.

Syntactic features: whether each unit corresponds to a single syntactic subtree, and if so, the top PoS tag of the subtree; the distance of each unit to their lowest common ancestor in the syntax tree (intra-sentential only).

Entity transition features: The type and the number of entity transitions across the two units. We adopt Barzilay and Lapata (2008)'s entity-based local coherence model to represent a document by an entity grid, and extract local transitions among entities in continuous discourse constituents. We use bigram and trigram transitions with syntactic roles attached to each entity.

[4] We implicitly made an assumption that the parsing time is dominated by the time to perform inference on CRF chains. However, for complex features, the time required for feature computation might be dominant. Nevertheless, a careful caching strategy can accelerate feature computation, since a large number of multi-sentential chains overlap with each other.

Cue phrase features: Whether a cue phrase occurs in the first or last EDU of each unit. The cue phrase list is based on the connectives collected by Knott and Dale (1994)

Post-editing features: The depth of each unit in the initial tree.

8 Experiments

For pre-processing, we use the Stanford CoreNLP (Klein and Manning, 2003; de Marneffe et al., 2006; Recasens et al., 2013) to syntactically parse the texts and extract coreference relations, and we use Penn2Malt[5] to lexicalize syntactic trees to extract dominance features.

For local models, our structure models are trained using MALLET (McCallum, 2002) to include constraints over transitions between adjacent labels, and our relation models are trained using CRFSuite (Okazaki, 2007), which is a fast implementation of linear-chain CRFs.

The data that we use to develop and evaluate our discourse parser is the RST Discourse Treebank (RST-DT) (Carlson et al., 2001), which is a large corpus annotated in the framework of RST. The RST-DT consists of 385 documents (347 for training and 38 for testing) from the *Wall Street Journal*. Following previous work on the RST-DT (Hernault et al., 2010; Feng and Hirst, 2012; Joty et al., 2012; Joty et al., 2013), we use 18 coarse-grained relation classes, and with nuclearity attached, we have a total set of 41 distinct relations. Non-binary relations are converted into a cascade of right-branching binary relations.

9 Results and Discussion

9.1 Parsing accuracy

We compare four different models using manual EDU segmentation. In Table 1, the *j*CRF model in the first row is the optimal CRF model proposed by Joty et al. (2013). gSVM^{FH} in the second row is our implementation of HILDA's greedy parsing algorithm using Feng and Hirst (2012)'s enhanced feature set. The third model, *g*CRF, represents our greedy CRF-based discourse parser, and the last row, gCRF^{PE}, represents our parser with the post-editing component included.

In order to conduct a direct comparison with Joty et al.'s model, we use the same set of evaluation metrics, i.e., the unlabeled and labeled precision, recall, and F-score[6] as defined by Marcu (2000). For evaluating relations, since there is a skewed distribution of different relation types in the corpus, we also include the macro-averaged F1-score (MAFS)[7] as another metric, to emphasize the performance of infrequent relation types. We report the MAFS separately for the correctly retrieved constituents (i.e., the span boundary is correct) and all constituents in the reference tree.

Model	Span	Nuc	Relation	
			Acc	MAFS
*j*CRF	82.5	68.4	55.7	N/A
gSVM^{FH}	82.8	67.1	52.0	27.4/23.3
*g*CRF	84.9*	69.9*	57.2*	35.3/31.3
gCRF^{PE}	**85.7***†	**71.0***†	**58.2***†	**36.2/32.3**
Human	88.7	77.7	65.8	N/A

$*$: significantly better than gSVM^{FH} ($p < .01$)
$\dagger$: significantly better than *g*CRF ($p < .01$)

Table 1: Performance of different models using gold-standard EDU segmentation, evaluated using the constituent accuracy (%) for span, nuclearity, and relation. For relation, we also report the macro-averaged F1-score (MAFS) for correctly retrieved constituents (before the slash) and for all constituents (after the slash). Statistical significance is verified using Wilcoxon's signed-rank test.

As demonstrated by Table 1, our greedy CRF models perform significantly better than the other two models. Since we do not have the actual output of Joty et al.'s model, we are unable to conduct significance testing between our models and theirs. But in terms of overall accuracy, our *g*CRF model outperforms their model by 1.5%. Moreover, with post-editing enabled, gCRF^{PE} significantly ($p < .01$) outperforms our initial model *g*CRF by another 1% in relation assignment, and this overall accuracy of 58.2% is close to 90% of human performance. With respect to the macro-averaged F1-scores, adding the post-editing component also obtains about 1% improvement.

However, the overall MAFS is still at the lower

[5] http://stp.lingfil.uu.se/~nivre/research/Penn2Malt.html.

[6] For manual segmentation, precision, recall, and F-score are the same.

[7] MAFS is the F1-score averaged among all relation classes by equally weighting each class. Therefore, we cannot conduct significance test between different MAFS.

	Avg	Min	Max
# of EDUs	61.74	4	304
# of Sentences	26.11	2	187
# of EDUs per sentence	2.36	1	10

Table 2: Characteristics of the 38 documents in the test data.

end of 30% for all constituents. Our error analysis shows that, for two relation classes, TOPIC-CHANGE and TEXTUAL-ORGANIZATION, our model fails to retrieve any instance, and for TOPIC-COMMENT and EVALUATION, our model scores a class-wise F_1 score lower than 5%. These four relation classes, apart from their infrequency in the corpus, are more abstractly defined, and thus are particularly challenging.

9.2 Parsing efficiency

We further illustrate the efficiency of our parser by demonstrating the time consumption of different models.

First, as shown in Table 2, the average number of sentences in a document is 26.11, which is already too large for optimal parsing models, e.g., the CKY-like parsing algorithm in *j*CRF, let alone the fact that the largest document contains several hundred of EDUs and sentences. Therefore, it should be seen that non-optimal models are required in most cases.

In Table 3, we report the parsing time[8] for the last three models, since we do not know the time of *j*CRF. Note that the parsing time excludes the time cost for any necessary pre-processing. As can be seen, our *g*CRF model is considerably faster than *g*SVM^{FH}, because, on one hand, feature computation is expensive in *g*SVM^{FH}, since *g*SVM^{FH} utilizes a rich set of features; on the other hand, in *g*CRF, we are able to accelerate decoding by multi-threading MALLET (we use four threads). Even for the largest document with 187 sentences, *g*CRF is able to produce the final tree after about 40 seconds, while *j*CRF would take over 16 hours assuming each DCRF decoding takes only 0.01 second. Although enabling post-editing doubles the time consumption, the overall time is still acceptable in practice, and the loss of efficiency can be compensated by the improvement in accuracy.

[8]Tested on a Linux system with four duo-core 3.0GHz processors and 16G memory.

Model	**Parsing Time (seconds)**		
	Avg	Min	Max
*g*SVM^{FH}	11.19	0.42	124.86
*g*CRF	5.52	0.05	40.57
*g*CRF^{PE}	10.71	0.12	84.72

Table 3: The parsing time (in seconds) for the 38 documents in the test set of RST-DT. Time cost of any pre-processing is excluded from the analysis.

10 Conclusions

In this paper, we presented an efficient text-level discourse parser with time complexity linear in the total number of sentences in the document. Our approach was to adopt a greedy bottom-up tree-building, with two linear-chain CRFs as local probabilistic models, and enforce reasonable constraints in the first CRF's Viterbi decoding. While significantly outperforming the state-of-the-art model by Joty et al. (2013), our parser is much faster in practice. In addition, we propose a novel idea of post-editing, which modifies a fully-built discourse tree by considering information from upper-level constituents. We show that, although doubling the time consumption, post-editing can further boost the parsing performance to close to 90% of human performance.

In future work, we wish to further explore the idea of post-editing, since currently we use only the depth of the subtrees as upper-level information. Moreover, we wish to study whether we can incorporate constraints into the relation models, as we do to the structure models. For example, it might be helpful to train the relation models using additional criteria, such as Generalized Expectation (Mann and McCallum, 2008), to better take into account some prior knowledge about the relations. Last but not least, as reflected by the low MAFS in our experiments, some particularly difficult relation types might need specifically designed features for better recognition.

Negation Focus Identification with Contextual Discourse Information

Abstract

Negative expressions are common in natural language text and play a critical role in information extraction. However, the performances of current systems are far from satisfaction, largely due to its focus on intra-sentence information and its failure to consider inter-sentence information. In this paper, we propose a graph model to enrich intra-sentence features with inter-sentence features from both lexical and topic perspectives. Evaluation on the *SEM 2012 shared task corpus indicates the usefulness of contextual discourse information in negation focus identification and justifies the effectiveness of our graph model in capturing such global information.

1 Introduction

Negation is a grammatical category which comprises various kinds of devices to reverse the truth value of a proposition (Morante and Sporleder, 2012). For example, sentence (1) could be interpreted as *it is not the case that he stopped*.

(1) *He didn't stop.*

Negation expressions are common in natural language text. According to the statistics on biomedical literature genre (Vincze et al., 2008), 19.44% of sentences contain negative expressions. The percentage rises to 22.5% on Conan Doyle stories (Morante and Daelemans, 2012). It is interesting that a negative sentence may have both negative and positive meanings. For example, sentence (2) could be interpreted as *He stopped, but not until he got to Jackson Hole* with positive part *he stopped* and negative part *until he got to Jackson Hole*. Moreover, a negative expression normally interacts with some special part in the sentence, referred as negation focus in linguistics. Formally, negation focus is defined as the special part in the sentence, which is most prominently or explicitly negated by a negative expression. Hereafter, we denote negative expression in ***boldface*** and negation focus *underlined*.

(2) *He did**n't** stop until he got to Jackson Hole.*

While people tend to employ stress or intonation in speech to emphasize negation focus and thus it is easy to identify negation focus in speech corpora, such stress or intonation information often misses in the dominating text corpora. This poses serious challenges on negation focus identification. Current studies (e.g., Blanco and Moldovan, 2011; Rosenberg and Bergler, 2012) sort to various kinds of intra-sentence information, such as lexical features, syntactic features, semantic role features and so on, ignoring less-obvious inter-sentence information. This largely defers the performance of negation focus identification and its wide applications, since such contextual discourse information plays a critical role on negation focus identification. Take following sentence as an example.

(3) *Helen did**n't** allow her youngest son to play the violin.*

In sentence (3), there are several scenarios on identification of negation focus, with regard to negation expression ***n't***, given different contexts:
Scenario A: Given sentence *But her husband did* as next sentence, the negation focus should be *Helen*, yielding interpretation *the person who didn't allow the youngest son to play the violin is Helen but not her husband*.
Scenario B: Given sentence *She thought that he didn't have the artistic talent like her eldest son* as next sentence, the negation focus should be *the youngest son*, yielding interpretation *Helen*

Baltimore, Maryland, USA, June 23-25 2014.

thought that her eldest son had the talent to play the violin, but the youngest son didn't.
Scenario C: Given sentence *Because of her neighbors' protests* as previous sentence, the negation focus should be *play the violin,* yielding interpretation *Helen didn't allow her youngest son to play the violin, but it didn't show whether he was allowed to do other things*.

In this paper, to well accommodate such contextual discourse information in negation focus identification, we propose a graph model to enrich normal intra-sentence features with various kinds of inter-sentence features from both lexical and topic perspectives. Besides, the standard PageRank algorithm is employed to optimize the graph model. Evaluation on the *SEM 2012 shared task corpus (Morante and Blanco, 2012) justifies our approach over several strong baselines.

The rest of this paper is organized as follows. Section 2 overviews the related work. Section 3 presents several strong baselines on negation focus identification with only intra-sentence features. Section 4 introduces our topic-driven word-based graph model with contextual discourse information. Section 5 reports the experimental results and analysis. Finally, we conclude our work in Section 6.

2 Related Work

Earlier studies of negation were almost in linguistics (e.g. Horn, 1989; van der Wouden, 1997), and there were only a few in natural language processing with focus on negation recognition in the biomedical domain. For example, Chapman et al. (2001) developed a rule-based negation recognition system, NegEx, to determine whether a finding mentioned within narrative medical reports is present or absent. Since the release of the BioScope corpus (Vincze et al., 2008), a freely available resource consisting of medical and biological texts, machine learning approaches begin to dominate the research on negation recognition (e.g. Morante et al., 2008; Li et al., 2010).

Generally, negation recognition includes three subtasks: cue detection, which detects and identifies possible negative expressions in a sentence, scope resolution, which determines the grammatical scope in a sentence affected by a negative expression, and focus identification, which identifies the constituent in a sentence most prominently or explicitly negated by a negative expression. This paper concentrates on the third subtask, negation focus identification.

Due to the increasing demand on deep understanding of natural language text, negation recognition has been drawing more and more attention in recent years, with a series of shared tasks and workshops, however, with focus on cue detection and scope resolution, such as the BioNLP 2009 shared task for negative event detection (Kim et al., 2009) and the ACL 2010 Workshop for scope resolution of negation and speculation (Morante and Sporleder, 2010), followed by a special issue of *Computational Linguistics* (Morante and Sporleder, 2012) for modality and negation.

The research on negation focus identification was pioneered by Blanco and Moldovan (2011), who investigated the negation phenomenon in semantic relations and proposed a supervised learning approach to identify the focus of a negation expression. However, although Morante and Blanco (2012) proposed negation focus identification as one of the *SEM'2012 shared tasks, only one team (Rosenberg and Bergler, 2012) [1] participated in this task. They identified negation focus using three kinds of heuristics and achieved 58.40 in F1-measure. This indicates great expectation in negation focus identification.

The key problem in current research on negation focus identification is its focus on intra-sentence information and large ignorance of inter-sentence information, which plays a critical role in the success of negation focus identification. For example, Ding (2011) made a qualitative analysis on implied negations in conversation and attempted to determine whether a sentence was negated by context information, from the linguistic perspective. Moreover, a negation focus is always associated with authors' intention in article. This indicates the great challenges in negation focus identification.

3 Baselines

Negation focus identification in *SEM'2012 shared tasks is restricted to verbal negations annotated with MNEG in PropBank, with only the constituent belonging to a semantic role selected as negation focus. Normally, a verbal negation expression (*not* or *n't*) is grammatically associated with its corresponding verb (e.g., *He did**n't** stop*). For details on annotation guidelines and

[1] In *SEM'2013, the shared task is changed with focus on "Semantic Textual Similarity".

examples for verbal negations, please refer to Blanco and Moldovan (2011).

For comparison, we choose the state-of-the-art system described in Blanco and Moldovan (2011), which employed various kinds of syntactic features and semantic role features, as one of our baselines. Since this system adopted C4.5 for training, we name it as *Baseline*$^{C4.5}$. In order to provide a stronger baseline, besides those features adopted in *Baseline*$^{C4.5}$, we added more refined intra-sentence features and adopted ranking Support Vector Machine (SVM) model for training. We name it as *Baseline*^{SVM}.

Following is a list of features adopted in the two baselines, for both Baseline$^{C4.5}$ and Baseline^{SVM},

- Basic features: first token and its part-of-speech (POS) tag of the focus candidate; the number of tokens in the focus candidate; relative position of the focus candidate among all the roles present in the sentence; negated verb and its POS tag of the negative expression;
- Syntactic features: the sequence of words from the beginning of the governing VP to the negated verb; the sequence of POS tags from the beginning of the governing VP to the negated verb; whether the governing VP contains a CC; whether the governing VP contains a RB.
- Semantic features: the syntactic label of semantic role A1; whether A1 contains POS tag DT, JJ, PRP, CD, RB, VB, and WP, as defined in Blanco and Moldovan (2011); whether A1 contains token any, anybody, anymore, anyone, anything, anytime, anywhere, certain, enough, full, many, much, other, some, specifics, too, and until, as defined in Blanco and Moldovan (2011); the syntactic label of the first semantic role in the sentence; the semantic label of the last semantic role in the sentence; the thematic role for A0/A1/A2/A3/A4 of the negated predicate.

and for *Baseline*^{SVM} only,

- Basic features: the named entity and its type in the focus candidate; relative position of the focus candidate to the negative expression (before or after).
- Syntactic features: the dependency path and its depth from the focus candidate to the negative expression; the constituent path and its depth from the focus candidate to the negative expression;

4 Exploring Contextual Discourse Information for Negation Focus Identification

While some of negation focuses could be identified by only intra-sentence information, others must be identified by contextual discourse information. Section 1 illustrates the necessity of such contextual discourse information in negation focus identification by giving three scenarios of different discourse contexts for negation expression ***n't*** in sentence (3).

For better illustration of the importance of contextual discourse information, Table 1 shows the statistics of intra- and inter-sentence information necessary for manual negation focus identification with 100 instances randomly extracted from the held-out dataset of *SEM'2012 shared task corpus. It shows that only 17 instances can be identified by intra-sentence information. It is surprising that inter-sentence information is indispensable in 77 instances, among which 42 instances need only inter-sentence information and 35 instances need both intra- and inter-sentence information. This indicates the great importance of contextual discourse information on negation focus identification. It is also interesting to note 6 instances are hard to determine even given both intra- and inter-sentence information.

Info	Number
#Intra-Sentence Only	17
#Inter-Sentence Only	42
#Both	35
#Hard to Identify	6

(Note: "Hard to Identify" means that it is hard for a human being to identify the negation focus even given both intra- and inter-sentence information.)

Table 1. Statistics of intra- and inter-sentence information on negation focus identification.

Statistically, we find that negation focus is always related with what authors repeatedly states in discourse context. This explains why contextual discourse information could help identify negation focus. While inter-sentence information provides the global characteristics from the discourse context perspective and intra-sentence information provides the local features from lexical, syntactic and semantic perspectives, both have their own contributions on negation focus identification.

In this paper, we first propose a graph model to gauge the importance of contextual discourse

information. Then, we incorporate both intra- and inter-sentence features into a machine learning-based framework for negation focus identification.

4.1 Graph Model

Graph models have been proven successful in many NLP applications, especially in representing the link relationships between words or sentences (Wan and Yang, 2008; Li et al., 2009). Generally, such models could construct a graph to compute the relevance between document theme and words.

In this paper, we propose a graph model to represent the contextual discourse information from both lexical and topic perspectives. In particular, a word-based graph model is proposed to represent the explicit relatedness among words in a discourse from the lexical perspective, while a topic-driven word-based model is proposed to enrich the implicit relatedness between words, by adding one more layer to the word-based graph model in representing the global topic distribution of the whole dataset. Besides, the PageRank algorithm (Page et al., 1998) is adopted to optimize the graph model.

Word-based Graph Model:

A word-based graph model can be defined as $G_{word}(W, E)$, where $W=\{w_i\}$ is the set of words in one document and $E=\{e_{ij}|w_i, w_j \in W\}$ is the set of directed edges between these words, as shown in Figure 1.

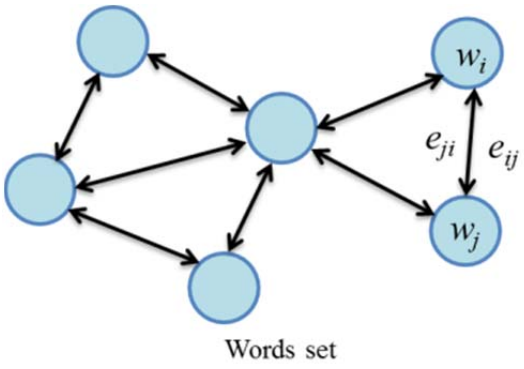

Figure 1. Word-based graph model.

In the word-based graph model, word node w_i is weighted to represent the correlation of the word with authors' intention. Since such correlation is more from the semantic perspective than the grammatical perspective, only content words are considered in our graph model, ignoring functional words (e.g., *the*, *to*,…). Especially, the content words limited to those with part-of-speech tags of JJ, NN, PRP, and VB. For simplicity, the weight of word node w_i is initialized to 1.

In addition, directed edge e_{ij} is weighted to represent the relatedness between word w_i and word w_j in a document with transition probability $P(j|i)$ from i to j, which is normalized as follows:

$$P(j|i) = \frac{Sim(w_i,w_j)}{\sum_k Sim(w_i,w_k)} \quad (1)$$

where k represents the nodes in discourse, and $Sim(w_i,w_j)$ denotes the similarity between w_i and w_j. In this paper, two kinds of information are used to calculate the similarity between words. One is word co-occurrence (if word w_i and word w_j occur in the same sentence or in the adjacent sentences, $Sim(w_i,w_j)$ increases 1), and the other is WordNet (Miller, 1995) based similarity. Please note that $Sim(w_i,w_i) = 0$ to avoid self-transition, and $Sim(w_i,w_j)$ and $Sim(w_j,w_i)$ may not be equal.

Finally, the weights of word nodes are calculated using the PageRank algorithm as follows:

$$Score^{(0)}(w_i) = 1$$
$$Score^{(n+1)}(w_i) = d\sum_{j\neq i} Score^{(n)}(w_j) \times P(j|i) + (1-d) \quad (2)$$

where d is the damping factor as in the PageRank algorithm.

Topic-driven Word-based Graph Model

While the above word-based graph model can well capture the relatedness between content words, it can only partially model the focus of a negation expression since negation focus is more directly related with topic than content. In order to reduce the gap, we propose a topic-driven word-based model by adding one more layer to refine the word-based graph model over the global topic distribution, as shown in Figure 2.

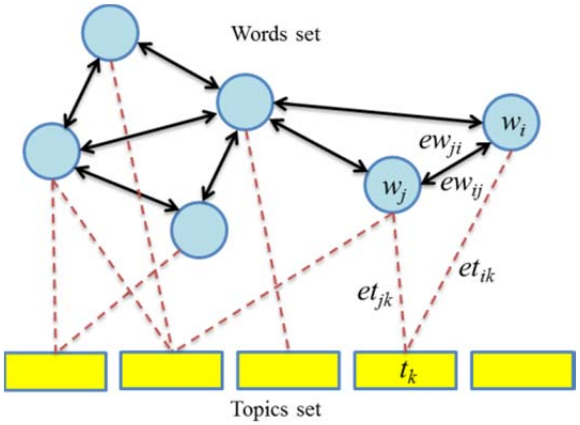

Figure 2. Topic-driven word-based graph model.

Here, the topics are extracted from all the documents in the *SEM 2012 shared task using the LDA Gibbs Sampling algorithm (Griffiths, 2002). In the topic-driven word-based graph model, the first layer denotes the relatedness among content words as captured in the above word-based graph model, and the second layer denotes the topic distribution, with the dashed lines between these two layers indicating the word-topic model return by LDA.

Formally, the topic-driven word-based two-layer graph is defined as G_{topic} (W, T, E_w, E_t), where $W=\{w_i\}$ is the set of words in one document and $T=\{t_i\}$ is the set of topics in all documents; $E_w=\{ew_{ij}|w_i, w_j \in W\}$ is the set of directed edges between words and $E_t=\{et_{ij}|w_i \in W, t_j \in T\}$ is the set of undirected edges between words and topics; transition probability $P_w(j|i)$ of ew_{ij} is defined as the same as $P(j|i)$ of the word-based graph model. Besides, transition probability $P_t(i,m)$ of et_{ij} in the word-topic model is defined as:

$$P_t(i,m) = \frac{Rel(w_i,t_m)}{\sum_k Rel(w_i,t_k)} \quad (3)$$

where $Rel(w_i, t_m)$ is the weight of word w_i in topic t_m calculated by the LDA Gibbs Sampling algorithm. On the basis, the transition probability $P_w(j|i)$ of ew_{ij} is updated by calculating as following:

$$P'_w(j|i) = \theta \cdot P_w(j|i) + (1-\theta) \cdot \frac{P_t(i,m) \times P_t(j,m)}{\sum_k P_t(i,k) \times P_t(j,k)} \quad (4)$$

where k represents all topics linked to both word w_i and word w_j, and $\theta \in [0,1]$ is the coefficient controlling the relative contributions from the lexical information in current document and the topic information in all documents.

Finally, the weights of word nodes are calculated using the PageRank algorithm as follows:

$$Score^{(0)}(w_i) = 1$$
$$Score^{(n+1)}(w_i) = d \sum_{j \neq i} Score^{(n)}(w_j) \times P'_w(j|i) + (1-d) \quad (5)$$

where d is the damping factor as in the PageRank algorithm.

4.2 Negation Focus Identification via Graph Model

Given the graph models and the PageRank optimization algorithm discussed above, four kinds of contextual discourse information are extracted as inter-sentence features (Table 2).

In particular, the total weight and the max weight of words in the focus candidate are calculated as follows:

$$Weight_{total} = \sum_i Score^{(final)}(w_i) \quad (6)$$

$$Weight_{max} = \max_i Score^{(final)}(w_i) \quad (7)$$

where i represents the content words in the focus candidate. These two kinds of weights focus on different aspects about the focus candidate with the former on the contribution of content words, which is more beneficial for a long focus candidate, and the latter biased towards the focus candidate which contains some critical word in a discourse.

No	Feature
1	Total weight of words in the focus candidate using the co-occurrence similarity.
2	Max weight of words in the focus candidate using the co-occurrence similarity.
3	Total weight of words in the focus candidate using the WordNet similarity.
4	Max weight of words in the focus candidate using the WordNet similarity.

Table 2. Inter-sentence features extracted from graph model.

For evaluating the contribution of contextual discourse information on negation focus identification directly, we incorporate the four inter-sentence features from the topic-driven word-based graph model into a negation focus identifier.

5 Experimentation

In this section, we describe experimental settings and systematically evaluate our negation focus identification approach with focus on exploring the effectiveness of contextual discourse information.

5.1 Experimental Settings

Dataset

In all our experiments, we employ the *SEM'2012 shared task corpus (Morante and Blanco, 2012)[2]. As a freely downloadable resource, the *SEM shared task corpus is annotated on top of PropBank, which uses the WSJ section of the Penn TreeBank. In particular, negation focus annotation on this corpus is restricted to verbal negations (with corresponding mark

[2] http://www.clips.ua.ac.be/sem2012-st-neg/

MNEG in PropBank). On 50% of the corpus annotated by two annotators, the inter-annotator agreement was 0.72 (Blanco and Moldovan, 2011). Along with negation focus annotation, this corpus also contains other annotations, such as POS tag, named entity, chunk, constituent tree, dependency tree, and semantic role.

In total, this corpus provides 3,544 instances of negation focus annotations. For fair comparison, we adopt the same partition as *SEM'2012 shared task in all our experiments, i.e., with 2,302 for training, 530 for development, and 712 for testing. Although for each instance, the corpus only provides the current sentence, the previous and next sentences as its context, we sort to the Penn TreeBank[3] to obtain the corresponding document as its discourse context.

Evaluation Metrics

Same as the *SEM'2012 shared task, the evaluation is made using precision, recall, and F1-score. Especially, a true positive (TP) requires an exact match for the negation focus, a false positive (FP) occurs when a system predicts a non-existing negation focus, and a false negative (FN) occurs when the gold annotations specify a negation focus but the system makes no prediction. For each instance, the predicted focus is considered correct if it is a complete match with a gold annotation.

Beside, to show whether an improvement is significant, we conducted significance testing using z-test, as described in Blanco and Moldovan (2011).

Toolkits

In our experiments, we report not only the default performance with gold additional annotated features provided by the *SEM'2012 shared task corpus and the Penn TreeBank, but also the performance with various kinds of features extracted automatically, using following toolkits:

- Syntactic Parser: We employ the Stanford Parser[4] (Klein and Manning, 2003; De Marneffe et al., 2006) for tokenization, constituent and dependency parsing.
- Named Entity Recognizer: We employ the Stanford NER[5] (Finkel et al., 2005) to obtain named entities.
- Semantic Role Labeler: We employ the semantic role labeler, as described in Punyakanok et al (2008).
- Topic Modeler: For estimating transition probability Pt(i,m), we employ GibbsLDA++[6], an LDA model using Gibbs Sampling technique for parameter estimation and inference.
- Classifier: We employ SVM^{Light} [7] with default parameters as our classifier.

5.2 Experimental Results

With Only Intra-sentence Information

Table 3 shows the performance of the two baselines, the decision tree-based classifier as in Blanco and Moldovan (2011) and our ranking SVM-based classifier. It shows that our ranking SVM-based baseline slightly improves the F1-measure by 2.52% over the decision tree-based baseline, largely due to the incorporation of more refined features.

System	P(%)	R(%)	F1
Baseline$^{C4.5}$	66.73	49.93	57.12
Baseline^{SVM}	60.22	59.07	59.64

Table 3. Performance of baselines with only intra-sentence information.

Error analysis of the ranking SVM-based baseline on development data shows that 72% of them are caused by the ignorance of inter-sentence information. For example, among the 42 instances listed in the category of "#Inter-Sentence Only" in Table 1, only 7 instances can be identified correctly by the ranking SVM-based classifier. With about 4 focus candidates in one sentence on average, this percentage is even lower than random.

With Only Inter-sentence Information

For exploring the usefulness of pure contextual discourse information in negation focus identification, we only employ inter-sentence features into ranking SVM-based classifier. First of all, we estimate two parameters for our topic-driven word-based graph model: topic number T for topic model and coefficient θ between $P_w(j|i)$ and $P_t(i,m)$ in Formula 4.

Given the LDA Gibbs Sampling model with parameters $\alpha = 50/T$ and $\beta = 0.1$, we vary T from 20 to 100 with an interval of 10 to find the opti-

[6] http://gibbslda.sourceforge.net/
[7] http://svmlight.joachims.org

mal T. Figure 3 shows the experiment results of varying T (with $\theta = 0.5$) on development data. It shows that the best performance is achieved when T = 50 with 51.11 in F1). Therefore, we set T as 50 in our following experiments.

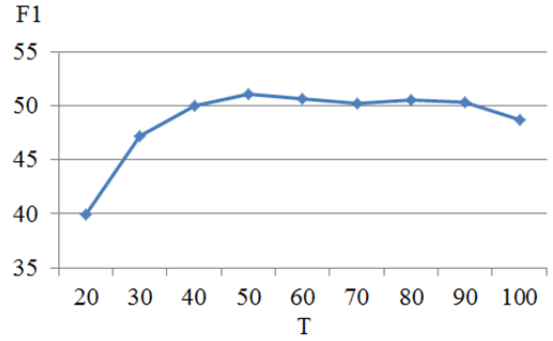

Figure 3. Performance with varying T.

For parameter θ, a trade-off between the transition probability $P_w(j|i)$ (word to word) and the transition probability $P_t(i,m)$ (word and topic) to update $P'_w(j|i)$, we vary it from 0 to 1 with an interval of 0.1. Figure 4 shows the experiment results of varying θ (with T=50) on development data. It shows that the best performance is achieved when $\theta = 0.6$, which are adopted hereafter in all our experiments. This indicates that direct lexical information in current document contributes more than indirect topic information in all documents on negation focus identification. It also shows that direct lexical information in current document and indirect topic information in all documents are much complementary on negation focus identification.

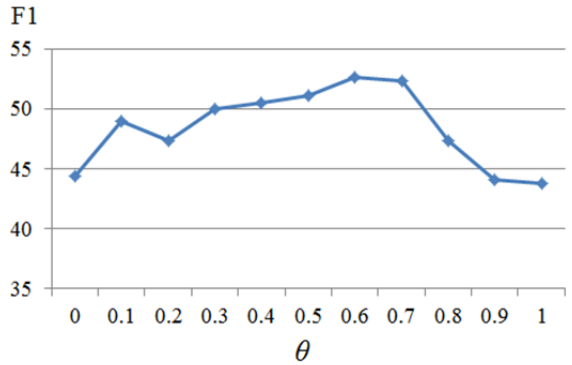

Figure 4. Performance with varying θ.

System	P(%)	R(%)	F1
using word-based graph model	45.62	42.02	43.75
using topic-driven word-based graph model	54.59	50.76	52.61

Table 4. Performance with only inter-sentence information.

Table 4 shows the performance of negation focus identification with only inter-sentence features. It also shows that the system with inter-sentence features from the topic-driven word-based graph model significantly improves the F1-measure by 8.86 over the system with inter-sentence features from the word-based graph model, largely due to the usefulness of topic information.

In comparison with Table 3, it shows that the system with only intra-sentence features achieves better performance than the one with only inter-sentence features (59.64 vs. 52.61 in F1-measure).

With both Intra- and Inter-sentence Information

Table 5 shows that enriching intra-sentence features with inter-sentence features significantly ($p<0.01$) improve the performance by 9.85 in F1-measure than the better baseline. This indicates the usefulness of such contextual discourse information and the effectiveness of our topic-driven word-based graph model in negation focus identification.

System	P(%)	R(%)	F1
Baseline$^{C4.5}$ with intra feat. only	66.73	49.93	57.12
Baseline^{SVM} with intra feat. only	60.22	59.07	59.64
Ours with Both feat. using word-based GM	64.93	62.47	63.68
Ours with Both feat. using topic-driven word-based GM	71.67	67.43	69.49

(Note: "feat." denotes features; "GM" denotes graph model.)

Table 5. Performance comparison of systems on negation focus identification.

System	P(%)	R(%)	F1
Baseline$^{C4.5}$ with intra feat. only (auto)	60.94	44.62	51.52
Baseline^{SVM} with intra feat. Only (auto)	53.81	51.67	52.72
Ours with Both feat. using word-based GM (auto)	58.77	57.19	57.97
Ours with Both feat. using topic-driven word-based GM (auto)	66.74	64.53	65.62

Table 6. Performance comparison of systems on negation focus identification with automatically extracted features.

Besides, Table 6 shows the performance of our best system with all features automatically extracted using the toolkits as described in Section 5.1. Compared with our best system employing gold additional annotated features (the last line in Table 5), the homologous system with automatically extracted features (the last line in Table 6) only decrease of less than 4 in F1-measure. This demonstrates the achievability of our approach.

In comparison with the best-reported performance on the *SEM'2012 shared task (Rosenberg and Bergler, 2012), our system performs better by about 11 in F-measure.

5.3 Discussion

While this paper verifies the usefulness of contextual discourse information on negation focus identification, the performance with only inter-sentence features is still weaker than that with only intra-sentence features. There are two main reasons. On the one hand, the former employs an unsupervised approach without prior knowledge for training. On the other hand, the usefulness of inter-sentence features depends on the assumption that a negation focus relates to the meaning of which is most relevant to authors' intention in a discourse. If there lacks relevant information in a discourse context, negation focus will become difficult to be identified only by inter-sentence features.

Error analysis also shows that some of the negation focuses are very difficult to be identified, even for a human being. Consider the sentence (3) in Section 1, if given sentence *because of her neighbors' protests, but her husband doesn't think so* as its following context, both *Helen* and *to play the violin* can become the negation focus. Moreover, the inter-annotator agreement in the first round of negation focus annotation can only reach 0.72 (Blanco and Moldovan, 2011). This indicates inherent difficulty in negation focus identification.

6 Conclusion

In this paper, we propose a graph model to enrich intra-sentence features with inter-sentence features from both lexical and topic perspectives. In this graph model, the relatedness between words is calculated by word co-occurrence, WordNet-based similarity, and topic-driven similarity. Evaluation on the *SEM 2012 shared task corpus indicates the usefulness of contextual discourse information on negation focus identification and our graph model in capturing such global information.

In future work, we will focus on exploring more contextual discourse information via the graph model and better ways of integrating intra- and inter-sentence information on negation focus identification.

Abstract

Automatic extraction of new words is an indispensable precursor to many NLP tasks such as Chinese word segmentation, named entity extraction, and sentiment analysis. This paper aims at extracting *new sentiment words* from large-scale user-generated content. We propose a fully unsupervised, purely data-driven framework for this purpose. We design statistical measures respectively to quantify the utility of a lexical pattern and to measure the possibility of a word being a new word. The method is almost free of linguistic resources (except POS tags), and requires no elaborated linguistic rules. We also demonstrate how new sentiment word will benefit sentiment analysis. Experiment results demonstrate the effectiveness of the proposed method.

1 Introduction

New words on the Internet have been emerging all the time, particularly in user-generated content. Users like to update and share their information on social websites with their own language styles, among which new political/social/cultural words are constantly used.

However, such new words have made many natural language processing tasks more challenging. Automatic extraction of new words is indispensable to many tasks such as Chinese word segmentation, machine translation, named entity extraction, question answering, and sentiment analysis. New word detection is one of the most critical issues in Chinese word segmentation. Recent studies (Sproat and Emerson, 2003) (Chen, 2003) have shown that more than 60% of word segmentation errors result from new words. Statistics show that more than 1000 new Chinese words appear every year (Thesaurus Research Center, 2003). These words are mostly domain-specific technical terms and time-sensitive political/social /cultural terms. Most of them are not yet correctly recognized by the segmentation algorithm, and remain as out of vocabulary (OOV) words.

New word detection is also important for sentiment analysis such as opinionated phrase extraction and polarity classification. A sentiment phrase with complete meaning should have a correct boundary, however, characters in a new word may be broken up. For example, in a sentence " 表演/n 非常/adv 给/v 力/n（artists' performance is very impressive）" the two Chinese characters "给/v 力/n(cool; powerful)" should always be extracted together. In polarity classification, new words can be informative features for classification models. In the previous example, "给力(cool; powerful)" is a strong feature for classification models while each single character is not. Adding new words as feature in classification models will improve the performance of polarity classification, as demonstrated later in this paper.

This paper aims to detect new word for sentiment analysis. We are particulary interested in extracting *new sentiment word* that can express opinions or sentiment, which is of high value towards sentiment analysis. *New sentiment word*, as exemplified in Table 1, is a sub-class of multi-word expressions which is a sequence of neighboring words *"whose exact and unambiguous meaning or connotation cannot be derived from the meaning or connotation of its components"* (Choueka, 1988). Such new words cannot be directly identified using grammatical rules, which poses a major challenge to automatic analysis. Moreover, existing lexical resources never have adequate and timely coverage since new words appear constantly. People thus resort to statistical methods such as Pointwise Mutual Information (Church and Hanks, 1990), Symmetrical Conditional Probability

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 531–541,
Baltimore, Maryland, USA, June 23-25 2014.

(da Silva and Lopes, 1999), Mutual Expectation (Dias et al., 2000), Enhanced Mutual Information (Zhang et al., 2009), and Multi-word Expression Distance (Bu et al., 2010).

New word	English Translation	Polarity
口爱	lovely	positive
杯具	tragic/tragedy	negative
给力	very cool; powerful	positive
坑爹	reverse one's expectation	negative

Table 1: Examples of new sentiment word.

Our central idea for new sentiment word detection is as follows: Starting from very few seed words (for example, just one seed word), we can extract lexical patterns that have strong statistical association with the seed words; the extracted lexical patterns can be further used in finding more new words, and the most probable new words can be added into the seed word set for the next iteration; and the process can be run iteratively until a stop condition is met. The key issues are to measure the utility of a pattern and to quantify the possibility of a word being a new word. The main contributions of this paper are summarized as follows:

- We propose a novel framework for new word detection from large-scale user-generated data. This framework is fully unsupervised and purely data-driven, and requires very lightweight linguistic resources (i.e., only POS tags).
- We design statistical measures to quantify the utility of a pattern and to quantify the possibility of a word being a new word, respectively. No elaborated linguistic rules are needed to filter undesirable results. This feature may enable our approach to be portable to other languages.
- We investigate the problem of polarity prediction of new sentiment word and demonstrate that inclusion of new sentiment word benefits sentiment classification tasks.

The rest of the paper is structured as follows: we will introduce related work in the next section. We will describe the proposed method in Section 3, including definitions, the overview of the algorithm, and the statistical measures for addressing the two key issues. We then present the experiments in Section 4. Finally, the work is summarized in Section 5.

2 Related Work

New word detection has been usually interweaved with word segmentation, particularly in Chinese NLP. In these works, new word detection is considered as an integral part of segmentation, where new words are identified as the most probable segments inferred by the probabilistic models; and the detected new word can be further used to improve word segmentation. Typical models include conditional random fields proposed by (Peng et al., 2004), and a joint model trained with adaptive online gradient descent based on feature frequency information (Sun et al., 2012).

Another line is to treat new word detection as a separate task, usually preceded by part-of-speech tagging. The first genre of such studies is to leverage complex linguistic rules or knowledge. For example, Justeson and Katz (1995) extracted technical terminologies from documents using a regular expression. Argamon et al. (1998) segmented the POS sequence of a multi-word into small POS tiles, counted tile frequency in the new word and non-new-word on the training set respectively, and detected new words using these counts. Chen and Ma (2002) employed morphological and statistical rules to extract Chinese new word. The second genre of the studies is to treat new word detection as a classification problem. Zhou (2005) proposed a discriminative Markov Model to detect new words by chunking one or more separated words. In (Li et al., 2005), new word detection was viewed as a binary classification problem. However, these supervised models requires not only heavy engineering of linguistic features, but also expensive annotation of training data.

User behavior data has recently been explored for finding new words. Zheng et al. (2009) explored user typing behaviors in Sogou Chinese Pinyin input method to detect new words. Zhang et al. (2010) proposed to use dynamic time warping to detect new words from query logs. However, both of the work are limited due to the public unavailability of expensive commercial resources.

Statistical methods for new word detection have been extensively studied, and in some sense exhibit advantages over linguistics-based methods. In this setting, new word detection is mostly

known as multi-word expression extraction. To measure multi-word association, the first model is Pointwise Mutual Information (PMI) (Church and Hanks, 1990). Since then, a variety of statistical methods have been proposed to measure bi-gram association, such as Log-likelihood (Dunning, 1993) and Symmetrical Conditional Probability (SCP) (da Silva and Lopes, 1999). Among all the 84 bi-gram association measures, PMI has been reported to be the best one in Czech data (Pecina, 2005). In order to measure arbitrary n-grams, most common strategies are to separate n-gram into two parts X and Y so that existing bi-gram methods can be used (da Silva and Lopes, 1999; Dias et al., 2000; Schone and Jurafsky, 2001). Zhang et al. (2009) proposed Enhanced Mutual Information (EMI) which measures the cohesion of n-gram by the frequency of itself and the frequency of each single word. Based on the information distance theory, Bu et al. (2010) proposed multi-word expression distance (MED) and the normalized version, and reported superior performance to EMI, SCP, and other measures.

3 Methodology

3.1 Definitions

Definition 3.1 (**Adverbial word**). Words that are used mainly to modify a verb or an adjective, such as "太(too)", "非常(very)", "十分(very)", and "特别(specially)".

Definition 3.2 (**Auxiliary word**). Words that are auxiliaries, model particles, or punctuation marks. In Chinese, such words are like "着,了,啦,的,啊", and punctuation marks include "，。！？；： " and so on.

Definition 3.3 (**Lexical Pattern**). A lexical pattern is a triplet $< AD, *, AU >$, where AD is an adverbial word, the wildcard $*$ means an arbitrary number of words [1], and AU denotes an auxiliary word.

Table 2 gives some examples of lexical patterns. In order to obtain lexical patterns, we can define regular expressions with POS tags [2] and apply the regular expressions on POS tagged texts. Since the tags of adverbial and auxiliary words are relatively static and can be easily identified, such a method can safely obtain lexical patterns.

Pattern	Frequency
<"都",*,"了">	562,057
<"都",*,"的">	387,649
<"太",*,"了">	380,470
<"不",*,"， ">	369,702

Table 2: Examples of lexical pattern. The frequency is counted on 237,108,977 Weibo posts.

3.2 The Algorithm Overview

The algorithm works as follows: starting from very few seed words (for example, a word in Table 1), the algorithm can find lexical patterns that have strong statistical association with the seed words in which the likelihood ratio test (LRT) is used to quantify the degree of association. Subsequently, the extracted lexical patterns can be further used in finding more new words. We design several measures to quantify the possibility of a candidate word being a new word, and the top-ranked words will be added into the seed word set for the next iteration. The process can be run iteratively until a stop condition is met. Note that we do not augment the pattern set ($\mathcal{P}$) at each iteration, instead, we keep a fixed small number of patterns during iteration because this strategy produces optimal results.

From linguistic perspectives, new sentiment words are commonly modified by adverbial words and thus can be extracted by lexical patterns. This is the reason why the algorithm will work. Our algorithm is in spirit to double propagation (Qiu et al., 2011), however, the differences are apparent in that: firstly, we use very lightweight linguistic information (except POS tags); secondly, our major contributions are to propose statistical measures to address the following key issues: first, to measure the utility of lexical patterns; second, to measure the possibility of a candidate word being a new word.

3.3 Measuring the Utility of a Pattern

The first key issue is to quantify the utility of a pattern at each iteration. This can be measured by the association of a pattern to the current word set used in the algorithm. The likelihood ratio tests (Dunning, 1993) is used for this purpose. This association model has also been used to model association between opinion target words by (Hai et

[1] We set the number to 3 words in this work considering computation costs.

[2] Such expressions are very simple and easy to write because we only need to consider POS tags of adverbial and auxiliary word.

Algorithm 1: New word detection algorithm

Input:
$\mathcal{D}$: a large set of POS tagged posts
$\mathcal{W}_s$: a set of seed words
k_p: the number of patterns chosen at each iteration
k_c: the number of patterns in the candidate pattern set
k_w: the number of words added at each iteration
K: the number of words returned
Output: A list of ranked new words $\mathcal{W}$

Obtain all lexical patterns using regular expressions on $\mathcal{D}$;
Count the frequency of each lexical pattern and extract words matched by each pattern ;
Obtain top k_c frequent patterns as candidate pattern set $\mathcal{P}_c$ and top 5,000 frequent words as candidate word set $\mathcal{W}_c$;
$\mathcal{P} = \Phi$; $\mathcal{W}$=$\mathcal{W}_s$; t = 0 ;
for $|\mathcal{W}| < K$ **do**
    Use $\mathcal{W}$ to score each pattern in $\mathcal{P}_c$ with $U(p)$;
    $\mathcal{P} = \{top\ k_p\ patterns\}$;
    Use $\mathcal{P}$ to extract new words and if the words are in $\mathcal{W}_c$, score them with $F(w)$;
    $\mathcal{W} = \mathcal{W} \bigcup \{top\ k_w\ words\}$;
    $\mathcal{W}_c$ = $\mathcal{W}_c$ - $\mathcal{W}$;
Sort words in $\mathcal{W}$ with $F(w)$;
Output the ranked list of words in $\mathcal{W}$;

al., 2012).

The LRT is well known for not relying critically on the assumption of normality, instead, it uses the asymptotic assumption of the generalized likelihood ratio. In practice, the use of likelihood ratios tends to result in significant improvements in text-analysis performance.

In our problem, LRT computes a contingency table of a pattern p and a word w, derived from the corpus statistics, as given in Table 3, where $k_1(w, p)$ is the number of documents that w matches pattern p, $k_2(w, \bar{p})$ is the number of documents that w occurs while p does not, $k_3(\bar{w}, p)$ is the number of documents that p occurs while w does not, and $k_4(\bar{w}, \bar{p})$ is the number of documents containing neither p nor w.

Statistics	p	$\bar{p}$
w	$k_1(w, p)$	$k_2(w, \bar{p})$
$\bar{w}$	$k_3(\bar{w}, p)$	$k_4(\bar{w}, \bar{p})$

Table 3: Contingency table for likelihood ratio test (LRT).

Based on the statistics shown in Table 3, the likelihood ratio tests (LRT) model captures the statistical association between a pattern p and a word w by employing the following formula:

$$LRT(p, w) = log \frac{L(\rho_1, k_1, n_1) * L(\rho_2, k_2, n_2)}{L(\rho, k_1, n_1) * L(\rho, k_2, n_2)} \quad (1)$$

where:
$L(\rho, k, n) = \rho^k * (1 - \rho)^{n-k}$; $n_1 = k_1 + k_3$; $n_2 = k_2 + k_4$; $\rho_1 = k_1/n_1$; $\rho_2 = k_2/n_2$; $\rho = (k_1 + k_2)/(n_1 + n_2)$.

Thus, the utility of a pattern can be measured as follows:

$$U(p) = \sum_{w_i \in \mathcal{W}} LRT(p, w_i) \quad (2)$$

where $\mathcal{W}$ is the current word set used in the algorithm (see Algorithm 1).

3.4 Measuring the Possibility of Being New Words

Another key issue in the proposed algorithm is to quantify the possibility of a candidate word being a new word. We consider several factors for this purpose.

3.4.1 Likelihood Ratio Test

Very similar to the pattern utility measure, LRT can also be used to measure the association of a candidate word to a given pattern set, as follows:

$$LRT(w) = \sum_{p_i \in \mathcal{P}} LRT(w, p_i) \quad (3)$$

where $\mathcal{P}$ is the current pattern set used in the algorithm (see Algorithm 1), and p_i is a lexical pattern.

This measure only quantifies the association of a candidate word to the given pattern set. It tells nothing about the possibility of a word being a new word, however, a new *sentiment* word, should have close association with the lexical patterns. This has linguistic interpretations because new sentiment words are commonly modified by adverbial words and thus should have close association with lexical patterns. This measure is proved to be an influential factor by our experiments in Section 4.3.

3.4.2 Left Pattern Entropy

If a candidate word is a new word, it will be more commonly used with diversified lexical patterns since the non-compositionality of new word means that the word can be used in many different linguistic scenarios. This can be measured by information entropy, as follows:

$$LPE(w) = -\sum_{l_i \in L(\mathcal{P}_c, w)} \frac{c(l_i, w)}{N(w)} * log \frac{c(l_i, w)}{N(w)} \quad (4)$$

where $L(\mathcal{P}_c, w)$ is the set of left word of all patterns by which word w can be matched in $\mathcal{P}_c$, $c(l_i, w)$ is the count that word w can be matched by patterns whose left word is l_i, and $N(w)$ is the count that word w can be matched by the patterns in $\mathcal{P}_c$. Note that we use $\mathcal{P}_c$, instead of $\mathcal{P}$, because the latter set is very small while computing entropy needs a large number of patterns. Tuning the size of $\mathcal{P}_c$ will be further discussed in Section 4.4.

3.4.3 New Word Probability

Some words occur very frequently and can be widely matched by lexical patterns, but they are not new words. For example, " 爱吃(love to eat)" and " 爱说(love to talk)" can be matched by many lexical patterns, however, they are not new words due to the lack of non-compositionality. In such words, each single character has high probability to be a word. Thus, we design the following measure to favor this observation.

$$NWP(w) = \prod_{i=1}^{n} \frac{p(w_i)}{1 - p(w_i)} \quad (5)$$

where $w = w_1 w_2 \dots w_n$, each w_i is a single character, and $p(w_i)$ is the probability of the character w_i being a word, as computed as follows:

$$p(w_i) = \frac{all(w_i) - s(w_i)}{all(w_i)}$$

where $all(w_i)$ is the total frequency of w_i, and $s(w_i)$ is the frequency of w_i being a single character word. Obviously, in order to obtain the value of $s(w_i)$, some particular Chinese word segmentation tool is required. In this work, we resort to ICTCLAS (Zhang et al., 2003), a widely used tool in the literature.

3.4.4 Non-compositionality Measures

New words are usually multi-word expressions, where a variety of statistical measures have been proposed to detect multi-word expressions. Thus, such measures can be naturally incorporated into our algorithm.

The first measure is enhanced mutual information (EMI) (Zhang et al., 2009):

$$EMI(w) = log_2 \frac{F/N}{\prod_{i=1}^{n} \frac{F_i - F}{N}} \quad (6)$$

where F is the number of posts in which a multi-word expression $w = w_1 w_2 \dots w_n$ occurs, F_i is the number of posts where w_i occurs, and N is the total number of posts. The key idea of EMI is to measure word pair' s dependency as the ratio of its probability of being a multi-word to its probability of not being a multi-word. The larger the value, the more possible the expression will be a multi-word expression.

The second measure we take into account is normalized multi-word expression distance (Bu et al., 2010), which has been proposed to measure the non-compositionality of multi-word expressions.

$$NMED(w) = \frac{log|\mu(w)| - log|\phi(w)|}{logN - log|\phi(w)|} \quad (7)$$

where $\mu(w)$ is the set of documents in which all single words in $w = w_1 w_2 \dots w_n$ co-occur, $\phi(w)$ is the set of documents in which word w occurs as a whole, and N is the total number of documents. Different from EMI, this measure is a strict distance metric, meaning that a smaller value indicates a larger possibility of being a multi-word expression. As can be seen from the formula, the key idea of this metric is to compute the ratio of the co-occurrence of all words in a multi-word expressions to the occurrence of the whole expression.

3.4.5 Configurations to Combine Various Factors

Taking into account the aforementioned factors, we have different settings to score a new word, as follows:

$$F_{LRT}(w) = LRT(w) \quad (8)$$

$$F_{LPE}(w) = LRT(w) * LPE(w) \quad (9)$$

$$F_{NWP}(w) = LRT(w) * LPE(w) * NWP(w) \quad (10)$$

$$F_{EMI}(w) = LRT(w) * LPE(w) * EMI(w) \quad (11)$$

$$F_{NMED}(w) = \frac{LRT(w) * LPE(w)}{NMED(w)} \quad (12)$$

4 Experiment

In this section, we will conduct the following experiments: first, we will compare our method to several baselines, and perform parameter tuning with extensive experiments; second, we will classify polarity of new sentiment words using two methods; third, we will demonstrate how new sentiment words will benefit sentiment classification.

4.1 Data Preparation

We crawled 237,108,977 Weibo posts from http://www.weibo.com, the largest social website in China. These posts range from January of 2011 to December of 2012. The posts were then part-of-speech tagged using a Chinese word segmentation tool named ICTCLAS (Zhang et al., 2003).

Then, we asked two annotators to label the top 5,000 frequent words that were extracted by lexical patterns as described in Algorithm 1. The annotators were requested to judge whether a candidate word is a new word, and also to judge the polarity of a new word (positive, negative, and neutral). If there is a disagreement on either of the two tasks, discussions are required to make the final decision. The annotation led to 323 new words, among which there are 116 positive words, 112 negative words, and 95 neutral words[3].

4.2 Evaluation Metric

As our algorithm outputs a ranked list of words, we adapt average precision to evaluate the performance of new sentiment word detection. The metric is computed as follows:

$$AP(K) = \frac{\sum_{k=1}^{K} P(k) * rel(k)}{\sum_{k=1}^{K} rel(k)}$$

where $P(k)$ is the precision at cut-off k, $rel(k)$ is 1 if the word at position k is a new word and 0 otherwise, and K is the number of words in the ranked list. A perfect list (all top K items are correct) has an AP value of 1.0.

4.3 Evaluation of Different Measures and Comparison to Baselines

First, we assess the influence of likelihood ratio test, which measures the association of a word to the pattern set. As can be seen from Table 4, the association model (LRT) remarkably boosts the performance of new word detection, indicating LRT is a key factor for new sentiment word extraction. From linguistic perspectives, new sentiment words are commonly modified by adverbial words and thus should have close association with lexical patterns.

Second, we compare different settings of our method to two baselines. The first one is enhanced mutual information (EMI) where we set $F(w) = EMI(w)$ (Zhang et al., 2009) and the second baseline is normalized multi-word expression distance (NMED) (Bu et al., 2010) where we set $F(w) = NMED(w)$. The results are shown in Figure 1. As can be seen, all the proposed measures outperform the two baselines (EMI and $NMED$) remarkably and consistently. The setting of F_{NMED} produces the best performance. Adding $NMED$ or EMI leads to remarkable improvements because of their capability of measuring non-compositionality of new words. Only using LRT can obtain a fairly good results when K is small, however, the performance drops sharply because it's unable to measure non-compositionality. Comparison between $LRT + LPE$ (or $LRT + LPE + NWP$) and LRT shows that inclusion of left pattern entropy also boosts the performance apparently. However, the new word probability (NWP) has only marginal contribution to improvement.

In the above experiments, we set $k_p = 5$ (the number of patterns chosen at each iteration) and $k_w = 10$ (the number of words added at each iteration), which is the optimal setting and will be discussed in the next subsection. And only one seed word "坑爹(reverse one's expectation)" is used.

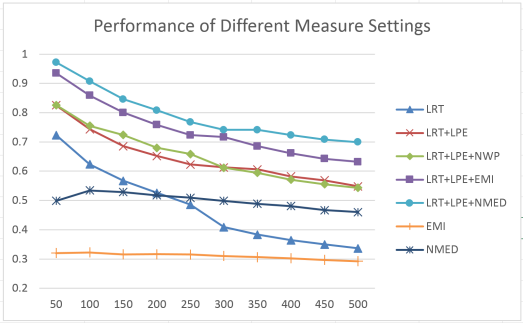

Figure 1: Comparative results of different measure settings. X-axis is the number of words returned (K), and Y-axis is average precision ($AP(K)$).

[3] All the resources are available upon request.

$top\ K\ words \Rightarrow$	100	200	300	400	500
LPE	0.366	0.324	0.286	0.270	0.259
LRT+LPE	**0.743**	**0.652**	**0.613**	**0.582**	**0.548**

Table 4: Results with vs. without likelihood ratio test (LRT).

4.4 Parameter Tuning

Firstly, we will show how to obtain the optimal settings of k_p and k_w. The measure setting we take here is $F_{NMED}(w)$, as shown in Formula (12). Again, we choose only one seed word "坑爹(reverse one's expectation)", and the number of words returned is set to $K = 300$. Results in Table 5 show that the performance drops consistently across different k_w settings when the number of patterns increases. Note that at the early stage of Algorithm 1, larger k_p (perhaps with noisy patterns) may lead to lower quality of new words; while larger k_w (perhaps with noisy seed words) may lead to lower quality of lexical patterns. Therefore, we choose the optimal setting to small numbers, as $k_p = 5, k_w = 10$.

Secondly, we justify whether the proposed algorithm is sensitive to the number of seed words. We set $k_p = 5$ and $k_w = 10$, and take F_{NMED} as the weighting measure of new word. We experimented with only one seed word, two, three, and four seed words, respectively. The results in Table 6 show very stable performance when different numbers of seed words are chosen. It's interesting that the performance is totally the same with different numbers of seed words. By looking into the pattern set and the selected words at each iteration, we found that the pattern set ($\mathcal{P}$) converges soon to the same set after a few iterations; and at the beginning several iterations, the selected words are almost the same although the order of adding the words is different. Since the algorithm will finally sort the words at step (11) and $\mathcal{P}$ is the same, the ranking of the words becomes all the same.

Lastly, we need to decide the optimal number of patterns in $\mathcal{P}_c$ (that is, k_c in Algorithm 1) because the set has been used in computing left pattern entropy, see Formula (4). Too small size of $\mathcal{P}_c$ may lead to insufficient estimation of left pattern entropy. Results in Table 7 shows that larger $\mathcal{P}_c$ decrease the performance, particularly when the number of words returned (K) becomes larger. Therefore, we set $|\mathcal{P}_c| = 100$.

4.5 Polarity Prediction of New Sentiment Words

In this section, we attempt to classifying the polarity of the annotated 323 new words. Two methods are adapted with different settings for this purpose. The first one is majority vote (MV), and the second one is pointwise mutual information, similar to (Turney and Littman, 2003). The majority vote method is formulated as below:

$$MV(w) = \sum_{w_p \in PW} \frac{\#(w, w_p)}{|PW|} - \sum_{w_n \in NW} \frac{\#(w, w_n)}{|NW|}$$

where PW and NW are a positive and negative set of emoticons (or seed words) respectively, and $\#(w, w_p)$ is the co-occurrence count of the input word w and the item w_p. The polarity is judged according to this rule: if $MV(w) > th_1$, the word w is positive; if $MV(w) < -th_1$ the word negative; otherwise neutral. The threshold th_1 is manually tuned.

And PMI is computed as follows:

$$PMI(w) = \sum_{w_p \in PW} \frac{PMI(w, w_p)}{|PW|} - \sum_{w_n \in NW} \frac{PMI(w, w_n)}{|NW|}$$

where $PMI(x, y) = log_2(\frac{Pr(x,y)}{Pr(x)*Pr(y)})$, and $Pr(\cdot)$ denotes probability. The polarity is judged according to the rule: if $PMI(w) > th_2$, w is positive; if $PMI(w) < -th_2$ negative; otherwise neutral. The threshold th_2 is manually tuned.

As for the resources PW and NW, we have three settings. The first setting (denoted by

k_w \ k_p	2	3	4	5	10	20	50
5	0.753	0.738	0.746	0.741	0.741	0.734	0.715
10	0.753	0.738	0.746	0.741	0.741	0.728	0.712
15	0.753	0.738	0.746	0.741	0.754	0.734	0.718
20	0.763	0.738	0.744	0.749	0.749	0.735	0.717

Table 5: Parameter tuning results for k_p and k_w. The measure setting is $F_{NMED}(w)$, the seed word set is {"坑爹(reverse one's expectation)"}, and the number of words returned is $K = 300$.

$\#\ seeds \Rightarrow$	1	2	3	4
K=100	0.907	0.907	0.907	0.907
K=200	0.808	0.808	0.808	0.808
K=300	0.741	0.741	0.741	0.741
K=400	0.709	0.709	0.709	0.709
K=500	0.685	0.685	0.685	0.685

Table 6: Performance with different numbers of seed words. The measure setting is $F_{NMED}(w)$, and $k_p = 5$, $k_w = 10$. The seed words are chosen from Table 1.

Large_Emo) is a set of most frequent 36 emoticons in which there are 21 positive and 15 negative emoticons respectively. The second one (denoted by Small_Emo) is a set of 10 emoticons, which are chosen from the 36 emoticons, as shown in Table 8. The third one (denoted by Opin_Words) is two sets of seed opinion words, where PW={高兴(happy),大方(generous),漂亮(beautiful), 善良(kind), 聪明(smart)} and NW ={伤心(sad),小气(mean),难看(ugly), 邪恶(wicked), 笨(stupid)}.

The performance of polarity prediction is shown in Table 9. In two-class polarity classification, we remove neutral words and only make prediction with positive/negative classes. The first observation is that the performance of using emoticons is much better than that of using seed opinion words. We conjecture that this may be because new sentiment words are more frequently co-occurring with emoticons than with these opinion words. The second observation is that three-class polarity classification is much more difficult than two-class polarity classification because many extracted new words are nouns such as "基友(gay)","菇凉(girl)", and "盆友(friend)". Such nouns are more difficult to classify sentiment orientation.

4.6 Application of New Sentiment Words to Sentiment Classification

In this section, we justify whether inclusion of new sentiment word would benefit sentiment classification. For this purpose, we randomly sampled and annotated 4,500 Weibo posts that contain at least one opinion word in the union of the Hownet [4] opinion lexicons and our annotated new words. We apply two models for polarity classification. The first model is a lexicon-based model (denoted by $Lexicon$) that counts the number of positive and negative opinion words in a post respectively, and classifies a post to be positive if there are more positive words than negative ones, and to be negative otherwise. The second model is a SVM model in which opinion words are used as feature, and 5-fold cross validation is conducted.

We experiment with different settings of Hownet lexicon resources:

- Hownet opinion words (denoted by Hownet): After removing some obviously inappropriate words, the left lexicons have 627 positive opinion words and 1,038 negative opinion words, respectively.
- Compact Hownet opinion words (denoted by cptHownet): we count the frequency of the above opinion words on the training data and remove words whose document frequency is less than 2. This results in 138 positive words and 125 negative words.

Then, we add into the above resources the labeled new polar words(denoted by NW, including 116 positive and 112 negative words) and the top 100 words produced by the algorithm (denoted by $T100$), respectively. Note that the lexicon-based model requires the sentiment orientation of each dictionary entry [5], we thus manually label the po-

[4] http://www.keenage.com/html/c_index.html.

[5] This is not necessary for the SVM model. All words in the top 100 words can be used as feature.

$\|\mathcal{P}_c\| \Rightarrow$	50	100	200	300	400	500
K=100	0.907	0.905	0.916	0.916	0.888	0.887
K=200	0.808	0.810	0.778	0.776	0.766	0.764
K=300	0.741	0.731	0.722	0.726	0.712	0.713
K=400	0.709	0.708	0.677	0.675	0.656	0.655
K=500	0.685	0.683	0.653	0.646	0.626	0.627

Table 7: Tuning the number of patterns in $\mathcal{P}_c$. The measure setting is $F_{NMED}(w)$, $k_p = 5$, $k_w = 10$, and the seed word set is {"坑爹(reverse one's expectation)"}.

Emoticon	Polarity	Emoticon	Polarity
	positive		negative
	positive		negative
	positive		negative
	positive		negative
	positive		negative

Methods $\Rightarrow$	Majority vote	PMI
Two-class polarity classification		
Large_Emo	0.861	0.865
Small_Emo	0.846	0.851
Opin_Words	0.697	0.654
Three-class polarity classification		
Large_Emo	0.598	0.632
Small_Emo	0.551	0.635
Opin_Words	0.449	0.486

Table 9: The accuracy of two/three-class polarity classification.

larity of all top 100 words (we did NOT remove incorrect new word). This results in 52 positive and 34 negative words.

Results in Table 10 show that inclusion of new words in both models improves the performance remarkably. In the setting of the original lexicon (Hownet), both models obtain 2-3% gains from the inclusion of new words. Similar improvement is observed in the setting of the compact lexicon. Note, that $T100$ is automatically obtained from Algorithm 1 so that it may contain words that are not new sentiment words, but the resource also improves performance remarkably.

5 Conclusion

In order to extract *new sentiment words* from large-scale user-generated content, this paper proposes a fully unsupervised, purely data-driven, and

	# Pos/Neg	Lexicon	SVM
Hownet	627/1,038	0.737	0.756
Hownet+NW	743/1,150	0.770	0.779
Hownet+T100	679/1,172	0.761	0.774
cptHownet	138/125	0.738	0.758
cptHownet+NW	254/237	0.774	0.782
cptHownet+T100	190/159	0.764	0.775

Table 10: The accuracy of polarity classfication of Weibo post with/without new sentiment words. N-W includes 116/112 positive/negative words, and T100 contains 52/34 positive/negative words.

almost knowledge-free (except POS tags) framework. We design statistical measures to quantify the utility of a lexical pattern and to measure the possibility of a word being a new word, respectively. The method is almost free of linguistic resources (except POS tags), and does not rely on elaborated linguistic rules. We conduct extensive experiments to reveal the influence of different statistical measures in new word finding. Comparative experiments show that our proposed method outperforms baselines remarkably. Experiments also demonstrate that inclusion of new sentiment words benefits sentiment classification definitely.

From linguistic perspectives, our framework is capable to extract *adjective* new words because the lexical patterns usually modify adjective words. As future work, we are considering how to extract other types of new sentiment words, such as *nounal* new words that can express sentiment.

Abstract

The sentiment captured in opinionated text provides interesting and valuable information for social media services. However, due to the complexity and diversity of linguistic representations, it is challenging to build a framework that accurately extracts such sentiment. We propose a semi-supervised framework for generating a domain-specific sentiment lexicon and inferring sentiments at the *segment* level. Our framework can greatly reduce the human effort for building a domain-specific sentiment lexicon with high quality. Specifically, in our evaluation, working with just 20 manually labeled reviews, it generates a domain-specific sentiment lexicon that yields weighted average F-Measure gains of 3%. Our sentiment classification model achieves approximately 1% greater accuracy than a state-of-the-art approach based on elementary discourse units.

1 Introduction

Automatically extracting sentiments from user-generated opinionated text is important in building social media services. However, the complexity and diversity of the linguistic representations of sentiments make this problem challenging.

High-quality sentiment lexicons can improve the performance of sentiment analysis models over general-purpose lexicons (Choi and Cardie, 2009). More advanced methods such as (Kanayama and Nasukawa, 2006) adopt domain knowledge by extracting sentiment words from the domain-specific corpus. However, depending on the context, the same word can have different polarities even in the same domain (Liu, 2012).

In respect to sentiment classification, Pang et al. (2002) infer the sentiments using basic features, such as bag-of-words. To capture more complex linguistic phenomena, leading approaches (Nakagawa et al., 2010; Jo and Oh, 2011; Kim et al., 2013) apply more advanced models but assume one document or sentence holds one sentiment. However, this is often not the case. Sentiments can change within one document, one sentence, or even one clause. Also, existing approaches infer sentiments without considering the changes of sentiments within or between clauses. However, these changes can be successfully exploited for inferring fine-grained sentiments.

To address the above shortcomings of lexicon and granularity, we propose a semi-supervised framework named ReNew. (1) Instead of using sentences, ReNew uses *segments* as the basic units for sentiment classification. Segments can be shorter than sentences and therefore help capture fine-grained sentiments. (2) ReNew leverages the relationships between consecutive segments to infer their sentiments and automatically generates a domain-specific sentiment lexicon in a semi-supervised fashion. (3) To capture the contextual sentiment of words, ReNew uses dependency relation pairs as the basic elements in the generated sentiment lexicon.

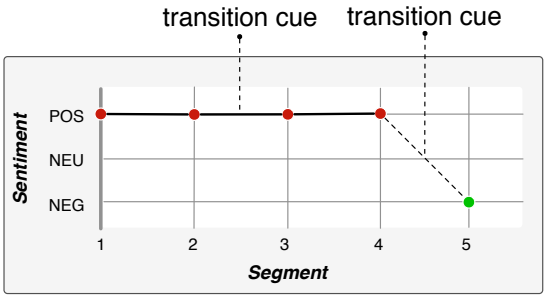

Figure 1: Segments in a Tripadvisor review.

Consider a part of a review from Tripadvisor.[1] We split it into six segments with sentiment labels.

[1] http://www.tripadvisor.com/ShowUserReviews-g32655-d81765-r100000013

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 542–551,
Baltimore, Maryland, USA, June 23-25 2014.

"... (**1: POS**) *The hotel was clean and comfortable.* (**2: POS**) *Service was friendly* (**3: POS**) *even providing us a late-morning check-in.* (**4: POS**) *The room was quiet and comfortable,* (**5: NEG**) *but it was beginning to show a few small signs of wear and tear. ...*"

Figure 1 visualizes the sentiment changes within the text. The sentiment remains the same across Segments 1 to 4. The sentiment transition between Segments 4 and 5 is indicated by the transition cue "but"—which signals conflict and contradiction. Assuming we know Segment 4 is positive, given the fact that Segment 5 starts with "but," we can infer with high confidence that the sentiment in Segment 5 changes to neutral or negative even without looking at its content. After classifying the sentiment of Segment 5 as NEG, we associate the dependency relation pairs {"sign", "wear"} and {"sign", "tear"} with that sentiment.

ReNew can greatly reduce the human effort for building a domain-specific sentiment lexicon with high quality. Specifically, in our evaluation on two real datasets, working with just 20 manually labeled reviews, ReNew generates a domain-specific sentiment lexicon that yields weighted average F-Measure gains of 3%. Additionally, our sentiment classification model achieves approximately 1% greater accuracy than a state-of-the-art approach based on elementary discourse units (Lazaridou et al., 2013).

The rest of this paper is structured as follows. Section 2 introduces some essential background. Section 3 illustrates ReNew. Section 4 presents our experiments and results. Section 5 reviews some related work. Section 6 concludes this paper and outlines some directions for future work.

2 Background

Let us introduce some of the key terminology used in ReNew. A **segment** is a sequence of words that represents at most one sentiment. A segment can consist of multiple consecutive clauses, up to a whole sentence. Or, it can be shorter than a clause. A **dependency relation** defines a binary relation that describes whether a pairwise syntactic relation among two words holds in a sentence. In ReNew, we exploit the Stanford typed dependency representations (de Marneffe et al., 2006) that use triples to formalize dependency relations. A domain-specific sentiment lexicon contains three lists of dependency relations, associated respectvely with positive, neutral, or negative sentiment.

Given a set of reviews, the tasks of sentiment analysis in ReNew are (1) splitting each review into segments, (2) associating each segment with a sentiment label (positive, neutral, negative), and (3) automatically generating a domain-specific sentiment lexicon. We employ Conditional Random Fields (Lafferty et al., 2001) to predict the sentiment label for each segment. Given a sequence of segments $\bar{x} = (x_1, \cdots, x_n)$ and a sequence of sentiment labels $\bar{y} = (y_1, \cdots, y_n)$, the CRFs model $p(\bar{y}|\bar{x})$ as follows.

$$p(\bar{y}|\bar{x}) = \frac{1}{Z(\bar{x})} \exp \sum_{j}^{J} (\omega_j \cdot F_j(\bar{x}, \bar{y}))$$

$$F_j(\bar{x}, \bar{y}) = \sum_{i=1}^{n} f_j(y_{i-1}, y_i, \bar{x}, i)$$

where ω is a set of weights learned in the training process to maximize $p(\bar{y}|\bar{x})$. $Z(\bar{x})$ is a normalization constant that is the sum of all possible label sequences. And, F_j is a feature function that sums f_j over $i \in (1, n)$, where n is the length of $\bar{y}$, and f_j can have arbitrary dependencies on the observation sequence $\bar{x}$ and neighboring labels.

3 Framework

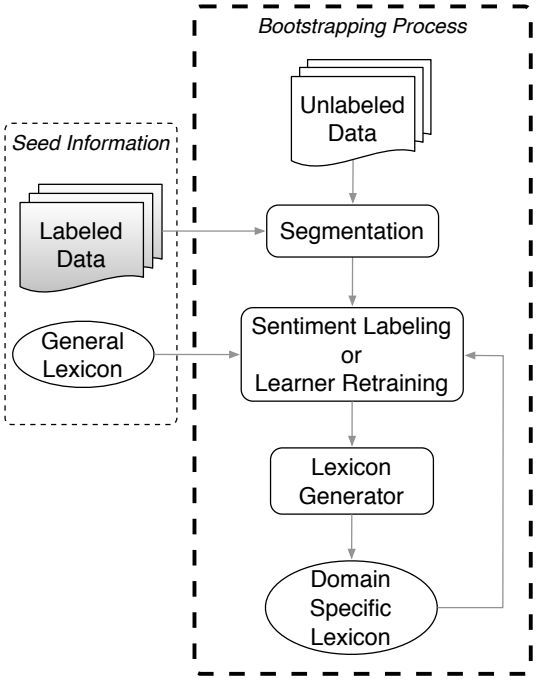

Figure 2: The ReNew framework schematically.

Figure 2 illustrates ReNew. Its inputs include

a general sentiment lexicon and a small labeled training dataset. We use a general sentiment lexicon and the training dataset as prior knowledge to build the initial learners.

On each iteration in the bootstrapping process, additional unlabeled data is first segmented. Second, the learners predict labels for segments based on current knowledge. Third, the lexicon generator determines which newly learned dependency relation triples to promote to the lexicon. At the end of each iteration, the learners are retrained via the updated lexicon so as to classify better on the next iteration. After labeling all of the data, we obtain the final version of our learners along with a domain-specific lexicon.

3.1 Rule-Based Segmentation Algorithm

Algorithm 1 Rule-based segmentation.

Require: Review dataset T
1: **for all** review r in T **do**
2: Remove HTML tags
3: Expand typical abbreviations
4: Mark special name-entities
5: **for all** sentence m in r **do**
6: **while** m contains a transition cue **and** m is not empty **do**
7: Extract subclause p that contains the transition cue
8: Add p as segment s into segment list
9: Remove p from m
10: **end while**
11: Add the remaining part in m as segment s into segment list
12: **end for**
13: **end for**

The algorithm starts with a review dataset T. Each review r from dataset T is first normalized by a set of hard-coded rules (lines 2–4) to remove unnecessary punctuations and HTML tags, expand typical abbreviations, and mark special name entities (e.g., replace a URL by #LINK# and replace a monetary amount "$78.99" by #MONEY#).

After the normalization step, it splits each review r into sentences, and each sentence into subclauses (lines 6–10) provided transition cues occur. In effect, the algorithm converts each review into a set of segments.

Note that ReNew captures and uses the sentiment changes. Therefore, our segmentation algorithm considers only two specific types of transition cues including contradiction and emphasis.

3.2 Sentiment Labeling

ReNew starts with a small labeled training set. Knowledge from this initial training set is not sufficient to build an accurate sentiment classification model or to generate a domain-specific sentiment lexicon. Unlabeled data contains rich knowledge, and it can be easily obtained. To exploit this resource, on each iteration, the sentiment labeling component, as shown in Figure 3, labels the data by using multiple learners and a label integrator. We have developed a forward (FR) and a backward relationship (BR) learner to learn relationships among segments.

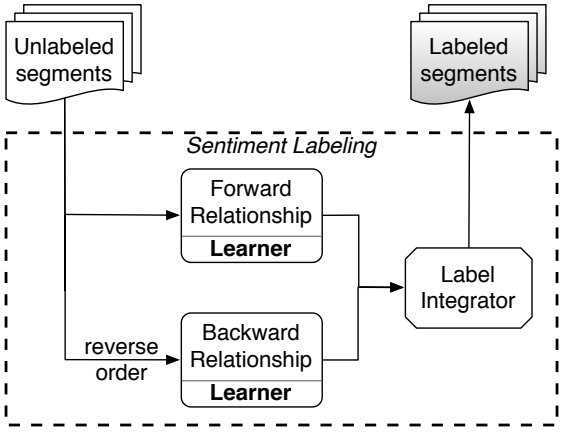

Figure 3: Sentiment labeling.

3.2.1 FR and BR Learners

The FR learner learns the relationship between the current segment and the next. Given the sentiment label and content of a segment, it tries to find the best possible sentiment label of the next segment. The FR Learner tackles the following situation where two segments are connected by a transition word, but existing knowledge is insufficient to infer the sentiment of the second segment. For instance, consider the following review sentence.[2]

(1) *The location is great,* (2) ***but*** *the staff was pretty ho-hum about everything from checking in, to AM hot coffee, to PM bar.*

The sentence contains two segments. We can easily infer the sentiment polarity of Segment 1 based on the word "great" that is commonly included in many general sentiment lexicons. For Segment 2, without any context information, it is difficult to infer its sentiment. Although the

[2]http://www.tripadvisor.com/ShowUserReviews-g60763-d93589-r10006597

word "ho-hum" indicates a negative polarity, it is not a frequent word. However, the conjunction "but" clearly signals a contrast. So, given the fact that the former segment is positive, a pre-trained FR learner can classify the latter as negative. The Backward Relationship (BR) learner does the same but with the segments in each review in reverse order.

3.2.2 Label Integrator

Given the candidate sentiment labels suggested by the two learners, the label integrator first selects the label with confidence greater than or equal to a preset threshold. Segments are left unlabeled if their candidate labels belong to mutually exclusive categories with the same confidence.

3.3 Lexicon Generator

In each iteration, after labeling a segment, the lexicon generator identifies new triples automatically. As shown in Figure 4, this module contains two parts: a Triple Extractor and a Lexicon Integrator. For each sentiment, the Triple Extractor (TE) extracts candidate dependency relation triples using a novel rule-based approach. The Lexicon Integrator (LI) evaluates the proposed candidates and promotes the most supported candidates to the corresponding sentiment category in the domain-specific lexicon.

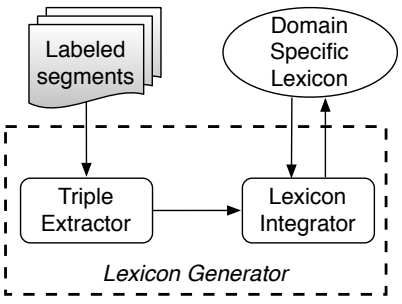

Figure 4: Lexicon generator module.

3.3.1 Triple Extractor (TE)

The TE follows the steps below, for segments that contain only one clause, as demonstrated in Figure 5 for *"The staff was slow and definitely not very friendly."* The extracted triples are $root\_nsubj$(slow, staff), $nsubj$(slow, staff), and $nsubj$(not_friendly, staff).

1. Generate a segment's dependency parse tree.
2. Identify the root node of each clause in the segment.
3. Remove all triples except those marked E in Table 1.
4. Apply the rules in Table 2 to add or modify triples.
5. Suggest the types of triples marked L in Table 1 to the lexicon integrator.

Table 1: Dependency relation types used in extracting (E) and domain-specific lexicon (L).

Types	Explanation	E	L
$amod$	adjectival modifier	√	√
$acomp$	adjectival complement	√	√
$nsubj$	nominal subject	√	√
neg	negation modifier	√	
$conj\_and$	words coordinated by "and" or similar	√	
$prep\_with$	words coordinated by "with"	√	
$root$	root node	√	
$root\_amod$	amod root node		√
$root\_acomp$	acomp root node		√
$root\_nsubj$	nsubj root node		√
$neg\_pattern$	"neg" pattern		√

Table 1 describes all seven types of triples used in the domain-specific lexicon. Among them, $amod$, $acomp$, and $nsubj$ are as in (de Marneffe et al., 2006). And, $root\_amod$ captures the root node of a sentence when it also appears in the adjectival modifier triple, similarly for $root\_acomp$ and $root\_nsubj$. We observe that the word of the root node is often related to the sentiment of a sentence and this is especially true when this word also appears in the adjectival modifier, adjectival complement, or negation modifier triple.

Zhang et al. (2010) propose the $no\_pattern$ that describes a word pair whose first word is "No" followed by a noun or noun phrase. They show that this pattern is a useful indicator for sentiment analysis. In our dataset, in addition to "No," we observe the frequent usage of "Nothing" followed by an adjective. For example, users may express a negative feeling about a hotel using sentence such as "Nothing special." Therefore, we create the $neg\_pattern$ to capture a larger range of possible word pairs. In ReNew, $neg\_pattern$ is "No" or "Nothing" followed by a noun or noun phrase or an adjective.

3.3.2 Lexicon Integrator (LI)

The Lexicon Integrator promotes candidate triples with a frequency greater than or equal to a preset

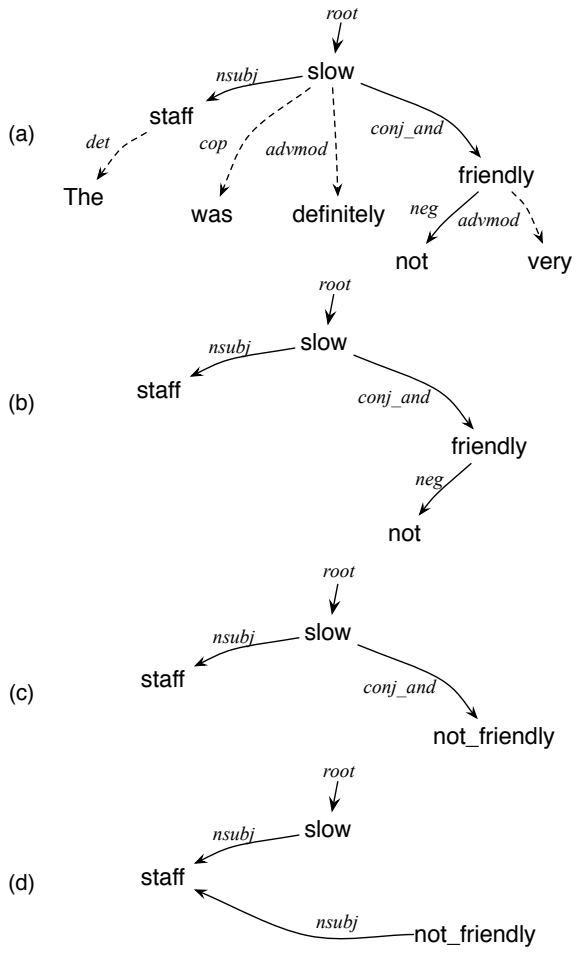

Figure 5: Extracting sentiment triples from a segment that contains one clause. (a) The initial dependency parse tree. (b) Remove nonsentiment triples. (c) Handle negation triples. (d) Build relationships.

threshold. The frequency list is updated in each iteration. The LI first examines the prior knowledge represented as an ordered list of the governors of all triples, each is attached with an ordered list of its dependents. Then, based on the triples promoted in this iteration, the order of the governors and their dependents is updated. Triples are not promoted if their governors or dependents appear in a predetermined list of stopwords.

The LI promotes triples by respecting mutual exclusion and the existing lexicon. In particular, it does not promote triples if they exist in multiple sentiment categories or if they already belong to a different sentiment category.

Finally, for each sentiment, we obtain seven sorted lists corresponding to *amod*, *acomp*, *nsubj*, *root_amod*, *root_acomp*, *root_nsubj*, and *neg_pattern*. These lists form the domain-specific sentiment lexicon.

Table 2: Rules for extracting sentiment triples.

Rule	Function	Condition	Result
R_1	Handle Negation	word w_i; $neg(w_{gov}, w_{dep})$; $w_i = w_{gov}$;	$w_i = w_{dep} + \text{“\_”} + w_i$
R_2	Build Relationships $(conj\_and, amod)$	word w_i and w_j; $conj\_and(w_i, w_j)$; $amod(w_{gov}, w_i)$;	$amod(w_{gov}, w_i)$ $amod(w_{gov}, w_j)$
R_3	Build Relationships $(conj\_and, acomp)$	word w_i and w_j; $conj\_and(w_i, w_j)$; $acomp(w_{gov}, w_i)$;	$acomp(w_{gov}, w_i)$ $acomp(w_{gov}, w_j)$
R_4	Build Relationships $(conj\_and, nsubj)$	word w_i and w_j; $conj\_and(w_i, w_j)$; $nsubj(w_i, w_{dep})$;	$nsubj(w_i, w_{dep})$ $nsubj(w_j, w_{dep})$

3.4 Learner Retraining

At the end of each iteration, ReNew retrains each learner as shown in Figure 6. Newly labeled segments are selected by a filter. Then, given an updated lexicon, learners are retrained to perform better on the next iteration. Detailed description of the filter and learner are presented below.

3.4.1 Filter

The filter seeks to prevent labeling errors from accumulating during bootstrapping. In ReNew, newly acquired training samples are segments with labels that are predicted by old learners. Each predicted label is associated with a confidence value. The filter is applied to select those labeled segments with confidence greater than or equal to a preset threshold.

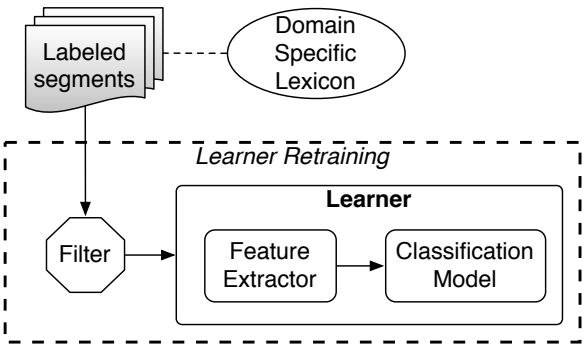

Figure 6: Retrain a relationship learner.

3.4.2 Learner

As Section 3.2 describes, ReNew uses learners to capture different types of relationships among segments to classify sentiment by leveraging these relationships. Each learner contains two components: a feature extractor and a classification model. To train a learner, the feature extractor first converts labeled segments into feature vectors

Table 3: A list of transition types used in ReNew.

Transition Types	Examples
Agreement, Addition, and Similarity	also, similarly, as well as, ...
Opposition, Limitation, and Contradiction	but, although, in contrast, ...
Cause, Condition, and Purpose	if, since, as/so long as, ...
Examples, Support, and Emphasis	including, especially, such as, ...
Effect, Consequence, and Result	therefore, thus, as a result ...
Conclusion, Summary, and Restatement	overall, all in all, to sum up, ...
Time, Chronology, and Sequence	until, eventually, as soon as, ...

for training a CRF-based sentiment classification model. The feature extractor generates five kinds of features as below.

Grammar: part-of-speech tag of every word, the type of phrases and clauses (if known).

Opinion word: To exploit a general sentiment lexicon, we use two binary features indicating the presence or absence of a word in the positive or negative list in a general sentiment lexicon.

Dependency relation: The lexicon generated by ReNew uses the Stanford typed dependency representation as its structure.

Transition cue: For tracking the changes of the sentiment, we exploit seven types of transition cues, as shown in Table 3.

Punctuation, special name-entity, and segment position: Some punctuation symbols, such as "!", are reliable carriers of sentiments. We mark special named-entities, such as time, money, and so on. In addition, we use segment positions (beginning, middle, and end) in reviews as features.

4 Experiments

To assess ReNew's effectiveness, we prepare two hotel review datasets crawled from Tripadvisor. One dataset contains a total of 4,017 unlabeled reviews regarding 802 hotels from seven US cities. The reviews are posted by 340 users, each of whom contributes at least ten reviews. The other dataset contains 200 reviews randomly selected from Tripadvisor. We collected ground-truth labels for this dataset by inviting six annotators in two groups of three. Each group labeled the same 100 reviews. We obtained the labels for each segment consist as positive, neutral, or negative. Fleiss' kappa scores for the two groups were 0.70 and 0.68, respectively, indicating substantial agreement between our annotators.

The results we present in the remainder of this section rely upon the following parameter values. The confidence thresholds used in the Label Integrator and filter are both set to 0.9 for positive labels and 0.7 for negative and neutral labels. The minimum frequency used in the Lexicon Integrator for selecting triples is set to 4.

4.1 Feature Function Evaluation

Our first experiment evaluates the effects of different combinations of features. To do this, we first divide all features into four basic feature sets: *T* (transition cues), *P* (punctuations, special name-entities, and segment positions), *G* (grammar), and *OD* (opinion words and dependency relations). We train 15 sentiment classification models using all basic features and their combinations. Figure 7 shows the results of a 10-fold cross validation on the 200-review dataset (light grey bars show the accuracy of the model trained without using transition cue features).

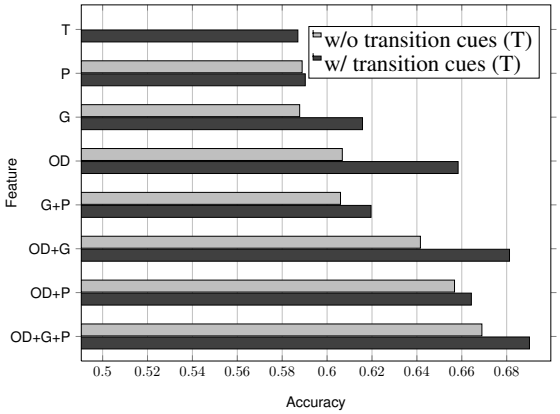

Figure 7: Accuracy using different features.

The feature *OD* yields the best accuracy, followed by *G*, *P*, and *T*. Although *T* yields the worst accuracy, incorporating it improves the resulting accuracy of the other features, as shown by the dark grey bars. In particular, the accuracy of *OD* is markedly improved by adding *T*. The model trained using all the feature sets yields the best accuracy.

4.2 Relationship Learners Evaluation

Our second experiment evaluates the impact of the relationship learners and the label integrator. To this end, we train and compare sentiment classification models using three configurations. The first configuration (FW-L) uses only the FR learner; the second (BW-L) only the BR learner. ALL-L uses both the FR and BR learners, together with a label integrator. We evaluate them with 10-fold cross

validation on the 200-review dataset.

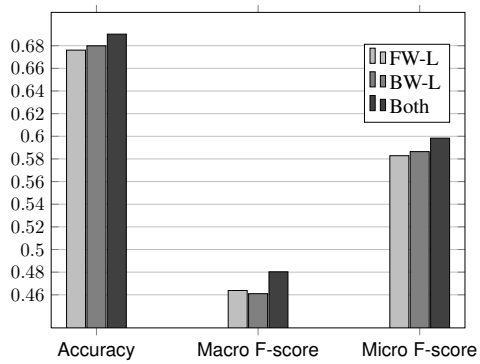

Figure 8: Comparison among the learners.

Figure 8 reports the accuracy, macro F-score, and micro F-score. It shows that the BR learner produces better accuracy and a micro F-score than the FR learner but a slightly worse macro F-score. Jointly considering both learners with the label integrator achieves better results than either alone. The results demonstrate the effectiveness of our sentiment labeling component.

4.3 Domain-Specific Lexicon Assessment

Our third experiment evaluates the quality of the domain-specific lexicon automatically generated by ReNew. To do this, we first transform each of the 200 labeled reviews into feature vectors. Then we retrain Logistic Regression models using WEKA (Hall et al., 2009). Note that we use only the features extracted from the lexicons themselves. This is important because to compare only the lexicons' impact on sentiment classification, we need to avoid the effect of other factors, such as syntax, transition cues, and so on. We compare models trained using (1) our domain-specific lexicon, (2) Affective Norms for English Words (ANEW) (Bradley and Lang, 1999), and (3) Linguistic Inquiry and Word Count (LIWC) (Tausczik and Pennebaker, 2010). ANEW and LIWC are well-known general sentiment lexicons.

Table 4 shows the results obtained by 10-fold cross validation. Each weighted average is computed according to the number of segments in each class. The table shows the significant advantages of the lexicon generated by ReNew. ANEW achieves the highest recall for the positive class, but the lowest recalls in the negative and neutral classes. Regarding the neutral class, both ANEW and LIWC achieve poor results. The weighted average measures indicate our lexicon has the highest overall quality.

Our domain-specific lexicon contains distinguishable aspects associated with sentiment words. For example, the aspect "staff" is associated with positive words (e.g., "nice," "friendli," "help," "great," and so on) and negative words (e.g., "okai," "anxiou," "moodi," "effici," and so on). We notice that some positive words also occur on the negative side. This may be for two reasons. First, some sentences that contain positive words may convey a negative sentiment, such as "The staff should be more efficient." Second, the bootstrapping process in ReNew may introduce some wrong words by mistakenly labeling the sentiment of the segments. These challenges suggest useful directions for the future work.

4.4 Lexicon Generation and Sentiment Classification

Our fourth experiment evaluates the robustness of ReNew's lexicon generation process as well as the performance of the sentiment classification models using these lexicons. We first generate ten domain-specific lexicons by repeatedly following these steps: For the first iteration, (1) build a training dataset by randomly selecting 20 labeled reviews (about 220 segments) and (2) train the learners using the training dataset and LIWC. For each iteration thereafter, (1) label 400 reviews from the unlabeled dataset (4,071 reviews) and (2) update the lexicon and retrain the learners. After labeling all of the data, output a domain-specific lexicon.

To evaluate the benefit of using domain-specific sentiment lexicons, we train ten sentiment classification models using the ten lexicons and then compare them, pairwise, against models trained with the general sentiment lexicon LIWC. Each model consists of an FR learner, a BR learner, and a label integrator. Each pairwise comparison is evaluated on a testing dataset with 10-fold cross validation. Each testing dataset consists of 180 randomly selected reviews (about 1,800 segments). For each of the pairwise comparisons, we conduct a paired t-test to determine if the domain-specific sentiment lexicon can yield better results.

Figure 9 shows the pairwise comparisons of accuracy between the two lexicons. Each group of bars represents the accuracy of two sentiment classification models trained using LIWC (CRFs-General) and the generated domain-specific lexicon (CRFs-Domain), respectively. The solid line corresponds to a baseline model that takes the ma-

Table 4: Comparison results of different lexicons.

	ANEW			LIWC			ReNew		
	Precision	Recall	F-Measure	Precision	Recall	F-Measure	Precision	Recall	F-Measure
Positive	0.59	**0.994**	0.741	0.606	0.975	0.747	**0.623**	0.947	**0.752**
Negative	0.294	0.011	0.021	**0.584**	0.145	0.232	0.497	**0.202**	**0.288**
Neutral	0	0	0	0	0	0	**0.395**	**0.04**	**0.073**
Weighted average	0.41	0.587	0.44	0.481	0.605	0.489	**0.551**	**0.608**	**0.518**

jority classification strategy. Based on the distribution of the datasets, the majority class of all datasets is positive. We can see that models using either the general lexicon or the domain-specific lexicon achieve higher accuracy than the baseline model. Domain-specific lexicons produce significantly higher accuracy than general lexicons. In the figures below, we indicate significance to 10%, 5%, and 1% as '$\cdot$', '$*$', and '$**$', respectively.

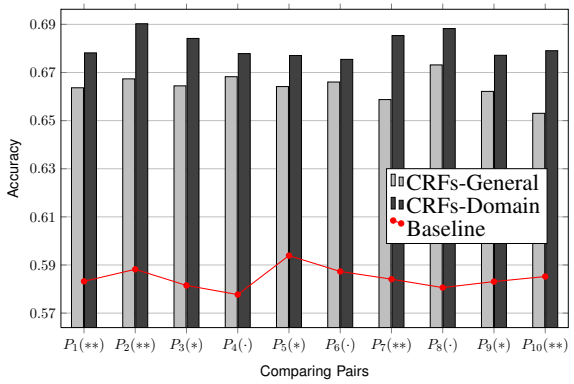

Figure 9: Accuracy with different lexicons.

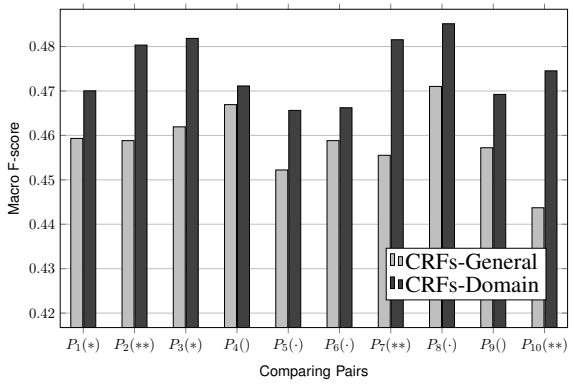

Figure 10: Macro F-score with different lexicons.

Figure 10 and 11 show the pairwise comparisons of macro and micro F-score together with the results of the paired t-tests. We can see that the domain-specific lexicons (dark-grey bars) consistently yield better results than their corresponding general lexicons (light-grey bars).

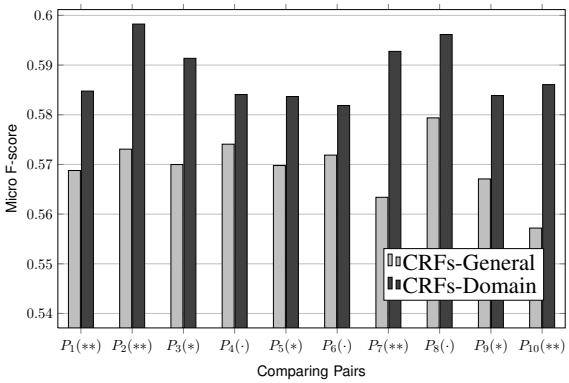

Figure 11: Micro F-score with different lexicons.

ReNew starts with LIWC and a labeled dataset and generates ten lexicons and sentiment classification models by iteratively learning 4,017 unlabeled reviews without any human guidance. The above results show that the generated lexicons contain more domain-related information than the general sentiment lexicons. Also, note that the labeled datasets we used contain only 20 labeled reviews. This is an easy requirement to meet.

4.5 Comparison with Previous Work

Our fifth experiment compares ReNew with Lazaridou et al.'s (2013) approach for sentiment classification using discourse relations. Like ReNew, Lazaridou et al.'s approach works on the sub sentential level. However, it differs from ReNew in three aspects. First, the basic units of their model are elementary discourse units (EDUs) from Rhetorical Structure Theory (RST) (Mann and Thompson, 1988). Second, their model considers the forward relationship between EDUs, whereas ReNew captures both forward and backward relationship between segments. Third, they use a generative model to capture the transition distributions over EDUs whereas ReNew uses a discriminative model to capture the transition sequences of segments.

EDUs are defined as minimal units of text and consider many more relations than the two types

Table 5: Comparison of our framework with previous work on sentiment classification.

Method	Accuracy
EDU-Model (Lazaridou et al.)	0.594
ReNew (our method)	**0.605**

of transition cues underlying our segments. We posit that EDUs are too fine-grained for sentiment analysis. Consider the following sentence from Lazaridou et al.'s dataset with its EDUs identified.

(1) *My husband called the front desk* (2) *to complain.*

Unfortunately, EDU (1) lacks sentiment and EDU (2) lacks the topic. Although Lazaridou et al.'s model can capture the forward relationship between any two consecutive EDUs, it cannot handle such cases because their model assumes that each EDU is associated with a topic and a sentiment. In contrast, ReNew finds just one segment in the above sentence.

Just to compare with Lazaridou et al., we apply our sentiment labeling component at the level of EDUs. Their labeled dataset contains 65 reviews, corresponding to 1,541 EDUs. Since this dataset is also extracted from Tripadvisor, we use the domain-specific lexicon automatically learned by ReNew based on our 4,071 unlabeled reviews. Follow the same training and testing regimen (10-fold cross validation), we compare ReNew with their model. As shown in Table 5, ReNew outperforms their approach on their dataset: Although ReNew is not optimized for EDUs, it achieves better accuracy.

5 Related Work

Two bodies of work are relevant. First, to generate sentiment lexicons, existing approaches commonly generate a sentiment lexicon by extending dictionaries or sentiment lexicons. Hu and Liu (2004), manually collect a small set of sentiment words and expand it iteratively by searching synonyms and antonyms in WordNet (Miller, 1995). Rao and Ravichandran (2009) formalize the problem of sentiment detection as a semi-supervised label propagation problem in a graph. Each node represents a word, and a weighted edge between any two nodes indicates the strength of the relationship between them. Esuli and Sebastiani (2006) use a set of classifiers in a semi-supervised fashion to iteratively expand a manually defined lexicon. Their lexicon, named SentiWordNet, comprises the synset of each word obtained from WordNet. Each synset is associated with three sentiment scores: positive, negative, and objective.

Second, for sentiment classification, Nakagawa et al. (2010) introduce a probabilistic model that uses the interactions between words within one sentence for inferring sentiments. Socher et al. (2011) introduce a semi-supervised approach that uses recursive autoencoders to learn the hierarchical structure and sentiment distribution of a sentence. Jo and Oh (2011) propose a probabilistic generative model named ASUM that can extract aspects coupled with sentiments. Kim et al. (2013) extend ASUM by enabling its probabilistic model to discover a hierarchical structure of the aspect-based sentiments. The above works apply sentence-level sentiment classification and their models are not able to capture the relationships between or among clauses.

6 Conclusions and Future Work

The leading lexical approaches to sentiment analysis from text are based on fixed lexicons that are painstakingly built by hand. There is little a priori justification that such lexicons would port across application domains. In contrast, ReNew seeks to automate the building of domain-specific lexicons beginning from a general sentiment lexicon and the iterative application of CRFs. Our results are promising. ReNew greatly reduces the human effort for generating high-quality sentiment lexicons together with a classification model. In future work, we plan to apply ReNew to additional sentiment analysis problems such as review quality analysis and sentiment summarization.

Abstract

We study the problem of generating an English sentence given an underlying probabilistic grammar, a world and a communicative goal. We model the generation problem as a Markov decision process with a suitably defined reward function that reflects the communicative goal. We then use probabilistic planning to solve the MDP and generate a sentence that, with high probability, accomplishes the communicative goal. We show empirically that our approach can generate complex sentences with a speed that generally matches or surpasses the state of the art. Further, we show that our approach is anytime and can handle complex communicative goals, including negated goals.

1 Introduction

Suppose someone wants to tell their friend that they saw a dog chasing a cat. Given such a *communicative goal*, most people can formulate a sentence that satisfies the goal very quickly. Further, they can easily provide multiple similar sentences, differing in details but all satisfying the general communicative goal, with no or very little error. Natural language generation (NLG) develops techniques to extend similar capabilities to automated systems. In this paper, we study the restricted NLG problem: given a grammar, lexicon, world and a communicative goal, output a valid English sentence that satisfies this goal. The problem is restricted because in our work, we do not consider the issue of how to fragment a complex goal into multiple sentences (discourse planning).

Though restricted, this NLG problem is still difficult. A key source of difficulty is the nature of the grammar, which is generally large, probabilistic and ambiguous. Some NLG techniques use sampling strategies (Knight and Hatzivassiloglou, 1995) where a set of sentences is sampled from a data structure created from an underlying grammar and ranked according to how well they meet the communicative goal. Such approaches naturally handle statistical grammars, but do not solve the generation problem in a goal-directed manner. Other approaches view NLG as a *planning* problem (Koller and Stone, 2007). Here, the communicative goal is treated as a predicate to be satisfied, and the grammar and vocabulary are suitably encoded as logical operators. Then automated classical planning techniques are used to derive a plan which is converted into a sentence. This is an elegant formalization of NLG, however, restrictions on what current planning techniques can do limit its applicability. A key limitation is the logical nature of automated planning systems, which do not handle probabilistic grammars, or force ad-hoc approaches for doing so (Bauer and Koller, 2010). A second limitation comes from restrictions on the goal: it may be difficult to ensure that some specific piece of information should *not* be communicated, or to specify preferences over communicative goals, or specify general conditions, like that the sentence should be readable by a sixth grader. A third limitation comes from the search process: without strong heuristics, most planners get bogged down when given communicative goals that require chaining together long sequences of operators (Koller and Petrick, 2011).

In our work, we also view NLG as a planning problem. However, we differ in that our underlying formalism for NLG is a suitably defined *Markov decision process* (MDP). This setting allows us to address the limitations outlined

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 552–561,
Baltimore, Maryland, USA, June 23-25 2014.

above: it is naturally probabilistic, and handles probabilistic grammars; we are able to specify complex communicative goals and general criteria through a suitably-defined reward function; and, as we show in our experiments, recent developments in fast planning in large MDPs result in a generation system that can rapidly deal with very specific communicative goals. Further, our system has several other desirable properties: it is an anytime approach; with a probabilistic grammar, it can naturally be used to sample and generate multiple sentences satisfying the communicative goal; and it is robust to large grammar sizes. Finally, the decision-theoretic setting allows for a precise tradeoff between exploration of the grammar and vocabulary to find a better solution and exploitation of the current most promising (partial) solution, instead of a heuristic search through the solution space as performed by standard planning approaches.

Below, we first describe related work, followed by a detailed description of our approach. We then empirically evaluate our approach and a state-of-the-art baseline in several different experimental settings and demonstrate its effectiveness at solving a variety of NLG tasks. Finally, we discuss future extensions and conclude.

2 Related Work

Two broad lines of approaches have been used to attack the general NLG problem. One direction can be thought of as "overgeneration and ranking." Here some (possibly probabilistic) structure is used to generate multiple candidate sentences, which are then ranked according to how well they satisfy the generation criteria. This includes work based on chart generation and parsing (Shieber, 1988; Kay, 1996). These generators assign semantic meaning to each individual token, then use a set of rules to decide if two words can be combined. Any combination which contains a semantic representation equivalent to the input at the conclusion of the algorithm is a valid output from a chart generation system. Other examples of this idea are the HALogen/Nitrogen systems (Langkilde-Geary, 2002). HALogen uses a two-phase architecture where first, a "forest" data structure that compactly summarizes possible expressions is constructed. The structure allows for a more efficient and compact representation compared to lattice structures that were previously used in statistical sentence generation approaches. Using dynamic programming, the highest ranked sentence from this structure is then output. Many other systems using similar ideas exist, e.g. (White and Baldridge, 2003; Lu et al., 2009).

A second line of attack formalizes NLG as an AI planning problem. SPUD (Stone et al., 2003), a system for NLG through microplanning, considers NLG as a problem which requires realizing a deliberative process of goal-directed activity. Many such NLG-as-planning systems use a pipeline architecture, working from their communicative goal through discourse planning and sentence generation. In discourse planning, information to be conveyed is selected and split into sentence-sized chunks. These sentence-sized chunks are then sent to a *sentence generator*, which itself is usually split into two tasks, *sentence planning* and *surface realization* (Koller and Petrick, 2011). The sentence planner takes in a sentence-sized chunk of information to be conveyed and enriches it in some way. This is then used by a *surface realization* module which encodes the enriched semantic representation into natural language. This chain is sometimes referred to as the "NLG Pipeline" (Reiter and Dale, 2000).

Another approach, called *integrated generation*, considers both sentence generation portions of the pipeline together (Koller and Stone, 2007). This is the approach taken in some modern generators like CRISP (Koller and Stone, 2007) and PCRISP (Bauer and Koller, 2010). In these generators, the input semantic requirements and grammar are encoded in PDDL (Fox and Long, 2003), which an off-the-shelf planner such as Graphplan (Blum and Furst, 1997) uses to produce a list of applications of rules in the grammar. These generators generate parses for the sentence at the same time as the sentence, which keeps them from generating realizations that are grammatically incorrect, and keeps them from generating grammatical structures that cannot be realized properly.

In the NLG-as-planning framework, the choice of grammar representation is crucial in treating NLG as a planning problem; the grammar provides the actions that the planner will use to generate a sentence. Tree Adjoining Grammars (TAGs) are a common choice (Koller and Stone, 2007; Bauer and Koller, 2010). TAGs are tree-based grammars consisting of two sets of trees, called initial trees and auxiliary or adjoining trees. An

entire initial tree can replace a leaf node in the sentence tree whose label matches the label of the root of the initial tree in a process called "substitution." Auxiliary trees, on the other hand, encode recursive structures of language. Auxiliary trees have, at a minimum, a root node and a foot node whose labels match. The foot node must be a leaf of the auxiliary tree. These trees are used in a three-step process called "adjoining". The first step finds an adjoining location by searching through our sentence to find any subtree with a root whose label matches the root node of the auxiliary tree. In the second step, the target subtree is removed from the sentence tree, and placed in the auxiliary tree as a direct replacement for the foot node. Finally, the modified auxiliary tree is placed back in the sentence tree in the original target location. We use a variation of TAGs in our work, called a lexicalized TAG (LTAG), where each tree is associated with a lexical item called an anchor.

Though the NLG-as-planning approaches are elegant and appealing, a key drawback is the difficulty of handling probabilistic grammars, which are readily handled by the overgeneration and ranking strategies. Recent approaches such as PCRISP (Bauer and Koller, 2010) attempt to remedy this, but do so in a somewhat ad-hoc way, by transforming the probabilities into costs, because they rely on deterministic planning to actually realize the output. In this work, we directly address this by using a more expressive underlying formalism, a Markov decision process (MDP). We show empirically that this modification has other benefits as well, such as being anytime and an ability to handle complex communicative goals beyond those that deterministic planners can handle.

We note that prior work exists that uses MDPs for NLG (Lemon, 2011). That work differs from ours in several key respects: (i) it considers NLG at a coarse level, for example choosing the type of utterance (in a dialog context) and how to fill in specific slots in a template, (ii) the source of uncertainty is not language-related but comes from things like uncertainty in speech recognition, and (iii) the MDPs are solved using reinforcement learning and not planning, which is impractical in our setting. However, that work does consider NLG in the context of the broader task of dialog management, which we leave for future work.

3 Sentence Tree Realization with UCT

In this section, we describe our approach, called Sentence Tree Realization with UCT (STRUCT). We describe the inputs to STRUCT, followed by the underlying MDP formalism and the probabilistic planning algorithm we use to generate sentences in this MDP.

3.1 Inputs to STRUCT

STRUCT takes three inputs in order to generate a single sentence. These inputs are a grammar (including a lexicon), a communicative goal, and a world specification.

STRUCT uses a first-order logic-based semantic model in its communicative goal and world specification. This model describes named "entities," representing general things in the world. Entities with the same name are considered to be the same entity. These entities are described using first-order logic predicates, where the name of the predicate represents a statement of truth about the given entities. In this semantic model, the communicative goal is a list of these predicates with variables used for the entity names. For instance, a communicative goal of 'red(d), dog(d)' (in English, "say anything about a dog which is red.") would match a sentence with the semantic representation 'red(subj), dog(subj), cat(obj), chased(subj, obj)', like "The red dog chased the cat", for instance.

A grammar contains a set of PTAG trees, divided into two sets (initial and adjoining). These trees are annotated with the entities in them. Entities are defined as any element anchored by precisely one node in the tree which can appear in a statement representing the semantic content of the tree. In addition to this set of trees, the grammar contains a list of words which can be inserted into those trees, turning the PTAG into an PLTAG. We refer to this list as a lexicon. Each word in the lexicon is annotated with its first-order logic semantics with any number of entities present in its subtree as the arguments.

A world specification is simply a list of all statements which are true in the world surrounding our generation. Matching entity names refer to the same entity. We use the closed world assumption, that is, any statement not present in our world is false. Before execution begins, our grammar is pruned to remove entries which cannot possibly be used in generation for the given problem, by tran-

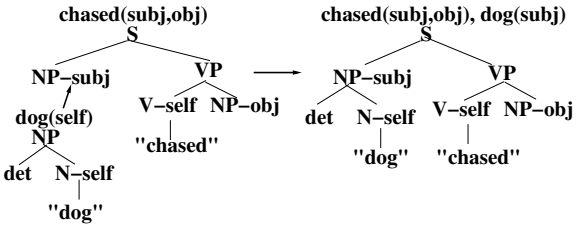

Figure 1: An example tree substitution operation in STRUCT.

sitively discovering all predicates that hold about the entities mentioned in the goal in the world, and eliminating all trees not about any of these. This often allows STRUCT to be resilient to large grammar sizes, as our experiments will show.

3.2 Specification of the MDP

We formulate NLG as a planning problem on a Markov decision process (MDP) (Puterman, 1994). An MDP is a tuple (S, A, T, R, γ) where S is a set of states, A is a set of actions available to an agent, $T : S \times A \times S \rightarrow [0, 1]$ is a possibly stochastic function defining the probability $T(s, a, s')$ with which the environment transitions to s' when the agent does a in state s. $R : S \times A \times S \rightarrow \mathbb{R}$ is a real-valued reward function that specifies the utility of performing action a in state s to reach another state. Finally, γ is a discount factor that allows planning over infinite horizons to converge. In such an MDP, the agent selects actions at each state to optimize the expected infinite-horizon discounted reward.

In the MDP we use for NLG, we must define each element of the tuple in such a way that a plan in the MDP becomes a sentence in a natural language. Our set of states, therefore, will be partial sentences which are in the language defined by our PLTAG input. There are an infinite number of these states, since TAG adjoins can be repeated indefinitely. Nonetheless, given a specific world and communicative goal, only a fraction of this MDP needs to be explored, and, as we show below, a good solution can often be found quickly using a variation of the UCT algorithm (Kocsis and Szepesvari, 2006).

Our set of actions consist of all single substitutions or adjoins at a particular valid location in the tree (example shown in Figure 1). Since we are using PLTAGs in this work, this means every action adds a word to the partial sentence. In situations where the sentence is complete (no nonterminals without children exist), we add a dummy action that the algorithm may choose to stop generation and emit the sentence. Based on these state and action definitions, the transition function takes a mapping between a partial sentence / action pair and the partial sentences which can result from one particular PLTAG adjoin / substitution, and returns the probability of that rule in the grammar.

In order to control the search space, we restrict the structure of the MDP so that while substitutions are available, only those operations are considered when determining the distribution over the next state, without any adjoins. We do this is in order to generate a complete and valid sentence quickly. This allows STRUCT to operate as an anytime algorithm, described further below.

The immediate value of a state, intuitively, describes closeness of an arbitrary partial sentence to our communicative goal. Each partial sentence is annotated with its semantic information, built up using the semantic annotations associated with the PLTAG trees. Thus we use as a reward a measure of the match between the semantic annotation of the partial tree and the communicative goal. That is, the larger the overlap between the predicates, the higher the reward. For an exact reward signal, when checking this overlap, we need to substitute each combination of entities in the goal into predicates in the sentence so we can return a high value if there are any mappings which are both possible (contain no statements which are not present in the grounded world) and mostly fulfill the goal (contain most of the goal predicates). However, this is combinatorial; also, most entities within sentences do not interact (e.g. if we say "the white rabbit jumped on the orange carrot," the whiteness of the rabbit has nothing to do with the carrot), and finally, an approximate reward signal generally works well enough unless we need to emit nested subclauses. Thus as an approximation, we use a reward signal where we simply count how many individual predicates overlap with the goal with *some* entity substitution. In the experiments, we illustrate the difference between the exact and approximate reward signals.

The final component of the MDP is the discount factor. We generally use a discount factor of 1; this is because we are willing to generate lengthy sentences in order to ensure we match our goal. A discount factor of 1 can be problematic in general since it can cause rewards to diverge, but since

there are a finite number of terms in our reward function (determined by the communicative goal and the fact that because of lexicalization we do not loop), this is not a problem for us.

3.3 The Probabilistic Planner

We now describe our approach to solving the MDP above to generate a sentence. Determining the optimal policy at *every* state in an MDP is polynomial in the size of the state-action space (Brafman and Tennenholtz, 2003), which is intractable in our case. But for our application, we do not need to find the optimal policy. Rather we just need to *plan* in an MDP to achieve a *given* communicative goal. Is it possible to do this without exploring the entire state-action space? Recent work answers this question affirmatively. New techniques such as sparse sampling (Kearns et al., 1999) and UCT (Kocsis and Szepesvari, 2006) show how to generate near-optimal plans in large MDPs with a time complexity that is independent of the state space size. Using the UCT approach with a suitably defined MDP (explained above) allows us to naturally handle probabilistic grammars as well as formulate NLG as a planning problem, unifying the distinct lines of attack described in Section 2. Further, the theoretical guarantees of UCT translate into fast generation in many cases, as we demonstrate in our experiments.

Online planning in MDPs as done by UCT follows two steps. From each state encountered, we construct a lookahead tree and use it to estimate the utility of each action in this state. Then, we take the best action, the system transitions to the next state and the procedure is repeated. In order to build a lookahead tree, we use a "rollout policy." This policy has two components: if it encounters a state already in the tree, it follows a "tree policy," discussed further below. If it encounters a new state, the policy reverts to a "default" policy that randomly samples an action. In all cases, any rewards received during the rollout search are backed up. Because this is a Monte Carlo estimate, typically, we run several simultaneous trials, and we keep track of the rewards received by each choice and use this to select the best action at the root.

The tree policy needed by UCT for a state s is the action a in that state which maximizes:

$$P(s,a) = Q(s,a) + c\sqrt{\frac{lnN(s)}{N(s,a)}} \qquad (1)$$

Algorithm 1 STRUCT algorithm.

Require: Number of simulations $numTrials$, Depth of lookahead $maxDepth$, time limit T
Ensure: Generated sentence tree

```
bestSentence ← nil
while time limit not reached do
    state ← empty sentence tree
    while state not terminal do
        for numTrials do
            testState ← state
            currentDepth ← 0
            if testState has unexplored actions then
                Apply one unexplored PLTAG production sampled from the PLTAG distribution to testState
                currentDepth++
            end if
            while currentDepth < maxDepth do
                Apply PLTAG production selected by tree policy (Equation 1) or default policy as required
                currentDepth++
            end while
            calculate reward for testState
            associate reward with first action taken
        end for
        state ← maximum reward testState
        if state score > bestSentence score and state has no nonterminal leaf nodes then
            bestSentence ← state
        end if
    end while
end while
return bestSentence
```

Here $Q(s,a)$ is the estimated value of a as observed in the tree search, computed as a sum over future rewards observed after (s,a). $N(s)$ and $N(s,a)$ are visit counts for the state and state-action pair. Thus the second term is an exploration term that biases the algorithm towards visiting actions that have not been explored enough. c is a constant that trades off exploration and exploitation. This essentially treats each action decision as a bandit problem; previous work shows that this approach can efficiently select near-optimal actions at each state.

We use a modified version of UCT in order to

increase its usability in the MDP we have defined. First, because we receive frequent, reasonably accurate feedback, we favor breadth over depth in the tree search. That is, it is more important in our case to try a variety of actions than to pursue a single action very deep. Second, UCT was originally used in an adversarial environment, and so is biased to select actions leading to the best average reward rather than the action leading to the best overall reward. This is not true for us, however, so we choose the latter action instead.

With the MDP definition above, we use our modified UCT to find a solution sentence (Algorithm 1). After every action is selected and applied, we check to see if we are in a state in which the algorithm could terminate (i.e. the sentence has no nonterminals yet to be expanded). If so, we determine if this is the best possibly-terminal state we have seen so far. If so, we store it, and continue the generation process. Whenever we reach a terminal state, we begin again from the start state of the MDP. Because of the structure restriction above (substitution before adjoin), STRUCT generates a valid sentence quickly. This enables STRUCT to perform as an anytime algorithm, which if interrupted will return the highest-value complete and valid sentence it has found. This also allows partial completion of communicative goals if not all goals can be achieved simultaneously in the time given.

4 Empirical Evaluation

In this section, we compare STRUCT to a state-of-the-art NLG system, CRISP, [1] and evaluate three hypotheses: (i) STRUCT is comparable in speed and generation quality to CRISP as it generates increasingly large referring expressions, (ii) STRUCT is comparable in speed and generation quality to CRISP as the size of the grammar which they use increases, and (iii) STRUCT is capable of communicating complex propositions, including multiple concurrent goals, negated goals, and nested subclauses.

For these experiments, STRUCT was implemented in Python 2.7. We used a 2010 version of CRISP which uses a Java-based GraphPlan implementation. All of our experiments were run on a 4-core AMD Phenom II X4 995 processor clocked at 3.2 GHz. Both systems were given access to 8 GB of RAM. The times reported are from the start of the generation process, eliminating variations due to interpreter startup, input parsing, etc.

[1] We were unfortunately unable to get the PCRISP system to compile, and so we could not evaluate it.

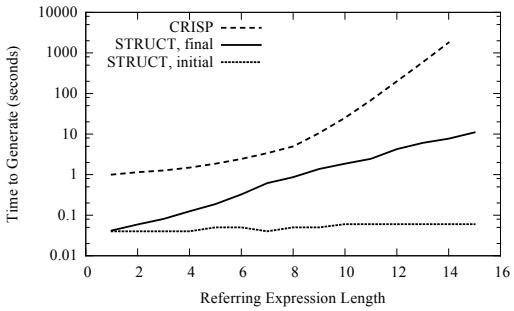

Figure 2: Experimental comparison between STRUCT and CRISP: Generation time vs. length of referring expression

4.1 Comparison to CRISP

We begin by describing experiments comparing STRUCT to CRISP. For these experiments, we use the approximate reward function for STRUCT.

Referring Expressions We first evaluate CRISP and STRUCT on their ability to generate referring expressions. Following prior work (Koller and Petrick, 2011), we consider a series of sentence generation problems which require the planner to generate a sentence like "The Adj_1 Adj_2 ... Adj_k dog chased the cat.", where the string of adjectives is a string that distinguishes one dog (whose identity is specified in the problem description) from all other entities in the world. In this experiment, $maxDepth$ was set equal to 1, since each action taken improved the sentence in a way measurable by our reward function. $numTrials$ was set equal to $k(k+1)$, since this is the number of adjoining sites available in the final step of generation, times the number of potential words to adjoin. This allows us to ensure successful generation in a single loop of the STRUCT algorithm.

The experiment has two parameters: j, the number of adjectives in the grammar, and k, the number of adjectives necessary to distinguish the entity in question from all other entities. We set $j = k$ and show the results in Figure 2. We observe that CRISP was able to achieve sub-second or similar times for all expressions of less than length 5, but its generation times increase exponentially past that point, exceeding 100 seconds for some plans at length 10. At length 15, CRISP failed to generate a referring expression;

after 90 minutes the Java garbage collector terminated the process. STRUCT (the "STRUCT_final" line) performs much better and is able to generate much longer referring expressions without failing. Later experiments had successful referring expression generation of lengths as high as 25. The "STRUCT_initial" curve shows the time taken by STRUCT to come up with the first complete sentence, which partially solves the goal and which (at least) could be output if generation was interrupted and no better alternative was found. As can be seen, this always happens very quickly.

Grammar Size. We next evaluate STRUCT and CRISP's ability to handle larger grammars. This experiment is set up in the same way as the one above, with the exception of l "distracting" words, words which are not useful in the sentence to be generated. l is defined as $j - k$. In these experiments, we vary l between 0 and 50. Figure 3a shows the results of these experiments. We observe that CRISP using GraphPlan, as previously reported in (Koller and Petrick, 2011), handles an increase in number of unused actions very well. Prior work reported a difference on the order of single milliseconds moving from $j = 1$ to $j = 10$. We report similar variations in CRISP runtime as j increases from 10 to 60: runtime increases by approximately 10% over that range.

No Pruning. If we do not prune the grammar (as described in Section 3.1), STRUCT's performance is similar to CRISP using the FF planner (Hoffmann and Nebel, 2001), also profiled in (Koller and Petrick, 2011), which increased from 27 ms to 4.4 seconds over the interval from $j = 1$ to $j = 10$. STRUCT's performance is less sensitive to larger grammars than this, but over the same interval where CRISP increases from 22 seconds of runtime to 27 seconds of runtime, STRUCT increases from 4 seconds to 32 seconds. This is due almost entirely to the required increase in the value of $numTrials$ as the grammar size increases. At the low end, we can use $numTrials = 20$, but at $l = 50$, we must use $numTrials = 160$ in order to ensure perfect generation as soon as possible. Note that, as STRUCT is an anytime algorithm, valid sentences are available very early in the generation process, despite the size of the set of adjoining trees. This time does not change substantially with increases in grammar size. However, the time to perfect this solution does.

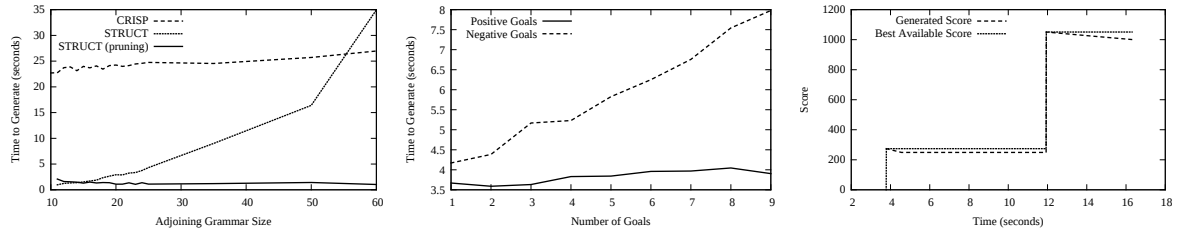
With Pruning. STRUCT's performance improves significantly if we allow for pruning. This experiment involving distracting words is an example of a case where pruning will perform well. When we apply pruning, we find that STRUCT is able to ignore the effect of additional distracting words. Experiments showed roughly constant times for generation for $j = 1$ through $j = 5000$. Our experiments do not show any significant impact on runtime due to the pruning procedure itself, even on large grammars.

4.2 Complex Communicative Goals

In the next set of experiments, we illustrate that STRUCT can solve a variety of complex communicative goals such as negated goals, conjuctions and goals requiring nested subclauses to be output.

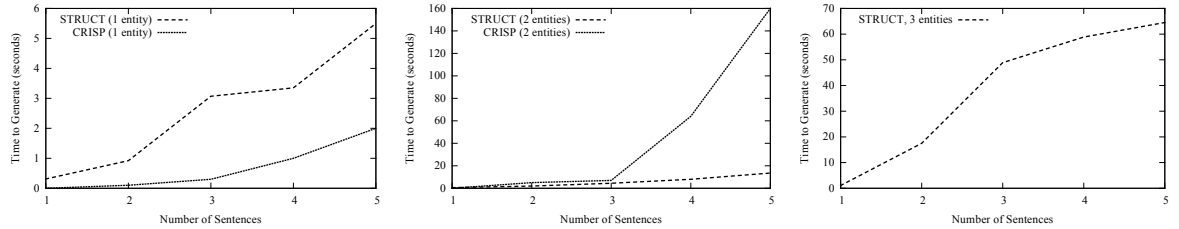
Multiple Goals. We first evaluate STRUCT's ability to accomplish multiple communicative goals when generating a single sentence. In this experiment, we modify the problem from the previous section. In that section, the referred-to dog was unique, and it was therefore possible to produce a referring expression which identified it unambiguously. In this experiment, we remove this condition by creating a situation in which the generator will be forced to ambiguously refer to several dogs. We then add to the world a number of adjectives which are common to each of these possible referents. Since these adjectives do not further disambiguate their subject, our generator should not use them in its output. We then encode these adjectives into communicative goals, so that they will be included in the output of the generator despite not assisting in the accomplishment of disambiguation. For example, assume we had two black cats, and we wanted to say that one of them was sleeping, but we wanted to emphasize that it was a black cat. We would have as our goal both "sleeps(c)" and "black(c)". We want the generator to say "the black cat sleeps", instead of simply "the cat sleeps."

We find that, in all cases, these otherwise useless adjectives are included in the output of our generator, indicating that STRUCT is successfully balancing multiple communicative goals. As we show in figure 3b (the "Positive Goals" curve) , the presence of additional satisfiable semantic goals does not substantially affect the time required for generation. We are able to accomplish this task with the same very high frequency as the CRISP



(a) Effect of grammar size (b) Effect of multiple/ negated goals (c) Effect of nested subclauses

Figure 3: STRUCT experiments (see text for details).



(a) One entity ("The man sat and the girl sat and ..."). (b) Two entities ("The dog chased the cat and ..."). (c) Three entities ("The man gave the girl the book and ...").

Figure 4: Time taken by STRUCT to generate sentences with conjunctions with varying numbers of entities.

comparisons, as we use the same parameters.

Negated Goals. We now evaluate STRUCT's ability to generate sentences given negated communicative goals. We again modify the problem used earlier by adding to our lexicon several new adjectives, each applicable only to the target of our referring expression. Since our target can now be referred to unambiguously using only one adjective, our generator should just select one of these new adjectives (we experimentally confirmed this). We then encode these adjectives into negated communicative goals, so that they will not be included in the output of the generator, despite allowing a much shorter referring expression. For example, assume we have a tall spotted black cat, a tall solid-colored white cat, and a short spotted brown cat, but we wanted to refer to the first one without using the word "black".

We find that these adjectives which should have been selected immediately are omitted from the output, and that the sentence generated is the best possible under the constraints. This demonstrates that STRUCT is balancing these negated communicative goals with its positive goals. Figure 3b (the "Negative Goals" curve) shows the impact of negated goals on the time to generation. Since this experiment alters the grammar size, we see the time to final generation growing linearly with grammar size. The increased time to generate can be traced directly to this increase in grammar size. This is a case where pruning does not help us in reducing the grammar size; we cannot optimistically prune out words that we do not plan to use. Doing so might reduce the ability of STRUCT to produce a sentence which partially fulfills its goals.

Nested subclauses. Next, we evaluate STRUCT's ability to generate sentences with nested subclauses. An example of such a sentence is "The dog which ate the treat chased the cat." This is a difficult sentence to generate for several reasons. The first, and clearest, is that there are words in the sentence which do not help to increase the score assigned to the partial sentence. Notably, we must adjoin the word "which" to "the dog" during the portion of generation where the sentence reads "the dog chased the cat". This decision requires us to do planning deeper than one level in the MDP, which increases the number of simulations STRUCT requires in order to get the correct result. In this case, we require lookahead further into the tree than depth 1. We need to know that using "which" will allow us to further specify which dog is chasing the cat; in order to do this we must use at least $d = 3$. Our reward function must determine this with, at a minimum, the actions corresponding to "which", "ate", and "treat". For these experiments, we use the exact reward function for STRUCT.

Despite this issue, STRUCT is capable of generating these sentences. Figure 3c shows the score of STRUCT's generated output over time for two nested clauses. Notice that, because the exact reward function is being used, the time to generate is longer in this experiment. To the best of our knowledge, CRISP is not able to generate sentences of this form due to an insufficiency in the way it handles TAGs, and consequently we present our results without this baseline.

Conjunctions. Finally, we evaluate STRUCT's ability to generate sentences including conjunctions. We introduce the conjunction "and", which allows for the root nonterminal of a new sentence ('S') to be adjoined to any other sentence. We then provide STRUCT with multiple goals. Given sufficient depth for the search ($d = 3$ was sufficient for our experiments, as our reward signal is fine-grained), STRUCT will produce two sentences joined by the conjunction "and". Again, we follow prior work in our experiment design (Koller and Petrick, 2011).

As we can see in Figures 4a, 4b, and 4c, STRUCT successfully generates results for conjunctions of up to five sentences. This is not a hard upper bound, but generation times begin to be impractically large at that point. Fortunately, human language tends toward shorter sentences than these unwieldy (but technically grammatical) sentences.

STRUCT increases in generation time both as the number of sentences increases and as the number of objects per sentences increases. We compare our results to those presented in (Koller and Petrick, 2011) for CRISP with the FF Planner. They attempted to generate sentences with three entities and failed to find a result within their 4 GB memory limit. As we can see, CRISP generates a result slightly faster than STRUCT when we are working with a single entity, but works much much slower for two entities and cannot generate results for a third entity. According to Koller's findings, this is because the search space grows by a factor of the universe size with the addition of another entity (Koller and Petrick, 2011).

5 Conclusion

We have proposed STRUCT, a general-purpose natural language generation system which is comparable to current state-of-the-art generators. STRUCT formalizes the generation problem as an MDP and applies a version of the UCT algorithm, a fast online MDP planner, to solve it. Thus, STRUCT naturally handles probabilistic grammars. We demonstrate empirically that STRUCT is anytime, comparable to existing generation-as-planning systems in certain NLG tasks, and is also capable of handling other, more complex tasks such as negated communicative goals.

Though STRUCT has many interesting properties, many directions for exploration remain. Among other things, it would be desirable to integrate STRUCT with discourse planning and dialog systems. Fortunately, reinforcement learning has already been investigated in such contexts (Lemon, 2011), indicating that an MDP-based generation procedure could be a natural fit in more complex generation systems. This is a primary direction for future work. A second direction is that, due to the nature of the approach, STRUCT is highly amenable to parallelization. None of the experiments reported here use parallelization, however, to be fair to CRISP. We plan to parallelize STRUCT in future work, to take advantage of current multicore architectures. This should obviously further reduce generation time.

STRUCT is open source and available from github.com upon request.

Generating Code-switched Text for Lexical Learning

Igor Labutov

Abstract

A vast majority of L1 vocabulary acquisition occurs through incidental learning during reading (Nation, 2001; Schmitt et al., 2001). We propose a probabilistic approach to generating code-mixed text as an L2 technique for increasing retention in adult lexical learning through reading. Our model that takes as input a bilingual dictionary and an English text, and generates a code-switched text that optimizes a defined "learnability" metric by constructing a factor graph over lexical mentions. Using an artificial language vocabulary, we evaluate a set of algorithms for generating code-switched text automatically by presenting it to *Mechanical Turk* subjects and measuring recall in a sentence completion task.

1 Introduction

Today, an adult trying to learn a new language is likely to embrace an age-old and widely accepted practice of learning vocabulary through curated word lists and rote memorization. Yet, it is not uncommon to find yourself surrounded by speakers of a foreign language and instinctively pick up words and phrases without ever seeing the definition in your native tongue. Hearing "pass *le sale* please" at the dinner table from your in-laws visiting from abroad, is unlikely to make you think twice about passing the salt. Humans are extraordinarily good at inferring meaning from context, whether this context is your physical surrounding, or the surrounding text in the paragraph of the word that you don't yet understand.

Recently, a novel method of L2 language teaching had been shown effective in improving adult lexical acquisition rate and retention [1]. This technique relies on a phenomenon that elicits a natural simulation of L1-like vocabulary learning in adults — significantly closer to L1 learning for L2 learners than any model studied previously. By infusing foreign words into text in the learner's native tongue into low-surprisal contexts, the lexical acquisition process is facilitated naturally and non-obtrusively. Incidentally, this phenomenon occurs "in the wild" and is termed *code-switching* or *code-mixing*, and refers to the linguistic pattern of bilingual speakers swapping words and phrases between two languages during speech. While this phenomenon had received significant attention from both a socio-linguistic (Milroy and Muysken, 1995) and theoretical linguistic perspectives (Belazi et al., 1994; Bhatt, 1997) (including some computational studies), only recently has it been hypothesizes that "code-switching" is a marking of bilingual proficiency, rather than deficiency (Genesee, 2001).

Until recently it was widely believed that incidental lexical acquisition through reading can only occur for words that occur at sufficient density in a single text, so as to elicit the "noticing" effect needed for lexical acquisition to occur (Cobb, 2007). Recent neurophysiological findings, however, indicate that even a single incidental exposure to a novel word in a sufficiently constrained context is sufficient to trigger an early integration of the word in the brain's semantic network (Borovsky et al., 2012).

An approach explored in this paper, and motivated by the above findings, exploits "constraining" contexts in text to introduce novel words. A state-of-the-art approach for generating such text is based on an expert annotator whose job is to decide which words to "switch out" with novel foreign words (from hereon we will refer to the "switched out" word as the *source* word and to the "switched in" word as the *target* word). Consequently the process is labor-intensive and leads to

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 562–571,
Baltimore, Maryland, USA, June 23-25 2014.

a "one size fits all solution" that is insensitive to the learner's skill level or vocabulary proficiency. This limitation is also cited in literature as a significant roadblock to the widespread adaptation of graded reading series (Hill, 2008). A reading-based tool that follows the same principle, i.e. by systematic exposure of a learner to an incrementally more challenging text, will result in more effective learning (Lantolf and Appel, 1994).

To address the above limitation, we develop an approach for automatically generating such "code-switched" text with an explicit goal of maximizing the lexical acquisition rate in adults. Our method is based on a global optimization approach that incorporates a "knowledge model" of a user with the content of the text, to generate a sequence of lexical "switches". To facilitate the selection of "switch points", we learn a discriminative model for predicting switch point locations on a corpus that we collect for this purpose (and release to the community). Below is a high-level outline of this paper.

- We formalize our approach within a probabilistic graphical model framework, inference in which yields "code-switched" text that maximizes a surrogate to the acquisition rate objective.
- We compare this global method to several baseline techniques, including the strong "high-frequency" baseline.
- We analyze the operating range in which our model is effective and motivate the near-future extension of this approach with the proposed improvements.

2 Related Work

Our proposed approach to the computational generation of code-switched text, for the purpose of L2 pedagogy, is influenced by a number of fields that studied aspects of this phenomenon from distinct perspectives. In this section, we briefly describe a motivation from the areas of socio- and psycho- linguistics and language pedagogy research that indicate the promise of this approach.

2.1 Code-switching as a natural phenomenon

Code-switching (or code-mixing) is a widely studied phenomenon that received significant attention over the course of the last three decades, across the disciplines of sociolinguistics, theoretical and psycholinguistics and even literary and cultural studies (predominantly in the domain of *Spanish-English* code-switching) (Lipski, 2005).

Code-switching that occurs naturally in bilingual populations, and especially in children, has for a long time been considered a marking of incompetency in the second language. A more recent view on this phenomenon, however, suggests that due to the underlying syntactic complexity of code-switching, code-switching is actually a marking of bilingual fluency (Genesee, 2001). More recently, the idea of employing code-switching in the classroom, in a form of conversation-based exercises, has attracted the attention of multiple researchers and educators (Moodley, 2010; Macaro, 2005), yielding promising results in an elementary school study in South-Africa.

2.2 Computational Approaches to Code-switching

Additionally, there has been a limited number of studies of the computational approaches to code-switching, and in particular code-switched text generation. Solorio and Liu (2008), record and transcribe a corpus of Spanish-English code-mixed conversation to train a generative model (Naive Bayes) for the task of predicting code-switch points in conversation. Additionally they test their trained model in its ability to generate code-switched text with convincing results. Building on their work, (Adel et al., 2012) employ additional features and a recurrent network language model for modeling code-switching in conversational speech. Adel and collegues (2011) propose a statistical machine translation-based approach for generating code-switched text. We note, however, that the primary goal of these methods is in the faithful modeling of the natural phenomenon of code-switching in bilingual populations, and not as a tool for language teaching. While useful in generating coherent, syntactically constrained code-switched texts in its own right, none of these methods explicitly consider code-switching as a vehicle for teaching language, and thus do not take on an optimization-based view with an objective of improving lexical acquisition through the reading of the generated text. More recently, and concurrently with our work, Google's Language Immersion app employs the principle of

code-switching for language pedagogy, by generating code-switched web content, and allowing its users to tune it to their skill level. It does not, however, seem to model the user explicitly, nor is it clear if it performs any optimization in generating the text, as no studies have been published to date.

2.3 Computational Approaches to Sentence Simplification

Although not explicitly for teaching language, computational approaches that facilitate accessibility to texts that might otherwise be too difficult for its readers, either due to physical or learning disabilities, or language barriers, are relevant. In the recent work of (Kauchak, 2013), for example demonstrates an approach to increasing readability of texts by learning from unsimplified texts. Approaches in this area span methods for simplifying lexis (Yatskar et al., 2010; Biran et al., 2011), syntax (Siddharthan, 2006; Siddharthan et al., 2004), discourse properties (Hutchinson, 2005), and making technical terminology more accessible to non-experts (Elhadad and Sutaria, 2007). While the resulting texts are of great potential aid to language learners and may implicitly improve upon a reader's language proficiency, they do not explicitly attempt to promote learning as an objective in generating the simplified text.

2.4 Recent Neurophysiological findings

Evidence for the potential effectiveness of code-switching for language acquisition, stem from the recent findings of (Borovsky et al., 2012), who have shown that even a single exposure to a novel word in a constrained context, results in the integration of the word within your existing semantic base, as indicated by a change in the N400 electrophysiological response recorded from the subjects' scalps. N400 ERP marker has been found to correlate with the semantic "expectedness" of a word (Kutas and Hillyard, 1984), and is believed to be an early indicator of word learning. Furthermore, recent work of (Frank et al., 2013), show that word surprisal predicts N400, providing concrete motivation for artificial manipulation of text to explicitly elicit word learning through natural reading, directly motivating our approach. Prior to the above findings, it was widely believed that for evoking "incidental" word learning through reading alone, the word must appear with sufficiently high frequency within the text, such as to elicit the "noticing" effect — a prerequisite to lexical acquisition (Schmidt and Schmidt, 1995; Cobb, 2007).

3 Model

3.1 Overview

The formulation of our model is primarily motivated by two hypotheses that have been validated experimentally in the cognitive science literature. We re-state these hypotheses in the language of "surprisal":

1. Inserting a *target* word into a **low surprisal** context increases the rate of that word's integration into a learner's lexicon.

2. Multiple exposures to the word in **low surprisal** contexts increases rate of that word's integration.

Hypothesis 1 is supported by evidence from (Borovsky et al., 2012; Frank et al., 2013), and hypothesis 2 is supported by evidence from (Schmidt and Schmidt, 1995). We adopt the term "low-surprisal" context to identify contexts (e.g. n-grams) that are highly predictive of the target word (e.g. trailing word in the n-gram). The motivation stems from the recent evidence (Frank et al., 2013) that low-surprisal contexts affect the N400 response and thus correlate with word acquisition. To realize a "code-switched" mixture that adheres maximally to the above postulates, it is self-evident that a non-trivial optimization problem must be solved. For example, naively selecting a few words that appear in low-surprisal contexts may facilitate their acquisition, but at the expense of other words within the same context that may appear in a larger number of low-surprisal contexts further in the text.

To address this problem, we approach it with a formulation of a factor graph that takes global structure of the text into account. Factor graph formalism allows us to capture local features of individual contexts, such as lexical and syntactic surprisal, while inducing dependencies between consequent "switching decisions" in the text. Maximizing likelihood of the joint probability under the factorization of this graph yields an optimal sequence of these "switching decisions" in the entirety of the text. Maximizing joint likelihood, as we will show in the next section, is a surrogate to maximizing the probability of the learner acquiring novel words through the process of reading the generated text.

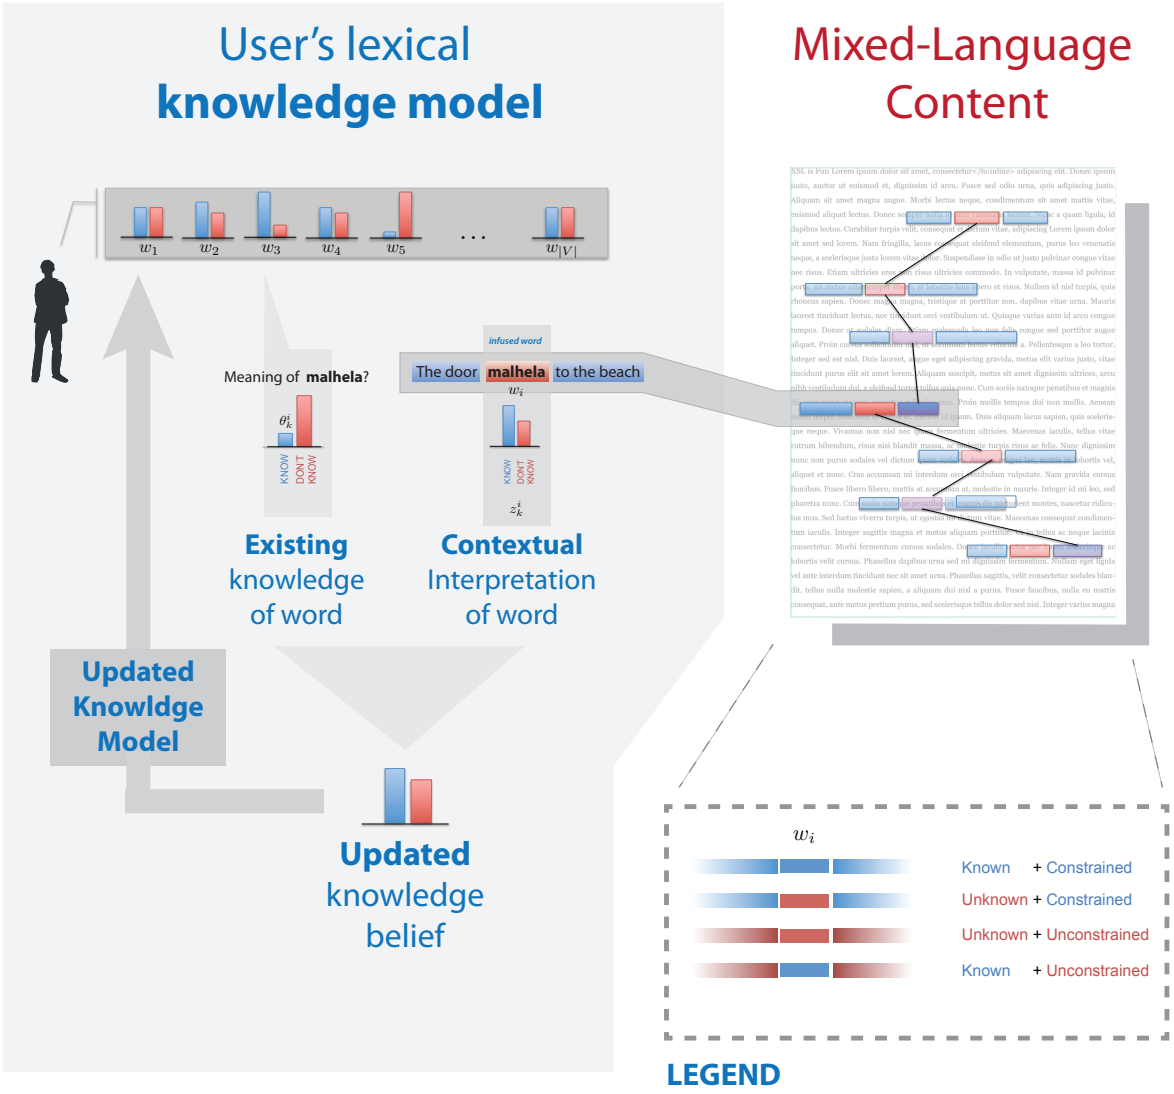

Figure 1: Overview of the approach. Probabilistic learner model (PLM) provides the current value of the belief in the learner's knowledge of any given word. Local contextual model provides the value of the belief in learning the word from the context alone. Upon exposure of the learner to the word in the given context, PLM is updated with the posterior belief in the user's knowledge of the word.

3.2 Language Learner Model

A simplified model of the learner, that we shall term a *Probabilistic Learner Model* (PLM) serves as a basis for our approach. PLM is a model of a learner's lexical knowledge at any given time. PLM models the learner as a vector of independent Bernoulli distributions, where each component represents a probability of the learner knowing the corresponding word. We motivate a probabilistic approach by taking the perspective of measuring *our* belief in the learner's knowledge of any given word, rather than the learner's uncertainty in own knowledge. Formally, we can fully specify this model for learner i as follows:

$$U_i = (\pi_0^i, \pi_1^i, \ldots, \pi_{|V|}^i) \quad (1)$$

where V is the vocabulary set — identical across all users, and π_j^i is our degree of belief in the learner i's knowledge of a target word $w_j \in V$. Statistical estimation techniques exist for estimating an individual's vocabulary size, such as (Bhat and Sproat, 2009; Beglar, 2010), and can be di-

rectly employed for estimating the parameters of this model as our prior belief about user i's knowledge.

The primary motivation behind a probabilistic user model, is to provide a mechanism for updating these probabilities as the user progresses through her reading. Maximizing the parameters of the PLM under a given finite span of code-switched text, thus, provides a handle for generating optimal code-switched content. Additionally, a probabilistic approach allows for a natural integration of the user model with the uncertainty in other components of the system, such as uncertainty in determining the degree of constraint imposed by the context, and in bitext alignment.

3.3 Model overview

At the high level, as illustrated in Figure 1, our approach integrates the model of the learner (PLM) with the local contextual features to update the PLM parameters incrementally as the learner progresses through the text. The fundamental assumption behind our approach is that the learner's knowledge of a given word *after* observing it in a sentence is a function of 1) the learner's previous knowledge of the word, *prior* to observing it in a given sentence and 2) a degree of constraint that a given context imposes on the meaning of the novel word, and is directly related to the surprisal of novel word in that context. Broadly, as the learner progresses from one sentence to the next, exposing herself to more novel words, the updated parameters of the language model in turn guide the selection of new "switch-points" for replacing source words with the target foreign words. In practice, however, this process is carried out implicitly and off-line by optimizing the estimated progress of the learner's PLM, without dynamic feedback. Next, we describe the model in detail.

3.4 Switching Factor Graph Model

To aid in the specification of the factor graph structure, we introduce new terminology. Because the PLM is updated progressively, we will refer to the parameters of the PLM for a given word w_i after observing its k^{th} appearance (instance) in the text, as the learner's *state* of knowledge of that word, and denote it as a binary random variable z_k^i.

$$P(z_k^i = 1) = \begin{cases} \text{Probability that} \\ \text{word } w_i \in V \\ \text{is understood on } k^{th}\text{exposure} \end{cases}$$

Without explicit testing of the user, this variable is hidden. We can view the prior learning model as the parameters of the vector of random variables $(z_0^0, z_0^1, \ldots z_0^{|V|})$.

The key to our approach is in how the parameters of these hidden variables are updated from repeated exposures to words in various contexts. Intuitively, an update to the parameter of z_k^i from z_{k-1}^i occurs after the learner observes word w_i in a context (this may be an n-gram, an entire sentence or paragraph containing w_i, but we will restrict our attention to fixed-length n-grams). Intuitively an update to the parameter of z_{k-1}^i will depend on how "constrained" the meaning of w_i is in the given context. We will refer to it as the "learnability", denoted by L_i^k, of word w_i on its k^{th} appearance, given its context. Formally, we will define "learnability" as follows:

$$P(L_k^i = 1 | w^i, \mathbf{w}^{\setminus i}, \mathbf{z}_k^{\setminus i}) = P(\text{constrained}(w_i) = 1 | \mathbf{w}) \prod_{i \neq j} P(z_k^j = 1) \quad (2)$$

where $\mathbf{w}^{\setminus i}$ represents the set of words that comprise the context window of w_i, not including w_i, and $\mathbf{z}_k^{\setminus i}$ are the states corresponding to each of the words in $\mathbf{w}^{\setminus i}$. $P(\text{constrained}(w_i) = 1 | \mathbf{w})$ is a real value (scaled between 0 and 1) that represents the degree of constraint imposed on the meaning of word w_i by its context. This value comes from a binary prediction model trained to predict the "predictability" of a word in its context, and is based on the dataset that we collected (described later in the paper). Generally, this value may come directly from the surprisal quantity given by a language model, or may incorporate additional features that are found informative in predicting the constraint on the word. Finally, the quantity is weighted by the parameters of the state variables corresponding to the words other than w_i contained in the context. This encodes an intuition that a degree of predictability of a given word given its context is related to the learner's knowledge of the other words in that context. If, for example, in the sentence "pass me the salt and pepper, please", both "salt" and "pepper" are substituted with their foreign translations that the learner is unlikely to know, it's equally unlikely that she will learn them after being exposed to this context, as the context itself will not offer sufficient

information for both words to be inferred simultaneously. On the other hand, substituting "salt" and "pepper" individually, is likely to make it much easier to infer the meaning of the other.

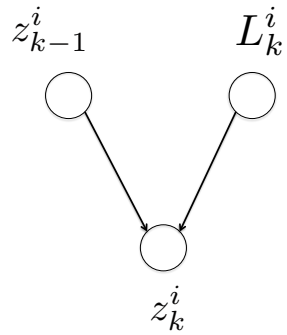

Figure 2: A noisy-OR combination of the learner's previous state of knowledge of the word z^i_{k-1} and the word's "learnability" in the observed context L^i_k

The updated parameter of z^i_k is obtained from a noisy-OR combination of the parameters of z^i_{k-1} and L^i_k:

$$P(z^i_k = 1 | z^i_{k-1}, L^i_k) = \\ 1 - [1 - P(L^i_k = 1)][1 - P(z_{k-1} = 1)]$$

A noisy-OR-based CPD provides a convenient and tractable approximation in capturing the intended intuition: updated state of knowledge of a given word will increase if the word is observed in a "good" context, or if the learner already knows the word.

Combining Equation 2 for each word in the context using the noisy-OR, the updated state for word w_i will now be conditioned on $z^i_{k-1}, \mathbf{z}^{\setminus i}_k, \mathbf{w}_k$. Because of the dependence of each z in the context on all other hidden variables in that context, we can capture the dependence using a single factor per context, with all of the z variables taking part in a clique, whose dimension is the size of the context.

We will now introduce a dual interpretation of the z variables: as "switching" variables that decide whether a given word will be replaced with its translation in the foreign language. If, for example, all of the words have high probability of being known by a learner, than maximizing the joint likelihood of the model will result in most of the words "switched-out" — a desired result. For an arbitrary prior PLM and the input text, maximizing joint likelihood will result in the selection of "switched-out" words that have the highest final probability of being "known" by the learner.

3.5 Inference

The problem of selecting "switch-points" reduces to the problem of inference in the resulting factor graph. Unfortunately, without a fairly strong constraint on the collocation of switched words, the resulting graph will contain loops, requiring techniques of approximate inference. To find the optimal settings of the z variables, we apply the loopy max-sum algorithm. While variants of loopy belief propagation, in general, are not guaranteed to converge, we found that the convergence does indeed occur in our experiments.

3.6 Predicting "predictable" words

We carried out experiments to determine which words are likely to be inferred from their context. The collected data-set is then used to train a logistic regression classifier to predict which words are likely to be easily inferred from their context. We believe that this dataset may also be useful to researchers in studying related phenomena, and thus make it publicly available.

For this task, we focus only on the following context features for predicting the "predictability" of words: n-gram probability, vector-space similarity score, coreferring mentions. N-gram probability and vector-space similarity [2] score are all computed within a fixed-size window of the word (trigrams using Microsoft N-gram service). *Coreference* feature is a binary feature which indicates whether the word has a co-referring mention in a 3-sentence window preceding a given context (obtained using Stanford's CoreNLP package). We train L2-regularized logistic regression to predict a binary label $L \in \{\text{Constrained}, \text{Unconstrained}\}$ using a crowd-sourced corpus described below.

3.7 Corpus Construction

For collecting data about which words are likely to be "predicted" given their content, we developed an Amazon Mechanical Turk task that presented turkers with excerpts of a short story (English translation of "The Man who Repented" by

[2] we employ C&W word embeddings from `http://metaoptimize.com/projects/wordreprs/`

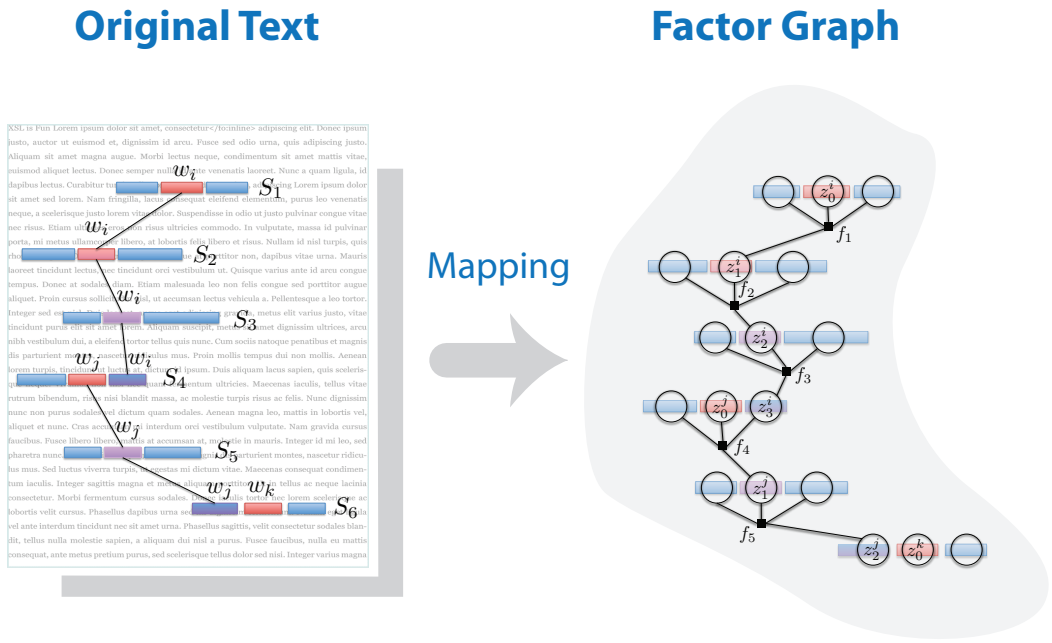

Figure 3: Sequence of sentences in the text (left) is mapped into a factor graph, whose nodes correspond to specific occurences of individual words, connected in a clique corresponding to a context in which the word occurs.

Ana Maria Matute), with some sentences containing a blank in place of a word. Only content words were considered for the task. Turkers were required to type in their best guess, and the number of semantically similar guesses were counted by an average number of 6 other turkers. A ratio of the median of semantically similar guesses to the total number of guesses was then taken as the score representing "predictability" of the word being guessed in the given context. All words corresponding to blanks whose scores were equal to and above 0.6 were than taken as a positive label (Constrained) and scores below 0.6 were taken as a negative label (Unconstrained). Turkers that judged the semantic similarity of the guesses of other turkers achieved an average Cohen's kappa agreement of 0.44, indicating fair to poor agreement.

4 Experiments

We carried out experiments on the effectiveness of our approach using the Amazon Mechanical Turk platform. Our experimental procedure was as follows: 162 turkers were partitioned into four groups, each corresponding to a treatment condition: OPT (N=34), HF (N=41), $RANDOM$ (N=43), MAN (N=44). Each condition corresponded to a model used to generate the presented code-switched text. For all experiments, the text used was a short story "Lottery" by Shirley Jackson, and a total number of replaced words was controlled (34). Target vocabulary consisted of words from an artificial language, generated statically by a mix of words from several languages. Below we describe the individual treatment conditions:

The café was dark and pokey.

The front overlooked the road and the rear the beach.

The door leading to the beach was hung with a reed curtain swaying in the breeze.

With every gust of wind it crackled a little like a slight rattle of bones.

Old Tomeu was sitting on the doorstep, leisurely stroking a well-worn tobacco pouch of black leather.

Figure 4: Visualization of the most "predictable" words in an excerpt from the "The Man who Repented" by Ana Maria Matute (English translation). Font-size correlates with the score given by judge turkers in evaluating guesses of other turkers that were presented with the same text, but the word replaced with a blank. Snippet of the dataset that we release publicly.

RANDOM (Baseline): words for switching are

selected at random from content only words.

HF (*High Frequency*) Baseline: words for switching are selected at random from a ranked list of words that occur most frequently in the presented text.

MAN (*Manual*) Baseline: words for switching are selected manually by the author, based on the intuition of which words are most likely to be guessed in context.

OPT (*Optimization-based*): factor graph-based model proposed in this paper is used for generating code-switched content. The total number of switched words generated by this method is used as a constant for all baselines.

Turkers were solicited to participate in a study that involved "reading a short story with a twist" (title of HIT). Not the title, nor the description gave away the purpose of the study, nor that it would be followed by a quiz. Time was not controlled for this study, but on average turkers took 27 minutes to complete the reading. Upon completing the reading portion of the task, turkers were presented with novel sentences that featured the words observed during reading, where only one of the sentences used the word in a semantically correct way. Turkers were asked to select the sentence that "made the most sense". An example of the sentences presented during the test:

> *Example 1*
>
> ✓ My edzino loves to go shopping every weekend.
>
> The edzino was too big to explore on our own, so went with a group.
>
> English word: **wife**
>
> *Example 2*
>
> ✓ His unpreadvers were utterly confusing and useless.
>
> The unpreadvers was so strong, that he had to go to a hospital.
>
> English word: **directions**

A "recall" metric was computed for each turker, defined as the ratio of correctly selected sentences to the total number of sentences presented. The "grand-average recall" across all turkers was then computed and reported here.

5 Results

We perform a one-way ANOVA across the four groups listed above, with the resulting $F = 11.38$ and $p = 9.7e{-}7$. Consequently, multiple pairwise comparison of the models was performed with the Bonferroni-corrected pairwise t-test, yielding the only significantly different recall means between $HF - MAN$ ($p = 0.00018$), $RANDOM - MAN$ ($p = 2.8e-6$), $RANDOM - OPT$ ($p = 0.00587$). The results indicate that, while none of the automated methods ($RANDOM$, HF, OPT) outperform manually generated code-switched text, OPT outperforms the $RANDOM$ baseline (no decisive conclusion can be drawn with respect to the $HF - RANDOM$ pair). Additionally, we note, that for words with frequency less than 4, OPT produces recall that is on average higher than the HF baseline (p=0.043, Welch's t-test), but at the expense of higher frequency words.

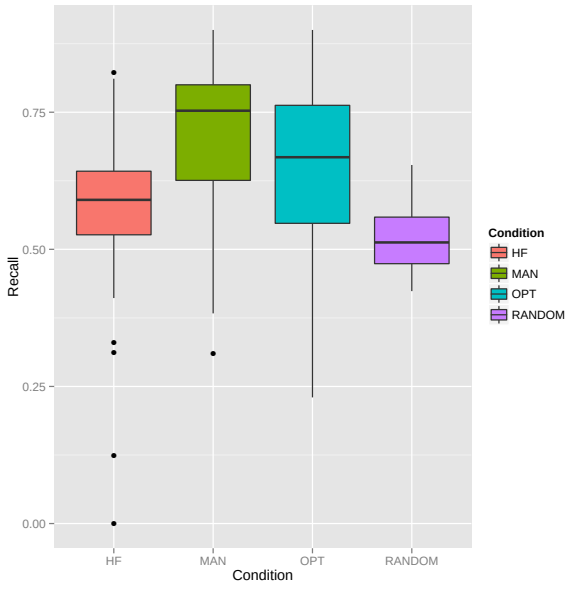

Figure 5: Results presented for 4 groups, subjected to 4 treatment conditions: $RANDOM$, HF, MAN, OPT. Recall performance for each group corresponds to the average ratio of selected sentences that correctly utilize code-switched words in novel contexts, across all turkers.

6 Discussion

We observe from our experiments that the optimization-based approach does not in general outperform the HF baseline. The strength of the

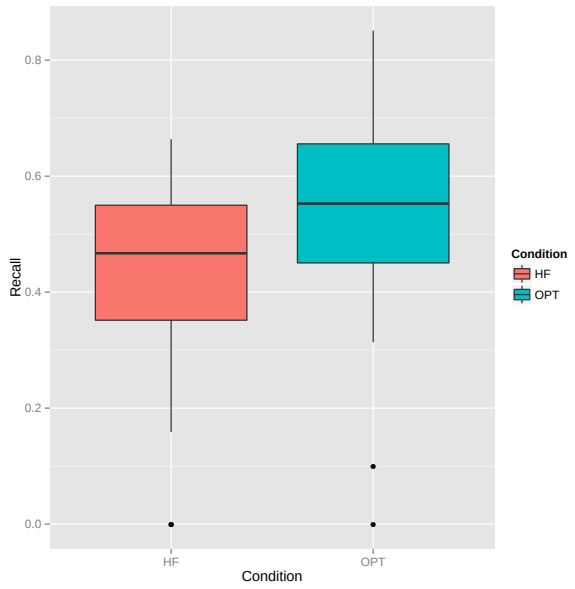

Figure 6: Subset of the results for 2 of the 4 treatment conditions: HF and OPT that correspond to recall only for words with item frequency in the presented text below 4.

frequency-based baseline is attributed to a well-known phenomenon that item frequency promotes the "noticing" effect during reading, critical for triggering incidental lexical acquisition. Generating code-switched text by replacing high frequency content words, thus, in general is a simple and viable approach for generating effective reading-based L2 curriculum aids. However, this method is fundamentally less flexible than the optimization-based method proposed in this paper, for several reasons:

- The optimization-based method explicitly models the learner and thus generates code-switched text progressively more fit for a given individual, even across a sequence of multiple texts. A frequency-based baseline alone would generate content at approximately the same level of difficulty consistently, with the pattern that words that tend to have high frequency in the natural language in general to be the ones that are "switched-out" most often.

- An optimization-based approach is able to elicit higher recall in low frequency words, as the mechanism for their selection is driven by the context in which these words appear, rather than frequency alone, favoring those that are learned more readily through context.

  Moreover, the proposed method in this paper is extensible to more sophisticated learner models, with a potential to surpass the results presented here. Another worthwhile application of this method is as a nested component within a larger optimization-based tool, that in addition to generating code-switched text as demonstrated here, aids in selecting content (such as popular books) as units in the code-switched curriculum.

7 Future Work

In this work we demonstrated a pilot implementation of a model-based, optimization-based approach to content generation for assisting in the reading-based L2 language acquisition. Our approach is based on static optimization, and while it would, in theory progress in difficulty with more reading, its open-loop nature precludes it from maintaining an accurate model of the learner in the long-term. For generating effecting L2 content, it is important that the user be kept in a "zone of proximal development" — a tight region where the level of the taught content is at just the right difficulty. Maintaining an accurate internal model of the learner is the single most important requirement for achieving this functionality. Closed-loop learning, with active user feedback is, thus, going to be functionally critical component of any system of this type that is designed to function in the long-term.

Additionally, our approach is currently a proof-of-concept of an automated method for generating content for assisted L2 acquisition, and is limited to artificial language and only isolated lexical items. The next step would be to integrate bitext alignment across texts in two natural languages, inevitably introducing another stochastic component into the pipeline. Extending this method to larger units, like chunks and simple grammar is another important avenue along which we are taking this work. Early results from concurrent research indicate that "code-switched based" method proposed here is also effective in eliciting acquisition of multi-word chunks.

Abstract

Chinese is an ancient hieroglyphic. It is inattentive to structure. Therefore, segmenting and parsing Chinese are more difficult and less accurate. In this paper, we propose an Omni-word feature and a soft constraint method for Chinese relation extraction. The Omni-word feature uses every potential word in a sentence as lexicon feature, reducing errors caused by word segmentation. In order to utilize the structure information of a relation instance, we discuss how soft constraint can be used to capture the local dependency. Both Omni-word feature and soft constraint make a better use of sentence information and minimize the influences caused by Chinese word segmentation and parsing. We test these methods on the ACE 2005 RDC Chinese corpus. The results show a significant improvement in Chinese relation extraction, outperforming other methods in F-score by 10% in 6 relation types and 15% in 18 relation subtypes.

1 Introduction

Information Extraction (IE) aims at extracting syntactic or semantic units with concrete concepts or linguistic functions (Grishman, 2012; McCallum, 2005). Instead of dealing with the whole documents, focusing on designated information, most of the IE systems extract named entities, relations, quantifiers or events from sentences.

The relation recognition task is to find the relationships between two entities. Successful recognition of relation implies correctly detecting both the relation arguments and relation type. Although this task has received extensive research. The performance of relation extraction is still unsatisfactory with a F-score of 67.5% for English (23 subtypes) (Zhou et al., 2010). Chinese relation extraction also faces a weak performance having F-score about 66.6% in 18 subtypes (Dandan et al., 2012).

The difficulty of Chinese IE is that Chinese words are written next to each other without delimiter in between. Lacking of orthographic word makes Chinese word segmentation difficult. In Chinese, a single sentence often has several segmentation paths leading to the segmentation ambiguity problem (Liang, 1984). The lack of delimiter also causes the Out-of-Vocabulary problem (OOV, also known as *new word detection*) (Huang and Zhao, 2007). These problems are worsened by the fact that Chinese has a large number of characters and words. Currently, the state-of-the-art Chinese OOV recognition system has performance about 75% in recall (Zhong et al., 2012). The errors caused by segmentation and OOV will accumulate and propagate to subsequent processing (e.g. part-of-speech (POS) tagging or parsing).

Therefore, the Chinese relation extraction is more difficult. According to our survey, compared to the same work in English, the Chinese relation extraction researches make less significant progress.

Based on the characteristics of Chinese, in this paper, an Omni-word feature and a soft constraint method are proposed for Chinese relation extraction. We apply these approaches in a maximum entropy based system to extract relations from the ACE 2005 corpus. Experimental results show that our method has made a significant improvement.

The contributions of this paper include

1. Propose a novel Omni-word feature for Chinese relation extraction. Unlike the traditional segmentation based method, which is a partition of the sentence, the Omni-word feature uses every potential word in a sentence as lexicon feature.

2. Aiming at the Chinese inattentive structure, we utilize the soft constraint to capture the local dependency in a relation instance. Four constraint conditions are proposed to gener-

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 572–581,
Baltimore, Maryland, USA, June 23-25 2014.

ate combined features to capture the local dependency and maximize the classification determination.

The rest of this paper is organized as follows. Section 2 introduces the related work. The Omni-word feature and soft constrain are proposed in Section 3. We give the experimental results in Section 3.2 and analyze the performance in Section 4. Conclusions are given in Section 5.

2 Related Work

There are two paradigms extracting the relationship between two entities: the Open Relation Extraction (ORE) and the Traditional Relation Extraction (TRE) (Banko et al., 2008).

Based on massive and heterogeneous corpora, the ORE systems deal with millions or billions of documents. Even strict filtrations or constrains are employed to filter the redundancy information, they often generate tens of thousands of relations dynamically (Hoffmann et al., 2010). The practicability of ORE systems depends on the adequateness of information in a big corpus (Brin, 1999). Most of the ORE systems utilize weak supervision knowledge to guide the extracting process, such as: Databases (Craven and Kumlien, 1999), Wikipedia (Wu and Weld, 2007; Hoffmann et al., 2010), Regular expression (Brin, 1999; Agichtein and Gravano, 2000), Ontology (Carlson et al., 2010; Mohamed et al., 2011) or Knowledge Base extracted automatically from Internet (Mintz et al., 2009; Takamatsu et al., 2012). However, when iteratively coping with large heterogeneous data, the ORE systems suffer from the "semantic drift" problem, caused by error accumulation (Curran et al., 2007). Agichtein, Carlson and Fader et al. (2010; 2011; 2000) propose syntactic and semantic constraints to prevent this deficiency. The soft constraints, proposed in this paper, are combined features like these syntactic or semantic constraints, which will be discussed in Section 3.2.

The TRE paradigm takes hand-tagged examples as input, extracting predefined relation types (Banko et al., 2008). The TRE systems use techniques such as: Rules (Regulars, Patterns and Propositions) (Miller et al., 1998), Kernel method (Zhang et al., 2006b; Zelenko et al., 2003), Belief network (Roth and Yih, 2002), Linear programming (Roth and Yih, 2007), Maximum entropy (Kambhatla, 2004) or SVM (GuoDong et al., 2005). Compared to the ORE systems, the TRE systems have a robust performance. Disadvantages of the TRE systems are that the manually annotated corpus is required, which is time-consuming and costly in human labor. And migrating between different applications is difficult. However, the TRE systems are evaluable and comparable. Different systems running on the same corpus can be evaluated appropriately.

In the field of Chinese relation extraction, Liu et al. (2012) proposed a convolution tree kernel. Combining with external semantic resources, a better performance was achieved. Che et al. (2005) introduced a feature based method, which utilized lexicon information around entities and was evaluated on Winnow and SVM classifiers. Li and Zhang et al. (2008; 2008) explored the position feature between two entities. For each type of these relations, a SVM was trained and tested independently. Based on *Deep Belief Network*, Chen et al. (2010) proposed a model handling the high dimensional feature space. In addition, there are mixed models. For example, Lin et al. (2010) employed a model, combining both the feature based and the tree kernel based methods.

Despite the popularity of kernel based method, Huang et al. (2008) experimented with different kernel methods and inferred that simply migrating from English kernel methods can result in a bad performance in Chinese relation extraction. Chen and Li et al. (2008; 2010) also pointed out that, due to the inaccuracy of Chinese word segmentation and parsing, the tree kernel based approach is inappropriate for Chinese relation extraction. The reason of the tree kernel based approach not achieve the same level of accuracy as that from English may be that segmenting and parsing Chinese are more difficult and less accurate than processing English.

In our research, we proposed an Omni-word feature and a soft constraint method. Both approaches are based on the Chinese characteristics. Therefore, better performance is expected. In the following, we introduce the feature construction, which discusses the proposed two approaches.

3 Feature Construction

In this section, the employed candidate features are discussed. And four constraint conditions are proposed to transform the candidate features into combined features. The soft constraint is the

method to generate the combine features[1].

3.1 Candidate Feature Set

In the ACE corpus, an *entity* is an object or set of objects in the world. An *entity mention* is a reference to an entity. The entity mention is annotated with its full *extent* and its *head*, referred to as the *extend mention* and the *head mention* respectively. The extent mention includes both the head and its modifiers. Each *relation* has two entities as arguments: Arg-1 and Arg-2, referred to as E1 and E2. A *relation mention* (or instance) is the embodiment of a relation. It is referred by the sentence (or clause) in which the relation is located in. In our work, we focus on the detection and recognition of relation mention.

Relation identification is handled as a classification problem. Entity-related information (e.g. head noun, entity type, subtype, CLASS, LDC-TYPE, etc.) are supposed to be known and provided by the corpus. In our experiment, the entity type, subtype and the head noun are used.

All the employed features are simply classified into five categories: *Entity Type and Subtype*, *Head Noun*, *Position Feature*, *POS Tag* and *Omni-word Feature*. The first four are widely used. The last one is proposed in this paper and is discussed in detail.

Entity Type and Subtype: In ACE 2005 RDC Chinese corpus, there are 7 entity types (Person, Organization, GPE, Location, Facility, Weapon and Vehicle) and 44 subtypes (e.g. Group, Government, Continent, etc.).

Head Noun: The head noun (or head mention) of entity mention is manually annotated. This feature is useful and widely used.

Position Feature: The position structure between two entity mentions (extend mentions). Because the entity mentions can be nested, two entity mentions may have four coarse structures: "E1 is before E2", "E1 is after E2", "E1 nests in E2" and "E2 nests in E1", encoded as: '`E1_B_E2`', '`E1_A_E2`', '`E1_N_E2`' and '`E2_N_E1`'.

POS Tag: In our model, we use only the adjacent entity POS tags, which lie in two sides of the entity mention. These POS tags are labelled by the ICTCLAS package[2]. The POS tags are not used independently. It is encoded by combining the POS tag with the adjacent entity mention information. For example '`E1_Right_n`' means that the right side of the first entity is a noun ("n").

Omni-word Feature: The notion of "word" in Chinese is vague and has never played a role in the Chinese philological tradition (Sproat et al., 1996). Some Chinese segmentation performance has been reported precision scores above 95% (Peng et al., 2004; Xue, 2003; Zhang et al., 2003). However, for the same sentence, even native peoples in China often disagree on word boundaries (Hoosain, 1992; Yan et al., 2010). Sproat et al. (1996) has showed that there is a consistence of 75% on the segmentation among different native Chinese speakers. The word-formation of Chinese also implies that the meanings of a compound word are made up, usually, by the meanings of words that contained in it (Hu and Du, 2012). So, fragments of phrase are also informative.

Because high precision can be received by using simple lexical features (Kambhatla, 2004; Li et al., 2008). Making better use of such information is beneficial. In consideration of the Chinese characteristics, we use *every potential word in a relation mention* as the lexical features. For example, relation mention '台北大安森林公园' (Taipei Daan Forest Park) has a "PART-WHOLE" relation type. The traditional segmentation method may generate four lexical features {'台北', '大安', '森林', '公园'}, which is a partition of the relation mention. On the other hand, the Omni-word feature denoting all the possible words in the relation mention may generate features as:

> {'台', '北', '大', '安', '森', '林', '公', '园', '台北', '大安', '森林', '公园', '森林公园', '大安森林公园'}[3]

Most of these features are nested or overlapped mutually. So, the traditional character-based or word-based feature is only a subset of the Omni-word feature. To extract the Omni-word feature, only a lexicon is required, then scan the sentence to collect every word.

Because the number of lexicon entry determines the dimension of the feature space, performance of Omni-word feature is influenced by the lexicon being employed. In this paper, we generate the lexicon by merging two lexicons. The first lexicon

[1] If without ambiguity, we also use the terminology of "soft constraint" denoting features generated by the employed constraint conditions.

[2] `http://ictclas.org/`

[3] The generated Omni-word features dependent on the employed lexicon.

is obtained by segmenting every relation instance using the ICTCLAS package, collecting very word produced by ICTCLAS. Because the ICTCLAS package was trained on annotated corpus containing many meaningful lexicon entries. We expect this lexicon to improve the performance. The second lexicon is *the Lexicon Common Words in Contemporary Chinese*[4].

Despite the Omni-word can be seen as a subset of n-Gram feature. It is not the same as the n-Gram feature. N-Gram features are more fragmented. In most of the instances, the n-Gram features have no semantic meanings attached to them, thus have varied distributions. Furthermore, for a single Chinese word, occurrences of 4 characters are frequent. Even 7 or more characters are not rare. Because Chinese has plenty of characters[5], when the corpus becoming larger, the n-Gram (n¿4) method is difficult to be adopted. On the other hand, the Omni-word can avoid these problems and take advantages of Chinese characteristics (the word-formation and the ambiguity of word segmentation).

3.2 Soft Constraint

The structure information (or dependent information) of relation instance is critical for recognition. However, even in English, "deeper" analysis (e.g. logical syntactic relations or predicate-argument structure) may suffer from a worse performance caused by inaccurate chunking or parsing. Hence, the local dependency contexts around the relation arguments are more helpful (Zhao and Grishman, 2005). Zhang et al. (2006a) also showed that Path-enclosed Tree (PT) achieves the best performance in the kernel based relation extraction. In this field, the tree kernel based method commonly uses the parse tree to capture the structure information (Zelenko et al., 2003; Culotta and Sorensen, 2004). On the other hand, the feature based method usually uses the combined feature to capture such structure information (GuoDong et al., 2005; Kambhatla, 2004).

In the open relation extraction domain, syntactic and semantic constraints are widely employed to prevent the "semantic drift" problem. Such constraints can also be seen as structural constraint. Most of these constraints are hard constraints. Any relation instance violating these constraints (or below a predefined threshold) will be abandoned. For example, Agichtein and Gravano (2000) generates patterns according to a *confidence threshold* (τ_t). Fader et al. (2011) utilizes a *confidence function*. And Carlson et al. (2010) filters candidate instances and patterns using the number of times they co-occurs.

Deleting of relation instances is acceptable for open relation extraction because it always deals with a big data set. But it's not suitable for traditional relation extraction, and will result in a low recall. Utilizing the notion of combined feature (GuoDong et al., 2005; Kambhatla, 2004), we replace the hard constraint by the soft constraint. Each soft constraint (combined feature) has a parameter trained by the classifier indicating the discrimination ability it has. No subjective or priori judgement is adopted to delete any potential determinative constraint (except for the reason of dimensionality reduction).

Most of the researches make use of the combined feature, but rarely analyze the influence of the approaches we combine them. In this paper, we use the soft constraint to model the local dependency. It is a subset of the combined feature, generated by four constraint conditions: *singleton*, *position sensitive*, *bin sensitive* and *semantic pair* . For every employed candidate feature, an appropriate constraint condition is selected to combine them with additional information to maximize the classification determination.

Singleton: A feature is employed as a singleton feature when it is used without combining with any information. In our experiments, only the *position feature* is used as singleton feature.

Position Sensitive: A position sensitive feature has a label indicating which entity mention it depends on. In our experiment, the *Head noun* and *POS Tag* are utilized as position sensitive features, which has been introduced in Section 3.1. For example, '台北_E1' means that the head noun '台北' depend on the first entity mention.

Semantic Pair: Semantic pair is generated by combining two semantic units. Two kinds of semantic pair are employed. Those are generated by combining two entity types or two entity subtypes into a semantic pair. For example, 'Person_Location' denotes that the type of the first relation argument is a "Person" (entity

[4]Published by *Ministry of Education of the People's Republic of China* in 2008, containing 56,008 entries.

[5]Currently, at least 13000 characters are used by native Chinese people. *Modern Chinese Dictionary*: http://www.cp.com.cn/

type) and the second is a "Location" (entity type). Semantic pair can capture both the semantic and structure information in a relation mention.

Bin Sensitive: In our study, *Omni-word feature* is not added as "bag of words". To use the Omni-word feature, we segment each relation mention by two entity mentions. Together with the two entity mentions, we get five parts: "FIRST", "MIDDLE", "END", "E1" and "E2" (or less, if the two entity mentions are nested). Each part is taken as an independent bin. A flag is used to distinguish them. For example, '台北_Bin_F', '台北_Bin_E1' and '台北_Bin_E' mean that the lexicon entry '台北' appears in three bins: the FIRST bin, the first entity mention (E1) bin and the END bin. They will be used as three independent features.

To sum up, among the five candidate feature sets, the position feature is used as a singleton feature. Both head noun and POS tag are position sensitive. Entity types and subtypes are employed as semantic pair. Only Omni-word feature is bin sensitive. In the following experiments, focusing on Chinese relation extraction, we will analyze the performance of candidate feature sets and study the influence of the constraint conditions.

sectionExperiments

In this section, methodologies of the Omni-word feature and the soft constraint are tested. Then they are compared with the state-of-the-art methods.

3.3 Settings and Results

We use the ACE 2005 RDC Chinese corpus, which was collected from newswires, broadcasts and weblogs, containing 633 documents with 6 major relation types and 18 subtypes. There are 8,023 relations and 9,317 relation mentions. After deleting 5 documents containing wrong annotations[6], we keep 9,244 relation mentions as positive instances.

To get the negative instances, each document is segmented into sentences[7]. Those sentences that do not contain any entity mention pair are deleted. For each of the remained sentences, we iteratively extract every entity mention pair as the arguments of relation instances for predicting. For example, suppose a sentence has three entity mentions: A,B and C. Because the relation arguments are order sensitive, six entity mention pairs can be generated: [A,B], [A,C], [B,C], [B,A], [C,A] and [C,B]. After discarding the entity mention pairs that were used as positive instances, we generated 93,283 negative relation instances labelled as "OTHER". Then, we have 7 relation types and 19 subtypes.

A maximum entropy multi-class classifier is trained and tested on the generated relation instances. We adopt the five-fold cross validation for training and testing. Because we are interested in the 6 annotated major relation types and the 18 subtypes, we average the results of five runs on the 6 positive relation types (and 18 subtypes) as the final performance. F-score is computed by

$$\frac{2 \times (Precision \times Recall)}{Precision + Recall}$$

To implement the maximum entropy model, the toolkit provided by Le (2004) is employed. The iteration is set to 30.

Five candidate feature sets are employed to generate the combined features. The *entity type and subtype*, *head noun*, *position feature* are referred to as $\mathcal{F}_{thp}$[8]. The POS tags are referred to as $\mathcal{F}_{pos}$. The Omni-word feature set is denoted by $\mathcal{F}_{ow}$.

Table 1 gives the performance of our system on the 6 types and 18 subtypes. Note that, in this paper, bare numbers and numbers in the parentheses represent the results of the 6 types and the 18 subtypes respectively.

Table 1: Performance on Type (Subtype)

Features	P	R	F
$\mathcal{F}_{thp}$	61.51 (52.92)	48.85 (36.92)	54.46 (43.49)
$\mathcal{F}_{ow}$	80.16 (66.98)	75.45 (54.85)	77.74 (60.31)
$\mathcal{F}_{thp} \cup \mathcal{F}_{pos}$	83.93 (69.83)	77.81 (61.63)	80.76 (65.47)
$\mathcal{F}_{thp} \cup \mathcal{F}_{ow}$	92.40 (81.94)	88.37 (70.69)	90.34 (75.90)
$\mathcal{F}_{thp} \cup \mathcal{F}_{pos} \cup \mathcal{F}_{ow}$	92.26 (80.52)	88.51 (70.96)	90.35 (75.44)

In Row 1, because $\mathcal{F}_{thp}$ are features directly obtained from annotated corpus, we take this per-

[6] DAVYZW_{20041230.1024, 20050110.1403, 20050111.1514, 20050127.1720, 20050201.1538}.

[7] The five punctuations are used as sentence boundaries: Period (。), Question mark (？), Exclamatory mark (！), Semicolon (；) and Comma (，).

[8] "thp" is an acronym of "**t**ype, **h**ead, **p**osition". Features in $\mathcal{F}_{thp}$ are the candidate features combined with the corresponding constraint conditions. The following $\mathcal{F}_{pos}$ and $\mathcal{F}_{ow}$ are the same.

formance as our referential performance. In Row 2, with only the $\mathcal{F}_{ow}$ feature, the F-score already reaches 77.74% in 6 types and 60.31% in 18 subtypes. The last row shows that adding the $\mathcal{F}_{pos}$ almost has no effect on the performance when both the $\mathcal{F}_{thp}$ and $\mathcal{F}_{ow}$ are in use. The results show that $\mathcal{F}_{ow}$ is effective for Chinese relation extraction.

The superiorities of Owni-word feature depend on three reasons. First, the specificity of Chinese word-formation indicates that the subphrases of Chinese word (or phrase) are also informative. Second, most of relation instances have limited context. The Owni-word feature, utilizing every possible word in them, is a better way to capture more information. Third, the entity mentions are manually annotated. They can precisely segment the relation instance into corresponding bins. Segmentation of bins bears the sentence structure information. Therefore, the Owni-word feature with bin information can make a better use of both the syntactic information and the local dependency.

3.4 Comparison

Various systems were proposed for Chinese relation extraction. We mainly focus on systems trained and tested on the ACE corpus. Table 2 lists three systems.

Table 2: Survey of Other Systems

System	P	R	F
Che et al. (2005)	76.13	70.18	73.27
Zhang et al. (2011)	80.71 (77.75)	62.48 (60.20)	70.43 (67.86)
Liu et al. (2012)	81.1 (79.1)	61.0 (57.5)	69.0 (66.6)

Che et al. (2005) was implemented on the ACE 2004 corpus, with 2/3 data for training and 1/3 for testing. The performance was reported on 7 relation types: 6 major relation types and the none relation (or negative instance). Zhang et al. (2011) was based on the ACE 2005 corpus with 75% data for training and 25% for testing. Performances about the 7 types and 19 subtypes were given. Both of them are feature based methods. Liu et al. (2012) is a kernel based method evaluated on the ACE 2005 corpus. The five-fold cross validation was used and declared the performances on 6 relation types and 18 subtypes.

The data preprocessing makes differences from our experiments to others. In order to give a better comparison with the state-of-the-art methods, based on our experiment settings and data, we implement the two feature based methods proposed by Che et al. (2005) and Zhang et al. (2011) in Table 2. The results are shown in Table 3.

In Table 3, Ei ($i \in 1, 2$) represents entity mention. "Order" in Che et al. (2005) denotes the position structure of entity mention pair. Four types of order are employed (the same as ours). $Word_{Ei\pm k}$ and $POS_{Ei\pm k}$ are the words and POS of Ei, "$\pm k$" means that it is the kth word (of POS) after (+) or before (-) the corresponding entity mention. In this paper, $k = 1$ and $k = 2$ were set.

In Row 2, the "Uni-Gram" represents the Unigram features of internal and external character sequences. Internal character sequences are the four entity extend and head mentions. Five kinds of external character sequences are used: one In-Between character sequence between E1 and E2 and four character sequences around E1 and E2 in a given window size w_s. The w_s is set to 4. The "Bi-Gram" is the 2-gram feature of internal and external character sequences. Instead of the 4 position structures, the 9 position structures are used. Please refer to Zhang et al. (2011) for the details of these 9 position structures.

In Table 3, it is shown that our system outperforms other systems, in F-score, by 10% on 6 relation types and by 15% on 18 subtypes.

For researchers who are interested in our work, the source code of our system and our implementations of Che et al. (2005) and Zhang et al. (2011) are available at `https://github.com/YPench/CRDC`.

4 Discussion

In this section, we analyze the influences of employed feature sets and constraint conditions on the performances.

Most papers in relation extraction try to augment the number of employed features. In our experiment, we found that this does not always guarantee the best performance, despite the classifier being adopted is claimed to control these features independently. Because features may interact mutually in an indirect way, even with the same feature set, different constraint conditions can have significant influences on the final performance.

In Section 3, we introduced five candidate feature sets. Instead of using them as independent features, we combined them with additional in-

Table 3: Comparing With the State-of-the-Art Methods

System	Feature Set	P	R	F
(Che et al., 2005)	Ei.Type, Ei.Subtype, Order, $Word_{Ei\pm1}$, $Word_{Ei\pm2}$, $POS_{Ei\pm1}$, $POS_{Ei\pm2}$	84.81 (64.89)	75.69 (52.99)	79.99 (58.34)
(Zhang et al., 2011)	Ei.Type, Ei.Subtype, 9 Position Feature, Uni-Gram, Bi-Gram	79.56 (66.78)	72.99 (54.56)	76.13 (60.06)
Ours	$\mathcal{F}_{thp} \cup \mathcal{F}_{pos} \cup \mathcal{F}_{ow}$	92.26 (80.52)	88.51 (70.96)	90.35 (75.44)

formation. We proposed four constraint conditions to generate the soft constraint features. In Table 4, the performances of candidate features are compared when different constraint conditions was employed.

In Column 3 of Table 4 (**Constraint Condition**), (1), (2), (3), (4) and (5) stand for the referential feature sets[9] in Table 1. Symbol "/" means that the corresponding candidate features in the referential feature set are substituted by the new constraint condition. **Par** in Column 4 is the number of parameters in the trained maximum entropy model, which indicate the model complexity. **I** in Column 5 is the influence on performance. "-" and "+" mean that the performance is decreased or increased.

The first observation is that the combined features are more powerful than used as *singletons*. Model parameters are increased by the combined features. Increasing of parameters projects the relation extraction problem into a higher dimensional space, making the decision boundaries become more flexible.

The named entities in the ACE corpus are also annotated with the CLASS and LDCTYPE labels. Zhou et al. (2010) has shown that these labels can result in a weaker performance. Row 1, 2 and 3 show that, no matter how they are used, the performances decrease obviously. The reason of the performance degradation may be caused by the problem of over-fitting or data sparseness.

At most of the time, increase of model parameters can result in a better performance. Except in Row 8 and Row 11, when two *head nouns* of entity pair were combined as *semantic pair* and when *POS tag* were combined with the entity type, the performances are decreased. There are 7356 head nouns in the training set. Combining two head nouns may increase the feature space by $7356 \times (7356 - 1)$. Such a large feature space makes the occurrence of features close to a random distribution, leading to a worse data sparseness.

In Row 4, 10 and 13, these features are used as *singleton*, the performance degrades considerably. This means that, the missing of sentence structure information on the employed features can lead to a bad performance.

Row 9 and 12 show an interesting result. Comparing the reference set (5) with the reference set (3), the *Head noun* and *adjacent entity POS tag* get a better performance when used as *singletons*. These results reflect the interactions between different features. Discussion of this issue is beyond this paper's scope. In this paper, for a better demonstration of the constraint condition, we still use the *Position Sensitive* as the default setting to use the *Head noun* and the *adjacent entity POS tag*.

Row 13 and 14 compare the *Omni-word feature* (*By-Omni-word*) with the traditional segmentation based feature (*By-Segmentation*). *By-Segmentation* denotes the traditional segmentation based feature set generated by a segmentation tool, collecting every output of relation mention. In this place, the ICTCLAS package is adopted too.

Conventionally, if a sentence is perfectly segmented, *By-Segmentation* is straightforward and effective. But, our experiment shows different observations. Row 13 and 14 show that the *Omni-word* method outperforms the traditional method. Especially, when the *bin* information is used (Row 15), the performance of *Omni-word feature* increases considerably.

Row 14 shows that, compared with the traditional method, the Omni-word feature improves the performance by about 8.79% in 6 relation types and 11.83% in 18 subtypes in F-core. Such improvement may reside in the three reasons discussed in Section 3.3.

In short, from Table 4 we have seen that the *en-*

[9](1), (2), (3), (4) and (5) denote $\mathcal{F}_{thp}$, $\mathcal{F}_{ow}$, $\mathcal{F}_{thp} \cup \mathcal{F}_{pos}$, $\mathcal{F}_{thp} \cup \mathcal{F}_{ow}$ and $\mathcal{F}_{thp} \cup \mathcal{F}_{pos} \cup \mathcal{F}_{ow}$ respectively.

Table 4: Influence of Feature Set

No.	Feature	Constraint Condition	Par	P	R	F	I
1	entity CLASS and LDCTYPE	(1)/as singleton	21,112 21,910	60.29 (41.70)	42.82 (25.18)	50.07 (31.40)	-4.39 -12.09
2		(1)/combined with positional Info	21,159 22,013	63.02 (41.61)	44.47 (26.31)	52.15 (32.24)	-2.31 -11.25

9		(5)/as singleton	100,963 115,499	92.50 (82.63)	88.90 (71.67)	90.66 (76.76)	+0.31 +1.32
10	adjacent entity POS tag	(3)/as singleton	21,450 22,409	72.66 (62.42)	61.16 (45.69)	66.41 (52.76)	-13.91 -8.13
11		(3)/combined with entity type	22,151 23,357	80.66 (63.41)	71.67 (53.16)	75.90 (57.83)	-4.42 -3.06
12		(5)/as singleton	106,931 121,194	92.50 (82.04)	88.66 (71.36)	90.54 (76.33)	+0.19 +0.89
13	Omni-word feature	(2)/*By-Segmentation* as singleton	36,916 41,652	67.19 (55.85)	60.12 (44.50)	63.46 (49.54)	-14.28 -10.77
14		(2)/*By-Segmentation* with bins	79,430 84,715	71.12 (54.76)	66.90 (43.50)	68.95 (48.48)	-8.79 -11.83
15		(2)/*By-Omni-word* as singleton	47,428 57,702	69.67 (54.85)	63.77 (48.84)	66.59 (51.67)	-11.15 -8.64
16		(5)/as singleton	57,321 67,722	91.43 (76.43)	86.37 (69.57)	88.83 (72.84)	-1.52 -2.60

tity type and subtype maximize the performance when used as *semantic pair*. *Head noun* and *adjacent entity POS tag* are employed to combine with positional information. *Omni-word feature* with bins information can increase the performance considerably. Our model (in Section 3.3) uses these settings. This insures that the performances of the candidate features are optimized.

5 Conclusion

In this paper, We proposed a novel Omni-word feature taking advantages of Chinese sub-phrases. We also introduced the soft constraint method for Chinese relation recognition. The soft constraint utilizes four constraint conditions to catch the structure information in a relation instance. Both the Omni-word feature and soft constrain make better use of information a sentence has, and minimize the deficiency caused by Chinese segmentation and parsing.

The size of the employed lexicon determines the dimension of the feature space. The first impression is that more lexicon entries result in more power. However, more lexicon entries also increase the computational complexity and bring in noises. In our future work, we will study this issue. The notion of soft constraints can also be extended to include more patterns, rules, regexes or syntac-

tic constraints that have been used for information extraction. The usability of these strategies is also left for future work.

Abstract

Active learning (AL) has been proven effective to reduce human annotation efforts in NLP. However, previous studies on AL are limited to applications in a single language. This paper proposes a bilingual active learning paradigm for relation classification, where the unlabeled instances are first jointly chosen in terms of their prediction uncertainty scores in two languages and then manually labeled by an oracle. Instead of using a parallel corpus, labeled and unlabeled instances in one language are translated into ones in the other language and all instances in both languages are then fed into a bilingual active learning engine as pseudo parallel corpora. Experimental results on the ACE RDC 2005 Chinese and English corpora show that bilingual active learning for relation classification significantly outperforms monolingual active learning.

1 Introduction

Semantic relation extraction between named entities (*aka*. entity relation extraction or more concisely relation extraction) is an important subtask of Information Extraction (IE) as well as Natural Language Processing (NLP). With its aim to identify and classify the semantic relationship between two entities (ACE 2002-2007), relation extraction is of great significance to many NLP applications, such as question answering, information fusion, social network construction, and knowledge mining and population etc.

In the literature, the mainstream research on relation extraction adopts statistical machine learning methods, which can be grouped into supervised learning (Zelenko et al., 2003; Culotta and Soresen, 2004; Zhou et al., 2005; Zhang et al., 2006; Qian et al., 2008; Chan and Roth, 2011), semi-supervised learning (Zhang et al., 2004; Chen et al., 2006; Zhou et al., 2008; Qian et al., 2010) and unsupervised learning (Hasegawa et al., 2004; Zhang et al., 2005) in terms of the amount of labeled training data they need. Usually the extraction performance depends heavily on the quality and quantity of the labeled data, however, the manual annotation of a large-scale corpus is labor-intensive and time-consuming. In the last decade researchers have turned to another effective learning paradigm--active learning (AL), which, given a small number of labeled instances and a large number of unlabeled instances, selects the most informative unlabeled instances to be manually annotated and add them into the training data in an iterative fashion. Essentially active learning attempts to decrease the quantity of labeled instances by enhancing their quality, gauged by their informativeness to the learner. Since its emergence, active learning has been successfully applied to many tasks in NLP (Engelson and Dagan, 1996; Hwa, 2004; Tomanek et al., 2007; Settles and Craven, 2008).

It is trivial to validate, as we will do later in this paper, that active learning can also alleviate the annotation burden for relation extraction in one language while retaining the extraction performance. However, there are cases when we may exploit relation extraction in multiple languages and there are corpora with relation instances annotated for more than one language, such as the ACE RDC 2005 English and Chinese corpora. Hu et al. (2013) shows that supervised relation extraction in one language (e.g. Chinese)

* Corresponding author

Baltimore, Maryland, USA, June 23-25 2014.

can be enhanced by relation instances translated from another language (e.g. English). This demonstrates that there is some complementariness between relation instances in two languages, particularly when the training data is scarce. One natural question is: Can this characteristic be made full use of so that active learning can maximally benefit relation extraction in two languages? To the best of our knowledge, so far the issue of joint active learning in two languages has yet been addressed. Moreover, the success of joint bilingual learning may lend itself to many inherent multilingual NLP tasks such as POS tagging (Yarowsky and Ngai, 2001), name entity recognition (Yarowsky et al., 2001), sentiment analysis (Wan, 2009), and semantic role labeling (Sebastian and Lapata, 2009) etc.

This paper proposes a bilingual active learning (BAL) paradigm to relation classification with a small number of labeled relation instances and a large number of unlabeled instances in two languages (non-parallel). Instead of using a parallel corpus which should have entity/relation alignment information and is thus difficult to obtain, this paper employs an off-the-shelf machine translator to translate both labeled and unlabeled instances from one language into the other language, forming pseudo parallel corpora. These translated instances along with the original instances are then fed into a bilingual active learning engine. Findings obtained from experiments with relation classification on the ACE 2005 corpora show that this kind of pseudo-parallel corpora can significantly improve the classification performance for both languages in a BAL framework.

The rest of the paper is organized as follows. Section 2 reviews the previous work on relation extraction while Section 3 describes our baseline systems. Section 4 elaborates on the bilingual active learning paradigm and Section 5 discusses the experimental results. Finally conclusions and directions for future work are presented in Section 6.

2 Related Work

While there are many studies in monolingual relation extraction, there are only a few on multilingual relation extraction in the literature.

Monolingual relation extraction: A wide range of studies on relation extraction focus on monolingual resources. As far as representation of relation instances is concerned, there are feature-based methods (Zhao et al., 2004; Zhou et al., 2005; Chan and Roth, 2011) and kernel-based methods (Zelenko et al., 2003; Zhang et al., 2006; Qian et al., 2008), mainly for the English language. Both methods are also widely used in relation extraction in other languages, such as those in Chinese relation extraction (Che et al., 2005; Li et al., 2008; Yu et al., 2010).

Multilingual relation extraction: There are only two studies related to multilingual relation extraction. Kim et al. (2010) propose a cross-lingual annotation projection approach which uses parallel corpora to acquire a relation detector on the target language. However, the mapping of two entities involved in a relation instance may leads to errors. Therefore, Kim and Lee (2012) further employ a graph-based semi-supervised learning method, namely Label Propagation (LP), to indirectly propagate labels from the source language to the target language in an iterative fashion. Both studies transfer relation annotations via parallel corpora from the resource-rich language (English) to the resource-poor language (Korean), but not vice versa. Based on a small number of labeled instances and a large number of unlabeled instances in both languages, our method differs from theirs in that we adopt a bilingual active learning paradigm via machine translation and improve the performance for both languages simultaneously.

Active Learning in NLP: Active learning has become an active research topic due to its potential to significantly reduce the amount of labeled training data while achieving comparable performance with supervised learning. It has been successfully applied to many NLP applications, such as POS tagging (Engelson and Dagan, 1996; Ringger et al., 2007), word sense disambiguation (Chan and Ng, 2007; Zhu and Hovy, 2007), sentiment detection (Brew et al., 2010; Li et al., 2012), syntactical parsing (Hwa, 2004; Osborne and Baldridge, 2004), and named entity recognition (Shen et al., 2004; Tomanek et al., 2007; Tomanek and Hahn, 2009) etc.

Different from these AL studies on a single task, Reichart et al. (2008) introduce a multi-task active learning (MTAL) paradigm, where unlabeled instances are selected for two annotation tasks (i.e. named entity and syntactic parse tree). They demonstrate that MTAL in the same language outperforms one-sided and random selection AL. From a different perspective, we propose an active learning framework for the same task, but across two different languages.

Another related study (Haffari and Sarkar, 2009) deals with active learning for multilingual

machine translation, which make use of multilingual corpora to decrease human annotation efforts by selecting highly informative sentences for a newly added language in multilingual parallel corpora. While machine translation inherently deals with multilingual parallel corpora, our task focuses on relation extraction by pseudo parallel corpora in two languages.

3 Baseline Systems

This section first introduces the fundamental supervised learning method, and then describes a baseline active learning algorithm.

3.1 Supervised Learning

We adopt the feature-based method for fundamental supervised relation classification, rather than the tree kernel-based method, since active learning needs a large number of iterations and the kernel-based method usually performs much slower than the feature-based one. Following is a list of our used features, much similar to Zhou et al. (2005):

a) Lexical features of entities and their contexts
- WM1: bag-of-words in the 1st entity mention
- HM1: headword of M1
- WM2: bag-of-words in the 2nd entity mention
- HM2: headword of M2
- HM12: combination of HM1 and HM2
- WBNULL: when no word in between
- WBFL: the only one word in between
- WBF: the first word in between when at least two words in between
- WBL: the last word in between when at least two words in between
- WBO: other words in between except the first and last words when at least three words in between

b) Entity type
- ET12: combination of entity types
- EST12: combination of entity subtypes
- EC12: combination of entity classes

c) Mention level
- ML12: combination of entity mention levels
- MT12: combination of LDC mention types

d) Overlap
- #WB: number of other mentions in between
- #MB: number of words in between
- M1>M2 or M1<M2: flag indicating whether M2/M1 is included in M1/M2.

3.2 Active Learning Algorithm

We use a pool-based active learning procedure with uncertainty sampling (Scheffer et al., 2001; Culotta and McCallum, 2005; Kim et al., 2006) for both Chinese and English relation classification as illustrated in Fig. 1. During iterations a batch of unlabeled instances are chosen in terms of their informativeness to the current classifier, labeled by an oracle and in turn added into the labeled data to retrain the classifier. Due to our focus on the effectiveness of bilingual active learning on relation classification, we only use uncertainty sampling without incorporating more complex measures, such as diversity and representativeness (Settles and Craven, 2008), and leave them for future work.

Algorithm uncertainty-based active learning

Input:
- *L*, labeled data set
- *U*, unlabeled data set
- *n*, batch size

Output:
- *SVM*, classifier

Repeat:
1. Train a single classifier *SVM* on *L*
2. Run the classifier on *U*
3. Find at most *n* instances in *U* that the classifier has the highest prediction uncertainty
4. Have these instances labeled by an oracle
5. Add them into *L*

Until: certain number of instances are labeled or certain performance is reached

Figure 1. Pool-based active learning with uncertainty sampling

Since the SVMLIB package used in this paper can output probabilities assigned to the class labels on an instance, we have three uncertainty metrics readily available, i.e., least confidence (**LC**), margin (**M**) and entropy (**E**). The NER experimental results on multiple corpora (Settles and Craven, 2008) show that there is no single clear winner among these three metrics. This conclusion is also validated by our preliminary experiments on the task of active learning relation extraction, thus we adopt the **LC** metric for simplicity. Specifically, with a sequence of K probabilities for a relation instance at some iteration, denoted as $\{p_1,p_2,\ldots p_K\}$ in the descending order, the **LC** metric of the relation instance can be simply picked as the first one, i.e.

$$H^{LC} = p_1 \quad (1)$$

Where K denotes the total number of relation classes. Note that this metric actually reflects prediction reliability (i.e. reverse uncertainty) rather than uncertainty in order to facilitate joint

confidence calculation for two languages (cf. §4.4). Intuitively, the smaller the H^{LC} is, the less confident the prediction is.

4 Bilingual Active Learning for Relation Classification

In this section, we elaborate on the bilingual active learning for relation extraction.

4.1 Problem Definition

With Chinese and English (designated as *c* and *e*) as two languages used in our study, this paper intends to address the task of bilingual relation classification, i.e., assigning relation labels to candidate instances that have semantic relationships. Suppose we have a small number of labeled instances in both languages, denoted as L_c and L_e (non-parallel) respectively, and a large number of unlabeled instances in both languages, denoted as U_c and U_e (non-parallel). The test instances in both languages are represented as T_c and T_e. In order to take full advantage of bilingual resources, we translate both labeled and unlabeled instances in one language to ones in the other language as follows:

$L_c \rightarrow L_{et}$
$U_c \rightarrow U_{et}$
$L_e \rightarrow L_{ct}$
$U_e \rightarrow L_{ct}$

The objective is to learn SVM classifiers in both languages, denoted as SVM_c and SVM_e respectively, in a BAL fashion to improve their classification performance.

4.2 Bilingual Active Learning Framework

Currently, AL is widely used in NLP tasks in a single language, i.e., during iterations unlabeled instances least confident only in one language are picked and manually labeled to augment the training data. The only exception is AL for machine translation (Haffari et al., 2009; Haffari and Sarkar, 2009), whose purpose is to select the most informative sentences in the source language to be manually translated into the target language. Previous studies (Reichart et al., 2008; Haffari and Sarkar, 2009) show that multi-task active learning (MTAL) can yield promising overall results, no matter whether they are two different tasks or the task of machine translation on multiple language pairs. If a specific NLP task on two languages, such as relation classification, can be regarded as two tasks, it is reasonable to argue that these two tasks can benefit each other when jointly performed in the BAL framework. Yet, to our knowledge, this issue remains unexplored.

An important issue for bilingual learning is how to obtain two language views for relation instances from multilingual resources. There are three solutions to this problem, i.e. parallel corpora (Lu et al., 2011), translated corpora (*aka*. pseudo parallel corpora) (Wan 2009), and bilingual lexicons (Oh et al., 2009). We adopt the one with pseudo parallel corpora, using the machine translation method to generate instances from one language to the other in the BAL paradigm, as depicted in Fig. 2.

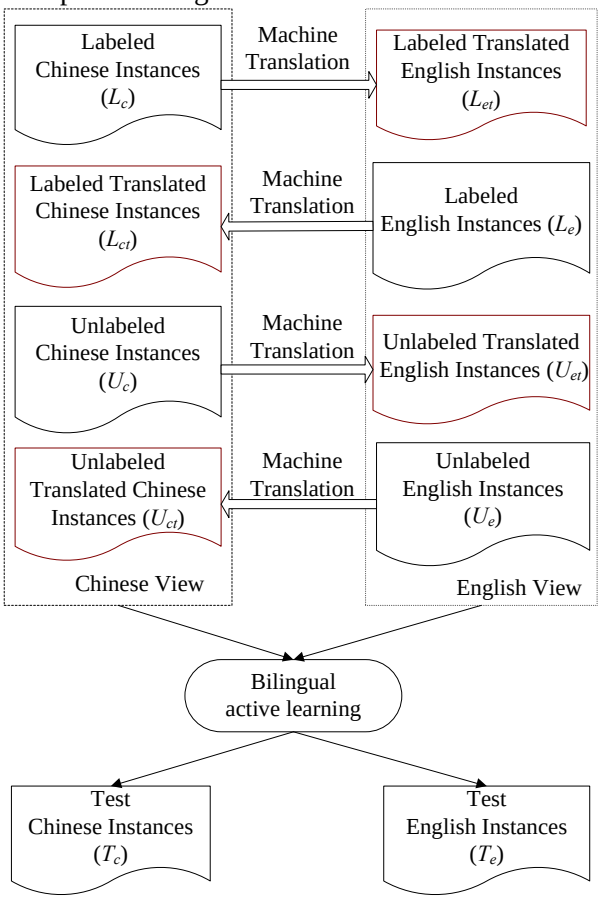

Figure 2. Framework of bilingual active learning

In order to make full use of pseudo parallel corpora, translated labeled and unlabeled instances are augmented in the following two ways:

- For labeled Chinese instances (L_c) and English instances (L_e), their translated counterparts (L_{et} and L_{ct}), along with their labels, are directly added into the labeled instances in the other language;
- For unlabeled Chinese instances (U_c) and English instances (U_e), during an active learning iteration the top *n* unlabeled instances in U_c and U_{et} which are least confidently jointly

predicted by SVM_c and SVM_e are labeled by an oracle and added to L_c and L_e respectively. (cf. §4.4)

4.3 Instance Projection via MT

Among the several off-the-shelf machine translation services, we select the Google Translator[1] because of its high quality and easy accessibility. Both the mentions of relation instances and the mentions of two involved entities are first translated into the other language via machine translation. Then, two entities in the original instance are aligned with their counterparts in the translated instance in order to form an aligned bilingual relation instance pair.

Instance translation

All the positive instances in the ACE 2005 Chinese and English corpora are translated to another language respectively, i.e. Chinese to English and vice versa. The relation instance is represented as the word sequence between two entities. This word sequence, rather than the whole sentence, is then translated to another language by the Google Translator. The reason is that, although this sequence loses partial contextual information of the relation instance, its translation quality is supposed to be better. Our preliminary experiments indicate that the addition of contextual information fail to benefit the task. After translation, word segmentation is performed on Chinese instances translated from English while tokenization is needed for translated English instances.

Entity alignment

The objective of entity alignment is to build a mapping from the entities in the original instances to the entities in the translated instances. Put in another way, entity alignment automatically marks the entity mentions in the translated instance, thereby the feature vector corresponding to the translated instance can be constructed. Entity alignment is vital in cross-language relation extraction whose difficulty lies in the fact that the same entity mention as an isolated phrase and as an integral phrase in the relation instance can be translated to different phrases. For example, the Chinese entity mention "官员" (*officer*) is translated to "officer" in isolation, it is, however, translated to "officials" when in the relation instance "叙利亚 官员" (*Syrian officials*).

[1] http://translate.google.com

Algorithm entity alignment

Input:

- M_e, entity mention in English
- R_e, relation instance in English
- M_{ct}, translation of M_e in Chinese
- R_c, translation of R_e in Chinese
- L, a lexicon consisting of entries like (e_i, c_i, p_i), where p_i is the translation probability from e_i to c_i
- α, probability threshold

Output:

- M_c, the counterpart of M_e in R_c

Steps:

1. If M_{ct} can be exactly found in R_c, then return M_{ct}
2. If the rightmost part of M_{ct} can be found in R_c, then this part can be returned
3. For very word w_e in M_e,
   a) If there exists a word w_c in R_c and (w_e, w_c, p) in L and $p>\alpha$, then (w_e, w_c) is a match of two words
   b) Return a successive sequence of matching words w_c
4. Return null

Figure 3. Entity alignment algorithm

Therefore, we devise some heuristics to align entity mentions between Chinese and English. The basic idea is that the word sequence in one mention successively matches the word sequence in the other mention. Take entity alignment from English to Chinese as an example, given entity mention M_e in relation instance R_e in English and their respective translations M_{ct} and R_c in Chinese, the objective of entity alignment is to find M_c, the counterpart of M_e in R_c. The procedure of entity alignment algorithm can be described in Fig. 3.

In the algorithm, the probability threshold α is empirically set to 0.002 where the precision and recall of entity alignment are balanced. Our lexicon is derived from the FBIS parallel corpus (#LDC2003E14), which is widely used in machine translation between English and Chinese. It should be noted that the process of relation translation and entity alignment are far from perfection, leading to reduction in the number of instances being mapping to the other language, i.e.

$$|L_c| > |L_{et}|$$
$$|U_c| > |U_{et}|$$
$$|L_e| > |L_{ct}|$$
$$|U_e| > |L_{ct}|$$

4.4 Bilingual Active Learning Algorithm

The basic idea of our BAL paradigm is that, while unlabeled instances uncertain in one lan-

guage are informative to the learner in that language, unlabeled instances jointly uncertain in both languages are informative to the learners in both languages, thus potentially improving classification performance for both languages more than their individual active learners do. This idea is embodied in the BAL algorithm in Fig. 4, where n is the batch size, i.e., the number of instances selected, labeled and augmented at each iteration.

Algorithm bilingual active learning

Input:

- L_c and U_c, labeled and unlabeled instances in Chinese, and L_{et} and U_{et}, their respective translation counterparts in English
- L_e and U_e, labeled and unlabeled instances in English, and L_{ct} and U_{ct}, their translation counterparts in Chinese
- n, batch size

Output:

- SVM_c and SVM_e, two classifiers for Chinese and English respectively

Initialize:

1. Add instances L_{ct} to L_c
2. Add instances L_{et} to L_e

Repeat:

1. Learn the Chinese classifier SVM_c from L_c
2. Use SVM_c to classify instances in U_c and U_{ct}
3. Learn the English classifier SVM_e from L_e
4. Use SVM_e to classify instances in U_e and U_{et}
5. Choose the n least confidently jointly predicted instance pairs $\{E_c|E_{et}\}$ from $\{U_c|U_{et}\}$, and have them labeled by an oracle
6. Choose the n least confidently jointly predicted instance pairs $\{E_e|E_{et}\}$ from $\{U_e|U_{ct}\}$, and have them labeled by an oracle
7. Remove E_c from U_c and E_e from U_e
8. Add instances $E_c \cup E_{ct}$ to L_c with their manual labels
9. Add instances $E_e \cup E_{et}$ to L_e with their manual labels

Until certain number of instances are labeled or certain performance is reached

Figure 4. Bilingual active learning algorithm

The key point of this algorithm lies in Step 5 and Step 6, where unlabeled instances from U_c and U_e are selected and labeled respectively. Take Chinese for an example, when gauging the prediction uncertainty for an unlabeled instance in U_c, not only its own uncertainty measure H_c predicted by SVM_c is considered, but also the uncertainty measure H_{et} for its translation counterpart in U_{et}, which is predicted by SVM_e, is considered. Generally, in order to jointly consider these two measures, there are three methods to compute their means, namely, arithmetic mean, geometric mean and harmonic mean. Preliminary experiments show that among these three means, there is no single winner, so we simply take the geometric mean defined as follows:

$$H_g = \sqrt{H_c * H_{et}} \quad (2)$$

Considering that we adopt the **LC** measure as the uncertainty score, when an instance in U_c can't find its translation counterpart in U_{et} due to translation error or entity alignment failure, H_{et} is set to 1, i.e. the maximum. Since the bigger H is, the more confident the prediction is, the less likely the instance will be chosen, in this way we discourage the unlabeled instances without translation counterparts.

5 Experimentation

We have systematically evaluated our BAL paradigm on the relation classification task using ACE RDC 2005 RDC Chinese and English corpora.

5.1 Experimental Settings

Corpora and Preprocessing

We use the ACE 2005 RDC Chinese and English corpora as the benchmark data (hereafter we refer to them as the Chinese corpus (ACE2005c) and the English corpus (ACE2005e) respectively). Both corpora have the same entity/relation hierarchies, which define 7 entity types, 6 major relation types. However, the Chinese corpus contains 633 documents and 9,147 positive relation instances while the English corpus only contains 498 files and 6,253 positive instances. Therefore, in order to balance the corpus scale to fairly evaluate bilingual active learning impact on relation classification, we randomly select 458 Chinese files and thus get 6,268 positive instances, comparable to the English corpus.

Preprocessing steps for both corpora include sentence splitting and tokenization (word segmentation for Chinese using ICTCLAS[2]). Then, positive relation mentions with word sequences between two entities and their feature vectors are extracted from sentences while negative relation mentions are simply discarded because we focus on the task of relation classification. After entity and relation mentions in one language are trans-

[2] http://ictclas.org/

lated into the other language using the Google translator, entity alignment is performed between relation mentions and their translations. Finally 4,747 Chinese relation mentions are successfully translated and aligned from English and vice versa, 4,936 English relation mentions are translated and aligned from Chinese.

SVMLIB (Chang and Lin, 2011) is selected as our classifier since it supports multi-class classification. The training parameters C (SVM) is set to 2.4 according to our previous work on relation extraction (Qian et al., 2010). Relation classification performance is evaluated using the standard Precision (P), Recall (R) and their harmonic average (F1) as well as *deficiency* measure (cf. latter in this section.). Overall performance scores are averaged over 10 runs. For each run, 1/40 and 1/5 randomly selected instances are used as the training and test set respectively while the remaining instances are used as the unlabeled set for further labeling during active learning iterations.

Methods for Comparison

For fair comparison, two baseline methods of supervised learning are included to augment their training sets with labeled instances during iterations. However, these labeled instances are chosen randomly from the corpus.

SL-MO (Supervised Learning with monolingual labeled instances): only the monolingual labeled instances are fed to the SVM classifiers for both Chinese and English relation classification respectively. The initial training data only contain L_c and L_e for Chinese and English respectively.

SL-CR (Supervised Learning with cross-lingual labeled instances): in addition to monolingual labeled instances (**SL-MO**), the training data for supervised learning contain labeled instances translated from the other language. That is, the initial training data contain L_c and L_{ct} for Chinese, or L_e and L_{et} for English. More important, at each iteration not only the labeled instances are added to the training data of its own language, but their translated instances are also added to the training data of the other language.

AL-MO (Active Learning with monolingual instances): labeled and unlabeled data for active learning only contain monolingual instances. No translated instances are involved. That is, the data contain L_c and U_c for Chinese, or L_e and U_e for English respectively. This is the normal active learning method applied to a single language.

AL-CR (Active Learning with cross-lingual instances): both the manually labeled instances and their translated ones are added to the respective training data. The initial training data contain L_c and L_{ct} for Chinese, or L_e and L_{et} for English. At each iteration, the n least confidently classified instances in U_c and U_e are labeled and added to the Chinese/English training data respectively. Their translated instances in U_{et} and U_{ct} are also added to the English/Chinese training data respectively.

AL-BI (Active Learning with bilingual labeled and unlabeled instances): similar to **AL-CR** with the exception that the unlabeled instances are chosen not by uncertainty scores in one language, but by the joint uncertainty scores in two languages. (cf. §4.4)

Evaluation Metric

Although learning curves are often used to evaluate the performance for active learning, it is preferable to quantitatively compare various active learning methods using a statistical metric *deficiency* (Schein and Ungar, 2007) defined as:

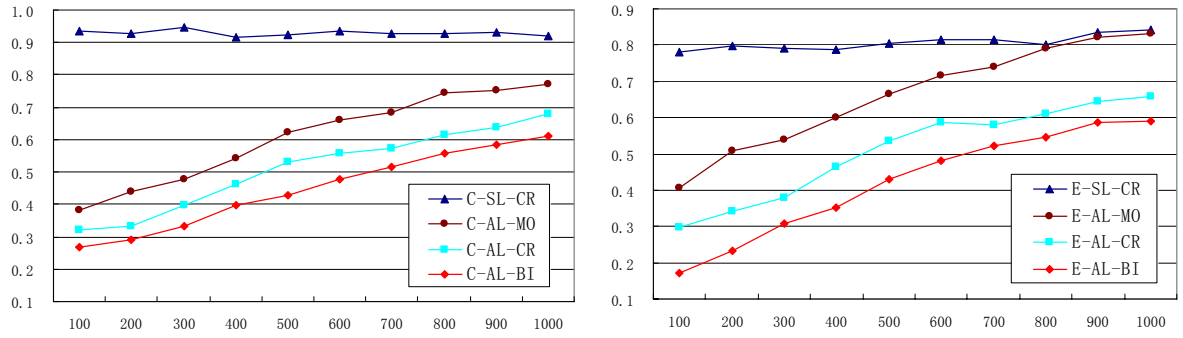
$$def_n(AL, REF) = \frac{\sum_{i=1}^{n}(F_n(REF) - F_i(AL))}{\sum_{i=1}^{n}(F_n(REF) - F_i(REF))} \quad (3)$$

Where n is the number of iterations involved in active learning and F_i is the F1-score of relation classification at the ith iteration. *REF* is the baseline active learning method and *AL* is an improved variant of *REF*, such as **AL-CR** or **AL-BI**. Essentially this *deficiency* metric measures the degree to which *REF* outperforms *AL*. Thus, smaller deficiency value (i.e. <1.0) indicates AL outperforms *REF* while a larger value (i.e. >1.0) indicates *AL* underperforms *REF*.

5.2 Experimental Results and Analysis

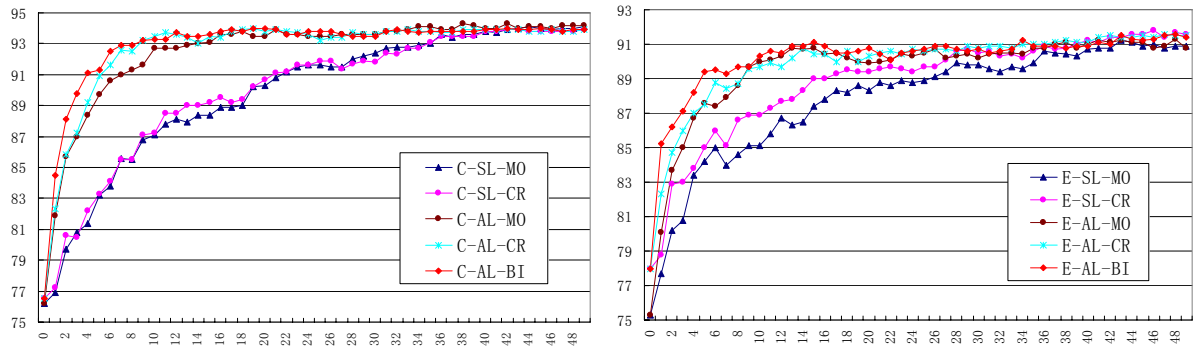
Comparison of overall deficiency

Table 1 compares the deficiency scores of relation classification on the Chinese (ACE2005c) and English corpora (ACE2005e) for various learning methods, i.e., **SL-CR**, **AL-MO**, **AL-CR** and **AL-BI**. Particularly, **SL-MO** is used as the baseline system against which deficiency scores for other methods are computed. The batch size n is set to 100 and iterations stop after all the unlabeled instances have run out of. Deficiency scores are averaged over 10 runs and the best ones are highlighted in bold font. Each run has a different test set and a different seed set.



(a) Chinese (b) English

Figure 5. Deficiency comparison for different batch sizes



(a) Chinese (b) English

Figure 6. Learning curves for different methods

The table shows that among the three active learning methods, bilingual active learning (**AL-BI**) achieves the best performance for both Chinese and English relation classification. This demonstrates that, bilingual active learning with jointly selecting the unlabeled instances can not only enhance relation classification for its own language, but also help relation classification for the other language due to the complementary nature of relation instances between Chinese and English.

Corpora	**SL-CR**	**AL-MO**	**AL-CR**	**AL-BI**
ACE2005c	0.934	0.383	0.323	**0.254**
ACE2005e	0.779	0.405	0.298	**0.160**

Table 1. Deficiency comparison of different methods

The table also shows the consistent utility of cross-lingual information for relation classification for both languages. When cross-lingual information is augmented, **SL-CR** outperforms **SL-MO** and **AL-CR** outperforms **AL-MO**.

Comparison of different batch sizes

Figure 5(a) and 5(b) illustrate the deficiency scores for four learning methods (**SL-CR**, **AL-MO**, **AL-CR** and **AL-BI**) against the **SL-MO** method with different batch sizes (n), where prefixes "C" and "E" denote Chinese and English respectively. The horizontal axes denote the range of n (<=1000) while the vertical ones denote the deficiency scores.

The figures show that the deficiency scores for three active learning methods run virtually parallel with each other while they increase monotonously with the batch size n. This suggests that for both Chinese and English **AL-BI** consistently performs best against other methods across a wide range of batch sizes, though the overall advantage of three active learning methods generally diminish.

Comparison of learning curves

In order to gain an intuition into how the performance evolves when the labeled instances are added into the training data during iterations, we depict the learning curves for various learning methods on the Chinese and English corpora in Fig. 6(a) and 6(b) respectively. The horizontal axes denote learning iterations while the vertical ones denote F1-scores. For simplicity of illustration the F1-scores are collected from one of the 10 runs.

The figures clearly demonstrate the performance difference for both languages among five methods at the beginning of iterations while F1-scores converge at the end of iterations. Particularly at the very outset, **AL-BI** outperforms other methods, quickly jumps to a very high point comparable to its best performance. However, after the 10th iteration the performance scores for the three AL variants tend to show trivial difference probably because most highly informative instances have already been added to the training data.

Comparison of annotation scale

In order to better compare BAL with other AL methods Figure 7 zooms out partial data on three AL methods in Fig. 6 and rescale the data for **AL-MO**, where "C" and "E" denote Chinese and English respectively. Likewise, the vertical axis denotes F1-scores while the horizontal axis denotes the number of instances labeled for **AL-CR** and **AL-BI**. However, for **AL-MO** that number is doubled. This figure tries to answer the question: to label *n* respective instances in both languages for BAL or to labeled *2n* instances in just one language for monolingual AL, can the former rival the latter?

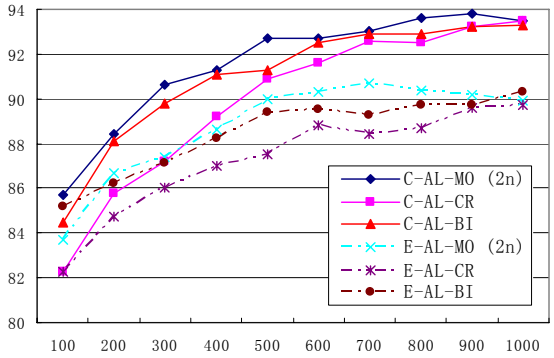


Figure 7. Comparison of annotation scale among three AL methods

The figure shows that for both Chinese and English, when the number of instances (*n*) to be labeled is no greater than 400, **AL-BI** with *n* instances can achieve comparable performance with **AL-MO** with *2n* instances. It implies that when the labeled instances are limited, labeling instances, half in one language and half in the other for BAL, is competitive against labeling the same total number of instances in just one language for monolingual AL, not to mention that the former can generate two relation extractors on two languages.

6 Conclusion

This paper proposes a bilingual active learning paradigm for Chinese and English relation classification. Given a small number of relation instances and a large number of unlabeled relation instances in both languages, we translate both the labeled and unlabeled instances in one language to the other as pseudo parallel corpora. After entity alignment, these labeled and unlabeled instances in both languages are fed into a bilingual active learning engine. Experiments with the task of relation classification on the ACE RDC 2005 Chinese and English corpora show that bilingual active learning can significantly outperforms monolingual active learning for both Chinese and English simultaneously. Moreover, we demonstrate that BAL across two languages can compete against monolingual AL when the annotation scale is limited, though the overall number of labeled instances remains the same.

For future work, on one hand, we plan to combine uncertainty sampling with diversity and informativeness measures; on the other hand, we intend to combine BAL with semi-supervised learning to further reduce human annotation efforts.

Learning Soft Linear Constraints with Application to Citation Field Extraction

Sam Anzaroot Alexandre Passos David Belanger Andrew McCallum
Department of Computer Science
University of Massachusetts, Amherst
{anzaroot, apassos, belanger, mccallum}@cs.umass.edu

Abstract

Accurately segmenting a citation string into fields for authors, titles, etc. is a challenging task because the output typically obeys various global constraints. Previous work has shown that modeling *soft constraints*, where the model is encouraged, but not require to obey the constraints, can substantially improve segmentation performance. On the other hand, for imposing *hard constraints*, dual decomposition is a popular technique for efficient prediction given existing algorithms for unconstrained inference. We extend dual decomposition to perform prediction subject to soft constraints. Moreover, with a technique for performing inference given soft constraints, it is easy to automatically generate large families of constraints and learn their costs with a simple convex optimization problem during training. This allows us to obtain substantial gains in accuracy on a new, challenging citation extraction dataset.

1 Introduction

Citation field extraction, an instance of information extraction, is the task of segmenting and labeling research paper citation strings into their constituent parts, including authors, editors, year, journal, volume, conference venue, etc. This task is important because citation data is often provided only in plain text; however, having an accurate structured database of bibliographic information is necessary for many scientometric tasks, such as mapping scientific sub-communities, discovering research trends, and analyzing networks of researchers. Automated citation field extraction needs further research because it has not yet reached a level of accuracy at which it can be practically deployed in real-world systems.

Hidden Markov models and linear-chain conditional random fields (CRFs) have previously been applied to citation extraction (Hetzner, 2008; Peng and McCallum, 2004) . These models support efficient dynamic-programming inference, but only model *local* dependencies in the output label sequence. However citations have strong *global* regularities not captured by these models. For example many book citations contain both an author section and an editor section, but none have two disjoint author sections. Since linear-chain models are unable to capture more than Markov dependencies, the models sometimes mislabel the *editor* as a second author. If we could enforce the global constraint that there should be only one author section, accuracy could be improved.

One framework for adding such global constraints into tractable models is *constrained inference*, in which at inference time the original model is augmented with restrictions on the outputs such that they obey certain global regularities. When hard constraints can be encoded as linear equations on the output variables, and the underlying model's inference task can be posed as linear optimization, one can formulate this constrained inference problem as an *integer linear program* (ILP) (Roth and Yih, 2004). Alternatively, one can employ *dual decomposition* (Rush et al., 2010). Dual decompositions's advantage over ILP is is that it can leverage existing inference algorithms for the original model as a black box. Such a modular algorithm is easy to implement, and works quite well in practice, providing certificates of optimality for most examples.

The above two approaches have previously been applied to impose *hard* constraints on a model's output. On the other hand, recent work has demonstrated improvements in citation field extraction by imposing *soft* constraints (Chang et al., 2012). Here, the model is not required obey the global constraints, but merely pays a penalty for their vi-

olation.

This paper introduces a novel method for imposing soft constraints via dual decomposition. We also propose a method for learning the penalties the prediction problem incurs for violating these soft constraints. Because our learning method drives many penalties to zero, it allows practitioners to perform 'constraint selection,' in which a large number of automatically-generated candidate global constraints can be considered and automatically culled to a smaller set of useful constraints, which can be run quickly at test time.

Using our new method, we are able to incorporate not only all the soft global constraints of Chang et al. (2012), but also far more complex data-driven constraints, while also providing stronger optimality certificates than their beam search technique. On a new, more broadly representative, and challenging citation field extraction data set, we show that our methods achieve a 17.9% reduction in error versus a linear-chain conditional random field. Furthermore, we demonstrate that our inference technique can use and benefit from the constraints of Chang et al. (2012), but that including our data-driven constraints on top of these is beneficial. While this paper focusses on an application to citation field extraction, the novel methods introduced here would easily generalize to many problems with global output regularities.

2 Background

2.1 Structured Linear Models

The overall modeling technique we employ is to add soft constraints to a simple model for which we have an existing efficient prediction algorithm. For this underlying model, we employ a chain-structured conditional random field (CRF), since CRFs have been shown to perform better than other simple unconstrained models like hidden markov models for citation extraction (Peng and McCallum, 2004). We produce a prediction by performing *MAP inference* (Koller and Friedman, 2009).

The MAP inference task in a CRF be can expressed as an optimization problem with a linear objective (Sontag, 2010; Sontag et al., 2011). Here, we define a binary indicator variable for each candidate setting of each factor in the graphical model. Each of these indicator variables is associated with the score that the factor takes on when it has the indictor variable's corresponding value. Since the log probability of some y in the CRF is proportional to sum of the scores of all the factors, we can concatenate the indicator variables as a vector y and the scores as a vector w and write the MAP problem as

$$\begin{aligned} \textbf{max.} \quad & \langle w, y \rangle \\ \textbf{s.t.} \quad & y \in \mathcal{U}, \end{aligned} \tag{1}$$

where the set $\mathcal{U}$ represents the set of valid configurations of the indicator variables. Here, the constraints are that all neighboring factors agree on the components of y in their overlap.

Structured Linear Models are the general family of models where prediction requires solving a problem of the form (1), and they do not always correspond to a probabilistic model. The algorithms we present in later sections for handling soft global constraints and for learning the penalties of these constraints can be applied to general structured linear models, not just CRFs, provided we have an available algorithm for performing MAP inference.

2.2 Dual Decomposition for Global Constraints

In order to perform prediction subject to various global constraints, we may need to augment the problem (1) with additional constraints. Dual Decomposition is a popular method for performing MAP inference in this scenario, since it leverages known algorithms for MAP in the base problem where these extra constraints have not been added (Komodakis et al., 2007; Sontag et al., 2011; Rush and Collins, 2012). In this case, the MAP problem can be formulated as a structured linear model similar to equation (1), for which we have a MAP algorithm, but where we have imposed some additional constraints $Ay \leq b$ that no longer allow us to use the algorithm. In other

Algorithm 1 DD: projected subgradient for dual decomposition with hard constraints

1: **while** has not converged **do**
2: $y^{(t)} = \text{argmax}_{y \in \mathcal{U}} \langle w + A^T \lambda, y \rangle$
3: $\lambda^{(t)} = \Pi_{0 \leq \cdot} \left[\lambda^{(t-1)} - \eta^{(t)} (Ay - b) \right]$

words, we consider the problem

$$\begin{aligned} \textbf{max.} \quad & \langle w, y \rangle \\ \textbf{s.t.} \quad & y \in \mathcal{U} \\ & Ay \leq b, \end{aligned} \tag{2}$$

for an arbitrary matrix A and vector b. We can write the Lagrangian of this problem as

$$L(y, \lambda) = \langle w, y \rangle + \lambda^T (Ay - b). \tag{3}$$

Regrouping terms and maximizing over the primal variables, we have the dual problem

$$\textbf{min.}_\lambda D(\lambda) = \max_{y \in \mathcal{U}} \langle w + A^T \lambda, y \rangle - \lambda^T b. \tag{4}$$

For any λ, we can evaluate the dual objective $D(\lambda)$, since the maximization in (4) is of the same form as the original problem (1), and we assumed we had a method for performing MAP in this. Furthermore, a subgradient of $D(\lambda)$ is $Ay^* - b$, for an y^* which maximizes this inner optimization problem. Therefore, we can minimize $D(\lambda)$ with the projected subgradient method (Boyd and Vandenberghe, 2004), and the optimal y can be obtained when evaluating $D(\lambda^*)$. Note that the subgradient of $D(\lambda)$ is the amount by which each constraint is violated by λ when maximizing over y.

Algorithm 1 depicts the basic projected subgradient descent algorithm for dual decomposition. The projection operator Π consists of truncating all negative coordinates of λ to 0. This is necessary because λ is a vector of dual variables for inequality constraints. The algorithm has converged when each constraint is either satisfied by $y^{(t)}$ with equality or its corresponding component of λ is 0, due to complimentary slackness (Boyd and Vandenberghe, 2004).

3 Soft Constraints in Dual Decomposition

We now introduce an extension of Algorithm 1 to handle soft constraints. In our formulation, a soft-constrained model imposes a penalty for each unsatisfied constraint, proportional to the amount by which it is violated. Therefore, our derivation parallels how soft-margin SVMs are derived from hard-margin SVMs by introducing auxiliary slack variables (Cortes and Vapnik, 1995). Note that when performing MAP subject to soft constraints, optimal solutions might not satisfy some constraints, since doing so would reduce the model's score by too much.

Consider the optimization problems of the form:

$$\begin{aligned} \textbf{max.} \quad & \langle w, y \rangle - \langle c, z \rangle \\ \textbf{s.t.} \quad & y \in \mathcal{U} \\ & Ay - b \leq z \\ & -z \leq 0, \end{aligned} \tag{5}$$

For positive c_i, it is clear that an optimal z_i will be equal to the degree to which $a_i^T y \leq b_i$ is violated. Therefore, we pay a cost c_i times the degree to which the ith constraint is violated, which mirrors how slack variables are used to represent the hinge loss for SVMs. Note that c_i has to be positive, otherwise this linear program is unbounded and an optimal value can be obtained by setting z_i to infinity.

Using a similar construction as in section 2.2 we write the Lagrangian as:

$$\begin{aligned} L(y, z, \lambda, \mu) = & \langle w, y \rangle - \langle c, z \rangle \\ & + \lambda^T (Ay - b - z) + \mu^T (-z). \end{aligned} \tag{6}$$

The optimality constraints with respect to z tell us that $-c - \lambda - \mu = 0$, hence $\mu = -c - \lambda$. Substituting, we have

$$L(y, \lambda) = \langle w, y \rangle + \lambda^T (Ay - b), \tag{7}$$

except the constraint that $\mu = -c - \lambda$ implies that for μ to be positive $\lambda \leq c$.

Since this Lagrangian has the same form as equation (3), we can also derive a dual problem, which is the same as in equation (4), with the additional constraint that each λ_i can not be bigger than its cost c_i. In other words, the dual problem can not penalize the violation of a constraint more than the soft constraint model in the primal would penalize you if you violated it.

This optimization problem can still be solved with projected subgradient descent and is depicted in Algorithm 2. The only modifications to Algorithm 1 are replacing the coordinate-wise projection $\Pi_{0 \leq \cdot}$ with $\Pi_{0 \leq \cdot \leq c}$ and how we check for convergence. Now, we check for the KKT conditions of (5), where for every constraint i, either the constraint is satisfied with equality, $\lambda_i = 0$, or $\lambda_i = c_i$.

Algorithm 2 Soft-DD: projected subgradient for dual decomposition with soft constraints

1: **while** has not converged **do**
2: $y^{(t)} = \text{argmax}_{y \in \mathcal{U}} \langle w + A^T \lambda, y \rangle$
3: $\lambda^{(t)} = \Pi_{0 \leq \cdot \leq c} \left[\lambda^{(t-1)} - \eta^{(t)} (Ay - b) \right]$

Therefore, implementing soft-constrained dual decomposition is as easy as implementing hard-constrained dual decomposition, and the per-iteration complexity is the same. We encourage further applications of soft-constraint dual decomposition to existing and new NLP problems.

3.1 Learning Penalties

One consideration when using soft v.s. hard constraints is that soft constraints present a new training problem, since we need to choose the vector c, the penalties for violating the constraints. An important property of problem (5) in the previous section is that it corresponds to a structured linear model over y and z. Therefore, we can apply known training algorithms for estimating the parameters of structured linear models to choose c.

All we need to employ the structured perceptron algorithm (Collins, 2002) or the structured SVM algorithm (Tsochantaridis et al., 2004) is a black-box procedure for performing MAP inference in the structured linear model given an arbitrary cost vector. Fortunately, the MAP problem for (5) can be solved using Soft-DD, in Algorithm 2.

Each penalty c_i has to be non-negative; otherwise, the optimization problem in equation (5) is ill-defined. This can be ensured by simple modifications of the perceptron and subgradient descent optimization of the structured SVM objective simply by truncating c coordinate-wise to be non-negative at every learning iteration.

Intuitively, the perceptron update increases the penalty for a constraint if it is satisfied in the ground truth and not in an inferred prediction, and decreases the penalty if the constraint is satisfied in the prediction and not the ground truth. Since we truncate penalties at 0, this suggests that we will learn a penalty of 0 for constraints in three categories: constraints that do not hold in the ground truth, constraints that hold in the ground truth but are satisfied in practice by performing inference in the base CRF model, and constraints that are satisfied in practice as a side-effect of imposing non-zero penalties on some other constraints . A similar analysis holds for the structured SVM approach.

Therefore, we can view learning the values of the penalties not just as parameter tuning, but as a means to perform 'constraint selection,' since constraints that have a penalty of 0 can be ignored. This property allows us to consider large families of constraints, from which the useful ones are automatically identified.

We found it beneficial, though it is not theoretically necessary, to learn the constraints on a held-out development set, separately from the other model parameters, as during training most constraints are satisfied due to overfitting, which leads to an underestimation of the relevant penalties.

4 Citation Extraction Data

We consider the UMass citation dataset, first introduced in Anzaroot and McCallum (2013). It has over 1800 citation from many academic fields, extracted from the arXiv. This dataset contains both coarse-grained and fine-grained labels; for example it contains labels for the segment of all authors, segments for each individual author, and for the first and last name of each author. There are 660 citations in the development set and 367 citation in the test set.

The labels in the UMass dataset are a concatenation of labels from a hierarchically-defined schema. For example, a first name of an author is tagged as: *authors/person/first*. In addition, individual tokens are labeled using a BIO label schema for each level in the hierarchy. BIO is a commonly used labeling schema for information extraction tasks. BIO labeling allows individual labels on tokens to label segmentation information as well as labels for the segments. In this schema, labels that begin segments are prepended with a *B*, labels that continue a segment are prepended with an *I*, and tokens that don't have a labeling in this schema are given an *O* label. For example, in a hierarchical BIO label schema the first token in the first name for the second author may be labeled as: *I-authors/B-person/B-first*.

An example labeled citation in this dataset can be viewed in figure 1.

5 Global Constraints for Citation Extraction

5.1 Constraint Templates

We now describe the families of global constraints we consider for citation extraction. Note these

constraints are all linear, since they depend only on the counts of each possible conditional random field label. Moreover, since our labels are BIO-encoded, it is possible, by counting B tags, to count how often each citation tag itself appears in a sentence. The first two families of constraints that we describe are general to any sequence labeling task while the last is specific to hierarchical labeling such as available in the UMass dataset.

Our sequence output is denoted as y and an element of this sequence is y_k.

We denote $[[y_k = i]]$ as the function that outputs 1 if y_k has a 1 at index i and 0 otherwise. Here, y_k represents an output tag of the CRF, so if $[[y_k = i]]$ = 1, then we have that y_k was given a label with index i.

5.2 Singleton Constraints

Singleton constraints ensure that each label can appear at most once in a citation. These are same global constraints that were used for citation field extraction in Chang et al. (2012). We define $s(i)$ to be the number of times the label with index i is predicted in a citation, formally:

$$s(i) = \sum_{y_k \in y} [[y_k = i]]$$

The constraint that each label can appear at most once takes the form:

$$s(i) <= 1$$

5.3 Pairwise Constraints

Pairwise constraints are constraints on the counts of two labels in a citation. We define $z_1(i, j)$ to be

$$z_1(i, j) = \sum_{y_k \in y} [[y_k = i]] + \sum_{y_k \in y} [[y_k = j]]$$

and $z_2(i, j)$ to be

$$z_2(i, j) = \sum_{y_k \in y} [[y_k = i]] - \sum_{y_k \in y} [[y_k = j]]$$

We consider all constraints of the forms: $z(i, j) \leq 0, 1, 2, 3$ and $z(i, j) \geq 0, 1, 2, 3$.

Note that some pairs of these constraints are redundant or logically incompatible. However, we are using them as soft constraints, so these constraints will not necessarily be satisfied by the output of the model, which eliminates concern over enforcing logically impossible outputs. Furthermore, in section 3.1 we described how our procedure for learning penalties will drive some penalties to 0, which effectively removes them from our set of constraints we consider. It can be shown, for example, that we will never learn non-zero penalties for certain pairs of logically incompatible constraints using the perceptron-style algorithm described in section 3.1 .

5.4 Hierarchical Equality Constraints

The labels in the citation dataset are hierarchical labels. This means that the labels are the concatenation of all the levels in the hierarchy. We can create constraints that are dependent on only one or couple of elements in the hierarchy.

We define $C(x, i)$ as the function that returns 1 if the output x contains the label i in the hierarchy and 0 otherwise. We define $e(i, j)$ to be

$$e(i, j) = \sum_{y_k \in y} [[C(y_k, i)]] - \sum_{y_k \in y} [[C(y_k, j)]]$$

Hierarchical equality constraints take the forms:

$$e(i, j) \geq 0 \quad (8)$$
$$e(i, j) \leq 0 \quad (9)$$

5.5 Local constraints

We constrain the output labeling of the chain-structured CRF to be a valid BIO encoding. This both improves performance of the underlying model when used without global constraints, as well as ensures the validity of the global constraints we impose, since they operate only on *B* labels. The constraint that the labeling is valid BIO can be expressed as a collection of pairwise constraints on adjacent labels in the sequence. Rather than enforcing these constraints using dual decomposition, they can be enforced directly when performing MAP inference in the CRF by modifying the dynamic program of the Viterbi algorithm to only allow valid pairs of adjacent labels.

5.6 Constraint Pruning

While the techniques from section 3.1 can easily cope with a large numbers of constraints at training time, this can be computationally costly, specially if one is considering very large constraint families. This is problematic because the size

Figure 2: Two examples where imposing soft global constraints improves field extraction errors. Soft-DD converged in 1 iteration on the first example, and 7 iterations on the second. When a reference is citing a book and not a section of the book, the correct labeling of the name of the book is title. In the first example, the baseline CRF incorrectly outputs booktitle, but this is fixed by Soft-DD, which penalizes outputs based on the constraint that booktitle should co-occur with an address label. In the second example, the unconstrained CRF output violates the constraint that title and status labels should not co-occur. The ground truth labeling also violates a constraint that title and language labels should not co-occur. At convergence of the Soft-DD algorithm, the correct labeling of language is predicted, which is possible because of the use of soft constraints.

Constraints	F1 score	Sparsity	# of cons

Table 1: Set of constraints learned and F1 scores. The last row depicts the result of inference using all constraints as hard constraints.

of some constraint families we consider grows quadratically with the number of candidate labels, and there are about 100 in the UMass dataset. Such a family consists of constraints that the sum of the counts of two different label types has to be bounded (a useful example is that there can't be more than one out of "phd thesis" and "journal"). Therefore, quickly pruning bad constraints can save a substantial amount of training time, and can lead to better generalization.

To do so, we calculate a score that estimates how useful each constraint is expected to be. Our score compares how often the constraint is violated in the ground truth examples versus our predictions. Here, prediction is done with respect to the base chain-structured CRF tagger and does not include global constraints. Note that it may make sense to consider a constraint that is sometimes violated in the ground truth, as the penalty learning algorithm can learn a small penalty for it, which will allow it to be violated some of the time. Our importance score is defined as, for each constraint c on labeled set D,

$$imp(c) = \frac{\sum_{d \in D} [[max_y w_d^T y]]_c}{\sum_{d \in D} [[y_d]]_c}, \qquad (10)$$

where $[[y]]_c$ is 1 if the constraint is violated on output y and 0 otherwise. Here, y_d denotes the ground truth labeling and w_d is the vector of scores for the CRF tagger.

We prune constraints by picking a cutoff value for $imp(c)$. A value of $imp(c)$ above 1 implies that the constraint is more violated on the predicted examples than on the ground truth, and hence that we might want to keep it.

We also find that the constraints that have the largest imp values are semantically interesting.

6 Related Work

There are multiple previous examples of augmenting chain-structured sequence models with terms capturing global relationships by expanding the chain to a more complex graphical model with non-local dependencies between the outputs. Inference in these models can be performed, for example, with loopy belief propagation (Bunescu and Mooney, 2004; Sutton and McCallum, 2004) or Gibbs sampling (Finkel et al., 2005). Belief propagation is prohibitively expensive in our

model due to the high cardinalities of the output variables and of the global factors, which involve all output variables simultaneously. There are various methods for exploiting the combinatorial structure of these factors, but performance would still have higher complexity than our method. While Gibbs sampling has been shown to work well tasks such as named entity recognition (Finkel et al., 2005), our previous experiments show that it does not work well for citation extraction, where it found only low-quality solutions in practice because the sampling did not mix well, even on a simple chain-structured CRF.

Recently, dual decomposition has become a popular method for solving complex structured prediction problems in NLP (Koo et al., 2010; Rush et al., 2010; Rush and Collins, 2012; Paul and Eisner, 2012; Chieu and Teow, 2012). Soft constraints can be implemented inefficiently using hard constraints and dual decomposition— by introducing copies of output variables and an auxiliary graphical model, as in Rush et al. (2012). However, at every iteration of dual decomposition, MAP must be run in this auxiliary model. Furthermore the copying of variables doubles the number of iterations needed for information to flow between output variables, and thus slows convergence. On the other hand, our approach to soft constraints has identical per-iteration complexity as for hard constraints, and is a very easy modification to existing hard constraint code.

Initial work in machine learning for citation extraction used Markov models with no global constraints. Hidden Markov models (HMMs), were originally employed for automatically extracting information from research papers on the CORA dataset (Seymore et al., 1999; Hetzner, 2008). Later, CRFs were shown to perform better on CORA, improving the results from the Hmm's token-level F1 of 86.6 to 91.5 with a CRF(Peng and McCallum, 2004).

Recent work on globally-constrained inference in citation extraction used an HMM^{CCM}, which is an HMM with the addition of global features that are restricted to have positive weights (Chang et al., 2012). Approximate inference is performed using beam search. This method increased the HMM token-level accuracy from 86.69 to 93.92 on a test set of 100 citations from the CORA dataset. The global constraints added into the model are simply that each label only occurs once per citation. This approach is limited in its use of an HMM as an underlying model, as it has been shown that CRFs perform significantly better, achieving 95.37 token-level accuracy on CORA (Peng and McCallum, 2004). In our experiments, we demonstrate that the specific global constraints used by Chang et al. (2012) help on the UMass dataset as well.

7 Experimental Results

Our baseline is the one used in Anzaroot and McCallum (2013), with some labeling errors removed. This is a chain-structured CRF trained to maximize the conditional likelihood using L-BFGS with L2 regularization.

We use the same features as Anzaroot and McCallum (2013), which include word type, capitalization, binned location in citation, regular expression matches, and matches into lexicons. In addition, we use a rule-based segmenter that segments the citation string based on punctuation as well as probable start or end segment words (e.g. 'in' and 'volume'). We add a binary feature to tokens that correspond to the start of a segment in the output of this simple segmenter. This final feature improves the F1 score on the cleaned test set from 94.0 F1 to 94.44 F1, which we use as a baseline score.

We then use the development set to learn the penalties for the soft constraints, using the perceptron algorithm described in section 3.1. MAP inference in the model with soft constraints is performed using Soft-DD, shown in Algorithm 2.

We instantiate constraints from each template in section 5.1, iterating over all possible labels that contain a *B* prefix at any level in the hierarchy and pruning all constraints with $imp(c) < 2.75$ calculated on the development set. We asses performance in terms of field-level F1 score, which is the harmonic mean of precision and recall for predicted segments.

Table 1 shows how each type of constraint family improved the F1 score on the dataset. Learning all the constraints jointly provides the largest improvement in F1 at 95.39. This improvement in F1 over the baseline CRF as well as the improvement in F1 over using only-one constraints was shown to be statistically significant using the Wilcoxon signed rank test with p-values < 0.05. In the all-constraints settings, 32.96% of the constraints have a learned parameter of 0, and therefore only

Stop	F1 score	Convergence	Avg Iterations
1	94.44	76.29%	1.0
2	95.07	83.38%	1.24
5	95.12	95.91%	1.61
10	95.39	99.18%	1.73

Table 2: Performance from terminating Soft-DD early. Column 1 is the number of iterations we allow each example. Column 3 is the % of test examples that converged. Column 4 is the average number of necessary iterations, a surrogate for the slowdown over performing unconstrained inference.

421 constraints are active. Soft-DD converges, and thus solves the constrained inference problem exactly, for all test set examples after at most 41 iterations. Running Soft-DD to convergence requires 1.83 iterations on average per example. Since performing inference in the CRF is by far the most computationally intensive step in the iterative algorithm, this means our procedure requires approximately twice as much work as running the baseline CRF on the dataset. On examples where unconstrained inference does not satisfy the constraints, Soft-DD converges after 4.52 iterations on average. For 11.99% of the examples, the Soft-DD algorithm satisfies constraints that were not satisfied during unconstrained inference, while in the remaining 11.72% Soft-DD converges with some constraints left unsatisfied, which is possible since we are imposing them as soft constraints.

We could have enforced these constraints as hard constraints rather than soft ones. This experiment is shown in the last row of Table 1, where F1 only improves to 94.6. In addition, running the DD algorithm with these constraints takes 5.21 iterations on average per example, which is 2.8 times slower than Soft-DD with learned penalties.

In Figure 2, we analyze the performance of Soft-DD when we don't necessarily run it to convergence, but stop after a fixed number of iterations on each test set example. We find that a large portion of our gain in accuracy can be obtained when we allow ourselves as few as 2 dual decomposition iterations. However, this only amounts to 1.24 times as much work as running the baseline CRF on the dataset, since the constraints are satisfied immediately for many examples.

In Figure 2 we consider two applications of our Soft-DD algorithm, and provide analysis in the caption.

We train and evaluate on the UMass dataset instead of CORA, because it is significantly larger, has a useful finer-grained labeling schema, and its annotation is more consistent. We were able to obtain better performance on CORA using our baseline CRF than the HMM^{CCM} results presented in Chang et al. (2012), which include soft constraints. Given this high performance of our base model on CORA, we did not apply our Soft-DD algorithm to the dataset. Furthermore, since the dataset is so small, learning the penalties for our large collection of constraints is difficult, and test set results are unreliable. Rather than compare our work to Chang et al. (2012) via results on CORA, we apply their constraints on the UMass data using Soft-DD and demonstrate accuracy gains, as discussed above.

7.1 Examples of learned constraints

We now describe a number of the useful constraints that receive non-zero learned penalties and have high importance scores, defined in Section 5.6. The importance score of a constraint provides information about how often it is violated by the CRF, but holds in the ground truth, and a non-zero penalty implies we enforce it as a soft constraint at test time.

The two singleton constraints with highest importance score are that there should only be at most one title segment in a citation and that there should be at most one author segment in a citation. The only one author constraint is particularly useful for correctly labeling editor segments in cases where unconstrained inference mislabels them as author segments. As can be seen in Table 3, editor fields are among the most improved with our new method, largely due to this constraint.

The two hierarchical constraints with the highest importance scores with non-zero learned penalties constrain the output such that number of person segments does not exceed the number of first segments and vice-versa. Together, these constraints penalize outputs in which the number of person segments do not equal the number of first segments, i.e., every author should have a first name.

One important pairwise constraint penalizes outputs in which thesis segments don't co-occur with school segments. School segments label the name of the university that the thesis was submitted to. The application of this constraint increases the performance of the model on school segments

Label	U	C	+
venue/series	35.29	66.67	31.37
venue/editor/person/first	66.67	94.74	28.07
venue/school	40.00	66.67	26.67
venue/editor/person/last	75.00	94.74	19.74
venue/editor	77.78	90.00	12.22
venue/editor/person/middle	81.82	91.67	9.85

Table 3: Labels with highest improvement in F1. U is in unconstrained inference. C is the results of constrained inference. + is the improvement in F1.

dramatically, as can be seen in table 3.

An interesting form of pairwise constraints penalize outputs in which some labels do not co-occur with other labels. Some examples of constraints in this form enforce that journal segments should co-occur with pages segments and that booktitle segments should co-occur with address segments. An example of the latter constraint being employed during inference is the first example in Figure 2. Here, the constrained inference penalizes output which contains a booktitle segment but no address segment. This penalization leads allows the constrained inference to correctly label the booktitle segment as a title segment.

The above example constraints are almost always satisfied on the ground truth, and would be useful to enforce as hard constraints. However, there are a number of learned constraints that are often violated on the ground truth but are still useful as soft constraints. Take, for example, the constraint that the number of number segments does not exceed the number of booktitle segments, as well as the constraint that it does not exceed the number of journal segments. These constraints are moderately violated on ground truth examples, however. For example, when booktitle segments co-occur with number segments but not with journal segments, the second constraint is violated. It is still useful to impose these soft constraints, as strong evidence from the CRF allows us to violate them, and they can guide the model to good predictions when the CRF is unconfident.

8 Conclusion

We introduce a novel modification to the standard projected subgradient dual decomposition algorithm for performing MAP inference subject to hard constraints to one for performing MAP in the presence of soft constraints. In addition, we offer an easy-to-implement procedure for learning the penalties on soft constraints. This method drives many penalties to zero, which allows users to automatically discover discriminative constraints from large families of candidates.

We show via experiments on a recent substantial dataset that using soft constraints, and selecting which constraints to use with our penalty-learning procedure, can lead to significant gains in accuracy. We achieve a 17% gain in accuracy over a chain-structured CRF model, while only needing to run MAP in the CRF an average of less than 2 times per example. This minor incremental cost over Viterbi, plus the fact that we obtain certificates of optimality on 100% of our test examples in practice, suggests the usefulness of our algorithm for large-scale applications. We encourage further use of our Soft-DD procedure for other structured prediction problems.

A Study of Concept-based Weighting Regularization for Medical Records Search

Yue Wang, Xitong Liu, Hui Fang
Department of Electrical & Computer Engineering,
University of Delaware, USA
{wangyue,xtliu,hfang}@udel.edu

Abstract

An important search task in the biomedical domain is to find medical records of patients who are qualified for a clinical trial. One commonly used approach is to apply NLP tools to map terms from queries and documents to concepts and then compute the relevance scores based on the concept-based representation. However, the mapping results are not perfect, and none of previous work studied how to deal with them in the retrieval process. In this paper, we focus on addressing the limitations caused by the imperfect mapping results and study how to further improve the retrieval performance of the concept-based ranking methods. In particular, we apply axiomatic approaches and propose two weighting regularization methods that adjust the weighting based on the relations among the concepts. Experimental results show that the proposed methods are effective to improve the retrieval performance, and their performances are comparable to other top-performing systems in the TREC Medical Records Track.

1 Introduction

With the increasing use of electronic health records, it becomes urgent to leverage this rich information resource about patients' health conditions to transform research in health and medicine. As an example, when developing a cohort for a clinical trial, researchers need to identify patients matching a set of clinical criteria based on their medical records during their hospital visits (Safran et al., 2007; Friedman et al., 2010). This selection process is clearly a domain-specific retrieval problem, which searches for *relevant medical records* that contain useful information about their corresponding patients' qualification to the criteria specified in a query, e.g., "female patient with breast cancer with mastectomies during admission".

Intuitively, to better solve this domain-specific retrieval problem, we need to understand the requirements specified in a query and identify the documents satisfying these requirements based on their semantic meanings. In the past decades, significant efforts have been put on constructing biomedical knowledge bases (Aronson and Lang, 2010; Lipscomb, 2000; Corporation, 1999) and developing natural language processing (NLP) tools, such as MetaMap, to utilize the information from the knowledge bases (Aronson, 2001; McInnes et al., 2009). These efforts make it possible to map free text to concepts and use these concepts to represent queries and documents.

Indeed, *concept-based representation* is one of the commonly used approaches that leverage knowledge bases to improve the retrieval performance (Limsopatham et al., 2013d; Limsopatham et al., 2013b). The basic idea is to represent both queries and documents as "bags of concepts", where the concepts are identified based on the information from the knowledge bases. This method has been shown to be more effective than traditional term-based representation in the medical record retrieval because of its ability to handle the ambiguity in the medical terminology. However, this method also suffers the limitation that its effectiveness depends on the accuracy of the concept mapping results. As a result, directly applying existing weighting strategies might lead to non-optimal retrieval performance.

In this paper, to address the limitation caused by the inaccurate concept mapping results, we propose to regularize the weighting strategies in the concept-based representation methods. Specifically, by applying the axiomatic approaches (Fang and Zhai, 2005), we analyze the retrieval func-

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 603–612,
Baltimore, Maryland, USA, June 23-25 2014.

tions with concept-based representation and find that they may violate some reasonable retrieval constraints. We then propose two concept-based weighting regularization methods so that the regularized retrieval functions would satisfy the retrieval constraints and achieve better retrieval performance. Experimental results over two TREC collections show that both proposed concept-based weighting regularization methods can improve the retrieval performance, and their performance is comparable with the best systems of the TREC Medical Records tracks (Voorhees and Tong, 2011; Voorhees and Hersh, 2012).

Many NLP techniques have been developed to understand the semantic meaning of textual information, and are often applied to improve the search accuracy. However, due to the inherent ambiguity of natural languages, the results of NLP tools are not perfect. One of our contributions is to present a general methodology that can be used to adjust existing IR techniques based on the inaccurate NLP results.

2 Related Work

The Medical Records track of the Text REtrieval Conference (TREC) provides a common platform to study the medical records retrieval problem and evaluate the proposed methods (Voorhees and Tong, 2011; Voorhees and Hersh, 2012).

Concept-based representation has been studied for the medical record retrieval problem (Limsopatham et al., 2013d; Limsopatham et al., 2013b; Limsopatham et al., 2013a; Qi and Laquerre, 2012; Koopman et al., 2011; Koopman et al., 2012). For example, Qi and Laquerre used MetaMap to generate the concept-based representation and then apply a vector space retrieval model for ranking, and their results are one of the top ranked runs in the TREC 2012 Medical Records track (Qi and Laquerre, 2012). To further improve the performance, Limsopatham et al. proposed a task-specific representation, i.e., using only four types of concepts (symptom, diagnostic test, diagnosis and treatment) in the concept-based representation and a query expansion method based on the relationships among the medical concepts (Limsopatham et al., 2013d; Limsopatham et al., 2013a). Moreover, they also proposed a learning approach to combine both term-based and concept-based representation to further improve the performance (Limsopatham et al., 2013b).

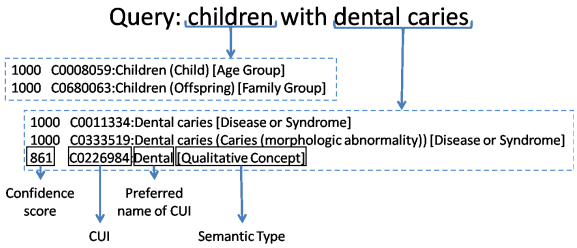

Figure 1: Example of MetaMap result for a query.

Our work is also related to domain-specific IR (Yan et al., 2011; Lin and Demner-Fushman, 2006; Zhou et al., 2007). For example, Yan et al. proposed a granularity-based document ranking model that utilizes ontologies to identify document concepts. However, none of the previous work has studied how to regularize the weight of concepts based on their relations.

It is well known that the effectiveness of a retrieval function is closely related to the weighting strategies (Fang and Zhai, 2005; Singhal et al., 1996). Various term weighting strategies have been proposed and studied for the term-based representation (Amati and Van Rijsbergen, 2002; Singhal et al., 1996; Robertson et al., 1996). However, existing studies on concept-based representation still used weighting strategies developed for term-based representation such as vector space models (Qi and Laquerre, 2012) and divergence from randomness (DFR) (Limsopatham et al., 2013a) and did not take the inaccurate concept mapping results into consideration. Compared with previous work, we focus on addressing the limitation caused by the inaccurate concept mapping. Note that our efforts are orthogonal to existing work, and it is expected to bring additional improvement to the retrieval performance.

3 Concept-based Representation for Medical Records Retrieval

3.1 Problem Formulation

We follow the problem setup used in the TREC medical record track (Voorhees and Tong, 2011; Voorhees and Hersh, 2012). The task is to retrieve relevant patient visits with respect to a query. Since each visit can be associated with multiple medical records, the relevance of a visit is related to the relevance of individual associated medical records. Existing studies computed the relevance

scores at either visit-level, where all the medical records of a visit are merged into a visit document (Demner-Fushman et al., 2012; Limsopatham et al., 2013c), or record-level, where we can first compute the relevance score of individual records and then aggregate their scores as the relevance score of a visit (Limsopatham et al., 2013c; Zhu and Carterette, 2012; Limsopatham et al., 2013d). In this paper, we focus on the visit-level relevance because of its simplicity. In particular, given a patient's visit, all the medical records generated from this visit are merged as a document. Note that our proposed concept-weighting strategies can also be easily applied to record-level relevance modeling.

Since the goal is to retrieve medical records of patients that satisfying requirements specified in a query, the relevance of medical records should be modeled based on how well they match all the requirements (i.e., aspects) specified in the queries.

3.2 Background: UMLS and MetaMap

Unified Medical Language System (UMLS) is a metathesaurus containing information from more than 100 controlled medical terminologies such as the Systematized Nomenclature of Medicine Clinical Terms (SNOMED-CT) and Medical Subject Headings (MeSH). Specifically, it contains the information about over 2.8 million biomedical concepts. Each concept is labeled with a Concept Unique Identifier (CUI) and has a preferred name and a semantic type.

Moreover, NLP tools for utilizing the information from UMLS have been developed. In particular, MetaMap (Aronson, 2001) can take a text string as the input, segment it into phrases, and then map each phrase to *multiple* UMLS CUIs with confidence scores. The confidence score is an indicator of the quality of the phrase-to-concept mapping by MetaMap. It is computed by four metrics: centrality, variation, coverage and cohesiveness (Aronson, 2001). These four measures try to evaluate the mapping from different angles, such as the involvement of the central part, the distance of the concept to the original phrase, and how well the concept matches the phrase. The maximum confidence in MetaMap is 1000.

Figure 1 shows the MetaMap results for an example query "children with dental caries". Two *query aspects*, i.e., "children" and "dental caries", are identified. Each of them is mapped to multiple concepts, and each concept is associated with the confidence score as well as more detailed information about this concept.

3.3 Concept-based Representation

Traditional retrieval models are based on "bag of terms" representation. One limitation of this representation is that relevance scores are computed based on the matching of terms rather than the meanings. As a result, the system may fail to retrieve the relevant documents that do not contain any query terms.

To overcome this limitation, concept-based representation has been proposed to bridge the vocabulary gap between documents and queries (Qi and Laquerre, 2012; Limsopatham et al., 2013b; Koopman et al., 2012). In particular, MetaMap is used to map terms from queries and documents (e.g., medical records) to the semantic concepts from biomedical knowledge bases such as UMLS. Within the concept-based representation, the query can then be represented as a bag of all the generated CUIs in the MetaMap results. For example, the query from Figure 1 can be represented as $\{C0008059, C0680063, C0011334, C0333519, C0226984\}$. Documents can be represented in a similar way.

After converting both queries and documents to concept-based representations using MetaMap, previous work applied existing retrieval functions such as vector space models (Singhal et al., 1996) to rank the documents. Note that when referring to existing retrieval functions in the paper, they include traditional keyword matching based functions such as pivoted normalization (Singhal et al., 1996), Okapi (Robertson et al., 1996), Dirichlet prior (Zhai and Lafferty, 2001) and basic axiomatic functions (Fang and Zhai, 2005).

4 Weighting Strategies for Concept-based Representation

4.1 Motivation

Although existing retrieval functions can be directly applied to concept-based representation, they may lead to non-optimal performance. This is mainly caused by the fact that MetaMap may generate more than one mapped concepts for an aspect, i.e., a semantic unit in the text.

Ideally, an aspect will be mapped to only *one* concept, and different concepts would represent different semantic meanings. Under such a situ-

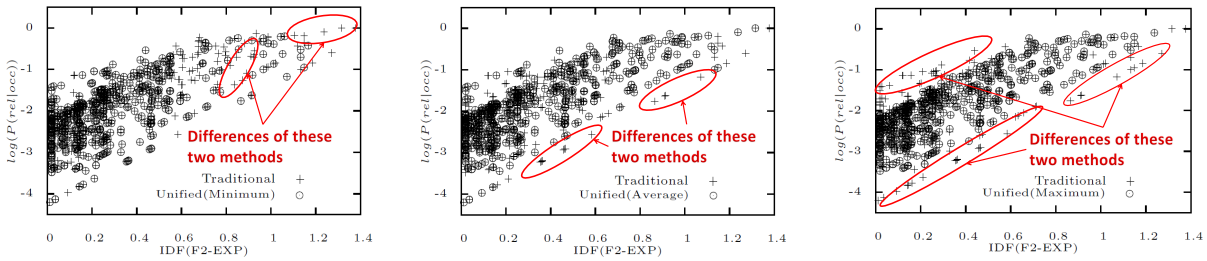

Figure 2: Exploratory data analysis (From left to right are choosing minimum, average and maximum IDF concepts as the representing concepts, respectively. The removed concepts are highlighted in the figures.).

ation, traditional retrieval functions would likely work well and generate satisfying retrieval performance since the relations among concepts are independent which is consistent with the assumptions made in traditional IR (Manning et al., 2008).

However, the mapping results generated by MetaMap are not perfect. Although MetaMap is able to rank all the candidate concepts with the confidence score and pick the most likely one, the accuracy is not very high. In particular, our preliminary results show that turning on the disambiguation functionality provided by MetaMap (i.e., returning only the most likely concept for each query) could lead to worse retrieval performance than using all the candidate mappings. Thus, we use the one-to-many mapping results generated by MetaMap, in which each aspect can be mapped to multiple concepts.

Unfortunately, such one-to-many concept mappings could hinder the retrieval performance in the following two ways.

- The multiple concepts generated from the same aspect are related, which is inconsistent with the independence assumption made in the existing retrieval functions (Manning et al., 2008). For example, as shown in Figure 1, "dental caries" is mapped to three concepts. It is clear that the concepts are related, but existing retrieval functions are unable to capture their relations and would compute the weight of each concept independently.

- The one-to-many mapping results generated by MetaMap could arbitrarily inflate the weights of some query aspects. For example, as shown in Figure 1, query aspect "children" is mapped to 2 concepts while "dental caries" is mapped to 3 concepts. In the existing retrieval functions, term occurrences are important relevance signals. However, when converting the text to concepts representation using MetaMap, the occurrences of the concepts are determined by not only the original term occurrences, a good indicator of relevance, but also the number of mapped concepts, which is determined by MetaMap and has nothing to do with the relevance status. As a result, the occurrences of concepts might not be a very accurate indicator of importance of the corresponding query aspect.

To address the limitations caused by the inaccurate mapping results, we propose to apply axiomatic approaches (Fang and Zhai, 2005) to regularize the weighting strategies for concept-based representation methods. In particular, we first formalize retrieval constraints that any reasonable concept-based representation methods should satisfy and then discuss how to regularize the existing weighting strategies to satisfy the constraints and improve the retrieval performance.

We first explain the notations used in this section. Q and D denote a query and a document with the concept-based representation. $S(Q, D)$ is the relevance score of D with respect to Q. e_i denotes a concept, and $\mathcal{A}(e)$ denotes the query aspect associated with e, i.e., a set of concepts that are mapped to the same phrases as e by using MetaMap. $i(e)$ is the normalized confidence score of the mapping for concept e generated by MetaMap. $c(e, D)$ denotes the occurrences of concept e in document D, $df(e)$ denotes the number of documents containing e. $|D|$ is the document length of D. $Imp_c(e)$ is the importance of the concept such as the concept IDF value, and $Imp_A(\mathcal{A})$ is the importance of the aspect.

4.2 Unified concept weighting regularization

We now discuss how to address the first challenge, i.e,. how to regularize the weighting strategy so that we can take into consideration the fact that concepts associated with the same query aspect are not independent. We call a concept is a *variant* of another one if both of them are associated with the same aspect.

Intuitively, given a query with two aspects, a document covering both aspects should be ranked higher than those covering only one aspect. We can formalize the intuition in the concept-based representation as the following constraint.

Unified Constraint: Let query be $Q = \{e_1, e_2, e_3\}$, and we know that e_2 is a variant of e_3. Assume we have two documents D_1 and D_2 with the same document length, i.e., $|D_1| = |D_2|$. If we know that $c(e_1, D_1) = c(e_3, D_2) > 0$, $c(e_1, D_2) = c(e_3, D_1) = 0$ and $c(e_2, D_1) = c(e_2, D_2) > 0$, then $S(Q, D_1) > S(Q, D_2)$.

It is clear that existing retrieval functions would violate this constraint since they ignore the relations among concepts.

One simple strategy to fix this problem is to merge all the concept variants as a single concept and select one representative concept to replace all occurrences of other variants in both queries and documents. By merging the concepts together, we are aiming to purify the concepts and make the similar concepts centralized so that the assumption that all the concepts are independent would hold.

Formally, the adjusted occurrences of a concept e in a document D is shown as follows:

$$c_{mod}(e, D) = \begin{cases} \sum_{e' \in EC(e)} c(e', D) & e = Rep(EC(e)) \\ 0 & e \neq Rep(EC(e)) \end{cases} \quad (1)$$

where $c(e, D)$ is the original occurrence of concept e in document D, $EC(e)$ denotes a set of all the variants of e including itself (i.e., all the concepts with the same preferred name as e), and $Rep(EC(e))$ denotes the representative concept from $EC(e)$.

It is trivial to prove that, with such changes, existing retrieval functions would satisfy the above constraint since the constraint implies TFC2 constraint defined in the previous study (Fang et al., 2004).

Now the remaining question is how to select the representative concept from all the variants. There are three options: select the concept with the maximum IDF, average IDF, or minimum IDF. We conduct exploratory data analysis on these three options. In particular, for each option, we generate a plot indicating the correlation between the IDF value of a concept and the relevance probability of the concept (i.e., the probability that a document containing the concept is relevant). Note that both original and replaced IDF values are shown in the plot for each option. Figure 2 shows the results. It is clear that the right plot (i.e., selecting the concept with the maximum IDF as the representative concept) is the best choice since the changes make the points less scattered. In fact, this can also be confirmed by experimental results as reported in Table 5. Thus, we use the concept with the maximum IDF value as the representative concept of all the variants.

4.3 Balanced concept weighting regularization

We now discuss how to address the second challenge, i.e., how to regularize the weighting strategy to deal with the arbitrarily inflated statistics caused by the one-to-many mappings.

The arbitrary inflation could impact the importance of the query aspects. For example, as shown in Figure 1, one aspect is mapped to two concepts while the other is mapped to three. Moreover, it could also impact the accuracy of the concept IDF values. Consider "colonoscopies" and "adult", it is clear that the first term is more important than the second one, which is consistent with their term IDF values, i.e., 7.52 and 2.92, respectively. However, with the concept-based representation, the IDF value of the concept "colonoscopies"(C0009378) is 2.72, which is even smaller than that of concept "adult" (C1706450), i.e., 2.92.

To fix the negative impact on query aspects, we could leverage the findings in the previous study (Zheng and Fang, 2010) and regularize the weighting strategy based on the length of query aspects to favor documents covering more query aspects. Since each concept mapping is associated with a confidence score, we can incorporate them into the regularization function as follows:

$$f(e, Q) = (1 - \alpha) + \alpha \cdot \Big(\frac{\sum_{e' \in Q} i(e')}{\sum_{e'' \in \mathcal{A}(e)} i(e'')} \Big), \quad (2)$$

where $i(e)$ is the normalized confidence score of concept e generated by MetaMap, and α is a parameter between 0 and 1 to control the effect of the regularization. When α is set to 0, there is no regularization. This regularization function aims to

penalize the weight of concept e based on its variants as well as the concepts from other aspects. In particular, a concept would receive more penalty (i.e., its weight will be decreased more) when it has more variants and the mappings of these variants are more accurate.

To fix the negative impact on the concept IDF values, we propose to regularize the weighting based on the importance of the query aspect. This regularization can be formalized as the following constraint.

Balanced Constraint: Let Q be a query with two concepts and the concepts are associated with different aspects, i.e., $Q = \{e_1, e_2\}$, and $\mathcal{A}(e_1) \neq \mathcal{A}(e_2)$. Assume D_1 and D_2 are two documents with the same length, i.e., $|D_1| = |D_2|$, and they cover different concepts with the same occurrences, i.e., $c(e_1, D_1) = c(e_2, D_2) > 0$ and $c(e_2, D_1) = c(e_1, D_2) = 0$. If we know $Imp_c(e_1) = Imp_c(e_2)$ and $Imp_A(\mathcal{A}(e_1)) < Imp_A(\mathcal{A}(e_2))$, then we have $S(Q, D_1) < S(Q, D_2)$.

This constraint requires that the relevance score of a document should be affected by not only the importance of the concepts but also the importance of the associated query aspect. In a way, the constraint aims to counteract the arbitrary statistics inflation caused by MetaMap results and balance the weight among concepts based on the importance of the associated query aspects. And it is not difficult to show that existing retrieval functions violate this constraint.

Now the question is how to revise the retrieval functions to make them satisfy this constraint. We propose to incorporate the importance of query aspect into the previous regularization function in Equation (2) as follows:

$$f(e, Q) = (1-\alpha) + \alpha \cdot \left(\frac{\sum_{e' \in Q} i(e')}{\sum_{e'' \in \mathcal{A}(e)} i(e'')} \right) \cdot Imp_A(\mathcal{A}(e)). \quad (3)$$

Note that $Imp_A(\mathcal{A}(e))$ is the importance of a query aspect and can be estimated based on the terms from the query aspect. In this paper, we use the maximum term IDF value from the aspect to estimate the importance, which performs better than using minimum and average IDF values as shown in the experiments (i.e., Table 6). We plan to study other options in the future work.

4.4 Discussions

Both proposed regularization methods can be combined with any existing retrieval functions. In this paper, we focus on one of the state of the art weighting strategies, i.e., F2-EXP function derived from axiomatic retrieval model (Fang and Zhai, 2005), and explain how to incorporate the regularization methods into the function.

The original F2-EXP retrieval function is shown as follows:

$$S(Q, D) = \sum_{e \in Q \cap D} c(e, Q) \cdot (\frac{N}{df(e)})^{0.35} \cdot \frac{c(e, D)}{c(e, D) + b + \frac{b \times |D|}{avdl}} \quad (4)$$

where b is a parameter control the weight of the document length normalization.

With the unified concept weighting regularization, the revised function based on F2-EXP function, i.e., *Unified*, is shown as follows:

$$S(Q, D) = \sum_{e \in Q \cap D} c_{mod}(e, Q) \cdot (\frac{N}{df(t)})^{0.35} \cdot \frac{c_{mod}(e, D)}{c_{mod}(e, D) + b + \frac{b \times |D|}{avdl}} \quad (5)$$

where $c_{mod}(e, D)$ and $c_{mod}(e, Q)$ denote the modified occurrences as shown in Equation (1). It can be shown that this function satisfies the unified constraint but violates the balanced constraint.

Following the similar strategy used in the previous study (Zheng and Fang, 2010), we can further incorporate the regularization function proposed in Equation (3) to the above function to make it satisfy the balanced constraint as follows:

$$S(Q, D) = \sum_{e \in Q \cap D} c_{mod}(e, Q) \cdot (\frac{N}{df(t)})^{0.35} \cdot f(e, Q) \cdot \frac{c_{mod}(e, D)}{c_{mod}(e, D) + b + \frac{b \times |D|}{avdl}} \quad (6)$$

where $f(e, Q)$ is the newly proposed regularization function as shown in Equation (3). This method is denoted as *Balanced*, and can be shown that it satisfies both constraints.

Table 1: Statistics of collections.

Concept	58,192	2,673	8.79	7.81

5 Experiments

5.1 Experiment Setup

We conduct experiments using two data sets from the TREC Medical Records track 2011 and 2012.

Table 2: Description of Methods

Name	Representation	Ranking strategies
Term-BL	Term	F2-EXP (i.e., Equation (4))
Concept-BL	Concept (i.e., Section 3.3)	F2-EXP (i.e., Equation (4))
TSConcept-BL	Task specific concept ((Limsopatham et al., 2013d))	F2-EXP (i.e., Equation (4))
Unified	Concept (i.e., Section 4.2)	F2-EXP + Unified (i.e., Equation (5))
Balanced	Concept (i.e., Section 4.3)	F2-EXP + Balanced (i.e., Equation (6))

Table 3: Performance under optimized parameter settings

	Med11		**Med12**	
	MAP	bpref	infNDCG	infAP
Term-BL	0.3474	0.4727	0.4695	0.2106
Concept-BL	0.3967	0.5476	0.5243	0.2497
TSConcept-BL	0.3964	0.5329	0.5283	0.2694
Unified	0.4235^{T}	0.5443^{T}	0.5416^{T}	0.2586^{T}
Balanced	$\mathbf{0.4561}^{T,C,TS}$	$\mathbf{0.5697}^{T,C,TS}$	$\mathbf{0.5767}^{T,C,TS}$	$\mathbf{0.2859}^{T,C,TS}$

The data sets are denoted as *Med11* and *Med12*. Both data sets used the same document collection with 100,866 medical records, each of which is associated with a unique patient visit to the hospital or emergency department. Since the task is to retrieve relevant visits, we merged all the records from a visit to form a single document for the visit, which leads to 17,198 documents in the collection. There are 34 queries in *Med11* and 47 in *Med12*. These queries were developed by domain experts based on the "inclusion criteria" of a clinical study (Voorhees and Tong, 2011; Voorhees and Hersh, 2012).

After applying MetaMap to both documents and queries, we can construct a concept-based collection. Since documents are often much longer, we can first segment them into sentences, get the mapping results for each sentence, and then merge them together to generate the concept-based representation for the documents.

Table 1 compares the statistics of the term-based and the concept-based collections, including the number of unique tokens in the collection (i.e., the number of terms for term-based representation and the number of concepts for concept-based representation), the average number of tokens in the documents (AvgDL) and the average number of tokens in the queries for these two collections (AvgQL11 and AvgQL12). It is interesting to see that the number of unique tokens is much smaller when using the concept-based indexing. This is expected since terms are semantically related and a group of related terms would be mapped to one semantic concept. Moreover, we observe that the document length and query length are similar for both collections. This is caused by the fact that concepts are related and the MetaMap would map an aspect to multiple related concepts.

Table 2 summarizes the methods that we compare in the experiments. Following the evaluation methodology used in the medical record track, we use MAP@1000 as the primary measure for *Med11* and also report bpref. For *Med12*, we take infNDCG@100 as the primary measure and also report infAP@100. Different measures were chosen for these two sets mainly because different pooling strategies were used to create the judgment pools (Voorhees and Hersh, 2012).

5.2 Performance Comparison

Table 3 shows the performance under optimized parameter settings for all the methods over both data sets. The performance is optimized in terms of MAP in *Med11*, and infNDCG in *Med12*, respectively. α and b are tuned from 0 to 1 with the step 0.1. Note that ^{T}, ^{C} and ^{TS} indicate improvement over Term-BL, Concept-BL and TSConcept-BL is statistically significant at 0.05 level based on Wilcoxon signed-rank test, respectively.

Results show that *Balanced* method can significantly improve the retrieval performance over both collections. *Unified* method outperforms the baseline methods in terms of the primary measure on both collections, although it fails to improve the infAP on *Med12* for one baseline method. It is not surprising to see that *Balanced* method is more effective than *Unified* since the former satisfies both of the proposed retrieval constraints while the lat-

Table 4: Testing Performance

Trained on	**Med12**		**Med11**	
Tested on	**Med11**		**Med12**	
Measures	MAP	bpref	infNDCG	infAP
Term-BL	0.3451	0.4682	0.4640	0.2040
Concept-BL	0.3895	0.5394	0.5194	0.2441
TSConcept-BL	0.3901	0.5286	0.5208	0.2662
Unified	$0.4176^{T,C}$	0.5391^{T}	0.5346^{T}	0.2514^{T}
Balanced	$\mathbf{0.4497}^{T,C,TS}$	$\mathbf{0.5627}^{T,C,TS}$	$\mathbf{0.5736}^{T,C,TS}$	$\mathbf{0.2811}^{T,C,TS}$

ter satisfies only one. Finally, we noticed that the performance difference between TSConcept-BL and Concept-BL is not as significant as the ones reported in the previous study (Limsopatham et al., 2013d), which is probably caused by the difference of problem set up (i.e., record-level vs. visit-level as discussed in Section 3.1).

We also conduct experiments to train parameters on one collection and compare the testing performance on the other collection. The results are summarized in Table 4. Clearly, *Balanced* is still the most effective regularization method. The testing performance is very close to the optimal performance, which indicates that the proposed methods are robust with respect to the parameter setting.

Moreover, we would like to point out that the testing performance of *Balanced* is comparable to the top ranked runs from the TREC Medical records track. For example, the performance of the best automatic system in *Med11* (e.g., CengageM11R3) is 0.552 in terms of bpref, while the performance of the best automatic system in *Med12* (e.g., udelSUM) is 0.578 in terms of infNDCG. Note that the top system of *Med12* used multiple external resources such as Wikipedia and Web, while we did not use such resources. Moreover, our performance might be further improved if we apply the result filtering methods used by many TREC participants (Leveling et al., 2012).

Table 5: Selecting representative concepts

	MAP	**bpref**
Unified (i.e., Unified-max)	**0.4235**	**0.5443**
Unified-min	0.3894	0.5202
Unified-avg	0.4164	0.5303

5.3 More Analysis

In the *Unified* method, we chose the concept with the maximum IDF as the representative concept among all the variants. We now conduct experiments on *Med11* to compare its performance with those of using average IDF and minimum IDF ones as the representative concept. The results are shown in Table 5. It is clear that using maximum IDF is the best choice, which is consistent with our observation from the data exploratory analysis shown in Figure 2.

Table 6: Estimating query aspect importance

	MAP	**bpref**
Balanced (i.e., Balanced-max)	**0.4561**	**0.5697**
Balanced-min	0.4216	0.5484
Balanced-avg	0.4397	0.5581

Table 7: Regularization components in *Balanced*

	MAP	**bpref**
Balanced	**0.4561**	**0.5697**
Confidence only	0.4294	0.5507
Importance only	0.4373	0.5598

In the *Balanced* method, we used the maximum IDF value to estimate the query importance. We also conduct experiments to compare its performance with those using the minimum and average IDF values. Table 6 summarizes the results, and shows that using the maximum IDF value performs better than the other choices.

As shown in Equation (3), the *Balanced* method regularizes the weights through two components: (1) normalized confidence score of each aspect, i.e., $\frac{\sum_{e' \in Q} i(e')}{\sum_{e'' \in \mathcal{A}(e)} i(e'')}$; and (2) the importance of the query aspect, i.e., $Imp_A(\mathcal{A}(e))$. To examine the effectiveness of each component, we conduct experiments using the modified *Balanced* method with only one of the components. The results are shown in Table 7. It is clear that both components are essential to improve the retrieval performance.

Finally, we report the performance improvement of the proposed methods over the *Concept-BL* for each query in Figure 3. Clearly, both of the

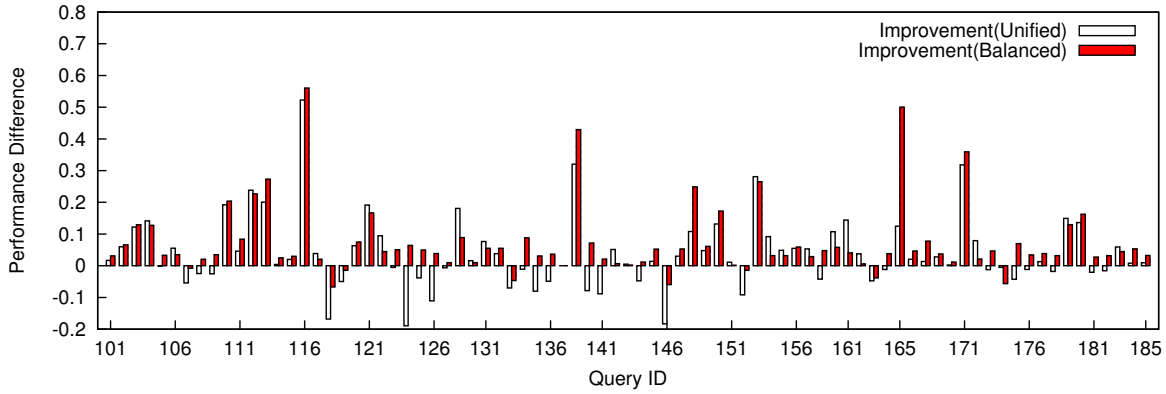

Figure 3: Improvement of proposed methods (Compared with the Concept-BL method).

proposed methods can improve the effectiveness of most queries, and the *Balanced* method is more robust than the *Unified* method.

6 Conclusions and Future Work

Medical record retrieval is an important domain-specific IR problem. Concept-based representation is an effective approach to dealing with ambiguity terminology in medical domain. However, the results of the NLP tools used to generate the concept-based representation are often not perfect. In this paper, we present a general methodology that can use axiomatic approaches as guidance to regularize the concept weighting strategies to address the limitations caused by the inaccurate concept mapping and improve the retrieval performance. In particular, we proposed two weighting regularization methods based on the relations among concepts. Experimental results show that the proposed methods can significantly outperform existing retrieval functions.

There are many interesting directions for our future work. First, we plan to study how to automatically predict whether to use concept-based indexing based on the quality of MetaMap results, and explore whether the proposed methods are applicable for other entity linking methods. Second, we will study how to leverage other information from knowledge bases to further improve the performance. Third, more experiments could be conducted to examine the effectiveness of the proposed methods when using other ranking strategies. Finally, it would be interesting to study how to follow the proposed methodology to study other domain-specific IR problems.

Abstract

Although the distributional hypothesis has been applied successfully in many natural language processing tasks, systems using distributional information have been limited to a single domain because the distribution of a word can vary between domains as the word's predominant meaning changes. However, if it were possible to *predict* how the distribution of a word changes from one domain to another, the predictions could be used to adapt a system trained in one domain to work in another. We propose an unsupervised method to predict the distribution of a word in one domain, given its distribution in another domain. We evaluate our method on two tasks: cross-domain part-of-speech tagging and cross-domain sentiment classification. In both tasks, our method significantly outperforms competitive baselines and returns results that are statistically comparable to current state-of-the-art methods, while requiring no task-specific customisations.

1 Introduction

The Distributional Hypothesis, summarised by the memorable line of Firth (1957) – *You shall know a word by the company it keeps* – has inspired a diverse range of research in natural language processing. In such work, a word is represented by the distribution of other words that co-occur with it. Distributional representations of words have been successfully used in many language processing tasks such as entity set expansion (Pantel et al., 2009), part-of-speech (POS) tagging and chunking (Huang and Yates, 2009), ontology learning (Curran, 2005), computing semantic textual similarity (Besançon et al., 1999), and lexical inference (Kotlerman et al., 2012).

However, the distribution of a word often varies from one domain[1] to another. For example, in the domain of portable computer reviews the word *lightweight* is often associated with positive sentiment bearing words such as *sleek* or *compact*, whereas in the movie review domain the same word is often associated with negative sentiment-bearing words such as *superficial* or *formulaic*. Consequently, the distributional representations of the word *lightweight* will differ considerably between the two domains. In this paper, given the distribution $\boldsymbol{w}_{\mathcal{S}}$ of a word w in the source domain $\mathcal{S}$, we propose an unsupervised method for *predicting* its distribution $\boldsymbol{w}_{\mathcal{T}}$ in a different target domain $\mathcal{T}$.

The ability to predict how the distribution of a word varies from one domain to another is vital for numerous adaptation tasks. For example, unsupervised cross-domain sentiment classification (Blitzer et al., 2007; Aue and Gamon, 2005) involves using sentiment-labeled user reviews from the source domain, and unlabeled reviews from both the source and the target domains to learn a sentiment classifier for the target domain. Domain adaptation (DA) of sentiment classification becomes extremely challenging when the distributions of words in the source and the target domains are very different, because the features learnt from the source domain labeled reviews might not appear in the target domain reviews that must be classified. By predicting the distribution of a word across different domains, we can find source domain features that are similar to the features in target domain reviews, thereby reducing the mismatch of features between the two domains.

We propose a two-step unsupervised approach to predict the distribution of a word across domains. First, we create two lower dimensional la-

[1] In this paper, we use the term *domain* to refer to a collection of documents about a particular topic, for example reviews of a particular kind of product.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 613–623,
Baltimore, Maryland, USA, June 23-25 2014.

tent feature spaces separately for the source and the target domains using Singular Value Decomposition (SVD). Second, we learn a mapping from the source domain latent feature space to the target domain latent feature space using Partial Least Square Regression (PLSR). The SVD smoothing in the first step both reduces the data sparseness in distributional representations of individual words, as well as the dimensionality of the feature space, thereby enabling us to efficiently and accurately learn a prediction model using PLSR in the second step. Our proposed cross-domain word distribution prediction method is unsupervised in the sense that it does not require any labeled data in either of the two steps.

Using two popular multi-domain datasets, we evaluate the proposed method in two prediction tasks: (a) predicting the POS of a word in a target domain, and (b) predicting the sentiment of a review in a target domain. Without requiring any task specific customisations, systems based on our distribution prediction method significantly outperform competitive baselines in both tasks. Because our proposed distribution prediction method is unsupervised and task independent, it is potentially useful for a wide range of DA tasks such entity extraction (Guo et al., 2009) or dependency parsing (McClosky et al., 2010). Our contributions are summarised as follows:

- Given the distribution $\boldsymbol{w}_{\mathcal{S}}$ of a word w in a source domain $\mathcal{S}$, we propose a method for learning its distribution $\boldsymbol{w}_{\mathcal{T}}$ in a target domain $\mathcal{T}$.
- Using the learnt distribution prediction model, we propose a method to learn a cross-domain POS tagger.
- Using the learnt distribution prediction model, we propose a method to learn a cross-domain sentiment classifier.

To our knowledge, ours is the first successful attempt to learn a model that predicts the distribution of a word across different domains.

2 Related Work

Learning semantic representations for words using documents from a single domain has received much attention lately (Vincent et al., 2010; Socher et al., 2013; Baroni and Lenci, 2010). As we have already discussed, the semantics of a word varies across different domains, and such variations are not captured by models that only learn a single semantic representation for a word using documents from a single domain.

The POS of a word is influenced both by its context (*contextual bias*), and the domain of the document in which it appears (*lexical bias*). For example, the word *signal* is predominately used as a noun in MEDLINE, whereas it appears predominantly as an adjective in the Wall Street Journal (WSJ) (Blitzer et al., 2006). Consequently, a tagger trained on WSJ would incorrectly tag *signal* in MEDLINE. Blitzer et al. (2006) append the source domain labeled data with predicted pivots (i.e. words that appear in both the source and target domains) to adapt a POS tagger to a target domain. Choi and Palmer (2012) propose a cross-domain POS tagging method by training two separate models: a generalised model and a domain-specific model. At tagging time, a sentence is tagged by the model that is most similar to that sentence. Huang and Yates (2009) train a Conditional Random Field (CRF) tagger with features retrieved from a smoothing model trained using both source and target domain unlabeled data. Adding latent states to the smoothing model further improves the POS tagging accuracy (Huang and Yates, 2012). Schnabel and Schütze (2013) propose a training set filtering method where they eliminate shorter words from the training data based on the intuition that longer words are more likely to be examples of productive linguistic processes than shorter words.

The sentiment of a word can vary from one domain to another. In Structural Correspondence Learning (SCL) (Blitzer et al., 2006; Blitzer et al., 2007), a set of pivots are chosen using pointwise mutual information. Linear predictors are then learnt to predict the occurrence of those pivots, and SVD is used to construct a lower dimensional representation in which a binary classifier is trained. Spectral Feature Alignment (SFA) (Pan et al., 2010) also uses pivots to compute an alignment between domain specific and domain independent features. Spectral clustering is performed on a bipartite graph representing domain specific and domain independent features to find a lower-dimensional projection between the two sets of features. The cross-domain sentiment-sensitive thesaurus (SST) (Bollegala et al., 2011) groups together words that express similar sentiments in

different domains. The created thesaurus is used to expand feature vectors during train and test stages in a binary classifier. However, unlike our method, SCL, SFA, or SST do *not* learn a prediction model between word distributions across domains.

Prior knowledge of the sentiment of words, such as sentiment lexicons, has been incorporated into cross-domain sentiment classification. He et al. (2011) propose a joint sentiment-topic model that imposes a sentiment-prior depending on the occurrence of a word in a sentiment lexicon. Ponomareva and Thelwall (2012) represent source and target domain reviews as nodes in a graph and apply a label propagation algorithm to predict the sentiment labels for target domain reviews from the sentiment labels in source domain reviews. A sentiment lexicon is used to create features for a document. Although incorporation of prior sentiment knowledge is a promising technique to improve accuracy in cross-domain sentiment classification, it is complementary to our task of distribution prediction across domains.

The *unsupervised* DA setting that we consider does not assume the availability of labeled data for the target domain. However, if a small amount of labeled data is available for the target domain, it can be used to further improve the performance of DA tasks (Xiao et al., 2013; Daumé III, 2007).

3 Distribution Prediction

3.1 In-domain Feature Vector Construction

Before we tackle the problem of learning a model to predict the distribution of a word across domains, we must first compute the distribution of a word from a single domain. For this purpose, we represent a word w using unigrams and bigrams that co-occur with w in a sentence as follows.

Given a document H, such as a user-review of a product, we split H into sentences, and lemmatize each word in a sentence using the RASP system (Briscoe et al., 2006). Using a standard stop word list, we filter out frequent non-content unigrams and select the remainder as unigram features to represent a sentence. Next, we generate bigrams of word lemmas and remove any bigrams that consists only of stop words. Bigram features capture negations more accurately than unigrams, and have been found to be useful for sentiment classification tasks. Table 1 shows the unigram and bigram features we extract for a sentence using this procedure. Using data from a single domain, we construct a feature co-occurrence matrix $\mathbf{A}$ in which columns correspond to unigram features and rows correspond to either unigram or bigram features. The value of the element a_{ij} in the co-occurrence matrix $\mathbf{A}$ is set to the number of sentences in which the i-th and j-th features co-occur.

sentence	This is an interesting and well researched book
unigrams (surface)	this, is, an, interesting, and, well, researched, book
unigrams (lemma)	this, be, an, interest, and, well, research, book
unigrams (features)	interest, well, research, book
bigrams (lemma)	this+be, be+an, an+interest, interest+and, and+well, well+research, research+book
bigrams (features)	an+interest, interest+and, and+well, well+research, research+book

Table 1: Extracting unigram and bigram features.

Typically, the number of unique bigrams is much larger than that of unigrams. Moreover, co-occurrences of bigrams are rare compared to co-occurrences of unigrams, and co-occurrences involving a unigram and a bigram. Consequently, in matrix $\mathbf{A}$, we consider co-occurrences only between unigrams vs. unigrams, and bigrams vs. unigrams. We consider each row in $\mathbf{A}$ as representing the distribution of a feature (i.e. unigrams or bigrams) in a particular domain over the unigram features extracted from that domain (represented by the columns of $\mathbf{A}$). We apply Positive Pointwise Mutual Information (PPMI) to the co-occurrence matrix $\mathbf{A}$. This is a variation of the Pointwise Mutual Information (PMI) (Church and Hanks, 1990), in which all PMI values that are less than zero are replaced with zero (Lin, 1998; Bullinaria and Levy, 2007). Let $\mathbf{F}$ be the matrix that results when PPMI is applied to $\mathbf{A}$. Matrix $\mathbf{F}$ has the same number of rows, n_r, and columns, n_c, as the raw co-occurrence matrix $\mathbf{A}$.

Note that in addition to the above-mentioned representation, there are many other ways to represent the distribution of a word in a particular domain (Turney and Pantel, 2010). For example, one can limit the definition of co-occurrence to words that are linked by some dependency relation (Pado and Lapata, 2007), or extend the window of co-occurrence to the entire document (Baroni and Lenci, 2010). Since the method we propose in Section 3.2 to predict the distribution of a word across domains does not depend on the particular

feature representation method, any of these alternative methods could be used.

To reduce the dimensionality of the feature space, and create dense representations for words, we perform SVD on $\mathbf{F}$. We use the left singular vectors corresponding to the k largest singular values to compute a rank k approximation $\hat{\mathbf{F}}$, of $\mathbf{F}$. We perform truncated SVD using SVDLIBC[2]. Each row in $\hat{\mathbf{F}}$ is considered as representing a word in a lower k ($\ll n_c$) dimensional feature space corresponding to a particular domain. Distribution prediction in this lower dimensional feature space is preferrable to prediction over the original feature space because there are reductions in overfitting, feature sparseness, and the learning time. We created two matrices, $\hat{\mathbf{F}}_{\mathcal{S}}$ and $\hat{\mathbf{F}}_{\mathcal{T}}$ from the source and target domains, respectively, using the above mentioned procedure.

3.2 Cross-Domain Feature Vector Prediction

We propose a method to learn a model that can predict the distribution $\boldsymbol{w}_{\mathcal{T}}$ of a word w in the target domain $\mathcal{T}$, given its distribution $\boldsymbol{w}_{\mathcal{S}}$ in the source domain $\mathcal{S}$. We denote the set of features that occur in both domains by $\mathcal{W} = \{w^{(1)}, \ldots, w^{(n)}\}$. In the literature, such features are often referred to as *pivots*, and they have been shown to be useful for DA, allowing the weights learnt to be transferred from one domain to another. Various criteria have been proposed for selecting a small set of pivots for DA, such as the mutual information of a word with the two domains (Blitzer et al., 2007). However, we do not impose any further restrictions on the set of pivots $\mathcal{W}$ other than that they occur in both domains.

For each word $w^{(i)} \in \mathcal{W}$, we denote the corresponding rows in $\hat{\mathbf{F}}_{\mathcal{S}}$ and $\hat{\mathbf{F}}_{\mathcal{T}}$ by column vectors $\boldsymbol{w}_{\mathcal{S}}^{(i)}$ and $\boldsymbol{w}_{\mathcal{T}}^{(i)}$. Note that the dimensionality of $\boldsymbol{w}_{\mathcal{S}}^{(i)}$ and $\boldsymbol{w}_{\mathcal{T}}^{(i)}$ need not be equal, and we may select different numbers of singular vectors to approximate $\hat{\mathbf{F}}_{\mathcal{S}}$ and $\hat{\mathbf{F}}_{\mathcal{T}}$. We model distribution prediction as a multivariate regression problem where, given a set $\{(\boldsymbol{w}_{\mathcal{S}}^{(i)}, \boldsymbol{w}_{\mathcal{T}}^{(i)})\}_{i=1}^{n}$ consisting of pairs of feature vectors selected from each domain for the pivots in $\mathcal{W}$, we learn a mapping from the inputs ($\boldsymbol{w}_{\mathcal{S}}^{(i)}$) to the outputs ($\boldsymbol{w}_{\mathcal{T}}^{(i)}$).

We use Partial Least Squares Regression (PLSR) (Wold, 1985) to learn a regression model using pairs of vectors. PLSR has been applied in Chemometrics (Geladi and Kowalski, 1986), producing stable prediction models even when the number of samples is considerably smaller than the dimensionality of the feature space. In particular, PLSR fits a smaller number of latent variables ($10 - 100$ in practice) such that the correlation between the feature vectors for pivots in the two domains are maximised in this latent space.

Algorithm 1 Learning a prediction model.

Input: $\mathbf{X}$, $\mathbf{Y}$, L.
Output: Prediction matrix $\mathbf{M}$.

1: Randomly select $\boldsymbol{\gamma}_l$ from columns in $\mathbf{Y}_l$.
2: $\boldsymbol{v}_l = {\mathbf{X}_l}^{\top}\boldsymbol{\gamma}_l / \left|\left|{\mathbf{X}_l}^{\top}\boldsymbol{\gamma}_l\right|\right|$
3: $\boldsymbol{\lambda}_l = \mathbf{X}_l\boldsymbol{v}_l$
4: $\boldsymbol{q}_l = {\mathbf{Y}_l}^{\top}\boldsymbol{\lambda}_l / \left|\left|{\mathbf{Y}_l}^{\top}\boldsymbol{\lambda}_l\right|\right|$
5: $\boldsymbol{\gamma}_l = \mathbf{Y}_l\boldsymbol{q}_l$
6: If $\boldsymbol{\gamma}_l$ is unchanged go to Line 7; otherwise go to Line 2
7: $c_l = {\boldsymbol{\lambda}_l}^{\top}\boldsymbol{\gamma}_l / \left|\left|{\boldsymbol{\lambda}_l}^{\top}\boldsymbol{\gamma}_l\right|\right|$
8: $\boldsymbol{p}_l = {\mathbf{X}_l}^{\top}\boldsymbol{\lambda}_l / {\boldsymbol{\lambda}_l}^{\top}\boldsymbol{\lambda}_l$
9: $\mathbf{X}_{l+1} = \mathbf{X}_l - \boldsymbol{\lambda}_l{\boldsymbol{p}_l}^{\top}$ and $\mathbf{Y}_{l+1} = \mathbf{Y}_l - c_l\boldsymbol{\lambda}_l{\boldsymbol{q}_l}^{\top}$.
10: Stop if $l = L$; otherwise $l = l + 1$ and return to Line 1.
11: Let $\mathbf{C} = \mathrm{diag}(c_1, \ldots, c_L)$, and $\mathbf{V} = [\boldsymbol{v}_1 \ldots \boldsymbol{v}_L]$
12: $\mathbf{M} = \mathbf{V}(\mathbf{P}^{\top}\mathbf{V})^{-1}\mathbf{C}\mathbf{Q}^{\top}$
13: **return** $\mathbf{M}$

Let $\mathbf{X}$ and $\mathbf{Y}$ denote matrices formed by arranging respectively the vectors $\boldsymbol{w}_{\mathcal{S}}^{(i)}$s and $\boldsymbol{w}_{\mathcal{T}}^{(i)}$ in rows. PLSR decomposes $\mathbf{X}$ and $\mathbf{Y}$ into a series of products between rank 1 matrices as follows:

$$\mathbf{X} \approx \sum_{l=1}^{L} \boldsymbol{\lambda}_l{\boldsymbol{p}_l}^{\top} = \boldsymbol{\Lambda}\mathbf{P}^{\top} \quad (1)$$

$$\mathbf{Y} \approx \sum_{l=1}^{L} \boldsymbol{\gamma}_l{\boldsymbol{q}_l}^{\top} = \boldsymbol{\Gamma}\mathbf{Q}^{\top}. \quad (2)$$

Here, $\boldsymbol{\lambda}_l$, $\boldsymbol{\gamma}_l$, $\boldsymbol{p}_l$, and $\boldsymbol{q}_l$ are column vectors, and the summation is taken over the rank 1 matrices that result from the outer product of those vectors. The matrices, $\boldsymbol{\Lambda}$, $\boldsymbol{\Gamma}$, $\mathbf{P}$, and $\mathbf{Q}$ are constructed respectively by arranging $\boldsymbol{\lambda}_l$, $\boldsymbol{\gamma}_l$, $\boldsymbol{p}_l$, and $\boldsymbol{q}_l$ vectors as columns.

Our method for learning a distribution prediction model is shown in Algorithm 1. It is based on the two block NIPALS routine (Wold, 1975; Rosipal and Kramer, 2006) and iteratively discovers L pairs of vectors $(\boldsymbol{\lambda}_l, \boldsymbol{\gamma}_l)$ such that the covariances, $\mathrm{Cov}(\boldsymbol{\lambda}_l, \boldsymbol{\gamma}_l)$, are maximised under the constraint $||\boldsymbol{p}_l|| = ||\boldsymbol{q}_l|| = 1$. Finally, the prediction matrix, $\mathbf{M}$ is computed using $\boldsymbol{\lambda}_l, \boldsymbol{\gamma}_l, \boldsymbol{p}_l, \boldsymbol{q}_l$. The predicted distribution $\hat{\boldsymbol{w}}_{\mathcal{T}}$ of a word w in $\mathcal{T}$ is given by

$$\hat{\boldsymbol{w}}_{\mathcal{T}} = \mathbf{M}\boldsymbol{w}_{\mathcal{S}}. \quad (3)$$

[2] http://tedlab.mit.edu/~dr/SVDLIBC/

Our distribution prediction learning method is unsupervised in the sense that it does not require manually labeled data for a particular task from any of the domains. This is an important point, and means that the distribution prediction method is independent of the task to which it may subsequently be applied. As we go on to show in Section 6, this enables us to use the same distribution prediction method for both POS tagging and sentiment classification.

4 Domain Adaptation

The main reason that a model trained only on the source domain labeled data performs poorly in the target domain is the *feature mismatch* – few features in target domain test instances appear in source domain training instances. To overcome this problem, we use the proposed distribution prediction method to find those related features in the source domain that correspond to the features appearing in the target domain test instances.

We consider two DA tasks: (a) cross-domain POS tagging (Section 4.1), and (b) cross-domain sentiment classification (Section 4.2). Note that our proposed distribution prediction method can be applied to numerous other NLP tasks that involve sequence labelling and document classification.

4.1 Cross-Domain POS Tagging

We represent each word using a set of features such as capitalisation (whether the first letter of the word is capitalised), numeric (whether the word contains digits), prefixes up to four letters, and suffixes up to four letters (Miller et al., 2011). Next, for each word w in a source domain labeled (i.e. manually POS tagged) sentence, we select its neighbours $u^{(i)}$ in the source domain as additional features. Specifically, we measure the similarity, $\mathrm{sim}(\boldsymbol{u}_{\mathcal{S}}^{(i)}, \boldsymbol{w}_{\mathcal{S}})$, between the source domain distributions of $u^{(i)}$ and w, and select the top r similar neighbours $u^{(i)}$ for each word w as additional features for w. We refer to such features as *distributional features* in this work. The value of a neighbour $u^{(i)}$ selected as a distributional feature is set to its similarity score $\mathrm{sim}(\boldsymbol{u}_{\mathcal{S}}^{(i)}, \boldsymbol{w}_{\mathcal{S}})$. Next, we train a CRF model using all features (i.e. capitalisation, numeric, prefixes, suffixes, and distributional features) on source domain labeled sentences.

We train a PLSR model, $\mathbf{M}$, that predicts the target domain distribution $\mathbf{M}\boldsymbol{u}_{\mathcal{S}}^{(i)}$ of a word $u^{(i)}$ in the source domain labeled sentences, given its distribution, $\boldsymbol{u}_{\mathcal{S}}^{(i)}$. At test time, for each word w that appears in a target domain test sentence, we measure the similarity, $\mathrm{sim}(\mathbf{M}\boldsymbol{u}_{\mathcal{S}}^{(i)}, \boldsymbol{w}_{\mathcal{T}})$, and select the most similar r words $u^{(i)}$ in the source domain labeled sentences as the distributional features for w, with their values set to $\mathrm{sim}(\mathbf{M}\boldsymbol{u}_{\mathcal{S}}^{(i)}, \boldsymbol{w}_{\mathcal{T}})$. Finally, the trained CRF model is applied to a target domain test sentence.

Note that distributional features are always selected from the source domain during both train and test times, thereby increasing the number of overlapping features between the trained model and test sentences. To make the inference tractable and efficient, we use a first-order Markov factorisation, in which we consider all pairwise combinations between the features for the current word and its immediate predecessor.

4.2 Cross-Domain Sentiment Classification

Unlike in POS tagging, where we must individually tag each word in a target domain test sentence, in sentiment classification we must classify the sentiment for the entire review. We modify the DA method presented in Section 4.1 to satisfy this requirement as follows.

Let us assume that we are given a set $\{(\boldsymbol{x}_{\mathcal{S}}^{(i)}, y^{(i)})\}_{i=1}^{n}$ of n labeled reviews $\boldsymbol{x}_{\mathcal{S}}^{(i)}$ for the source domain $\mathcal{S}$. For simplicity, let us consider binary sentiment classification where each review $\boldsymbol{x}^{(i)}$ is labeled either as positive (i.e. $y^{(i)} = 1$) or negative (i.e. $y^{(i)} = -1$). Our cross-domain binary sentiment classification method can be easily extended to the multi-class setting as well. First, we lemmatise each word in a source domain labeled review $\boldsymbol{x}_{\mathcal{S}}^{(i)}$, and extract both unigrams and bigrams as features to represent $\boldsymbol{x}_{\mathcal{S}}^{(i)}$ by a binary-valued feature vector. Next, we train a binary classification model, $\boldsymbol{\theta}$, using those feature vectors. Any binary classification algorithm can be used to learn $\boldsymbol{\theta}$. In our experiments, we used L2 regularised logistic regression.

Next, we train a PLSR model, $\mathbf{M}$, as described in Section 3.2 using unlabeled reviews in the source and target domains. At test time, we represent a test target review H using a binary-valued feature vector $\boldsymbol{h}$ of unigrams and bigrams of lemmas of the words in H, as we did for source domain labeled train reviews. Next, for each feature $w^{(j)}$ extracted from H, we measure the similarity,

$\text{sim}(\mathbf{M}\boldsymbol{u}_{\mathcal{S}}^{(i)}, \boldsymbol{w}_{\mathcal{T}}^{(j)})$, between the target domain distribution of $w^{(j)}$, and each feature (unigram or bigram) $u^{(i)}$ in the source domain labeled reviews. We score each source domain feature $u^{(i)}$ for its relatedness to H using the formula:

$$\text{score}(u^{(i)}, \mathsf{H}) = \frac{1}{|\mathsf{H}|} \sum_{j=1}^{|\mathsf{H}|} \text{sim}(\mathbf{M}\boldsymbol{u}_{\mathcal{S}}^{(i)}, \boldsymbol{w}_{\mathcal{T}}^{(j)}) \quad (4)$$

where $|\mathsf{H}|$ denotes the total number of features extracted from the test review H. We select the top scoring r features $u^{(i)}$ as distributional features for H, and append those to $\boldsymbol{h}$. The corresponding values of those distributional features are set to the scores given by Equation 4. Finally, we classify $\boldsymbol{h}$ using the trained binary classifier $\boldsymbol{\theta}$. Note that given a test review, we find the distributional features that are similar to *all* the words in the test review from the source domain. In particular, we *do not* find distributional features independently for each word in the test review. This enables us to find distributional features that are consistent with all the features in a test review.

4.3 Model Choices

For both POS tagging and sentiment classification, we experimented with several alternative approaches for feature weighting, representation, and similarity measures using development data, which we randomly selected from the training instances from the datasets described in Section 5.

For feature weighting for sentiment classification, we considered using the number of occurrences of a feature in a review and tf-idf weighting (Salton and Buckley, 1983). For representation, we considered distributional features $u^{(i)}$ in descending order of their scores given by Equation 4, and then taking the inverse-rank as the values for the distributional features (Bollegala et al., 2011). However, none of these alternatives resulted in performance gains. With respect to similarity measures, we experimented with cosine similarity and the similarity measure proposed by Lin (1998); cosine similarity performed consistently well over all the experimental settings. The feature representation was held fixed during these similarity measure comparisons.

For POS tagging, we measured the effect of varying r, the number of distributional features, using a development dataset. We observed that setting r larger than 10 did not result in significant improvements in tagging accuracy, but only increased the train time due to the larger feature space. Consequently, we set $r = 10$ in POS tagging. For sentiment analysis, we used all features in the source domain labeled reviews as distributional features, weighted by their scores given by Equation 4, taking the inverse-rank. In both tasks, we parallelised similarity computations using BLAS[3] level-3 routines to speed up the computations. The source code of our implementation is publicly available[4].

5 Datasets

To evaluate DA for POS tagging, following Blitzer et al. (2006), we use sections $2 - 21$ from Wall Street Journal (WSJ) as the source domain labeled data. An additional $100,000$ WSJ sentences from the 1988 release of the WSJ corpus are used as the source domain unlabeled data. Following Schnabel and Schütze (2013), we use the POS labeled sentences in the SACNL dataset (Petrov and McDonald, 2012) for the five target domains: QA forums, Emails, Newsgroups, Reviews, and Blogs. Each target domain contains around 1000 POS labeled test sentences and around $100,000$ unlabeled sentences.

To evaluate DA for sentiment classification, we use the Amazon product reviews collected by Blitzer et al. (2007) for four different product categories: books (**B**), DVDs (**D**), electronic items (**E**), and kitchen appliances (**K**). There are 1000 positive and 1000 negative sentiment labeled reviews for each domain. Moreover, each domain has on average $17,547$ unlabeled reviews. We use the standard split of 800 positive and 800 negative labeled reviews from each domain as training data, and the remainder for testing.

6 Experiments and Results

For each domain $\mathcal{D}$ in the SANCL (POS tagging) and Amazon review (sentiment classification) datasets, we create a PPMI weighted co-occurrence matrix $\mathbf{F}_{\mathcal{D}}$. On average, $\mathbf{F}_{\mathcal{D}}$ created for a target domain in the SANCL dataset contains $104,598$ rows and $65,528$ columns, whereas those numbers in the Amazon dataset are $27,397$ and $35,200$ respectively. In cross-domain sentiment classification, we measure the binary sentiment classification accuracy for the target domain

[3] http://www.openblas.net/

[4] http://www.csc.liv.ac.uk/~danushka/software.html

test reviews for each pair of domains (12 pairs in total for 4 domains). On average, we have $40,176$ pivots for a pair of domains in the Amazon dataset.

In cross-domain POS tagging, WSJ is always the source domain, whereas the five domains in SANCL dataset are considered as the target domains. For this setting we have 9822 pivots on average. The number of singular vectors k selected in SVD, and the number of PLSR dimensions L are set respectively to 1000 and 50 for the remainder of the experiments described in the paper. Later we study the effect of those two parameters on the performance of the proposed method. The L-BFGS (Liu and Nocedal, 1989) method is used to train the CRF and logistic regression models.

6.1 POS Tagging Results

Table 2 shows the token-level POS tagging accuracy for *unseen* words (i.e. words that appear in the target domain test sentences but not in the source domain labeled train sentences). By limiting the evaluation to unseen words instead of all words, we can evaluate the gain in POS tagging accuracy solely due to DA. The **NA** (no-adapt) baseline simulates the effect of not performing any DA. Specifically, in POS tagging, a CRF trained on source domain labeled sentences is applied to target domain test sentences, whereas in sentiment classification, a logistic regression classifier trained using source domain labeled reviews is applied to the target domain test reviews. The $\mathcal{S}_{\mathbf{pred}}$ baseline directly uses the source domain distributions for the words instead of projecting them to the target domain. This is equivalent to setting the prediction matrix $\mathbf{M}$ to the unit matrix. The $\mathcal{T}_{\mathbf{pred}}$ baseline uses the target domain distribution $\boldsymbol{w}_{\mathcal{T}}$ for a word w instead of $\mathbf{M}\boldsymbol{w}_{\mathcal{S}}$. If w does not appear in the target domain, then $\boldsymbol{w}_{\mathcal{T}}$ is set to the zero vector. The $\mathcal{S}_{pred}$ and $\mathcal{T}_{pred}$ baselines simulate the two alternatives of using source and target domain distributions instead of learning a PLSR model. The DA method proposed in Section 4.1 is shown as the **Proposed** method. **Filter** denotes the training set filtering method proposed by Schnabel and Schütze (2013) for the DA of POS taggers.

From Table 2, we see that the **Proposed** method achieves the best performance in all five domains, followed by the $\mathcal{T}_{pred}$ baseline. Recall that the $\mathcal{T}_{pred}$ baseline cannot find source domain words that do not appear in the target domain as distributional features for the words in the target domain test reviews. Therefore, when the overlap between the vocabularies used in the source and the target domains is small, $\mathcal{T}_{pred}$ cannot reduce the mismatch between the feature spaces. Poor performance of the $\mathcal{S}_{pred}$ baseline shows that the distributions of a word in the source and target domains are different to the extent that the distributional features found using source domain distributions are inadequate. The two baselines $\mathcal{S}_{pred}$ and $\mathcal{T}_{pred}$ collectively motivate our proposal to learn a distribution prediction model from the source domain to the target. The improvements of **Proposed** over the previously proposed **Filter** are statistically significant in all domains except the Emails domain (denoted by † in Table 2 according to the Binomial exact test at 95% confidence). However, the differences between the $\mathcal{T}_{pred}$ and **Proposed** methods are not statistically significant.

Target	NA	$\mathcal{S}_{pred}$	$\mathcal{T}_{pred}$	Filter	Proposed
QA	67.34	68.18	68.75	57.08	$\mathbf{69.28}^{\dagger}$
Emails	65.62	66.62	67.07	65.61	**67.09**
Newsgroups	75.71	75.09	75.57	70.37	$\mathbf{75.85}^{\dagger}$
Reviews	56.36	54.60	56.68	47.91	$\mathbf{56.93}^{\dagger}$
Blogs	76.64	54.78	76.90	74.56	$\mathbf{76.97}^{\dagger}$

Table 2: POS tagging accuracies on SANCL.

6.2 Sentiment Classification Results

In Figure 1, we compare the **Proposed** cross-domain sentiment classification method (Section 4.2) against several baselines and the current state-of-the-art methods. The baselines **NA**, $\mathcal{S}_{\mathbf{pred}}$, and $\mathcal{T}_{\mathbf{pred}}$ are defined similarly as in Section 6.1. **SST** is the Sentiment Sensitive Thesaurus proposed by Bollegala et al. (2011). **SST** creates a single distribution for a word using both source and target domain reviews, instead of two separate distributions as done by the **Proposed** method. **SCL** denotes the Structural Correspondence Learning method proposed by Blitzer et al. (2006). **SFA** denotes the Spectral Feature Alignment method proposed by Pan et al. (2010). **SFA** and **SCL** represent the current state-of-the-art methods for cross-domain sentiment classification. All methods are evaluated under the same settings, including train/test split, feature spaces, pivots, and classification algorithms so that any differences in performance can be directly attributable to their domain adaptability. For each domain, the accuracy obtained by a classifier trained using labeled data from that

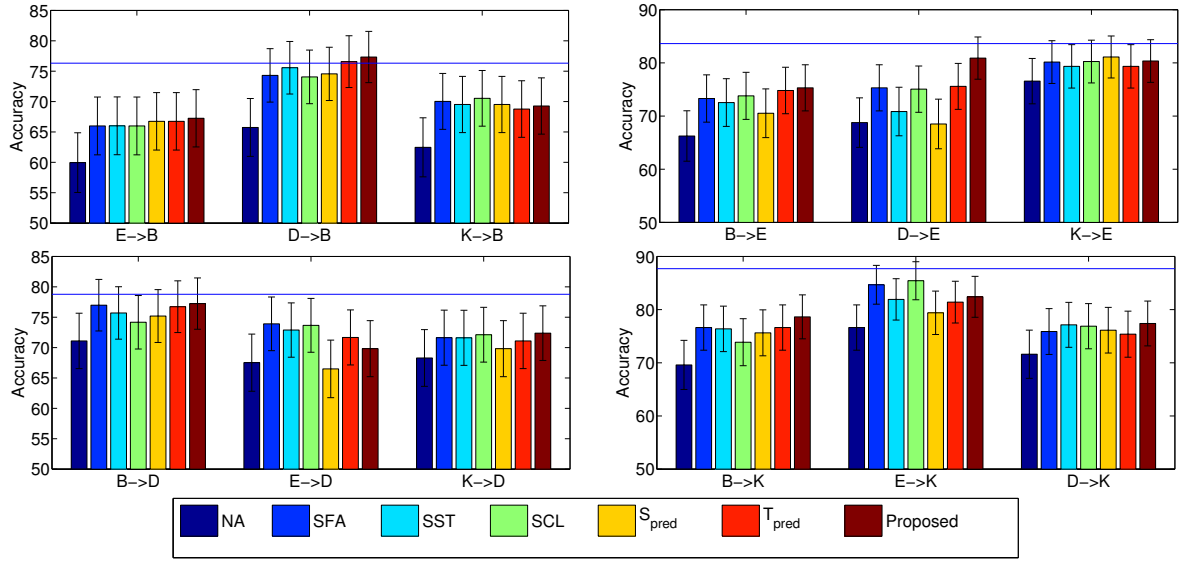

Figure 1: Cross-Domain sentiment classification.

domain is indicated by a solid horizontal line in each sub-figure. This upper baseline represents the classification accuracy we could hope to obtain if we were to have labeled data for the target domain. Clopper-Pearson 95% binomial confidence intervals are superimposed on each vertical bar.

From Figure 1 we see that the **Proposed** method reports the best results in 8 out of the 12 domain pairs, whereas **SCL**, **SFA**, and $\mathcal{S}_{\mathbf{pred}}$ report the best results in other cases. Except for the **D-E** setting in which **Proposed** method significantly outperforms both **SFA** and **SCL**, the performance of the **Proposed** method is not statistically significantly different to that of **SFA** or **SCL**.

The selection of pivots is vital to the performance of **SFA**. However, unlike **SFA**, which requires us to carefully select a small subset of pivots (ca. less than 500) using some heuristic approach, our **Proposed** method does not require any pivot selection. Moreover, **SFA** projects source domain reviews to a lower-dimensional latent space, in which a binary sentiment classifier is subsequently trained. At test time **SFA** projects a target review into this lower-dimensional latent space and applies the trained classifier. In contrast, our **Proposed** method predicts the distribution of a word in the target domain, given its distribution in the source domain, thereby explicitly *translating* the source domain reviews to the target. This property enables us to apply the proposed distribution prediction method to tasks other than sentiment analysis such as POS tagging where we must identify distributional features for individual words.

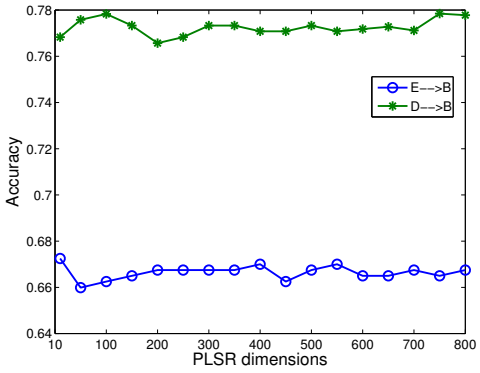

Figure 2: The effect of PLSR dimensions.

Unlike our distribution prediction method, which is unsupervised, **SST** requires labeled data for the source domain to learn a feature mapping between a source and a target domain in the form of a thesaurus. However, from Figure 1 we see that in 10 out of the 12 domain-pairs the **Proposed** method returns higher accuracies than **SST**.

To evaluate the overall effect of the number of singular vectors k used in the SVD step, and the number of PLSR components L used in Algorithm 1, we conduct two experiments. To evaluate the effect of the PLSR dimensions, we fixed $k = 1000$ and measured the cross-domain sentiment classification accuracy over a range of L values. As shown in Figure 2, accuracy remains stable across a wide range of PLSR dimensions. Because the time complexity of Algorithm 1 increases linearly with L, it is desirable that we select smaller L val-

$\mathrm{sim}(u_{\mathcal{S}}, w_{\mathcal{T}})$	segregation (0.1538), participation (0.1512), depression+era (0.1508)
$\mathrm{sim}(\mathbf{M}u_{\mathcal{S}}, w_{\mathcal{T}})$	small (0.2794), compact (0.2641), sturdy (0.2561)

Table 3: Top 3 distributional features $u \in \mathcal{S}$ for the word *lightweight* (w).

ues in practice.

To evaluate the effect of the SVD dimensions, we fixed $L = 100$ and measured the cross-domain sentiment classification accuracy for different k values as shown in Figure 3. We see an overall decrease in classification accuracy when k is increased. Because the dimensionality of the source and target domain feature spaces is equal to k, the complexity of the least square regression problem increases with k. Therefore, larger k values result in overfitting to the train data and classification accuracy is reduced on the target test data.

As an example of the distribution prediction method, in Table 3 we show the top 3 similar distributional features u in the *books* (source) domain, predicted for the *electronics* (target) domain word w = *lightweight*, by different similarity measures. Bigrams are indicted by a + sign and the similarity scores of the distributional features are shown within brackets.

Using the source domain distributions for both u and w (i.e. $\mathrm{sim}(u_{\mathcal{S}}, w_{\mathcal{S}})$) produces distributional features that are specific to the books domain, or to the dominant adjectival sense of *having no importance or influence*. On the other hand, using target domain distributions for u and w (i.e. $\mathrm{sim}(u_{\mathcal{T}}, w_{\mathcal{T}})$) returns distributional features of the dominant nominal sense of *lower in weight* frequently associated with electronic devices. Simply using source domain distributions $u_{\mathcal{S}}$ (i.e. $\mathrm{sim}(u_{\mathcal{S}}, w_{\mathcal{T}})$) returns totally unrelated distributional features. This shows that word distributions in source and target domains are very different and some adaptation is required prior to computing distributional features.

Interestingly, we see that by using the distributions predicted by the proposed method (i.e. $\mathrm{sim}(\mathbf{M}u_{\mathcal{S}}, w_{\mathcal{T}})$) we overcome this problem and find relevant distributional features from the source domain. Although for illustrative purposes we used the word *lightweight*, which occurs in both the source and the target domains, our proposed method does not require the source domain distribution $w_{\mathcal{S}}$ for a word w in a target domain document. Therefore, it can find distributional features even for words occurring only in the target domain, thereby reducing the feature mismatch between the two domains.

7 Conclusion

We proposed a method to predict the distribution of a word across domains. We first create a distributional representation for a word using the data from a single domain, and then learn a Partial Least Square Regression (PLSR) model to predict the distribution of a word in a target domain given its distribution in a source domain. We evaluated the proposed method in two domain adaptation tasks: cross-domain POS tagging and cross-domain sentiment classification. Our experiments show that without requiring any task-specific customisations to our distribution prediction method, it outperforms competitive baselines and achieves comparable results to the current state-of-the-art domain adaptation methods.

How to make words with vectors: Phrase generation in distributional semantics

Georgiana Dinu and **Marco Baroni**
Center for Mind/Brain Sciences
University of Trento, Italy
(georgiana.dinu|marco.baroni)@unitn.it

Abstract

We introduce the problem of *generation* in distributional semantics: Given a distributional vector representing some meaning, how can we generate the phrase that best expresses that meaning? We motivate this novel challenge on theoretical and practical grounds and propose a simple data-driven approach to the estimation of generation functions. We test this in a monolingual scenario (paraphrase generation) as well as in a cross-lingual setting (translation by synthesizing adjective-noun phrase vectors in English and generating the equivalent expressions in Italian).

1 Introduction

Distributional methods for semantics approximate the meaning of linguistic expressions with vectors that summarize the contexts in which they occur in large samples of text. This has been a very successful approach to lexical semantics (Erk, 2012), where semantic relatedness is assessed by comparing vectors. Recently these methods have been extended to phrases and sentences by means of composition operations (see Baroni (2013) for an overview). For example, given the vectors representing *red* and *car*, composition derives a vector that approximates the meaning of *red car*.

However, the link between language and meaning is, obviously, bidirectional: As message recipients we are exposed to a linguistic expression and we must compute its meaning (the *synthesis* problem). As message producers we start from the meaning we want to communicate (a "thought") and we must encode it into a word sequence (the *generation* problem). If distributional semantics is to be considered a proper semantic theory, then it must deal not only with synthesis (going from words to vectors), but also with generation (from vectors to words).

Besides these theoretical considerations, phrase generation from vectors has many useful applications. We can, for example, synthesize the vector representing the meaning of a phrase or sentence, and then generate alternative phrases or sentences from this vector to accomplish true *paraphrase generation* (as opposed to paraphrase detection or ranking of candidate paraphrases).

Generation can be even more useful when the source vector comes from another modality or language. Recent work on grounding language in vision shows that it is possible to represent images and linguistic expressions in a common vector-based semantic space (Frome et al., 2013; Socher et al., 2013). Given a vector representing an image, generation can be used to productively construct phrases or sentences that describe the image (as opposed to simply retrieving an existing description from a set of candidates). Translation is another potential application of the generation framework: Given a semantic space shared between two or more languages, one can compose a word sequence in one language and generate translations in another, with the shared semantic vector space functioning as interlingua.

Distributional semantics assumes a lexicon of atomic expressions (that, for simplicity, we take to be *words*), each associated to a vector. Thus, at the single-word level, the problem of generation is solved by a trivial *generation-by-synthesis* approach: Given an arbitrary target vector, "generate" the corresponding word by searching through the lexicon for the word with the closest vector to the target. This is however unfeasible for larger expressions: Given n vocabulary elements, this approach requires checking n^k phrases of length k. This becomes prohibitive already for relatively short phrases, as reasonably-sized vocabularies do not go below tens of thousands of words. The search space for 3-word phrases in a 10K-word vocabulary is already in the order of trillions. In

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 624–633,
Baltimore, Maryland, USA, June 23-25 2014.

this paper, we introduce a more direct approach to phrase generation, inspired by the work in compositional distributional semantics. In short, we revert the composition process and we propose a framework of data-induced, syntax-dependent functions that *decompose* a single vector into a vector sequence. The generated vectors can then be efficiently matched against those in the lexicon or fed to the decomposition system again to produce longer phrases recursively.

2 Related work

To the best of our knowledge, we are the first to explicitly and systematically pursue the generation problem in distributional semantics. Kalchbrenner and Blunsom (2013) use top-level, composed distributed representations of sentences to guide generation in a machine translation setting. More precisely, they condition the target language model on the composed representation (addition of word vectors) of the source language sentence.

Andreas and Ghahramani (2013) discuss the the issue of generating language from vectors and present a probabilistic generative model for distributional vectors. However, their emphasis is on *reversing* the generative story in order to derive composed meaning representations from word sequences. The theoretical generating capabilities of the methods they propose are briefly exemplified, but not fully explored or tested.

Socher et al. (2011) come closest to our target problem. They introduce a bidirectional language-to-meaning model for compositional distributional semantics that is similar in spirit to ours. However, we present a clearer decoupling of synthesis and generation and we use different (and simpler) training methods and objective functions. Moreover, Socher and colleagues do not train separate decomposition rules for different syntactic configurations, so it is not clear how they would be able to control the generation of different output structures. Finally, the potential for generation is only addressed in passing, by presenting a few cases where the generated sequence has the same syntactic structure of the input sequence.

3 General framework

We start by presenting the familiar synthesis setting, focusing on two-word phrases. We then introduce generation for the same structures. Finally, we show how synthesis and generation of longer phrases is handled by recursive extension of the two-word case. We assume a lexicon L, that is, a bi-directional look-up table containing a list of words L_w linked to a matrix L_v of vectors. Both synthesis and generation involve a trivial lexicon look-up step to retrieve vectors associated to words and *vice versa*: We ignore it in the exposition below.

3.1 Synthesis

To construct the vector representing a two-word phrase, we must compose the vectors associated to the input words. More formally, similarly to Mitchell and Lapata (2008), we define a syntax-dependent *composition* function yielding a phrase vector $\vec{p}$:

$$\vec{p} = \mathrm{f}_{\mathrm{comp_R}}(\vec{u}, \vec{v})$$

where $\vec{u}$ and $\vec{v}$ are the vector representations associated to words u and v. $\mathrm{f}_{\mathrm{comp_R}} : \mathbb{R}^d \times \mathbb{R}^d \rightarrow \mathbb{R}^d$ (for d the dimensionality of vectors) is a composition function specific to the syntactic relation R holding between the two words.[1]

Although we are not bound to a specific composition model, throughout this paper we use the method proposed by Guevara (2010) and Zanzotto et al. (2010) which defines composition as application of linear transformations to the two constituents followed by summing the resulting vectors: $\mathrm{f}_{\mathrm{comp_R}}(\vec{u}, \vec{v}) = W_1\vec{u} + W_2\vec{v}$. We will further use the following equivalent formulation:

$$\mathrm{f}_{\mathrm{comp_R}}(\vec{u}, \vec{v}) = W_R[\vec{u}; \vec{v}]$$

where $W_R \in R^{d \times 2d}$ and $[\vec{u}; \vec{v}]$ is the vertical concatenation of the two vectors (using Matlab notation). Following Guevara, we learn W_R using examples of word and phrase vectors directly extracted from the corpus (for the rest of the paper, we refer to these phrase vectors extracted non-compositionally from the corpus as *observed* vectors). To estimate, for example, the weights in the W_{AN} (adjective-noun) matrix, we use the corpus-extracted vectors of the words in tuples such as $\langle red, car, red.car \rangle$, $\langle evil, cat, evil.cat \rangle$, etc. Given a set of training examples stacked into matrices U, V (the constituent vectors) and P (the corresponding observed vectors), we estimate W_R by solving the least-squares regression problem:

[1] Here we make the simplifying assumption that all vectors have the same dimensionality, however this need not necessarily be the case.

$$\min_{W_R \in \mathbb{R}^{d \times 2d}} \|P - W_R[U;V]\| \quad (1)$$

We use the approximation of observed phrase vectors as objective because these vectors can provide direct evidence of the polysemous behaviour of words: For example, the corpus-observed vectors of *green jacket* and *green politician* reflect how the meaning of *green* is affected by its occurrence with different nouns. Moreover, it has been shown that for two-word phrases, despite their relatively low frequency, such corpus-observed representations are still difficult to outperform in phrase similarity tasks (Dinu et al., 2013; Turney, 2012).

3.2 Generation

Generation of a two-word sequence from a vector proceeds in two steps: decomposition of the phrase vectors into two constituent vectors, and search for the nearest neighbours of each constituent vector in L_v (the lexical matrix) in order to retrieve the corresponding words from L_w.

Decomposition We define a syntax-dependent *decomposition* function:

$$[\vec{u};\vec{v}] = \mathrm{f}_{\mathrm{decomp_R}}(\vec{p})$$

where $\vec{p}$ is a phrase vector, $\vec{u}$ and $\vec{v}$ are vectors associated to words standing in the syntactic relation R and $\mathrm{f}_{\mathrm{decomp_R}} : \mathbb{R}^d \rightarrow \mathbb{R}^d \times \mathbb{R}^d$.

We assume that decomposition is also a linear transformation, $W'_R \in \mathbb{R}^{2d \times d}$, which, given an input phrase vector, returns two constituent vectors:

$$\mathrm{f}_{\mathrm{decomp_R}}(\vec{p}) = W'_R\vec{p}$$

Again, we can learn from corpus-observed vectors associated to tuples of word pairs and the corresponding phrases by solving:

$$\min_{W'_R \in \mathbb{R}^{2d \times d}} \|[U;V] - W'_R P\| \quad (2)$$

If a composition function $\mathrm{f}_{\mathrm{comp_R}}$ is available, an alternative is to learn a function that can best *revert* this composition. The decomposition function is then trained as follows:

$$\min_{W'_R \in \mathbb{R}^{2d \times d}} \|[U;V] - W'_R W_R[U;V]\| \quad (3)$$

where the matrix W_R is a given composition function for the same relation R. Training with observed phrases, as in eq. (2), should be better at capturing the idiosyncrasies of the actual distribution of phrases in the corpus and it is more robust by being independent from the availability and quality of composition functions. On the other hand, if the goal is to revert as faithfully as possible the composition process and retrieve the original constituents (e.g., in a different modality or a different language), then the objective in eq. (3) is more motivated.

Nearest neighbour search We retrieve the nearest neighbours of each constituent vector $\vec{u}$ obtained by decomposition by applying a search function s:

$$\mathrm{NN}_{\vec{u}} = s(\vec{u}, L_v, t)$$

where $\mathrm{NN}_{\vec{u}}$ is a list containing the t nearest neighours of $\vec{u}$ from L_v, the lexical vectors. Depending on the task, t might be set to 1 to retrieve just one word sequence, or to larger values to retrieve t alternatives. The similarity measure used to determine the nearest neighbours is another parameter of the search function; we omit it here as we only experiment with the standard cosine measure (Turney and Pantel, 2010).[2]

3.3 Recursive (de)composition

Extension to longer sequences is straightforward if we assume binary tree representations as syntactic structures. In synthesis, the top-level vector can be obtained by applying composition functions recursively. For example, the vector of *big red car* would be obtained as: $\mathrm{f}_{\mathrm{comp_{AN}}}(\vec{big}, \mathrm{f}_{\mathrm{comp_{AN}}}(\vec{red}, \vec{car}))$, where $\mathrm{f}_{\mathrm{comp_{AN}}}$ is the composition function for adjective-noun phrase combinations. Conversely, for generation, we decompose the phrase vector with $\mathrm{f}_{\mathrm{decomp_{AN}}}$. The first vector is used for retrieving the nearest adjective from the lexicon, while the second vector is further decomposed.

In the experiments in this paper we assume that the syntactic structure is given. In Section 7, we discuss ways to eliminate this assumption.

[2]Note that in terms of computational efficiency, cosine-based nearest neighbour searches reduce to vector-matrix multiplications, for which many efficient implementations exist. Methods such as locality sensitive hashing can be used for further speedups when working with particularly large vocabularies (Andoni and Indyk, 2008).

4 Evaluation setting

In our empirical part, we focus on noun phrase generation. A noun phrase can be a single noun or a noun with one or more modifiers, where a modifier can be an adjective or a prepositional phrase. A prepositional phrase is in turn composed of a preposition and a noun phrase. We learn two composition (and corresponding decomposition) functions: one for modifier-noun phrases, trained on adjective-noun (AN) pairs, and a second one for prepositional phrases, trained on preposition-noun (PN) combinations. For the rest of this section we describe the construction of the vector spaces and the (de)composition function learning procedure.

Construction of vector spaces We test two types of vector representations. The *cbow* model introduced in Mikolov et al. (2013a) learns vector representations using a neural network architecture by trying to predict a target word given the words surrounding it. We use the word2vec software[3] to build vectors of size 300 and using a context window of 5 words to either side of the target. We set the sub-sampling option to 1e-05 and estimate the probability of a target word with the negative sampling method, drawing 10 samples from the noise distribution (see Mikolov et al. (2013a) for details). We also implement a standard *count*-based bag-of-words distributional space (Turney and Pantel, 2010) which counts occurrences of a target word with other words within a symmetric window of size 5. We build a 300Kx300K symmetric co-occurrence matrix using the top most frequent words in our source corpus, apply positive PMI weighting and Singular Value Decomposition to reduce the space to 300 dimensions. For both spaces, the vectors are finally normalized to unit length.[4]

For both types of vectors we use 2.8 billion tokens as input (ukWaC + Wikipedia + BNC). The Italian language vectors for the cross-lingual experiments of Section 6 were trained on 1.6 billion tokens from itWaC.[5] A word token is a word-form + POS-tag string. We extract both word vectors and the observed phrase vectors which are required for the training procedures. We sanity-check the two spaces on MEN (Bruni et al., 2012), a 3,000 items word similarity data set. *cbow* significantly outperforms *count* (0.80 vs. 0.72 Spearman correlations with human judgments). *count* performance is consistent with previously reported results.[6]

(De)composition function training The training data sets consist of the 50K most frequent $\langle u, v, p\rangle$ tuples for each phrase type, for example, $\langle red, car, red.car\rangle$ or $\langle in, car, in.car\rangle$.[7] We concatenate $\vec{u}$ and $\vec{v}$ vectors to obtain the $[U; V]$ matrix and we use the observed $\vec{p}$ vectors (e.g., the corpus vector of the *red.car* bigram) to obtain the phrase matrix P. We use these data sets to solve the least squares regression problems in eqs. (1) and (2), obtaining estimates of the composition and decomposition matrices, respectively. For the decomposition function in eq. (3), we replace the observed phrase vectors with those composed with $\mathrm{f}_{\mathrm{comp_R}}(\vec{u}, \vec{v})$, where $\mathrm{f}_{\mathrm{comp_R}}$ is the previously estimated composition function for relation R.

Composition function performance Since the experiments below also use composed vectors as input to the generation process, it is important to provide independent evidence that the composition model is of high quality. This is indeed the case: We tested our composition approach on the task of retrieving *observed* AN and PN vectors, based on their composed vectors (similarly to Baroni and Zamparelli (2010), we want to retrieve the observed *red.car* vector using $\mathrm{f}_{\mathrm{comp_{AN}}}(red, car)$). We obtain excellent results, with minimum accuracy of 0.23 (chance level <0.0001). We also test on the AN-N paraphrasing test set used in Dinu et al. (2013) (in turn adapting Turney (2012)). The dataset contains 620 ANs, each paired with a single-noun paraphrase (e.g., *false belief/fallacy*, *personal appeal/charisma*). The task is to rank all nouns in the lexicon by their similarity to the phrase, and return the rank of the correct paraphrase. Results are reported in the first row of Table 1. To facilitate comparison, we search, like Dinu et al., through a vocabulary containing the 20K most frequent nouns. The *count* vectors results are similar to those reported by Dinu and colleagues for the same model, and with *cbow* vec-

[6] See Baroni et al. (2014) for an extensive comparison of the two types of vector representations.

[7] For PNs, we ignore determiners and we collapse, for example, *in.the.car* and *in.car* occurrences.

Input	Output	**cbow**	**count**
A∘N	**N**	11	171
N	**A, N**	67,29	204,168

Table 1: Median rank on the AN-N set of Dinu et al. (2013) (e.g., *personal appeal/charisma*). First row: the A and N are composed and the closest N is returned as a paraphrase. Second row: the N vector is *decomposed* into A and N vectors and their nearest (POS-tag consistent) neighbours are returned.

tors we obtain a median rank that is considerably higher than that of the methods they test.

5 Noun phrase generation

5.1 One-step decomposition

We start with testing one-step decomposition by generating two-word phrases. A first straightforward evaluation consists in decomposing a phrase vector into the correct constituent words. For this purpose, we randomly select (and consequently remove) from the training sets 200 phrases of each type (AN and PN) and apply decomposition operations to 1) their corpus-observed vectors and 2) their composed representations. We generate two words by returning the nearest neighbours (with appropriate POS tags) of the two vectors produced by the decomposition functions. Table 2 reports generation accuracy, i.e., the proportion of times in which we retrieved the correct constituents. The search space consists of the top most frequent 20K nouns, 20K adjectives and 25 prepositions respectively, leading to chance accuracy <0.0001 for nouns and adjectives and <0.05 for prepositions. We obtain relatively high accuracy, with *cbow* vectors consistently outperforming *count* ones. Decomposing composed rather than observed phrase representations is easier, which is to be expected given that composed representations are obtained with a simpler, linear model. Most of the errors consist in generating synonyms (*hard case→difficult case*, *true cost → actual cost*) or related phrases (*stereo speakers→omni-directional sound*).

Next, we use the AN-N dataset of Dinu and colleagues for a more interesting evaluation of one-step decomposition. In particular, we reverse the original paraphrasing direction by attempting to generate, for example, *personal charm* from *charisma*. It is worth stressing the nature of the

Input	Output	**cbow**	**count**

P.N	**P, N**	0.93,0.79	0.60,0.57
A∘N	**A, N**	1.00,1.00	0.86,0.99
P∘N	**P, N**	1.00,1.00	1.00,1.00

Table 2: Accuracy of generation models at retrieving (at rank 1) the constituent words of adjective-noun (AN) and preposition-noun (PN) phrases. Observed (**A.N**) and composed representations (**A∘N**) are decomposed with observed- (eq. 2) and composed-trained (eq. 3) functions respectively.

paraphrase-by-generation task we tackle here and in the next experiments. Compositional distributional semantic systems are often evaluated on phrase and sentence paraphrasing data sets (Blacoe and Lapata, 2012; Mitchell and Lapata, 2010; Socher et al., 2011; Turney, 2012). However, these experiments assume a pre-compiled list of candidate paraphrases, and the task is to rank correct paraphrases above foils (paraphrase ranking) or to decide, for a given pair, if the two phrases/sentences are mutual paraphrases (paraphrase detection). Here, instead, we do not assume a given set of candidates: For example, in N→AN paraphrasing, any of $20K^2$ possible combinations of adjectives and nouns from the lexicon could be generated. This is a much more challenging task and it paves the way to more realistic applications of distributional semantics in generation scenarios.

The median ranks of the gold A and N of the Dinu set are shown in the second row of Table 1. As the top-generated noun is almost always, uninterestingly, the input one, we return the next noun. Here we report results for the more motivated corpus-observed training of eq. (2) (unsurprisingly, using composed-phrase training for the task of decomposing *single* nouns leads to lower performance).

Although considerably more difficult than the previous task, the results are still very good, with median ranks under 100 for the *cbow* vectors (random median rank at 10K). Also, the dataset provides only one AN paraphrase for each noun, out of many acceptable ones. Examples of generated phrases are given in Table 3. In addition to generating topically related ANs, we also see nouns disambiguated in different ways than intended in

Input	Output	Gold
reasoning	deductive thinking	abstract thought
jurisdiction	legal authority	legal power
thunderstorm	thundery storm	electrical storm
folk	local music	common people
superstition	old-fashioned religion	superstitious notion
vitriol	political bitterness	sulfuric acid
zoom	fantastic camera	rapid growth
religion	religious religion	religious belief

Table 3: Examples of generating ANs from Ns using the data set of Dinu et al. (2013).

the gold standard (for example *vitriol* and *folk* in Table 3). Other interesting errors consist of decomposing a noun into two words which both have the same meaning as the noun, generating for example *religion → religious religions*. We observe moreover that sometimes the decomposition reflects selectional preference effects, by generating adjectives that denote typical properties of the noun to be paraphrased (e.g., *animosity* is a *(political, personal,...) hostility* or a *fridge* is a *(big, large, small,...) refrigerator*). This effect could be exploited for tasks such as property-based concept description (Kelly et al., 2012).

5.2 Recursive decomposition

We continue by testing generation through *recursive* decomposition on the task of generating noun-preposition-noun (NPN) paraphrases of adjective-nouns (AN) phrases. We introduce a dataset containing 192 AN-NPN pairs (such as *pre-election promises→ promises before election*), which was created by the second author and additionally corrected by an English native speaker. The data set was created by analyzing a list of randomly selected frequent ANs. 49 further ANs (with adjectives such as *amazing* and *great*) were judged not NPN-paraphrasable and were used for the experiment reported in Section 7. The paraphrased subset focuses on preposition diversity and on including prepositions which are rich in semantic content and relevant to paraphrasing the AN. This has led to excluding *of*, which in most cases has the purely syntactic function of connecting the two nouns. The data set contains the following 14 prepositions: *after, against, at, before, between, by, for, from, in, on, per, under, with, without*.[8]

NPN phrase generation involves the application of two decomposition functions. In the first step we decompose using the modifier-noun rule ($f_{\mathrm{decomp_{AN}}}$). We generate a noun from the head slot vector and the "adjective" vector is further decomposed using $f_{\mathrm{decomp_{PN}}}$ (returning the top noun which is not identical to the previously generated one). The results, in terms of top 1 accuracy and median rank, are shown in Table 4. Examples are given in Table 5.

For observed phrase vector training, accuracy and rank are well above chance for all constituents (random accuracy 0.00005 for nouns and 0.04 for prepositions, corresponding median ranks: 10K, 12). Preposition generation is clearly a more difficult task. This is due at least in part to their highly ambiguous and broad semantics, and the way in which they interact with the nouns. For example, *cable through ocean* in Table 5 is a reasonable paraphrase of *undersea cable* despite the gold preposition being *under*. Other than several cases which are acceptable paraphrases but not in the gold standard, phrases related in meaning but not synonymous are the most common error (*overcast skies → skies in sunshine*). We also observe that often the A and N meanings are not fully separated when decomposing and "traces" of the adjective or of the original noun meaning can be found in *both* generated nouns (for example *nearby school → schools after school*). To a lesser degree, this might be desirable as a disambiguation-in-context effect as, for example, in *underground cavern*, *in secret* would not be a context-appropriate paraphrase of *underground*.

6 Noun phrase translation

This section describes preliminary experiments performed in a cross-lingual setting on the task of composing English AN phrases and generating Italian translations.

Creation of cross-lingual vector spaces A common semantic space is required in order to map words and phrases across languages. This problem has been extensively addressed in the bilingual lexicon acquisition literature (Haghighi et al., 2008; Koehn and Knight, 2002). We opt for a very simple yet accurate method (Klementiev et al., 2012; Rapp, 1999) in which a bilingual dictionary is used to identify a set of shared dimensions across spaces and the vectors of both languages are projected into the subspace defined by these (Subspace Projection - SP). This method is applicable to *count*-type vector spaces, for which the dimen-

[8]This dataset is available at `http://clic.cimec.unitn.it/composes`

Input	Output	Training	**cbow**	**count**
A∘N	**N, P, N**	observed	0.98(1),0.08(5.5),0.13(20.5)	0.82(1),0.17(4.5),0.05(71.5)
A∘N	**N, P, N**	composed	0.99(1),0.02(12), 0.12(24)	0.99(1),0.06(10), 0.05(150.5)

Table 4: Top 1 accuracy (median rank) on the AN→NPN paraphrasing data set. AN phrases are composed and then recursively decomposed into N, (P, N). Comma-delimited scores reported for first noun, preposition, second noun in this order. Training is performed on observed (eq. 2) and composed (eq. 3) phrase representations.

Input	Output	Gold
mountainous region	region in highlands	region with mountains
undersea cable	cable through ocean	cable under sea
underground cavern	cavern through rock	cavern under ground
interdisciplinary field	field into research	field between disciplines
inter-war years	years during 1930s	years between wars
post-operative pain	pain through patient	pain after operation
pre-war days	days after wartime	days before war
intergroup differences	differences between intergroup	differences between minorities
superficial level	level between levels	level on surface

Table 5: Examples of generating NPN phrases from composed ANs.

sions correspond to actual words. As the *cbow* dimensions do not correspond to words, we align the *cbow* spaces by using a small dictionary to learn a linear map which transforms the English vectors into Italian ones as done in Mikolov et al. (2013b). This method (Translation Matrix - TM) is applicable to both *cbow* and *count* spaces. We tune the parameters (TM or SP for *count* and dictionary size 5K or 25K for both spaces) on a standard task of translating English words into Italian. We obtain TM-5K for *cbow* and SP-25K for *count* as optimal settings. The two methods perform similarly for low frequency words while *cbow*-TM-5K significantly outperforms *count*-SP-25K for high frequency words. Our results for the *cbow*-TM-5K setting are similar to those reported by Mikolov et al. (2013b).

Cross-lingual decomposition training Training proceeds as in the monolingual case, this time concatenating the training data sets and estimating a single (de)-composition function for the two languages in the shared semantic space. We train both on observed phrase representations (eq. 2) and on composed phrase representations (eq. 3).

Adjective-noun translation dataset We randomly extract 1,000 AN-AN En-It phrase pairs from a phrase table built from parallel movie subtitles, available at `http://opus.lingfil.uu.se/` (OpenSubtitles2012, en-it) (Tiedemann, 2012).

Input	Output	**cbow**	**count**
A∘N(En)	**A,N** (It)	0.31,0.59	0.24,0.54
A∘N (It)	**A,N**(En)	0.50,0.62	0.28,0.48

Table 6: Accuracy of En→It and It→En phrase translation: phrases are composed in source language and decomposed in target language. Training on composed phrase representations (eq. (3)) (with observed phrase training (eq. 2) results are ≈50% lower).

Results are presented in Table 6. While in these preliminary experiments we lack a proper term of comparison, the performance is very good both quantitatively (random < 0.0001) and qualitatively. The En→It examples in Table 7 are representative. In many cases (e.g., *vicious killer*, *rough neighborhood*) we generate translations that are arguably more natural than those in the gold standard. Again, some differences can be explained by different disambiguations (*chest* as *breast*, as in the generated translation, or *box*, as in the gold). Translation into related but not equivalent phrases and generating the same meaning in both constituents (*stellar star*) are again the most significant errors. We also see cases in which this has the desired effect of disambiguating the constituents, such as in the examples in Table 8, showing the nearest neighbours when translating *black tie* and *indissoluble tie*.

Input	Output	Gold
vicious killer	assassino feroce (ferocious killer)	killer pericoloso
spectacular woman	donna affascinante (fascinating woman)	donna eccezionale
huge chest	petto grande (big chest)	scrigno immenso
rough neighborhood	zona malfamata (ill-repute zone)	quartiere difficile
mortal sin	peccato eterno (eternal sin)	pecato mortale
canine star	stella stellare (stellar star)	star canina

Table 7: En→It translation examples (back-translations of generated phrases in parenthesis).

black tie	
cravatta (tie)	**nero** (black)
velluto (velvet)	bianco (white)
giacca (jacket)	giallo (yellow)
indissoluble tie	
alleanza (alliance)	**indissolubile** (indissoluble)
legame (bond)	sacramentale (sacramental)
amicizia (friendship)	inscindibile (inseparable)

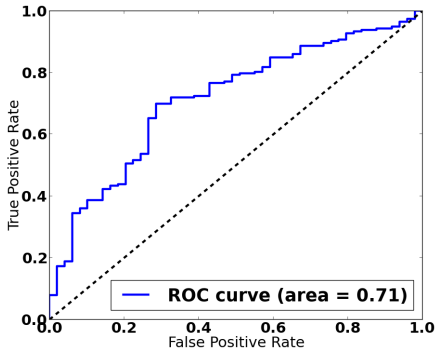

Figure 1: ROC of distinguishing ANs paraphrasable as NPNs from non-paraphrasable ones.

7 Generation confidence and generation quality

In Section 3.2 we have defined a search function s returning a list of lexical nearest neighbours for a constituent vector produced by decomposition. Together with the neighbours, this function can naturally return their similarity score (in our case, the cosine). We call the score associated to the top neighbour the *generation confidence*: if this score is low, the vector has no good match in the lexicon. We observe significant Spearman correlations between the generation confidence of a constituent and its quality (e.g., accuracy, inverse rank) in all the experiments. For example, for the AN(En)→AN(It) experiment, the correlations between the confidence scores and the inverse ranks for As and Ns, for both *cbow* and *count* vectors, range between 0.34 ($p < 1e^{-28}$) and 0.42. In the translation experiments, we can use this to automatically determine a subset on which we can translate with very high accuracy. Table 9 shows AN-AN accuracies and coverage when translating only if confidence is above a certain threshold.

Throughout this paper we have assumed that the syntactic structure of the phrase to be generated is given. In future work we will exploit the correlation between confidence and quality for the purpose of eliminating this assumption. As a concrete example, we can use confidence scores to distinguish the two subsets of the AN-NPN dataset introduced in Section 5: the ANs which are paraphrasable with an NPN from those that do not have this property. We assign an AN to the NPN-paraphrasable class if the mean confidence of the PN expansion in its attempted N(PN) decomposition is above a certain threshold. We plot the ROC curve in Figure 1. We obtain a significant AUC of 0.71.

8 Conclusion

In this paper we have outlined a framework for the task of generation with distributional semantic models. We proposed a simple but effective approach to reverting the composition process to obtain meaningful reformulations of phrases through a synthesis-generation process.

For future work we would like to experiment with more complex models for (de-)composition in order to improve the performance on the tasks we used in this paper. Following this, we

would like to extend the framework to handle arbitrary phrases, including making (confidence-based) choices on the syntactic structure of the phrase to be generated, which we have assumed to be given throughout this paper.

In terms of applications, we believe that the line of research in machine translation that is currently focusing on replacing parallel resources with large amounts of monolingual text provides an interesting setup to test our methods. For example, Klementiev et al. (2012) reconstruct phrase tables based on phrase similarity scores in semantic space. However, they resort to scoring phrase pairs extracted from an aligned parallel corpus, as they do not have a method to freely *generate* these. Similarly, in the recent work on common vector spaces for the representation of images and text, the current emphasis is on retrieving existing captions (Socher et al., 2014) and not actual generation of image descriptions.

From a more theoretical point of view, our work fills an important gap in distributional semantics, making it a bidirectional theory of the connection between language and meaning. We can now translate linguistic strings into vector "thoughts", and the latter into their most appropriate linguistic expression. Several neuroscientific studies suggest that thoughts are represented in the brain by patterns of activation over broad neural areas, and vectors are a natural way to encode such patterns (Haxby et al., 2001; Huth et al., 2012). Some research has already established a connection between neural and distributional semantic vector spaces (Mitchell et al., 2008; Murphy et al., 2012). Generation might be the missing link to powerful computational models that take the neural footprint of a thought as input and produce its linguistic expression.

Abstract

Traditional models of distributional semantics suffer from computational issues such as data sparsity for individual lexemes and complexities of modeling semantic composition when dealing with structures larger than single lexical items. In this work, we present a frequency-driven paradigm for robust distributional semantics in terms of semantically cohesive lineal constituents, or *motifs*. The framework subsumes issues such as differential compositional as well as non-compositional behavior of phrasal consituents, and circumvents some problems of data sparsity by design. We design a segmentation model to optimally partition a sentence into lineal constituents, which can be used to define distributional contexts that are less noisy, semantically more interpretable, and linguistically disambiguated. Hellinger PCA embeddings learnt using the framework show competitive results on empirical tasks.

1 Introduction

Meaning in language is a confluence of experientially acquired semantics of words or multi-word phrases, and their semantic composition to create new meanings. For instance, successfully interpreting a sentence such as

The old senator kicked the bucket.

requires the knowledge that the semantic connotations of 'kicking the bucket' as a unit are the same as those for 'dying'. Short of explicit supervision, such semantic mappings must be inferred by a new language speaker through inductive mechanisms operating on observed linguistic usage. This perspective of acquired meaning aligns with the 'meaning is usage' adage, consonant with Wittgenstein's view of semantics. At the same time, the ability to adaptively communicate elaborate meanings can only be conciled through Frege's principle of compositionality, i.e., meanings of larger linguistic constructs can be derived from the meanings of individual components, modulated by their syntactic interrelations. Indeed, most linguistic usage appears compositional. This is supported by the fact even with very limited vocabulary, children and non-native speakers can often communicate surprisingly effectively.

It can be argued that to be sustainable, inductive aspects of meaning must be recurrent enough to be learnable by new users. That is, a non-compositional phrase such as 'kick the bucket' is likely to persist in common parlance only if it is frequently used with its associated semantic mapping. If a usage-driven meaning of a motif is not recurrent enough, learning this mapping is inefficient in two ways. First, the sparseness of observations would severely limit accurate inductive acquisition by new observers. Second, the value of learning a very infrequent semantic mapping is likely marginal. This motivates the need for a frequency-driven view of lexical semantics. In particular, such a perspective can be especially advantageous for distributional semantics for reasons we outline below.

Distributional semantic models (DSMs) that represent words as distributions over neighbouring contexts have been particularly effective in capturing fine-grained lexical semantics (Turney et al., 2010). Such models have engendered improvements in diverse applications such as selectional preference modeling (Erk, 2007), word-sense discrimination (McCarthy and Carroll, 2003), automatic dictionary building (Curran, 2003), and information retrieval (Manning et al., 2008). However, while conventional DSMs consider colloca-

Table 1: Meaning representation by conventional DSMs vs notional ideal

tion strengths (through counts and PMI scores) of word neighbourhoods, they disregard much of the regularity in human language. Most significantly, word tokens that act as latent dimensions are often derived from arbitrary tokenization. The example given in Table 1 succinctly describes this. The first row in the table shows a representation of the meaning of the token 'crisis' that a conventional DSM might extract from the given sentence after stopword removal. While helpful, the representation seems unsatisfying since words such as 'press', 'wake' and 'shores' seem to have little to do with a crisis. From a semantic perspective, a representation similar to the second is more valuable: not only does it represent a semantic mapping for a more specific meaning, but the latent dimensions of the representation have are less noisy (e.g., while 'wake' is semantically ambiguous, its surrounding context in 'in wake of' disambiguates it) and more intuitive in regards of semantic interepretability. This is the overarching theme of this work: we present a frequency driven paradigm for extending distributional semantics to phrasal and sentential levels in terms of such semantically cohesive, recurrent lexical units or *motifs*.

We propose to identify such semantically cohesive motifs in terms of features inspired from frequency-characteristics, linguistic idiosyncrasies, and shallow syntactic analysis; and explore both supervised and semi-supervised models to optimally segment a sentence into such motifs. Through exploiting regularities in language usage, the framework can efficiently account for both compositional and non-compositional word usage, while avoiding the issue of data-sparsity by design. Our principal contributions in this paper are:

- We present a framework for extending distributional semantics to learn semantic representations of both words and phrases in terms of recurrent motifs, rather than arbitrary word tokens
- We present a simple model to segment a sentence into such motifs using a feature-set drawing from frequency statistics, information theory, linguistic theories and shallow syntactic analysis
- Word and phrasal representations learnt through the approach outperform conventional DSM representations on empirical tasks

This paper is organized as follows: In Section 2, we briefly review related work in the domain of compositional distributional semantics, and motivate our formulation. Section 3 describes our methodology, which consists of a frequency-driven segmentation model to partition text into semantically meaningful recurring lineal-subunits, a representation learning framework for learning new semantic embeddings based on this segmentation, and an approach to use such embeddings in downstream applications. We present experiments and empirical evaluations for our method in Section 4. Finally, we conclude in Section 5 with a summary of our principal findings, and a discussion of possible directions for future work.

2 Related Work

While DSMs have been valuable in representing semantics of single words, approaches to extend them to represent the semantics of phrases and sentences has met with only marginal success. While there is considerable variety in approaches and formulations, existing approaches for phrasal level and sentential semantics can broadly be partitioned into two categories.

2.1 Compositional approaches

These have aimed at using semantic representations for individual words to learn semantic representations for larger linguistic structures. These methods implicitly make an assumption of compositionality, and often include explicit computational models of compositionality. Notable among such models are the additive and multiplicative models of composition by Mitchell and Lapata (2008), Grefenstette et al. (2010), Baroni and

Zamparelli's (2010) model that differentially models content and function words for semantic composition, and Goyal et al.'s SDSM model (2013) that incorporates syntactic roles to model semantic composition. Notable among the most effective distributional representations are the recent deep-learning approaches by Socher et al. (2012), that model vector composition through non-linear transformations. While word embeddings and language models from such methods have been useful for tasks such as relation classification, polarity detection, event coreference and parsing; much of existing literature on composition is based on abstract linguistic theory and conjecture, and there is little evidence to support that learnt representations for larger linguistic units correspond to their semantic meanings. While works such as the SDSM model suffer from the *problem of sparsity* in composing structures beyond bigrams and trigrams, methods such as Mitchell and Lapata (2008)and (Socher et al., 2012) and Grefenstette and Sadrzadeh (2011) are restricted by significant *model biases* in representing semantic composition by generic algebraic operations. Finally, the assumption that semantic meanings for sentences could have representations similar to those for smaller individual tokens is in some sense unintuitive, and not supported by linguistic or semantic theories.

2.2 Tree kernels

Tree Kernel methods have gained popularity in the last decade for capturing syntactic information in the structure of parse trees (Collins and Duffy, 2002; Moschitti, 2006). Instead of procuring explicit representations, the kernel paradigm directly focuses on the larger goal of quantifying semantic similarity of larger linguistic units. Structural kernels for NLP are based on matching substructures within two parse trees , consisting of word-nodes with similar labels. These methods have been useful for eclectic tasks such as parsing, NER, semantic role labeling, and sentiment analysis. Recent approaches such as by Croce et al. (2011) and Srivastava et al. (2013) have attempted to provide formulations to incorporate semantics into tree kernels through the use of distributional word vectors at the individual word-nodes. While this framework is attractive in the lack of assumptions on representation that it makes, the use of distributional embeddings for individual tokens means that it suffers from the same shortcomings as described for the example in Table 1, and hence these methods model semantic relations between word-nodes very weakly. Figure 1 shows an example of the shortcomings of this general approach.

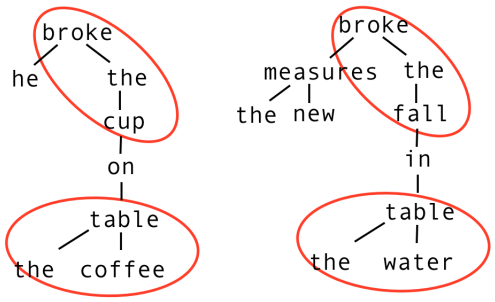

Figure 1: Tokenwise syntactic and semantic similarities don't imply sentential semantic similarity

While the two sentences in consideration have near-identical syntax and could be argued to have semantically aligned words in similar positions, the semantics of the complete sentences are widely divergent. Specifically, the 'bag of words' assumption in tree kernels doesn't suffice for these lexemes, and a stronger semantic model is needed to capture phrasal semantics as well as diverging inter-word relations such as in 'coffee table' and 'water table'. Our hypothesis is that a model that can even weakly identify recurrent motifs such as 'water table' or 'breaking a fall' would be helpful in building more effective semantic representations. A significant advantage of a frequency driven view is that it makes the concern of compositionality of recurrent phrases immaterial. If a motif occurs frequently enough in common parlance, its semantics could be captured with distributional models irrespective of whether its associated semantics are compositional or acquired.

2.3 Identifying multi-word expressions

Several approaches have focused on supervised identification of multi-word expressions (MWEs) through statistical (Pecina, 2008; Villavicencio et al., 2007) and linguistically motivated (Piao et al., 2005) techniques. More recently, hybrid methods based on both statistical as well as linguistic features have been popular (Tsvetkov and Wintner, 2011). Ramisch et al. (2008) demonstrate that adding part-of-speech tags to frequency counts substantially improves performance. Other methods have attempted to exploit morphological, syntactic and semantic characteristics of MWEs. In

particular, approaches such as Bannard (2007) use syntactic rigidity to characterize MWEs. While existing work has focused on the classification task of categorizing a phrasal constituent as a MWE or a non-MWE, the general ideas of most of these works are in line with our current framework, and the feature-set for our motif segmentation model is designed to subsume most of these ideas. It is worthwhile to point out that the task of motif segmentation is slightly different from MWE identification. Specifically, the onus on recurrent occurrences means that non-decomposibility is not an essential consideration for a word to be considered a motif. In line with the proposed paradigm, typical MWEs such as 'shoot the breeze', 'sour note' and 'hot dog' would be considered valid lineal motifs. [1] In addition, even decomposable recurrent lineal phrases such as 'love story', 'federal government', and 'millions of people' are marked as meaningful recurrent motifs. Finally, and least interestingly, we include common named entities such as 'United States' and 'Java Virtual Machine' within the ambit of motifs.

3 Method

In this section, we define our frequency-driven framework for distributional semantics in detail. As just described above, our definition for motifs is less specific than MWEs. With such a working definition, contiguous motifs are likely to make distributional representations less noisy and also assist in disambiguating context. Also, the lack of specificity ensures that such motifs are common enough to meaningfully influence distributional representation beyond single tokens. A method towards frequency-driven distributional semantics could involve the following principal components:

3.1 Linear segmentation model

The segmentation model forms the core of the framework. Ideally, it fragments a given sentence into non-overlapping, semantically meaningful, empirically frequent contiguous sub-units or motifs. The model accounts for possible segmentations of a sentence into potential motifs, and prefers recurrent and cohesive motifs through features that capture frequency-based and statistical features, as well as linguistic idiosyncracies. This is accomplished using a very simple linear chain model and a rich feature set consisting of a combination of frequency-driven, information theoretic and linguistically motivated features.

Let an observed sentence be denoted by $\mathbf{x}$, with the individual tokens x_i denoting the i'th token in the sentence. The segmentation model is a chain LVM (latent variable model) that aims to maximize a linear objective defined by:

$$J = \sum_i w_i f_i(y_k, y_{k-1}, \mathbf{x})$$

where f_i are arbitrary Markov features that can depend on segments (potential motifs) of the observed sentence $\mathbf{x}$, and contiguous latent states. The features are chosen so as to best represent frequency-based, statistical as well as linguistic considerations for treating a segment as an agglutinative unit, or a motif. In specific, these features could encode characteristics such as frequency statistics, collocation strengths and syntactic distinctness, or inflectional rigidity of the considered segments; described in detail in Section 3.2. The model is an instantiation of a simple featurized HMM, and the weighted sum of features corresponding to a segment is cognate with an affinity score for the 'stickiness' of the segment, i.e., the affinity for the segment to be treated as holistic unit or a single motif.

We also associate a penalizing cost for each non unary-motif to avoid aggressive agglutination of tokens. In particular, for an ngram occurrence to be considered a motif, the marginal contribution due to the affinity of the prospective motif should at minimum exceed this penalty. The weights for the affinity functions as well as these penalties are learnt from data using full as well as partial annotations. The latent state-variables y_k denotes the membership of the token $\mathbf{x_k}$ to a unary or a larger motif; and the state-sequence collectively gives the segmentation of the sentence. An individual state-variable y_k encodes a pairing of the size of the encompassing ngram motif, and the position of the word x_k within it. For instance, $y_k = T_3$ denotes that the token $\mathbf{x_k}$ is the final position in a trigram motif.

3.1.1 Inference of optimal segmentation

If the optimal weights w_i are known, inference for the best motif segmentation can be performed

[1] We note that since we take motifs as lineal units, the current method doesn't subsume several common non-contiguous MWEs such as 'let off' in 'let him off'.

in linear time (in the number of tokens) following the generalized Viterbi algorithm. A slightly modified version of Viterbi could also be used to find segmentations that are constrained to agree with some given motif boundaries, but can segment other parts of the sentence optimally under these constraints. This is necessary for the scenario of semi-supervised learning of weights with partially annotated sentences, as described later.

3.2 Learning motif affinities and penalties

We briefly discuss data-driven learning of weights for features that define the motif affinity scores and penalties. We describe learning of the model parameters with fully annotated training data, as well as an approach for learning motif segmentation that requires only partial supervision.

Supervised learning: In the supervised case, optimal state sequences $\mathbf{y^{(k)}}$ are fully observed for the training set. For this purpose, we created a dataset of 1000 sentences from the Simple English Wikipedia and the Gigaword Corpus, and manually annotated it with motif boundaries using BRAT (Stenetorp et al., 2012). In this case, learning can follow the online structured perceptron learning procedure by Collins (2002), where weights updates for the k'th training example $(\mathbf{x}^{(k)}, \mathbf{y}^{(k)})$ are given as:

$$w_i \leftarrow w_i + \alpha(f_i(\mathbf{x}^{(k)}, \mathbf{y}^{(k)}) - f_i(\mathbf{x}^{(k)}, \mathbf{y}'))$$

Here $\mathbf{y}' = Decode(\mathbf{x}^{(k)}, \mathbf{w})$ is the optimal Viterbi decoding using the current estimates of the weights. Updates are run for a large number of iterations until the change in objective drops below a threshold, and the learning rate α is adaptively modified as described in Collins et al. Implicitly, the weight learning algorithm can be seen as a gradient descent procedure minimizing the difference between the scores of highest scoring (Viterbi) state sequences, and the label state sequences.

Semi-supervised learning: In the semi-supervised case, the labels $y_i^{(k)}$ are known only for some of the tokens in $\mathbf{x^{(k)}}$. This is a commonplace scenario, where a part of a sentence has clear motif-boundaries, whereas the rest of the sentence is not annotated. For accumulating such data, we looked for occurrences of 2500 expressions from the WikiMWE dataset in sentences from the combined Simple English Wikipedia and Gigaword corpora. The query expressions in the retrieved sentences were marked with motif boundaries, while the remaining tokens in the sentences were left unannotated.

While the Viterbi algorithm can be used for tagging optimal state-sequences given the weights, the structured perceptron can learn optimal model weights given gold-standard sequence labels. Hence, in this case, we use a variation of the hard EM algorithm for learning. The algorithm proceeds as follows: in the E-step, we use the current values of weights to compute hard-expectations, i.e., the best scoring Viterbi sequences among those consistent with the observed state labels. In the M-step, we take the decoded state-sequences in the E-step as observed, and run perceptron learning to update feature weights w_i. Pseudocode of the learning algorithm for the partially labeled case is given in Algorithm 1.

Algorithm 1

1: **Input:** Partially labeled data $D = \{(x, y)_i\}$
2: **Output:** Weights w
3: **Initialization:** Set w_i randomly, $\forall i$
4: **for** $i : 1$ to $maxIter$ **do**
5: Decode D with current w to find optimal Viterbi paths that agree with (partial) ground truths.
6: Run Structured Perceptron algorithm with decoded tag-sequences to update weights w
7: **end for**
8: return w

The semi-supervised approach enables incorporation of significantly more training data. In particular, this method could be used in conjunction with a supervised approach. This would involve initializing the weights prior to the semi-supervised procedure with the weights from the supervised learning model, so as to seed the semi-supervised approach with reasonable model, and use the partially annotated data to fine-tune the supervised model. The sequential approach, akin to annealing weights, can efficiently utilize both full and partial annotations.

3.2.1 Feature engineering

In this section, we describe the principal features used in the segmentation model
Transitional features and penalties:

- Transitional features $f_{trans}(y_{i-1}, y_i) =$

I_{y_{i-1},y_i} [2] describing the transitional affinities of state pairs. Since our state definitions preclude certain transitions (such as from state T_2 to T_1), these weights are initialized to $-\infty$ to expedite training.

- N-gram penalties: f_{ngram} We define a penalty for tagging each non-unary motif as described before. For a motif to be tagged, the improvement in objective score should at least exceed the corresponding penalty. e.g., $f_{qgram}(y_i) = I_{y_i=Q_4}$ denotes the penalty for tagging a tetragram. [3]

Frequency-based, information theoretic, and POS features:

- Absolute and log-normalized motif frequencies $f_{ngram}(x_{i-n+1}, ...x_{i-1}, x_i, y_i)$. This feature is associated with a particular token-sequence and ngram-tag, and takes the value of the motif-frequency if the motif token-sequence matches the feature token-sequence, and is marked as with a matching tag. e.g., $f_{bgram}(x_{i-1} = love, x_i = \text{story}, y_i = B_2)$.

- Absolute and log-normalized motif frequencies for a particular POS-sequence. This feature is associated with a particular POS-tag sequence and ngram-tag, and takes the value of the motif-frequency if the motif token-sequence gets a matching tag, and is marked as with a matching ngram tag. e.g., $f_{bgram}(p_{i-1} = VB, p_i = NN, y_i = B_2)$.

- Medians and maxima of pairwise collocation statistics for tokens for a particular size of ngram motifs: we use the following statistics: pointwise mutual information, Chi-square statistic, and conditional probability. We also used POS sensitive versions of these, which performed much better than plain versions in our evaluations.

- Histogram counts of inflectional forms of token sequence for the corresponding ngram motif and POS sequence: this features takes the value of the count of inflectional forms of an ngram that account for 90% of occurrences of all inflectional forms.

- Entropies of histogram distributions of inflectional variants (described above).

- Features encoding syntactic rigidity: ratios and log-ratios of frequencies of an ngram motif and variations by replacing a token using near synonyms from its synset.

Additionally, a few feature for the segmentations model contained minor orthographic features based on word shape (length and capitalization patterns). Also, all numbers, URLs, and currency symbols were normalized to the special NUMERIC, URL, and CURRENCY tokens respectively. Finally, a gazetteer feature checked for occurrences of motifs in a gazetteer of named entities.

3.3 Representation learning

With the segmentation model described in the previous section, we process text from the English Gigaword corpus and the Simple English Wikipedia to partition sentences into motifs. Since the segmentation model accounts for the contexts of the entire sentence in determining motifs, different instances of the same token could evoke different meaning representations. Consider the following sentences tagged by the segmentation model, that would correspond to different representations of the token 'remains': once as a standalone motif, and once as part of an encompassing bigram motif ('remains classified').

Hog prices have declined sharply , while the cost of corn remains relatively high.

Even with the release of such documents, questions are not answered, since only the agency knows what remains classified

Given constituent motifs of each sentence in the data, we can now define neighbourhood distributions for unary or phrasal motifs in terms of other motifs (as envisioned in Table 1). In our experiments, we use a window-length of 5 adjoining motifs on either side to define the neighbourhood of a constituent. Naturally, in the presence of multi-word motifs, the neighbourhood boundary could be more extended than in a conventional DSM.

With such neighbourhood contexts, the distributional paradigm posits that semantic similarity between a pair of motifs can be given by a sense of 'distance' between the two distributions. Most popularly, traditional measures of vector distance

[2] Here, I denotes the indicator function

[3] It is straightforward to preclude partial n-gram annotations near sentence boundaries with prohibitive penalties.

such as the cosine similarity, Euclidean distance and City-block distance have been used in several distributional approaches. Additionally, several distance measures between discrete distributions exist in statistical literature, most famously the Kullback Leibler divergence, Bhattacharyya distance and the Hellinger distance. Recent work (Lebret and Lebret, 2013) has shown that the Hellinger distance is an especially effective measure in learning distributional embeddings, with Hellinger PCA being much more computationally inexpensive than neural language modeling approaches, while performing much better than standard PCA, and competitive with the state-of-the-art in downstream evaluations. Hence, we use the Hellinger measure between neighbourhood motif distributions in learning representations.

The Hellinger distance between two categorical distributions $P = (p_1...p_k)$ and $Q = (q_1...q_k)$ is defined as:

$$H(P,Q) = \frac{1}{\sqrt{2}}\sqrt{\sum_{i=1}^{k}(\sqrt{p_i} - \sqrt{q_i})^2}$$
$$= \frac{1}{\sqrt{2}}\left\|\sqrt{P} - \sqrt{Q}\right\|_2$$

The Hellinger measure has intuitively desirable properties: specifically, it can be seen as the Euclidean distance between the square-roots transformed distributions, where both vectors $\sqrt{P}$ and $\sqrt{Q}$ are length-normalized under the same(Euclidean) norm. Finally, we perform SVD on the motif similarity matrix (with size of the order of the total vocabulary in the corpus), and retain the first k principal eigenvectors to obtain low-dimensional vector representations that are more convenient to work with. In our preliminary experiments, we found that $k = 300$ gave quantitatively good results, with marginal change with added dimensionality. We use this setting for all our experiments.

4 Experiments

In this section, we describe some experimental evaluations and findings for our approach. We first quantitatively and qualitatively analyze the performance of the segmentation model, and then evaluate the distributional motif representations learnt by the model through two downstream applications.

4.1 Motif segmentation

In an evaluation of the motif segmentations model within the perspective of our framework, we believe that exact correspondence to human judgment is unrealistic, since guiding principles for defining motifs, such as semantic cohesion, are hard to define and only serve as working principles. However, for purposes of relative comparison, we quantitatively evaluate the performance of the motif segmentation models on the fully annotated dataset. For this experiment, the gold-annotated corpus was split into a training and test sets in a 9:1 proportion. A small fraction of the training split was set apart for development and validation. For this evaluation, we considered a motif boundary as correct only for an exact match, i.e., when both its boundaries (left and right) were correctly predicted. Also, since a majority of motifs are unary tokens, including them into consideration artificially boosts the accuracy, whereas we are more interested in the prediction of larger n-gram tokens. Hence we report results on the performance on only non-unary motifs.

	P	**R**	**F**
Rule-based baseline	0.85	0.10	0.18
Supervised	0.62	0.28	0.39
Semi-supervised	0.30	0.17	0.22
Supervised + annealing	0.69	0.38	0.49

Table 2: Results for motif segmentations

Table 2 shows the performance of the segmentation model with the three proposed learning approaches described earlier. For a baseline, we consider a rule-based model that simply learns all ngram segmentations seen in the training data, and marks any occurrence of a matching token sequence as a motif; without taking neighbouring context into account. We observe that this model has a very high precision (since many token sequences marked as motifs would recur in similar contexts, and would thus have the same motif boundaries). However, the rule-based method has a very row recall due to lack of generalization capabilities. We see that while all three learning algorithms perform better than the baseline, the performance of the purely unsupervised system is inferior to supervised approaches. This is not unexpected: the supervision provided to the model is very weak due to a lack of negative examples (which leads to spurious motif taggings,

While men often (openly or privately) sympathized with Prince Charles when the princess went public about her rotten marriage , women cheered her on.
The healthcare initiative has become a White elephant for the federal government.
Chirac and Juppe have made a bad situation worse by seeking to meet Maastricht criteria not by cutting spending, but by raising taxes still further.
Now , say Vatican observers , Pope John Paul II wants to show the world that many church members did resist the Third Reich and paid the price.

Table 3: Examples of output from sentence segmentation model

leading to a low precision), as well as no examples of transitions between adjacent motifs (to learn transitional weights and penalties). The supervised model expectedly outperforms both the rule-based and the semi-supervised systems. However, the supervised learning model with subsequent annealing outperforms the supervised model in terms of both precision and recall; showing the utility of the semi-supervised method when seeded with a good initial model, and the additive value of partially labeled data.

Qualitative analysis of motif-segmented sentences shows that our designed feature-set is effective and helpful in identifying semantically cohesive ngrams. Table 3 provides four examples. The first example correctly identifies 'went public', while missing out on the potential motif 'cheered her on'. In general, these examples illustrate that the model can identify idiomatic and idiosyncratic themes as well as commonly recurrent ngrams (in the second example, the model picks out 'has become' which is highly recurrent, but doesn't have the semantic cohesiveness of some of the other motifs). In particular, consider the second example, where the model picks 'white elephant' as a motif. In such cases, the disambiguating influence of context incorporated by the motif is apparent.

Elephant	White elephant
tusks	expensive
trunk	spend
african	biggest
white	the project
indian	very high
baby	multibillion dollar

The above table shows some of the top results for the unary token 'elephant' by frequency, and frequent unary and non-unary motifs for the motif 'white elephant' retrieved by the segmentation model.

4.2 Distributional representations

For evaluating distributional representations for motifs (in terms of other motifs) learnt by the framework, we test these representations in two downstream tasks: sentence polarity classification and metaphor detection. For sentence polarity, we consider the Cornell Sentence Polarity corpus by Pang and Lee (2005), where the task is to classify the polarity of a sentence as positive or negative. The data consists of 10662 sentences from movie reviews that have been annotated as either positive or negative. For composing the motifs representations to get judgments on semantic similarity of sentences, we use our recent Vector Tree Kernel approach The VTK approach defines a convolutional kernel over graphs defined by the dependency parses of sentences, using a vector representation at each graph node that representing a single lexical token. For our purposes, we modify the approach to merge the nodes of all tokens that constitute a motif occurrence, and use the motif representation as the vector associated with the node. Table 4 shows results for the sentence polarity task.

	P	**R**	**F1**
DSM	0.56	0.50	0.53
AVM	0.55	0.53	0.54
MVM	0.55	0.49	0.52
VTK	0.65	0.58	0.62
VTK + MotifDSM	**0.66**	**0.60**	**0.63**

Table 4: Results for Sentence Polarity detection

For this task, the motif based distributional embeddings vastly outperform a conventional distributional model (DSM) based on token distributions, as well as additive (AVM) and multiplicative (MVM) models of vector compositionality, as

proposed by Lapata et al. The model is competitive with the state-of-the-art VTK (Srivastava et al., 2013) that uses the SENNA neural embeddings by Collobert et al. (2011).

	P	R	F1
CRF	**0.74**	0.50	0.59
SVM+DSM	0.63	0.80	0.71
VTK+ SENNA	0.67	**0.87**	0.76
VTK+ MotifDSM	0.70	**0.87**	**0.78**

Table 5: Results for Metaphor identification

On the metaphor detection task, we use the Metaphor dataset (Hovy et al., 2013). The data consists of sentences with defined phrases, and the task consists of identifying the linguistic use in these phrases as metaphorical or literal. For this task, the motif based model is expected to perform well as common metaphorical usage is generally through idiosyncratic MWEs, which the motif based models is specially geared to capture through the features of the segmentation model. For this task, we again use the VTK formalism for combining vector representations of the individual motifs. Table 5 shows that the motif-based DSM does better than discriminative models such as CRFs and SVMs, and also slightly improves on the VTK kernel with distributional embeddings.

5 Conclusion

We have presented a new frequency-driven framework for distributional semantics of not only lexical items but also longer cohesive motifs. The theme of this work is a general paradigm of seeking motifs that are recurrent in common parlance, are semantically coherent, and are possibly non-compositional. Such a framework for distributional models avoids the issue of data sparsity in learning of representations for larger linguistic structures. The approach depends on drawing features from frequency statistics, statistical correlations, and linguistic theories; and this work provides a computational framework to jointly model recurrence and semantic cohesiveness of motifs through compositional penalties and affinity scores in a data driven way.

While being deliberately vague in our working definition of motifs, we have presented simple efficient formulations to extract such motifs that uses both annotated as well as partially unannotated data. The qualitative and quantitative analyis of results from our preliminary motif segmentation model indicate that such motifs can help to disambiguate contexts of single tokens, and provide cleaner, more interpretable representations. Finally, we obtain motif representations in form of low-dimensional vector-space embeddings, and our experimental findings indicate value of the learnt representations in downstream applications. We believe that the approach has considerable theoretical as well as practical merits, and provides a simple and clean formulation for modeling phrasal and sentential semantics.

In particular, we believe that ours is the first method that can invoke different meaning representations for a token depending on textual context of the sentence. The flexibility of having separate representations to model different semantic senses has considerable valuable, as compared with extant approaches that assign a single representation to each token, and are hence constrained to conflate several semantic senses into a common representation. The approach also elegantly deals with the problematic issue of differential compositional and non-compositional usage of words. Future work can focus on a more thorough quantitative evaluation of the paradigm, as well as extension to model non-contiguous motifs.

Lexical Inference over Multi-Word Predicates: A Distributional Approach

Omri Abend Shay B. Cohen Mark Steedman

School of Informatics, University of Edinburgh,
Edinburgh EH8 9AB, United Kingdom
{oabend,scohen,steedman}@inf.ed.ac.uk

Abstract

Representing predicates in terms of their argument distribution is common practice in NLP. Multi-word predicates (MWPs) in this context are often either disregarded or considered as fixed expressions. The latter treatment is unsatisfactory in two ways: (1) identifying MWPs is notoriously difficult, (2) MWPs show varying degrees of compositionality and could benefit from taking into account the identity of their component parts. We propose a novel approach that integrates the distributional representation of multiple sub-sets of the MWP's words. We assume a latent distribution over sub-sets of the MWP, and estimate it relative to a downstream prediction task. Focusing on the supervised identification of lexical inference relations, we compare against state-of-the-art baselines that consider a single sub-set of an MWP, obtaining substantial improvements. To our knowledge, this is the first work to address lexical relations between MWPs of varying degrees of compositionality within distributional semantics.

1 Introduction

Multi-word expressions (MWEs) constitute a large part of the lexicon and account for much of its growth (Jackendoff, 2002; Seaton and Macaulay, 2002). However, despite their importance, MWEs remain difficult to define and model, and consequently pose serious difficulties for NLP applications (Sag et al., 2001). Multi-word Predicates (MWPs; sometimes termed Complex Predicates) form an important and much addressed subclass of MWEs and are the focus of this paper.

MWPs are informally defined as multiple words that constitute a single predicate (Alsina et al., 1997). MWPs encompass a wide range of phenomena, including causatives, light verbs, phrasal verbs, serial verb constructions and many others, and pose considerable challenges to both linguistic theory and NLP applications (see Section 2). Part of the difficulty in treating them stems from their position on the borderline between syntax and the lexicon. It is therefore often unclear whether they should be treated as fixed expressions, as compositional phrases that reflect the properties of their component parts or as both.

This work addresses the modelling of MWPs within the context of distributional semantics (Turney and Pantel, 2010), in which predicates are represented through the distribution of arguments they may take. In order to collect meaningful statistics, the predicate's lexical unit should be sufficiently frequent and semantically unambiguous.

MWPs pose a challenge to such models, as naïvely collecting statistics over all instances of highly ambiguous verbs is likely to result in noisy representations. For instance, the verb "take" may appear in MWPs as varied as "take time", "take effect" and "take to the hills". This heterogeneity of "take" is likely to have a negative effect on downstream systems that use its distributional representation. For instance, while "take" and "accept" are often considered lexically similar, the high frequency in which "take" participates in non-compositional MWPs is likely to push the two verbs' distributional representations apart.

A straightforward approach to this problem is to represent the predicate as a conjunction of multiple words, thereby trading ambiguity for sparsity. For instance, the verb "take" could be conjoined with its object (e.g., "take care", "take a bus"). This approach, however, raises the challenge of identifying the sub-set of the predicate's words that should be taken to represent it (henceforth, its *lexical components* or LCs).

We propose a novel approach that addresses this

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 644–654,
Baltimore, Maryland, USA, June 23-25 2014.

challenge in the context of identifying lexical inference relations between predicates (Lin and Pantel, 2001; Schoenmackers et al., 2010; Melamud et al., 2013a, *inter alia*). A (lexical) inference relation $p_L \rightarrow p_R$ is said to hold if the relation denoted by p_R generally holds between a set of arguments whenever the relation p_L does. For instance, an inference relation holds between "annex" and "control" since if a country annexes another, it generally controls it. Most works to this task use distributional similarity, either as their main component (Szpektor and Dagan, 2008; Melamud et al., 2013b), or as part of a more comprehensive system (Berant et al., 2011; Lewis and Steedman, 2013).

For example, consider the verb "take". While the inference relation "*have* → *take*" does not generally hold, it does hold in the case of some light verbs, such as "*have a look* → *take a look*", underscoring the importance of taking more inclusive LCs into account. On the other hand, the predicate "likely to give a green light" is unlikely to appear often even within a very large corpus, and could benefit from taking its lexical sub-units (e.g., "likely" or "give a green light") into account.

We present a novel approach to the task that models the selection and relative weighting of the predicate's LCs using latent variables. This approach allows the classifier that uses the distributional representations to take into account the most relevant LCs in order to make the prediction. By doing so, we avoid the notoriously difficult problem of defining and identifying MWPs and account for predicates of various sizes and degrees of compositionality. To our knowledge, this is the first work to address lexical relations between MWPs of varying degrees of compositionality within distributional semantics.

We conduct experiments on the dataset of Zeichner et al. (2012) and compare our methods with analogous ones that select a fixed LC, using state-of-the-art feature sets. Our method obtains substantial performance gains across all scenarios.

Finally, we note that our approach is cognitively appealing. Significant cognitive findings support the claim that a speaker's lexicon consists of partially overlapping lexical units of various sizes, of which several can be evoked in the interpretation of an utterance (Jackendoff, 2002; Wray, 2008).

2 Background and Related Work

Inference Relations. The detection of inference relations between predicates has become a central task over the past few years (Sekine, 2005; Zanzotto et al., 2006; Schoenmackers et al., 2010; Berant et al., 2011; Melamud et al., 2013a, *inter alia*). Inference rules are used in a wide variety of applications including Question Answering (Ravichandran and Hovy, 2002), Information Extraction (Shinyama and Sekine, 2006), and as a main component in Textual Entailment systems (Dinu and Wang, 2009; Dagan et al., 2013).

Most approaches to the task used distributional similarity as a major component within their system. Lin and Pantel (2001) introduced DIRT, an unsupervised distributional system for detecting inference relations. The system is still considered a state-of-the-art baseline (Melamud et al., 2013a), and is often used as a component within larger systems. Schoenmackers et al. (2010) presented an unsupervised system for learning inference rules directly from open-domain web data. Melamud et al. (2013a) used topic models to combine type-level predicate inference rules with token-level information from their arguments in a specific context. Melamud et al. (2013b) used lexical expansion to improve the representation of infrequent predicates. Lewis and Steedman (2013) combined distributional and symbolic representations, evaluating on a Question Answering task, as well as on a quantification-focused entailment dataset.

Several studies tackled the task using supervised systems. Weisman et al. (2012) used a set of linguistically motivated features, but evaluated their system on a corpus that consists almost entirely of single-word predicates. Mirkin et al. (2006) presented a system for learning inference rules between nouns, using distributional similarity and pattern-based features. Hagiwara et al. (2009) identified synonyms using a supervised approach relying on distributional and syntactic features. Berant et al. (2011) used distributional similarity between predicates to weight the edges of an entailment graph. By imposing global constraints on the structure of the graph, they obtained a more accurate set of inference rules.

Previous work used simple methods to select the predicate's LC. Some filtered out frequent highly ambiguous verbs (Lewis and Steedman, 2013), others selected a single representative word (Melamud et al., 2013a), while yet others used multi-word LCs but treated them as fixed expressions (Lin and Pantel, 2001; Berant et al., 2011).

The goals of the above studies are largely com-

plementary to ours. While previous work focused either on improving the quality of the distributional representations themselves or on their incorporation into more elaborate systems, we focus on the integration of the distributional representation of multiple LCs to improve the identification of inference relations between MWPs.

MWP Extraction and Identification. MWPs have received considerable attention over the years in both theoretical and applicative contexts. Their position on the crossroads of syntax and the lexicon, their varying degrees of compositionality, as well as the wealth of linguistic phenomena they exhibit, made them the object of ongoing linguistic discussion (Alsina et al., 1997; Butt, 2010).

In NLP, the discovery and identification of MWEs in general and MWPs in particular has been the focus of much work over the years (Lin, 1999; Baldwin et al., 2003; Biemann and Giesbrecht, 2011). Despite wide interest, the field has yet to converge to a general and widely agreed-upon method for identifying MWPs. See (Ramisch et al., 2013) for an overview.

Most work on MWEs emphasized idiosyncratic or non-compositional expressions. Other lines of work focused on specific MWP classes such as light verbs (Tu and Roth, 2011; Vincze et al., 2013) and phrasal verbs (McCarthy et al., 2003; Pichotta and DeNero, 2013). Our work proposes a uniform treatment to MWPs of varying degrees of compositionality, and avoids defining MWPs explicitly by modelling their LCs as latent variables.

Compositional Distributional Semantics. Much work in recent years has concentrated on the relation between the distributional representations of composite phrases and the representations of their component sub-parts (Widdows, 2008; Mitchell and Lapata, 2010; Baroni and Zamparelli, 2010; Coecke et al., 2010). Several works have used compositional distributional semantics (CDS) representations to assess the compositionality of MWEs, such as noun compounds (Reddy et al., 2011) or verb-noun combinations (Kiela and Clark, 2013). Despite significant advances, previous work has mostly been concerned with highly compositional cases and does not address the distributional representation of predicates of varying degrees of compositionality.

3 Our Proposal: A Latent LC Approach

This section details our approach for distributionally representing MWPs by leveraging their component LCs. Section 3.1 describes our general approach, Section 3.2 presents our model and Section 3.3 details the feature set.

3.1 General Approach and Notation

We propose a method for addressing MWPs of varying degrees of compositionality through the integration of the distributional representation of multiple sub-sets of the predicate's words (LCs). We use it to tackle a supervised prediction task that represents predicates distributionally. Our model assumes a latent distribution over the LCs, and estimates its parameters so to best conform to the goals of the target prediction task.

Formally, given a predicate p, we denote the set of words comprising it as $W(p)$. The set of allowable LCs for p is denoted with $H_p \subset 2^{W(p)}$. H_p contains all sub-sets of p that we consider as apriori possible to represent p. For instance, if p is "likely to give a green light", H_p may include LCs such as "likely" or "give light". As our method is aimed at discovering the most relevant LCs, we do not attempt to analyze the MWPs in advance, but rather take an inclusive H_p, allowing the model to estimate the relative weights of the LCs.

The task we use as a testbed for our approach is the lexical inference identification task between predicates. Given a pair of predicates $p = (p_L, p_R)$, the task is to predict whether an inference relation holds between them. For instance, if p_L is "devour" and p_R is "eat greedily", the classifier should use the similarity between "devour" and "eat" in order to correctly predict an inference relation in this case. Selecting the wider LC "eat greedily" might result in sparser statistics. In other examples, however, taking a wider LC is potentially beneficial. For instance, the dissimilarity between "take" and "make" should not prevent the classifier from identifying the inference relation between "take a step" and "make a step".

Our statistical model aims at predicting the correct label by making use of partially overlapping LCs of various sizes, both for the premise left-hand side (LHS) predicate p_L and the hypothesis right-hand side (RHS) predicate p_R. More formally, we take the space of values for our latent LC variables to be $H_{p_L,p_R} = H_{p_L} \times H_{p_R}$.

Our evaluation dataset consists of pairs $p^{(i)} = (p_L^{(i)}, p_R^{(i)})$ for $i \in \{1, \ldots, M\}$, where M is the number of examples available, coupled with their gold-standard labels $y^{(i)} \in \{1, -1\}$. For brevity, we denote $H^{(i)} = H_{p^{(i)}} = H_{p_L^{(i)}, p_R^{(i)}}$. We also as-

sume the existence of a feature function $\Phi(p, y, h)$ which maps a triplet of a predicate pair p, an inference label y, and a latent state $h \in H_p$ to $\mathbb{R}^d$ for some integer d. We denote the training set by $\mathcal{D}$.

3.2 The Model

We address the task with a latent variable log-linear model, representing the LCs of the predicates. We choose this model for its generality, conceptual simplicity, and because it allows to easily incorporate various feature sets and sets of latent variables. We introduce L_2 regularization to avoid over-fitting. We use maximum likelihood estimation, and arrive at the following objective function:

$$L(w|\mathcal{D}) = \frac{1}{M}\sum_{i=1}^{M} \log P(y^{(i)}|p^{(i)}, w) - \frac{\lambda}{2}\|w\|^2 =$$

$$= \frac{1}{n}\sum_{i=1}^{n}\left(\log \sum_{h \in H^{(i)}} \exp\left(w^\top \Phi(p^{(i)}, y^{(i)}, h)\right) - \log Z(w, i)\right) - \frac{\lambda}{2}\|w\|^2$$

where:

$$Z(w, i) = \sum_{y \in \{-1,1\}} \sum_{h \in H^i} \exp(w^\top \Phi(p_i, y, h)).$$

We maximize L using the BFGS algorithm (Nocedal and Wright, 1999). The gradient (with respect to w) is the following:

$$\nabla L = \mathbb{E}_h[\Phi(p_i, y_i, h)] - \mathbb{E}_{h,y}[\Phi(p_i, y, h)] - \lambda \cdot w$$

H_p can be defined to be any sub-set of $2^{W(p)}$ given that taking an expectation over H can be done efficiently. It is therefore possible to use prior linguistic knowledge to consider only sub-sets of p that are likely to be non-compositional (e.g., verb-preposition or verb-noun pairs).

In our experiments we attempt to keep the approach maximally general, and define H_p to be the set of all subsets of size 1 or 2 of content words in W_p[1]. We bound the size of $h \in H_p$ in order to retain computational efficiency and a sufficient frequency of the LCs in H_p. MWPs of length greater than 2 are effectively approximated by their set of subsets of sizes 1 and 2.

Each h can therefore be written as a 4-tuple $(h_L^A, h_L^B, h_R^A, h_R^B)$, where h_L^A (h_R^A) denotes the first word of the LHS (RHS) predicate's LC. h_L^B (h_R^B) denotes the (possibly empty) second word of the predicate. Inference is carried out by maximizing $P(y|p^{(i)})$ over y. As $|H_p| = O(k^4)$, where k is the number of content words in p, and as the number of content words is usually small[2], inference can be carried out by directly summing over $H^{(i)}$.

Initialization. The introduction of latent variables into the log-linear model leads to a non-convex objective function. Consequently, BFGS is not guaranteed to converge to the global optimum, but rather to a stationary point. The result may therefore depend on the parameter initialization. Indeed, preliminary experiments showed that both initializing w to be zero and using a random initializer results in lower performance.

Instead, we initialize our model with a simplified convex model that fixes the LCs to be the pair of left-most content words comprising each of the predicates. This is a common method for selecting the predicate's LC (e.g., Melamud et al., 2013a). Once h has been fixed, the model collapses to a convex log-linear model. The optimal w is then taken as an initialization point for the latent variable model. While this method may still not converge to the global maximum, our experiments show that this initialization technique yields high quality values for w (see Section 6).

3.3 Feature Set

This section lists the features used for our experiments. We intentionally select a feature set that relies on either completely unsupervised or shallow processing tools that are available for a wide variety of languages and domains.

Given a predicate pair $p^{(i)}$, a label $y \in \{1, -1\}$ and a latent state $h \in H^{(i)}$, we define their feature vector as $\Phi(p^{(i)}, y, h) = y \cdot \Phi(p^{(i)}, h)$. The computation of $\Phi(p^{(i)}, h)$ requires a reference corpus $\mathcal{R}$ that contains triplets of the type (p, x, y) where p is a binary predicate and x and y are its arguments. We use the Reverb corpus as $\mathcal{R}$ in our experiments (Fader et al., 2011; see Section 4). We refrain from encoding features that directly reflect the vocabulary of the training set. Such features are not applicable beyond that set's vocabulary, and as available datasets contain no more than a few thousand examples, these features are unlikely to generalize well.

Table 1 presents the set of features we use in our experiments. The features can be divided into two main categories: similarity features between the LHS and the RHS predicates (table's top), and features that reflect the individual properties of each

[1] We use a POS tagger to identify content words. Prepositions are considered content words under this definition.

[2] $|H_p|$ is about 15 on average in our dataset, where less than 5% of the $H^{(i)}$ are of size greater than 50.

Category		Name	Description
	Similarity	COSINE	DIRT cosine similarity between the vectors of h_L and h_R
		$\mathrm{COSINE_A}$	DIRT cosine similarity between the vectors of h_L^A and h_R^A
		BInc	DIRT BInc similarity between the vectors of h_L and h_R
		$\mathrm{BInc_A}$	DIRT BInc similarity between the vectors of h_L^A and h_R^A
	Word A LHS	$\mathrm{POS_L^A}$	The most frequent POS tag for the lemma of h_L^A
		$\mathrm{POS2_L^A}$	The second most frequent POS tag for the word lemma of h_L^A
		$\mathrm{FREQ_L^A}$	The number of occurrences of h_L^A in the reference corpus
		$\mathrm{COMMON_L^A}$	A binary feature indicating whether h_L^A appears in both predicates
		$\mathrm{ORDINAL_L^A}$	The ordinal number of h_L^A among the content words of the LHS predicate
	Pair LHS	$\mathrm{POS_L^{AB}}$	The conjunction of POS_L^A and POS_L^B
		$\mathrm{FREQ_L^{AB}}$	The frequency of h_L^A and h_L^B in the reference corpus
		$\mathrm{PREFAB_L}$	$P(h_L^A \mid h_L^A)$ as estimated from the reference corpus
		$\mathrm{PREFBA_L}$	$P(h_L^B \mid h_L^A)$ as estimated from the reference corpus
		$\mathrm{PMIAB_L}$	The point-wise mutual information of h_L^A and h_L^B
	LDA	$\mathrm{TOPICS_L}$	$P(\mathrm{topic} \mid h_L)$ for each of the induced topics.
		$\mathrm{TOPICENT_L}$	The entropy of the topic distribution $P(\mathrm{topic} \mid h_L)$

Table 1: The feature set used in our experiments. The top part presents the similarity measures based on the DIRT approach. The rest of the listed features apply to the LHS predicate (h_L), and to the first word in it (h_L^A). Analogous features are introduced for the second word, h_L^B, and for the RHS predicate. The upper-middle part presents the word features for h_L^A. The lower-middle part presents features that apply where h_L is of size 2. The bottom part lists the LDA-based features.

of them. Within the LHS feature set, we distinguish between two sub-types of features: word features that encode the individual properties of h_L^A and h_L^B (table's upper middle part), and pair features that only apply to LCs of size 2 and reflect the relation between h_L^A and h_L^B (table's lower middle part). We further incorporate LDA-based features that reflect the selectional preferences of the predicates (table's bottom).

Distributional Similarity Features. The distributional similarity features are based on the DIRT system (Lin and Pantel, 2001). The score defines for each predicate p and for each argument slot $s \in \{L, R\}$ (corresponding to the arguments to the right and left of that predicate) a vector v_s^p which represents the distribution of arguments appearing in that slot. We take $v_s^p(x)$ to be the number of times that the argument x appeared in the slot s of the predicate p. Given these vectors, the similarity between the predicates p_1 and p_2 is defined as:

$$\mathrm{score}(p_1, p_2) = \sqrt{\mathrm{sim}(v_L^{p_1}, v_L^{p_2}) \cdot \mathrm{sim}(v_R^{p_1}, v_R^{p_2})}$$

where sim is some vector similarity measure.

We use two common similarity measures: the vector cosine metric, and the BInc (Szpektor and Dagan, 2008) similarity measure. These measures give complementary perspectives on the similarity between the predicates, as the cosine similarity is symmetric between the LHS and RHS predicates, while BInc takes into account the directionality of the inference relation. Preliminary experiments with other measures, such as those of Lin (1998) and Weeds and Weir (2003) did not yield additional improvements.

We encode the similarity of all measures for the pair h_L and h_R as well as the pair h_L^A and h_R^A. The latter feature is an approximation to the similarity between the heads of the predicates, as heads in English tend to be to the left of the predicates. These two features coincide for h values of size 1.

Word and Pair Features. These features encode the basic properties of the LC. The motivation behind them is to allow a more accurate leveraging of the similarity features, as well as to better determine the relative weights of $h \in H^{(i)}$.

The feature set is composed of four analogous sets corresponding to h_L^A,h_L^B,h_R^A and h_R^B, as well as two sets of features that capture relations between h_L^A, h_L^B and h_R^A, h_R^B (in cases h is of size 2). The features include the ordinal index of the word within the predicate, the lemma's frequency according to $\mathcal{R}$, and a feature that indicates whether that word's lemma also appears in both predicates of the pair. For instance, when considering the predicates "likely to come" and "likely to leave", "likely" appears in both predicates, while "come" and "leave" appear only in one of them.

In addition, we use POS-based features that encode the most frequent POS tag for the word lemma and the second most frequent POS tag (according to $\mathcal{R}$). Information about the second most frequent POS tag can be important in identifying light verb constructions, such as "take a swim" or "give a smile", where the object is derived from a verb. It can thus be interpreted as a generalization

of the feature that indicates whether the object is a deverbal noun, which is used by some light verb identification algorithms (Tu and Roth, 2011).

In cases where h_L is of size 2, we additionally encode features that apply to the conjunction of h_L^A and h_L^B. We encode the conjunction of their POS and the number of times the two lemmas occurred together in $\mathcal{R}$. We also introduce features that capture the statistical correlation between the words of h_L. To do so, we use point-wise mutual information, and the conditional probabilities $P(h_L^A|h_L^B)$ and $P(h_L^B|h_L^A)$. Similar measures have often been used for the unsupervised detection of MWEs (Villavicencio et al., 2007; Fazly and Stevenson, 2006). We also include the analogous set of features for h_R.

LDA-based Features. We further incorporate features based on a Latent Dirichlet Allocation (LDA) topic model (Blei et al., 2003). Several recent works have underscored the usefulness of using topic models to model a predicate's selectional preferences (Ritter et al., 2010; Dinu and Lapata, 2010; Séaghdha, 2010; Lewis and Steedman, 2013; Melamud et al., 2013a). We adopt the approach of Lewis and Steedman (2013), and define a pseudo-document for each LC in the evaluation corpus. We populate the pseudo-documents of an LC with its arguments according to $\mathcal{R}$. We then train an LDA model with 25 topics over these documents. This yields a probability distribution $P(\text{topic}|h)$ for each LC h, reflecting the types of arguments h may take.

We further include a feature for the entropy of the topic distribution of the predicate, which reflects its heterogeneity. This feature is motivated by the assumption that a heterogeneous predicate is more likely to benefit from selecting a more inclusive LC than a homogeneous one.

Technical Issues. All features used, except the similarity ones and the topic distribution features are binary. Frequency features are binned into 4 bins of equal frequency. We conjoin some of the feature sets by multiplying their values. Specifically, we add the cross product of the features of the category "Similarity" (see Table 1) with the rest of the features. In addition, we conjoin all LHS (RHS) features with an indicator feature that indicates whether h_L (h_R) is of size two. This results in 1605 non-constant features.

We further note that some LCs that appear in the evaluation corpus do not appear at all in $\mathcal{R}$. In our experiments they amounted to 0.2% of the LCs in our evaluation dataset. While previous work often discarded predicates below a certain frequency from the evaluation, we include them in order to facilitate comparison to future work. We assign the similarity features of such examples a 0 value, and assign their other numerical features the mean value of those features.

4 Experimental Setup

Corpora and Preprocessing. As a reference corpus $\mathcal{R}$, we use Reverb (Fader et al., 2011), a web-based corpus consisting of 15M web extractions of binary relations. Each relation is a triplet of a predicate and two arguments, one preceding it and one following it. Relations were extracted using regular expressions over the output of a POS tagger and an NP chunker. Each predicate may consist of a single verb, a verb and a preposition or a sequence of words starting in a verb and ending in a preposition, between which there may nouns, adjectives, adverbs, pronouns, determiners and verbs. The verb may also be a copula. Examples of predicates are "make the most of", "could be exchanged for" and "is happy with".

Reverb is an appealing reference corpus for this task for several reasons. First, it uses fairly shallow preprocessing technology which is available for many domains and languages. Second, Reverb applies considerable noise filtering, which results in extractions of fair quality. Third, our evaluation dataset is based on Reverb extractions.

We evaluate our algorithm on the dataset of Zeichner et al. (2012). This publicly available corpus[3] provides pairs of Reverb binary relations and an indication of whether an inference relation holds between them within the context of a specific pair of argument fillers. The corpus was compiled using distributional methods to detect pairs of relations in Reverb that are likely to have an inference relation between. Annotators, employed through Amazon Mechanical Turk, were then asked to determine whether each pair is meaningful, and if so, to determine whether an inference relation holds. Further measures were taken to monitor the accuracy of the annotation.

For example, the pair of predicates "make the most of" and "take advantage of" appears in the corpus as a pair between which an inference relation holds. The arguments in this case are "students" and "their university experience". An ex-

[3] http://tinyurl.com/krx2acd

ample of a pair between which an inference relation does not hold is "tend to neglect" and "underestimate the importance of", where the arguments are "Robert" and "his family".

The dataset contains 6,565 instances in total. We use 5,411 pairs of them, discarding instances that were deemed as meaningless by the annotators. We also discard cases where the set of arguments is reversed between the LHS and RHS predicates. In these examples, $p_R(x, y)$ is inferable from $p_L(y, x)$, rather than from $p_L(x, y)$. As there are less than 150 reversed instances in the corpus, experimenting on this sub-set is unlikely to be informative.

The average length of a predicate in the corpus is 2.7 words (including function words). In 87.3% of the predicate pairs, there was more than one LC (i.e., $|H_p| > 1$), underscoring the importance of correctly leveraging the different LCs. We randomly partition the corpus into a training set which contains 4,343 instances (∼80%), and a test set that contains 1,068 instances, maintaining the same positive to negative label ratio in both datasets[4]. Development was carried out using cross-validation on the training data (see below).

We use a Maximum Entropy POS Tagger, trained on the Penn Treebank, and the WordNet lemmatizer, both implemented within the NLTK package (Loper and Bird, 2002). To obtain a coarse-grained set of POS tags, we collapse the tag set to 7 categories: nouns, verbs, adjectives, adverbs, prepositions, the word "to" and a category that includes all other words. A Reverb argument is represented as the conjunction of its content words that appear more than 10 times in the corpus. Function words are defined according to their POS tags and include determiners, possessive pronouns, existential "there", numbers and coordinating conjunctions. Auxiliary verbs and copulas are also considered function words.

To compute the LDA features, we use the online variational Bayes algorithm of (Hoffman et al., 2010) as implemented in the *Gensim* software package (Rehurek and Sojka, 2010).

Evaluated Algorithms. The only two previous works on this dataset (Melamud et al., 2013a; Melamud et al., 2013b) are not directly comparable, as they used unsupervised systems and evaluated on sub-sets of the evaluation dataset. Instead, we use several baselines to demonstrate the usefulness of integrating multiple LCs, as well as the relative usefulness of our feature sets.

The simplest baseline is ALLNEG, which predicts the most frequent label in the dataset (in our case: "no inference"). The other evaluated systems are formed by taking various subsets of our feature set. We experiment with 4 feature sets. The smallest set, SIM, includes only the similarity features. This feature set is related to the compositional distributional model of Mitchell and Lapata (2010) (see Section 6). We note that despite recent advances in identifying predicate inference relations, the DIRT system (Lin and Pantel, 2001) remains a strong baseline, and is often used as a component in state-of-the-art systems (Berant et al., 2011), and specifically in the two aforementioned works that used the same evaluation corpus.

The next feature set BASIC includes the features found to be most useful during the development of the model: the most frequent POS tag, the frequency features and the feature Common. More inclusive is the feature set NO-LDA, which includes all features except the LDA features. Experiments with this set were performed in order to isolate the effect of the LDA features. Finally, ALL includes our complete set of features.

The more direct comparison is against partial implementations of our system where the LC h is deterministically selected. Determining h for each predicate yields a regular log-linear binary classification model. We use two variants of this baseline. The first, LEFTMOST, selects the left-most content word for each predicate. Similar selection strategy was carried out by Melamud et al. (2013a). The second, VPREP, selects h to be the verb along with its following preposition. In cases the predicate contains multiple verbs, the one preceding the preposition is selected, and where the predicate does not contain any non-copula verbs, it regresses to LEFTMOST. This LC selection method approximates a baseline that includes subcategorized prepositions. Such cases are highly frequent and account for a large portion of the MWPs in English. Including a verb's preposition in its LC was commonly done in previous work (e.g., Lewis and Steedman, 2013).

We also attempted to identify verb-preposition constructions using a dependency parser. Unfortunately, our evaluation dataset is only available in

[4]A script that replicates our train-test partition of the corpus can be found here: `http://homepages.inf.ed.ac.uk/oabend/mwpreds.html`

a lemmatized version, which posed a difficulty for the parser. Due to the low quality of the resulting parses, we implemented VPREP using POS-based regular expressions as defined above.

The full model is denoted with LATENTLC. For each system and feature set, we report results using 10-fold cross-validation on the training set, as well as results on the test set. Both cases use the same set of parameters determined by cross-validation on the training set. As the task at hand is a binary classification problem, we use accuracy scores to rate the performance of our systems.

5 Results

Table 2 presents the results of our experiments. Rows correspond to the evaluated algorithms, while columns correspond to the feature sets used and the evaluation scenarios (i.e., training set cross-validation or test set evaluation). Our experiments make first use of this dataset in its fullest form for the problem of supervised learning of inference relations, and may serve as a starting point for further exploration of this dataset.

For all feature sets and settings, LATENTLC scored highest, often with a considerable margin of up to 3.0% in the cross-validation and up to 4.6% on the test set relative to the LEFTMOST baseline, and 5.1% (cross-validation) and 6.8% (test) margins relative to VPREP.

The best scoring result of our LATENTLC model in the cross-validation scenario is 65.72%, obtained by the feature set All. The best scoring result by any of the baseline models in this scenario is 62.7%, obtained by the same feature set. For the test set scenario, LATENTLC obtained its highest accuracy, 65.73%, when using the feature set Basic. This is a substantial improvement over the highest scoring baseline model in this scenario that obtained 61.6% accuracy, using the feature set All. This performance gap is substantial when taking into consideration that the improvements obtained by the highly competitive DIRT similarity features using the stronger LEFTMOST baseline, result in an improvement of 3.1% and 5.3% over the trivial ALLNEG baseline in the test set and cross-validation scenarios respectively.

Comparing the different feature sets on our proposed model, we find that the Basic feature set gives a consistent and substantial increase over the Sim feature set. Improvements are of 2.8% (test) and 2.2% (cross-validation). Introducing more elaborate features (i.e., the feature sets NoLDA and All) yields some improvements in the cross-validation, but these improvements are not replicated on the test set. This may be due to idiosyncrasies in the test set that are averaged out in the cross-validation scenario.

For a qualitative analysis, we took the best performing model of the data set (i.e., with the Basic feature set), and extracted the set of instances where it made a correct prediction while both baselines made an error. This set contains many verb-preposition pairs, such as "list as → report as" or "submit via → deliver by", underscoring the utility of leveraging multiple LCs rather than considering only a head word (as with LEFTMOST) or the entire phrase (as with VPREP). Other examples in this set contain more complex patterns. These include the positive pairs "talk much about → have much to say about" and "increase with → go up with", and the negative "make prediction about → meet the challenge of" and "enjoy watching → love to play".

6 Discussion

Relation to CDS. Much recent work subsumed under the title *Compositional Distributional Semantics* addressed the distributional representation of multi-word phrases (see Section 2). This line of work focuses on compositional predicates, such as "kick the ball" and not on idiosyncratic predicates such as "kick the bucket".

A variant of the CDS approach can be framed within ours. Assume we wish to compute the similarity of the predicates $p_L = (w_1, ..., w_n)$ and $p_R = (w'_1, ..., w'_m)$. Let us denote the vector space representations of the individual words as $v_1, ..., v_n$ and $v'_1, ..., v'_m$ respectively. A standard approach in CDS is to compose distributional representations by taking their vector sum $v_L = v_1 + v_2 ... + v_n$ and $v_R = v'_1 + ... + v'_m$ (Mitchell and Lapata, 2010). One of the most effective similarity measures is the cosine similarity, which is a normalized dot product. The distributional similarity between p_L and p_R under this model is $\mathrm{sim}(p_L, p_R) = \sum_{i=1}^{n} \sum_{j=1}^{m} \mathrm{sim}(w_i, w'_j)$, where $\mathrm{sim}(w_i, w'_j)$ is the dot product between v_i and v'_j.

This similarity score is similar in spirit to a simplified version of our statistical model that restricts the set of allowable LCs H_p to be $\{(\{w_i\}, \{w'_j\}) | i \leq n, j \leq m\}$, i.e., only LCs of size 1. Indeed, taking H_p as above, and cosine similarity as the only feature (i.e., $w \in \mathbb{R}$), yields the distribution

Algorithm	Test Set				Cross Validation			
	Sim	Basic	NoLDA	All	Sim	Basic	NoLDA	All
LatentLC	**62.9**	**65.7**	**64.4**	**64.6**	**62.7** ± 1.9	**64.9** ± 1.9	**65.0** ± 1.7	**65.7** ±1.9
LeftMost	59.0	61.1	60.0	60.4	61.2 ± 2.1	62.5 ± 2.4	62.4 ±2.2	62.7 ± 2.0
VPrep	56.1	60.9	60.7	61.6*	58.1 ± 1.7	60.8 ± 2.2	60.4 ± 2.6	60.6 ± 2.2
AllNeg	55.9				55.9			

Table 2: Results for the various evaluated systems. Accuracy results are presented in percents, followed in the cross validation scenario by the standard deviation over the folds. The rows correspond to the various systems as defined in Section 4. LatentLC is our proposed model. The columns correspond to the various feature sets, from the least to the most inclusive. Sim includes only similarity features. Basic additionally includes POS-based and frequency features. NoLDA includes all features except LDA-based features. All is the full feature set. AllNeg is the classifier that invariably predicts the label "no inference". Bold marks best overall accuracy per column, and * marks figures that are not significantly worse (McNemar's test, $p < 0.05$). The same positive to negative label ratio was maintained in both the cross validation and test set scenarios. In all cases, LatentLC obtains substantial improvements over the baseline systems.

$$P(y|p) \propto \sum_{(w_i,w'_j)\in H_p} \exp\left(w \cdot y \cdot \mathrm{sim}(w_i, w'_j)\right).$$

This derivation highlights the relation of a simplified version of our approach to the additive CDS model, as both approaches effectively average over the similarities of all pairs of words in p_L and p_R. The derivation also highlights a few advantages of our approach. First, our approach allows to straightforwardly introduce additional features and to weight them in a way most consistent with the task at hand. Second, it allows much more flexibility in defining the set of allowable LCs, H_p. Specifically, H_p may contain LCs of sizes greater than 1. Third, our approach uses standard probabilistic modelling, and therefore has a natural statistical interpretation.

In order to appreciate the effect of these advantages, we perform an experiment that takes H to be the set of all LCs of size 1, and uses a single similarity measure. We run a 10-fold cross-validation on our training data, obtaining 61.3% accuracy using Cosine and 62.2% accuracy using BInc. The performance gap between these results and the accuracy obtained by our full model (65.7%) underscores the latter's effectiveness in integrating multiple features and LCs.

Effectiveness of Optimization Method. Our maximization of the log-likelihood function is not guaranteed to converge to a global optimum. Therefore, the quality of the learned parameters may be sensitive to the initialization point. We hereby describe an experiment that tests the sensitivity of our approach to such variance.

Selecting the highest scoring feature set on our test set (i.e., Basic), we ran the model with multiple initializers, by randomly perturbing our standard convex initializer (see Section 3). Concretely, given a convex initializer w, we select the starting point to be $w + \eta$, where $\eta_i \sim \mathcal{N}(0, \alpha|w_i|)$. We ran this experiment 400 times with $\alpha = 0.8$.

To combine the resulting weight vectors into a single classifier, we apply two types of standard approaches: a Product of Experts (Hinton, 2002), as well as a voting approach that selects the most frequently predicted label. Neither of these experiments yielded any significant performance gain. This demonstrates the robustness of our optimization method to the initialization point.

7 Conclusion

We have presented a novel approach to the distributional representation of multi-word predicates. Since MWPs demonstrate varying levels of compositionality, a uniform treatment of MWPs either as fixed expressions or through head words is lacking. Instead, our approach integrates multiple lexical units contained in the predicate. The approach takes into account both multi-word LCs that address low compositionality cases, as well as single-word LCs that address compositional cases and are more frequent. It assumes a latent distribution over the LCs of the predicates, and estimates it relative to a target application task.

We addressed the supervised inference identification task, obtaining substantial improvement over state-of-the-art baseline systems. In future work we intend to assess the benefit of this approach in MWP classes that are well-known from the literature. We believe that a permissive approach that integrates multiple analyses would perform better than standard single-analysis methods in a wide range of applications.

Abstract

The ability to accurately represent sentences is central to language understanding. We describe a convolutional architecture dubbed the Dynamic Convolutional Neural Network (DCNN) that we adopt for the semantic modelling of sentences. The network uses Dynamic k-Max Pooling, a global pooling operation over linear sequences. The network handles input sentences of varying length and induces a feature graph over the sentence that is capable of explicitly capturing short and long-range relations. The network does not rely on a parse tree and is easily applicable to any language. We test the DCNN in four experiments: small scale binary and multi-class sentiment prediction, six-way question classification and Twitter sentiment prediction by distant supervision. The network achieves excellent performance in the first three tasks and a greater than 25% error reduction in the last task with respect to the strongest baseline.

1 Introduction

The aim of a sentence model is to analyse and represent the semantic content of a sentence for purposes of classification or generation. The sentence modelling problem is at the core of many tasks involving a degree of natural language comprehension. These tasks include sentiment analysis, paraphrase detection, entailment recognition, summarisation, discourse analysis, machine translation, grounded language learning and image retrieval. Since individual sentences are rarely observed or not observed at all, one must represent a sentence in terms of features that depend on the words and short n-grams in the sentence that are frequently observed. The core of a sentence model involves a feature function that defines the process by which the features of the sentence are extracted from the features of the words or n-grams.

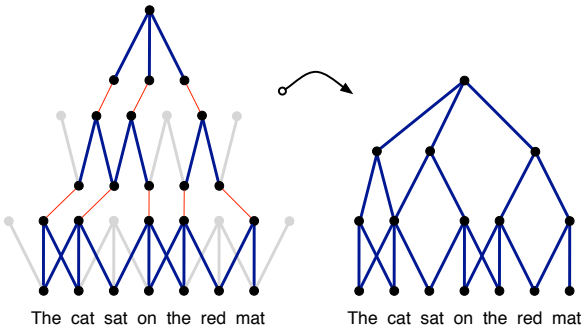

Figure 1: Subgraph of a feature graph induced over an input sentence in a Dynamic Convolutional Neural Network. The full induced graph has multiple subgraphs of this kind with a distinct set of edges; subgraphs may merge at different layers. The left diagram emphasises the pooled nodes. The width of the convolutional filters is 3 and 2 respectively. With dynamic pooling, a filter with small width at the higher layers can relate phrases far apart in the input sentence.

Various types of models of meaning have been proposed. Composition based methods have been applied to vector representations of word meaning obtained from co-occurrence statistics to obtain vectors for longer phrases. In some cases, composition is defined by algebraic operations over word meaning vectors to produce sentence meaning vectors (Erk and Padó, 2008; Mitchell and Lapata, 2008; Mitchell and Lapata, 2010; Turney, 2012; Erk, 2012; Clarke, 2012). In other cases, a composition function is learned and either tied to particular syntactic relations (Guevara, 2010; Zanzotto et al., 2010) or to particular word types (Baroni and Zamparelli, 2010; Coecke et al., 2010; Grefenstette and Sadrzadeh, 2011; Kartsaklis and Sadrzadeh, 2013; Grefenstette, 2013). Another approach represents the meaning of sentences by way of automatically extracted logical forms (Zettlemoyer and Collins, 2005).

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 655–665,
Baltimore, Maryland, USA, June 23-25 2014.

A central class of models are those based on neural networks. These range from basic neural bag-of-words or bag-of-n-grams models to the more structured recursive neural networks and to time-delay neural networks based on convolutional operations (Collobert and Weston, 2008; Socher et al., 2011; Kalchbrenner and Blunsom, 2013b). Neural sentence models have a number of advantages. They can be trained to obtain generic vectors for words and phrases by predicting, for instance, the contexts in which the words and phrases occur. Through supervised training, neural sentence models can fine-tune these vectors to information that is specific to a certain task. Besides comprising powerful classifiers as part of their architecture, neural sentence models can be used to condition a neural language model to generate sentences word by word (Schwenk, 2012; Mikolov and Zweig, 2012; Kalchbrenner and Blunsom, 2013a).

We define a convolutional neural network architecture and apply it to the semantic modelling of sentences. The network handles input sequences of varying length. The layers in the network interleave one-dimensional convolutional layers and dynamic k-max pooling layers. Dynamic k-max pooling is a generalisation of the max pooling operator. The max pooling operator is a non-linear subsampling function that returns the maximum of a set of values (LeCun et al., 1998). The operator is generalised in two respects. First, k-max pooling over a linear sequence of values returns the subsequence of k maximum values in the sequence, instead of the single maximum value. Secondly, the pooling parameter k can be dynamically chosen by making k a function of other aspects of the network or the input.

The convolutional layers apply one-dimensional filters across each row of features in the sentence matrix. Convolving the same filter with the n-gram at every position in the sentence allows the features to be extracted independently of their position in the sentence. A convolutional layer followed by a dynamic pooling layer and a non-linearity form a feature map. Like in the convolutional networks for object recognition (LeCun et al., 1998), we enrich the representation in the first layer by computing multiple feature maps with different filters applied to the input sentence. Subsequent layers also have multiple feature maps computed by convolving filters with all the maps from the layer below. The weights at these layers form an order-4 tensor. The resulting architecture is dubbed a Dynamic Convolutional Neural Network.

Multiple layers of convolutional and dynamic pooling operations induce a structured feature graph over the input sentence. Figure 1 illustrates such a graph. Small filters at higher layers can capture syntactic or semantic relations between non-continuous phrases that are far apart in the input sentence. The feature graph induces a hierarchical structure somewhat akin to that in a syntactic parse tree. The structure is not tied to purely syntactic relations and is internal to the neural network.

We experiment with the network in four settings. The first two experiments involve predicting the sentiment of movie reviews (Socher et al., 2013b). The network outperforms other approaches in both the binary and the multi-class experiments. The third experiment involves the categorisation of questions in six question types in the TREC dataset (Li and Roth, 2002). The network matches the accuracy of other state-of-the-art methods that are based on large sets of engineered features and hand-coded knowledge resources. The fourth experiment involves predicting the sentiment of Twitter posts using distant supervision (Go et al., 2009). The network is trained on 1.6 million tweets labelled automatically according to the emoticon that occurs in them. On the hand-labelled test set, the network achieves a greater than 25% reduction in the prediction error with respect to the strongest unigram and bigram baseline reported in Go et al. (2009).

The outline of the paper is as follows. Section 2 describes the background to the DCNN including central concepts and related neural sentence models. Section 3 defines the relevant operators and the layers of the network. Section 4 treats of the induced feature graph and other properties of the network. Section 5 discusses the experiments and inspects the learnt feature detectors.[1]

2 Background

The layers of the DCNN are formed by a convolution operation followed by a pooling operation. We begin with a review of related neural sentence models. Then we describe the operation of *one-dimensional convolution* and the classical Time-Delay Neural Network (TDNN) (Hinton, 1989; Waibel et al., 1990). By adding a max pooling

[1] Code available at `www.nal.co`

layer to the network, the TDNN can be adopted as a sentence model (Collobert and Weston, 2008).

2.1 Related Neural Sentence Models

Various neural sentence models have been described. A general class of basic sentence models is that of Neural Bag-of-Words (NBoW) models. These generally consist of a projection layer that maps words, sub-word units or n-grams to high dimensional embeddings; the latter are then combined component-wise with an operation such as summation. The resulting combined vector is classified through one or more fully connected layers.

A model that adopts a more general structure provided by an external parse tree is the Recursive Neural Network (RecNN) (Pollack, 1990; Küchler and Goller, 1996; Socher et al., 2011; Hermann and Blunsom, 2013). At every node in the tree the contexts at the left and right children of the node are combined by a classical layer. The weights of the layer are shared across all nodes in the tree. The layer computed at the top node gives a representation for the sentence. The Recurrent Neural Network (RNN) is a special case of the recursive network where the structure that is followed is a simple linear chain (Gers and Schmidhuber, 2001; Mikolov et al., 2011). The RNN is primarily used as a language model, but may also be viewed as a sentence model with a linear structure. The layer computed at the last word represents the sentence.

Finally, a further class of neural sentence models is based on the convolution operation and the TDNN architecture (Collobert and Weston, 2008; Kalchbrenner and Blunsom, 2013b). Certain concepts used in these models are central to the DCNN and we describe them next.

2.2 Convolution

The *one-dimensional convolution* is an operation between a vector of weights $\mathbf{m} \in \mathbb{R}^m$ and a vector of inputs viewed as a sequence $\mathbf{s} \in \mathbb{R}^s$. The vector $\mathbf{m}$ is the *filter* of the convolution. Concretely, we think of $\mathbf{s}$ as the input sentence and $\mathbf{s}_i \in \mathbb{R}$ is a single feature value associated with the i-th word in the sentence. The idea behind the one-dimensional convolution is to take the dot product of the vector $\mathbf{m}$ with each m-gram in the sentence $\mathbf{s}$ to obtain another sequence $\mathbf{c}$:

$$\mathbf{c}_j = \mathbf{m}^\intercal \mathbf{s}_{j-m+1:j} \tag{1}$$

Equation 1 gives rise to two types of convolution depending on the range of the index j. The *narrow* type of convolution requires that $s \geq m$ and yields

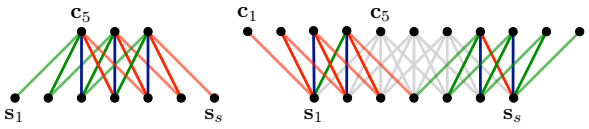

Figure 2: Narrow and wide types of convolution. The filter $\mathbf{m}$ has size $m = 5$.

a sequence $\mathbf{c} \in \mathbb{R}^{s-m+1}$ with j ranging from m to s. The *wide* type of convolution does not have requirements on s or m and yields a sequence $\mathbf{c} \in \mathbb{R}^{s+m-1}$ where the index j ranges from 1 to $s + m - 1$. Out-of-range input values $\mathbf{s}_i$ where $i < 1$ or $i > s$ are taken to be zero. The result of the narrow convolution is a subsequence of the result of the wide convolution. The two types of one-dimensional convolution are illustrated in Fig. 2.

The trained weights in the filter $\mathbf{m}$ correspond to a linguistic feature detector that learns to recognise a specific class of n-grams. These n-grams have size $n \leq m$, where m is the width of the filter. Applying the weights $\mathbf{m}$ in a wide convolution has some advantages over applying them in a narrow one. A wide convolution ensures that all weights in the filter reach the entire sentence, including the words at the margins. This is particularly significant when m is set to a relatively large value such as 8 or 10. In addition, a wide convolution guarantees that the application of the filter $\mathbf{m}$ to the input sentence $\mathbf{s}$ always produces a valid non-empty result $\mathbf{c}$, independently of the width m and the sentence length s. We next describe the classical convolutional layer of a TDNN.

2.3 Time-Delay Neural Networks

A TDNN convolves a sequence of inputs $\mathbf{s}$ with a set of weights $\mathbf{m}$. As in the TDNN for phoneme recognition (Waibel et al., 1990), the sequence $\mathbf{s}$ is viewed as having a time dimension and the convolution is applied over the time dimension. Each $\mathbf{s}_j$ is often not just a single value, but a vector of d values so that $\mathbf{s} \in \mathbb{R}^{d \times s}$. Likewise, $\mathbf{m}$ is a matrix of weights of size $d \times m$. Each row of $\mathbf{m}$ is convolved with the corresponding row of $\mathbf{s}$ and the convolution is usually of the narrow type. Multiple convolutional layers may be stacked by taking the resulting sequence $\mathbf{c}$ as input to the next layer.

The Max-TDNN sentence model is based on the architecture of a TDNN (Collobert and Weston, 2008). In the model, a convolutional layer of the narrow type is applied to the sentence matrix $\mathbf{s}$, where each column corresponds to the feature vec-

tor $\mathbf{w}_i \in \mathbb{R}^d$ of a word in the sentence:

$$\mathbf{s} = \begin{bmatrix} | & | & | \\ \mathbf{w}_1 & \dots & \mathbf{w}_s \\ | & | & | \end{bmatrix} \tag{2}$$

To address the problem of varying sentence lengths, the Max-TDNN takes the maximum of each row in the resulting matrix $\mathbf{c}$ yielding a vector of d values:

$$\mathbf{c}_{max} = \begin{bmatrix} \max(\mathbf{c}_{1,:}) \\ \vdots \\ \max(\mathbf{c}_{d,:}) \end{bmatrix} \tag{3}$$

The aim is to capture the most relevant feature, i.e. the one with the highest value, for each of the d rows of the resulting matrix $\mathbf{c}$. The fixed-sized vector $\mathbf{c}_{max}$ is then used as input to a fully connected layer for classification.

The Max-TDNN model has many desirable properties. It is sensitive to the order of the words in the sentence and it does not depend on external language-specific features such as dependency or constituency parse trees. It also gives largely uniform importance to the signal coming from each of the words in the sentence, with the exception of words at the margins that are considered fewer times in the computation of the narrow convolution. But the model also has some limiting aspects. The range of the feature detectors is limited to the span m of the weights. Increasing m or stacking multiple convolutional layers of the narrow type makes the range of the feature detectors larger; at the same time it also exacerbates the neglect of the margins of the sentence and increases the minimum size s of the input sentence required by the convolution. For this reason higher-order and long-range feature detectors cannot be easily incorporated into the model. The max pooling operation has some disadvantages too. It cannot distinguish whether a relevant feature in one of the rows occurs just one or multiple times and it forgets the order in which the features occur. More generally, the pooling factor by which the signal of the matrix is reduced at once corresponds to $s - m + 1$; even for moderate values of s the pooling factor can be excessive. The aim of the next section is to address these limitations while preserving the advantages.

3 Convolutional Neural Networks with Dynamic k-Max Pooling

We model sentences using a convolutional architecture that alternates wide convolutional layers with dynamic pooling layers given by *dynamic k-max pooling*. In the network the width of a feature map at an intermediate layer varies depending on the length of the input sentence; the resulting architecture is the Dynamic Convolutional Neural Network. Figure 3 represents a DCNN. We proceed to describe the network in detail.

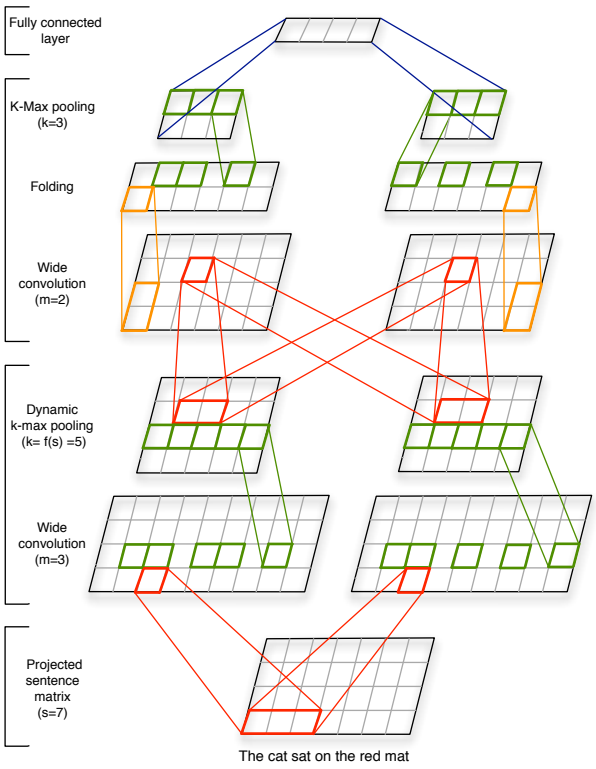

Figure 3: A DCNN for the seven word input sentence. Word embeddings have size $d = 4$. The network has two convolutional layers with two feature maps each. The widths of the filters at the two layers are respectively 3 and 2. The (dynamic) k-max pooling layers have values k of 5 and 3.

3.1 Wide Convolution

Given an input sentence, to obtain the first layer of the DCNN we take the embedding $\mathbf{w}_i \in \mathbb{R}^d$ for each word in the sentence and construct the sentence matrix $\mathbf{s} \in \mathbb{R}^{d \times s}$ as in Eq. 2. The values in the embeddings $\mathbf{w}_i$ are parameters that are optimised during training. A convolutional layer in the network is obtained by convolving a matrix of weights $\mathbf{m} \in \mathbb{R}^{d \times m}$ with the matrix of activations at the layer below. For example, the second layer is obtained by applying a convolution to the sentence matrix $\mathbf{s}$ itself. Dimension d and filter width m are hyper-parameters of the network. We let the operations be *wide* one-dimensional convolutions as described in Sect. 2.2. The resulting matrix $\mathbf{c}$ has dimensions $d \times (s + m - 1)$.

3.2 k-Max Pooling

We next describe a pooling operation that is a generalisation of the max pooling over the time dimension used in the Max-TDNN sentence model and different from the local max pooling operations applied in a convolutional network for object recognition (LeCun et al., 1998). Given a value k and a sequence $\mathbf{p} \in \mathbb{R}^p$ of length $p \geq k$, *k-max pooling* selects the subsequence $\mathbf{p}^k_{max}$ of the k highest values of $\mathbf{p}$. The order of the values in $\mathbf{p}^k_{max}$ corresponds to their original order in $\mathbf{p}$.

The k-max pooling operation makes it possible to pool the k most active features in $\mathbf{p}$ that may be a number of positions apart; it preserves the order of the features, but is insensitive to their specific positions. It can also discern more finely the number of times the feature is highly activated in $\mathbf{p}$ and the progression by which the high activations of the feature change across $\mathbf{p}$. The k-max pooling operator is applied in the network after the topmost convolutional layer. This guarantees that the input to the fully connected layers is independent of the length of the input sentence. But, as we see next, at intermediate convolutional layers the pooling parameter k is not fixed, but is dynamically selected in order to allow for a smooth extraction of higher-order and longer-range features.

3.3 Dynamic k-Max Pooling

A *dynamic k-max pooling* operation is a k-max pooling operation where we let k be a function of the length of the sentence and the depth of the network. Although many functions are possible, we simply model the pooling parameter as follows:

$$k_l = \max(\, k_{top},\, \lceil \frac{L-l}{L} s \rceil \,) \qquad (4)$$

where l is the number of the current convolutional layer to which the pooling is applied and L is the total number of convolutional layers in the network; k_{top} is the fixed pooling parameter for the topmost convolutional layer (Sect. 3.2). For instance, in a network with three convolutional layers and $k_{top} = 3$, for an input sentence of length $s = 18$, the pooling parameter at the first layer is $k_1 = 12$ and the pooling parameter at the second layer is $k_2 = 6$; the third layer has the fixed pooling parameter $k_3 = k_{top} = 3$. Equation 4 is a model of the number of values needed to describe the relevant parts of the progression of an l-th order feature over a sentence of length s. For an example in sentiment prediction, according to the equation a first order feature such as a positive word occurs *at most* k_1 times in a sentence of length s, whereas a second order feature such as a negated phrase or clause occurs at most k_2 times.

3.4 Non-linear Feature Function

After (dynamic) k-max pooling is applied to the result of a convolution, a bias $\mathbf{b} \in \mathbb{R}^d$ and a non-linear function g are applied component-wise to the pooled matrix. There is a single bias value for each row of the pooled matrix.

If we temporarily ignore the pooling layer, we may state how one computes each d-dimensional column a in the matrix $\mathbf{a}$ resulting after the convolutional and non-linear layers. Define $\mathbf{M}$ to be the matrix of diagonals:

$$\mathbf{M} = [\text{diag}(\mathbf{m}_{:,1}), \ldots, \text{diag}(\mathbf{m}_{:,m})] \qquad (5)$$

where $\mathbf{m}$ are the weights of the d filters of the wide convolution. Then after the first pair of a convolutional and a non-linear layer, each column a in the matrix $\mathbf{a}$ is obtained as follows, for some index j:

$$a = g\left(\mathbf{M} \begin{bmatrix} \mathbf{w}_j \\ \vdots \\ \mathbf{w}_{j+m-1} \end{bmatrix} + \mathbf{b}\right) \qquad (6)$$

Here a is a column of first order features. Second order features are similarly obtained by applying Eq. 6 to a sequence of first order features $a_j, ..., a_{j+m'-1}$ with another weight matrix $\mathbf{M}'$. Barring pooling, Eq. 6 represents a core aspect of the feature extraction function and has a rather general form that we return to below. Together with pooling, the feature function induces position invariance and makes the range of higher-order features variable.

3.5 Multiple Feature Maps

So far we have described how one applies a wide convolution, a (dynamic) k-max pooling layer and a non-linear function to the input sentence matrix to obtain a first order *feature map*. The three operations can be repeated to yield feature maps of increasing order and a network of increasing depth. We denote a feature map of the i-th order by $\mathbf{F}^i$. As in convolutional networks for object recognition, to increase the number of learnt feature detectors of a certain order, multiple feature maps $\mathbf{F}^i_1, \ldots, \mathbf{F}^i_n$ may be computed in parallel at the same layer. Each feature map $\mathbf{F}^i_j$ is computed by convolving a distinct set of filters arranged in a matrix $\mathbf{m}^i_{j,k}$ with each feature map $\mathbf{F}^{i-1}_k$ of the lower order $i-1$ and summing the results:

$$\mathbf{F}_j^i = \sum_{k=1}^{n} \mathbf{m}_{j,k}^i * \mathbf{F}_k^{i-1} \quad (7)$$

where $*$ indicates the wide convolution. The weights $\mathbf{m}_{j,k}^i$ form an order-4 tensor. After the wide convolution, first dynamic k-max pooling and then the non-linear function are applied individually to each map.

3.6 Folding

In the formulation of the network so far, feature detectors applied to an individual row of the sentence matrix $\mathbf{s}$ can have many orders and create complex dependencies across the same rows in multiple feature maps. Feature detectors in different rows, however, are independent of each other until the top fully connected layer. Full dependence between different rows could be achieved by making $\mathbf{M}$ in Eq. 5 a full matrix instead of a sparse matrix of diagonals. Here we explore a simpler method called *folding* that does not introduce any additional parameters. After a convolutional layer and before (dynamic) k-max pooling, one just sums every two rows in a feature map component-wise. For a map of d rows, folding returns a map of $d/2$ rows, thus halving the size of the representation. With a folding layer, a feature detector of the i-th order depends now on two rows of feature values in the lower maps of order $i-1$. This ends the description of the DCNN.

4 Properties of the Sentence Model

We describe some of the properties of the sentence model based on the DCNN. We describe the notion of the *feature graph* induced over a sentence by the succession of convolutional and pooling layers. We briefly relate the properties to those of other neural sentence models.

4.1 Word and n-Gram Order

One of the basic properties is sensitivity to the order of the words in the input sentence. For most applications and in order to learn fine-grained feature detectors, it is beneficial for a model to be able to discriminate whether a specific n-gram occurs in the input. Likewise, it is beneficial for a model to be able to tell the *relative* position of the most relevant n-grams. The network is designed to capture these two aspects. The filters $\mathbf{m}$ of the wide convolution in the first layer can learn to recognise specific n-grams that have size less or equal to the filter width m; as we see in the experiments, m in the first layer is often set to a relatively large value such as 10. The subsequence of n-grams extracted by the generalised pooling operation induces invariance to absolute positions, but maintains their order and relative positions.

As regards the other neural sentence models, the class of NBoW models is by definition insensitive to word order. A sentence model based on a recurrent neural network is sensitive to word order, but it has a bias towards the latest words that it takes as input (Mikolov et al., 2011). This gives the RNN excellent performance at language modelling, but it is suboptimal for remembering at once the n-grams further back in the input sentence. Similarly, a recursive neural network is sensitive to word order but has a bias towards the topmost nodes in the tree; shallower trees mitigate this effect to some extent (Socher et al., 2013a). As seen in Sect. 2.3, the Max-TDNN is sensitive to word order, but max pooling only picks out a single n-gram feature in each row of the sentence matrix.

4.2 Induced Feature Graph

Some sentence models use internal or external structure to compute the representation for the input sentence. In a DCNN, the convolution and pooling layers induce an internal feature graph over the input. A node from a layer is connected to a node from the next higher layer if the lower node is involved in the convolution that computes the value of the higher node. Nodes that are not selected by the pooling operation at a layer are dropped from the graph. After the last pooling layer, the remaining nodes connect to a single topmost root. The induced graph is a connected, directed acyclic graph with weighted edges and a root node; two equivalent representations of an induced graph are given in Fig. 1. In a DCNN without folding layers, each of the d rows of the sentence matrix induces a subgraph that joins the other subgraphs only at the root node. Each subgraph may have a different shape that reflects the kind of relations that are detected in that subgraph. The effect of folding layers is to join pairs of subgraphs at lower layers before the top root node.

Convolutional networks for object recognition also induce a feature graph over the input image. What makes the feature graph of a DCNN peculiar is the global range of the pooling operations. The (dynamic) k-max pooling operator can draw together features that correspond to words that are many positions apart in the sentence. Higher-order features have highly variable ranges that can be ei-

ther short and focused or global and long as the input sentence. Likewise, the edges of a subgraph in the induced graph reflect these varying ranges. The subgraphs can either be localised to one or more parts of the sentence or spread more widely across the sentence. This structure is internal to the network and is defined by the forward propagation of the input through the network.

Of the other sentence models, the NBoW is a shallow model and the RNN has a linear chain structure. The subgraphs induced in the Max-TDNN model have a single fixed-range feature obtained through max pooling. The recursive neural network follows the structure of an external parse tree. Features of variable range are computed at each node of the tree combining one or more of the children of the tree. Unlike in a DCNN, where one learns a clear hierarchy of feature orders, in a RecNN low order features like those of single words can be directly combined with higher order features computed from entire clauses. A DCNN generalises many of the structural aspects of a RecNN. The feature extraction function as stated in Eq. 6 has a more general form than that in a RecNN, where the value of m is generally 2. Likewise, the induced graph structure in a DCNN is more general than a parse tree in that it is not limited to syntactically dictated phrases; the graph structure can capture short or long-range semantic relations between words that do not necessarily correspond to the syntactic relations in a parse tree. The DCNN has internal input-dependent structure and does not rely on externally provided parse trees, which makes the DCNN directly applicable to hard-to-parse sentences such as tweets and to sentences from any language.

5 Experiments

We test the network on four different experiments. We begin by specifying aspects of the implementation and the training of the network. We then relate the results of the experiments and we inspect the learnt feature detectors.

5.1 Training

In each of the experiments, the top layer of the network has a fully connected layer followed by a softmax non-linearity that predicts the probability distribution over classes given the input sentence. The network is trained to minimise the cross-entropy of the predicted and true distributions; the objective includes an L_2 regularisation term over the parameters. The set of parameters comprises the word embeddings, the filter weights and the weights from the fully connected layers. The network is trained with mini-batches by back-propagation and the gradient-based optimisation is performed using the Adagrad update rule (Duchi et al., 2011). Using the well-known convolution theorem, we can compute fast one-dimensional linear convolutions at all rows of an input matrix by using Fast Fourier Transforms. To exploit the parallelism of the operations, we train the network on a GPU. A Matlab implementation processes multiple millions of input sentences per hour on one GPU, depending primarily on the number of layers used in the network.

Classifier	Fine-grained (%)	Binary (%)
NB	41.0	81.8
BINB	41.9	83.1
SVM	40.7	79.4
RECNTN	45.7	85.4
MAX-TDNN	37.4	77.1
NBOW	42.4	80.5
DCNN	**48.5**	**86.8**

Table 1: Accuracy of sentiment prediction in the movie reviews dataset. The first four results are reported from Socher et al. (2013b). The baselines NB and BINB are Naive Bayes classifiers with, respectively, unigram features and unigram and bigram features. SVM is a support vector machine with unigram and bigram features. RECNTN is a recursive neural network with a tensor-based feature function, which relies on external structural features given by a parse tree and performs best among the RecNNs.

5.2 Sentiment Prediction in Movie Reviews

The first two experiments concern the prediction of the sentiment of movie reviews in the Stanford Sentiment Treebank (Socher et al., 2013b). The output variable is binary in one experiment and can have five possible outcomes in the other: negative, somewhat negative, neutral, somewhat positive, positive. In the binary case, we use the given splits of 6920 training, 872 development and 1821 test sentences. Likewise, in the fine-grained case, we use the standard 8544/1101/2210 splits. Labelled phrases that occur as subparts of the training sentences are treated as independent training instances. The size of the vocabulary is 15448.

Table 1 details the results of the experiments.

Classifier	Features	Acc. (%)
HIER	unigram, POS, head chunks NE, semantic relations	91.0
MAXENT	unigram, bigram, trigram POS, chunks, NE, supertags CCG parser, WordNet	92.6
MAXENT	unigram, bigram, trigram POS, wh-word, head word word shape, parser hypernyms, WordNet	93.6
SVM	unigram, POS, wh-word head word, parser hypernyms, WordNet 60 hand-coded rules	95.0
MAX-TDNN	unsupervised vectors	84.4
NBOW	unsupervised vectors	88.2
DCNN	unsupervised vectors	93.0

Table 2: Accuracy of six-way question classification on the TREC questions dataset. The second column details the external features used in the various approaches. The first four results are respectively from Li and Roth (2002), Blunsom et al. (2006), Huang et al. (2008) and Silva et al. (2011).

In the three neural sentence models—the Max-TDNN, the NBoW and the DCNN—the word vectors are parameters of the models that are randomly initialised; their dimension d is set to 48. The Max-TDNN has a filter of width 6 in its narrow convolution at the first layer; shorter phrases are padded with zero vectors. The convolutional layer is followed by a non-linearity, a max-pooling layer and a softmax classification layer. The NBoW sums the word vectors and applies a non-linearity followed by a softmax classification layer. The adopted non-linearity is the $\tanh$ function. The hyper parameters of the DCNN are as follows. The binary result is based on a DCNN that has a wide convolutional layer followed by a folding layer, a dynamic k-max pooling layer and a non-linearity; it has a second wide convolutional layer followed by a folding layer, a k-max pooling layer and a non-linearity. The width of the convolutional filters is 7 and 5, respectively. The value of k for the top k-max pooling is 4. The number of feature maps at the first convolutional layer is 6; the number of maps at the second convolutional layer is 14. The network is topped by a softmax classification layer. The DCNN for the fine-grained result has the same architecture, but the filters have size 10 and 7, the top pooling parameter k is 5 and the number of maps is, respectively, 6 and 12. The networks use the $\tanh$ non-linear function. At training time we apply dropout to the penultimate layer after the last $\tanh$ non-linearity (Hinton et al., 2012).

Classifier	Accuracy (%)
SVM	81.6
BINB	82.7
MAXENT	83.0
MAX-TDNN	78.8
NBOW	80.9
DCNN	**87.4**

Table 3: Accuracy on the Twitter sentiment dataset. The three non-neural classifiers are based on unigram and bigram features; the results are reported from (Go et al., 2009).

We see that the DCNN significantly outperforms the other neural and non-neural models. The NBoW performs similarly to the non-neural n-gram based classifiers. The Max-TDNN performs worse than the NBoW likely due to the excessive pooling of the max pooling operation; the latter discards most of the sentiment features of the words in the input sentence. Besides the RecNN that uses an external parser to produce structural features for the model, the other models use n-gram based or neural features that do not require external resources or additional annotations. In the next experiment we compare the performance of the DCNN with those of methods that use heavily engineered resources.

5.3 Question Type Classification

As an aid to question answering, a question may be classified as belonging to one of many question types. The TREC questions dataset involves six different question types, e.g. whether the question is about a location, about a person or about some numeric information (Li and Roth, 2002). The training dataset consists of 5452 labelled questions whereas the test dataset consists of 500 questions.

The results are reported in Tab. 2. The non-neural approaches use a classifier over a large number of manually engineered features and hand-coded resources. For instance, Blunsom et al. (2006) present a Maximum Entropy model that relies on 26 sets of syntactic and semantic features including unigrams, bigrams, trigrams, POS tags, named entity tags, structural relations from a CCG parse and WordNet synsets. We evaluate the three neural models on this dataset with mostly the same hyper-parameters as in the binary senti-

POSITIVE

Figure 4: Top five 7-grams at four feature detectors in the first layer of the network.

ment experiment of Sect. 5.2. As the dataset is rather small, we use lower-dimensional word vectors with $d = 32$ that are initialised with embeddings trained in an unsupervised way to predict contexts of occurrence (Turian et al., 2010). The DCNN uses a single convolutional layer with filters of size 8 and 5 feature maps. The difference between the performance of the DCNN and that of the other high-performing methods in Tab. 2 is not significant ($p < 0.09$). Given that the only labelled information used to train the network is the training set itself, it is notable that the network matches the performance of state-of-the-art classifiers that rely on large amounts of engineered features and rules and hand-coded resources.

5.4 Twitter Sentiment Prediction with Distant Supervision

In our final experiment, we train the models on a large dataset of tweets, where a tweet is automatically labelled as positive or negative depending on the emoticon that occurs in it. The training set consists of 1.6 million tweets with emoticon-based labels and the test set of about 400 hand-annotated tweets. We preprocess the tweets minimally following the procedure described in Go et al. (2009); in addition, we also lowercase all the tokens. This results in a vocabulary of 76643 word types. The architecture of the DCNN and of the other neural models is the same as the one used in the binary experiment of Sect. 5.2. The randomly initialised word embeddings are increased in length to a dimension of $d = 60$. Table 3 reports the results of the experiments. We see a significant increase in the performance of the DCNN with respect to the non-neural n-gram based classifiers; in the presence of large amounts of training data these classifiers constitute particularly strong baselines. We see that the ability to train a sentiment classifier on automatically extracted emoticon-based labels extends to the DCNN and results in highly accurate performance. The difference in performance between the DCNN and the NBoW further suggests that the ability of the DCNN to both capture features based on long n-grams and to hierarchically combine these features is highly beneficial.

5.5 Visualising Feature Detectors

A filter in the DCNN is associated with a feature detector or neuron that learns during training to be particularly active when presented with a specific sequence of input words. In the first layer, the sequence is a continuous n-gram from the input sentence; in higher layers, sequences can be made of multiple separate n-grams. We visualise the feature detectors in the first layer of the network trained on the binary sentiment task (Sect. 5.2). Since the filters have width 7, for each of the 288 feature detectors we rank all 7-grams occurring in the validation and test sets according to their activation of the detector. Figure 5.2 presents the top five 7-grams for four feature detectors. Besides the expected detectors for positive and negative sentiment, we find detectors for particles such as 'not' that negate sentiment and such as 'too' that potentiate sentiment. We find detectors for multiple other notable constructs including 'all', 'or', 'with...that', 'as...as'. The feature detectors learn to recognise not just single n-grams, but patterns within n-grams that have syntactic, semantic or structural significance.

6 Conclusion

We have described a dynamic convolutional neural network that uses the dynamic k-max pooling operator as a non-linear subsampling function. The feature graph induced by the network is able to capture word relations of varying size. The network achieves high performance on question and sentiment classification without requiring external features as provided by parsers or other resources.

Abstract

We propose an online learning algorithm based on tensor-space models. A tensor-space model represents data in a compact way, and via rank-1 approximation the weight tensor can be made highly structured, resulting in a significantly smaller number of free parameters to be estimated than in comparable vector-space models. This regularizes the model complexity and makes the tensor model highly effective in situations where a large feature set is defined but very limited resources are available for training. We apply with the proposed algorithm to a parsing task, and show that even with very little training data the learning algorithm based on a tensor model performs well, and gives significantly better results than standard learning algorithms based on traditional vector-space models.

1 Introduction

Many NLP applications use models that try to incorporate a large number of linguistic features so that as much human knowledge of language can be brought to bear on the (prediction) task as possible. This also makes training the model parameters a challenging problem, since the amount of labeled training data is usually small compared to the size of feature sets: the feature weights cannot be estimated reliably.

Most traditional models are linear models, in the sense that both the features of the data and model parameters are represented as vectors in a vector space. Many learning algorithms applied to NLP problems, such as the Perceptron (Collins, 2002), MIRA (Crammer et al., 2006; McDonald et al., 2005; Chiang et al., 2008), PRO (Hopkins and May, 2011), RAMPION (Gimpel and Smith, 2012) etc., are based on vector-space models. Such models require learning individual feature weights directly, so that the number of parameters to be estimated is identical to the size of the feature set. When millions of features are used but the amount of labeled data is limited, it can be difficult to precisely estimate each feature weight.

In this paper, we shift the model from vector-space to tensor-space. Data can be represented in a compact and structured way using tensors as containers. Tensor representations have been applied to computer vision problems (Hazan et al., 2005; Shashua and Hazan, 2005) and information retrieval (Cai et al., 2006a) a long time ago. More recently, it has also been applied to parsing (Cohen and Collins, 2012; Cohen and Satta, 2013) and semantic analysis (Van de Cruys et al., 2013). A linear tensor model represents both features and weights in tensor-space, hence the weight tensor can be factorized and approximated by a linear sum of rank-1 tensors. This low-rank approximation imposes structural constraints on the feature weights and can be regarded as a form of regularization. With this representation, we no longer need to estimate individual feature weights directly but only a small number of "bases" instead. This property makes the the tensor model very effective when training a large number of feature weights in a low-resource environment. On the other hand, tensor models have many more degrees of "design freedom" than vector space models. While this makes them very flexible, it also creates much difficulty in designing an optimal tensor structure for a given training set.

We give detailed description of the tensor space

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 666–675,
Baltimore, Maryland, USA, June 23-25 2014.

model in Section 2. Several issues that come with the tensor model construction are addressed in Section 3. A tensor weight learning algorithm is then proposed in 4. Finally we give our experimental results on a parsing task and analysis in Section 5.

2 Tensor Space Representation

Most of the learning algorithms for NLP problems are based on vector space models, which represent data as vectors $\boldsymbol{\phi} \in \mathbb{R}^n$, and try to learn feature weight vectors $\boldsymbol{w} \in \mathbb{R}^n$ such that a linear model $y = \boldsymbol{w} \cdot \boldsymbol{\phi}$ is able to discriminate between, say, good and bad hypotheses. While this is a natural way of representing data, it is not the only choice. Below, we reformulate the model from vector to tensor space.

2.1 Tensor Space Model

A tensor is a multidimensional array, and is a generalization of commonly used algebraic objects such as vectors and matrices. Specifically, a vector is a 1^{st} order tensor, a matrix is a 2^{nd} order tensor, and data organized as a rectangular cuboid is a 3^{rd} order tensor etc. In general, a D^{th} order tensor is represented as $\mathcal{T} \in \mathbb{R}^{n_1 \times n_2 \times \ldots n_D}$, and an entry in $\mathcal{T}$ is denoted by $\mathcal{T}_{i_1,i_2,\ldots,i_D}$. Different dimensions of a tensor $1, 2, \ldots, D$ are named modes of the tensor.

Using a D^{th} order tensor as container, we can assign each feature of the task a D-dimensional index in the tensor and represent the data as tensors. Of course, shifting from a vector to a tensor representation entails several additional degrees of freedom, e.g., the order D of the tensor and the sizes $\{n_d\}_{d=1}^{D}$ of the modes, which must be addressed when selecting a tensor model. This will be done in Section 3.

2.2 Tensor Decomposition

Just as a matrix can be decomposed as a linear combination of several rank-1 matrices via SVD, tensors also admit decompositions[1] into linear combinations of "rank-1" tensors. A D^{th} order tensor $\mathcal{A} \in \mathbb{R}^{n_1 \times n_2 \times \ldots n_D}$ is rank-1 if it can be written as the outer product of D vectors, i.e.

$$\mathcal{A} = \mathbf{a}^1 \otimes \mathbf{a}^2 \otimes, \ldots, \otimes \mathbf{a}^D,$$

where $\mathbf{a}^i \in \mathbb{R}^{n_d}, 1 \leq d \leq D$. A D^{th} order tensor $\mathcal{T} \in \mathbb{R}^{n_1 \times n_2 \times \ldots n_D}$ can be factorized into a sum of component rank-1 tensors as

$$\mathcal{T} = \sum_{r=1}^{R} \mathcal{A}_r = \sum_{r=1}^{R} \mathbf{a}_r^1 \otimes \mathbf{a}_r^2 \otimes, \ldots, \otimes \mathbf{a}_r^D$$

where R, called the rank of the tensor, is the minimum number of rank-1 tensors whose sum equals $\mathcal{T}$. Via decomposition, one may approximate a tensor by the sum of H major rank-1 tensors with $H \leq R$.

2.3 Linear Tensor Model

In tensor space, a linear model may be written (ignoring a bias term) as

$$f(\boldsymbol{W}) = \boldsymbol{W} \circ \boldsymbol{\Phi},$$

where $\boldsymbol{\Phi} \in \mathbb{R}^{n_1 \times n_2 \times \ldots n_D}$ is the feature tensor, $\boldsymbol{W}$ is the corresponding weight tensor, and $\circ$ denotes the Hadamard product. If $\boldsymbol{W}$ is further decomposed as the sum of H major component rank-1 tensors, i.e. $\boldsymbol{W} \approx \sum_{h=1}^{H} \boldsymbol{w}_h^1 \otimes \boldsymbol{w}_h^2 \otimes, \ldots, \otimes \boldsymbol{w}_h^D$, then

$$\begin{aligned} & f(\boldsymbol{w}_1^1, \ldots, \boldsymbol{w}_1^D, \ldots, \boldsymbol{w}_h^1, \ldots, \boldsymbol{w}_h^D) \\ &= \sum_{h=1}^{H} \boldsymbol{\Phi} \times_1 \boldsymbol{w}_h^1 \times_2 \boldsymbol{w}_h^2 \ldots \times_D \boldsymbol{w}_h^D, \quad (1) \end{aligned}$$

where $\times_l$ is the l-mode product operator between a D^{th} order tensor $\mathcal{T}$ and a vector $\mathbf{a}$ of dimension n_d, yielding a $(D-1)^{\text{th}}$ order tensor such that

$$\begin{aligned} & (\mathcal{T} \times_l \mathbf{a})_{i_1,\ldots,i_{l-1},i_{l+1},\ldots,i_D} \\ &= \sum_{i_l=1}^{n_d} \mathcal{T}_{i_1,\ldots,i_{l-1},i_l,i_{l+1},\ldots,i_D} \cdot a_{i_l}. \end{aligned}$$

The linear tensor model is illustrated in Figure 1.

2.4 Why Learning in Tensor Space?

So what is the advantage of learning with a tensor model instead of a vector model? Consider the case where we have defined 1,000,000 features for our task. A vector space linear model requires estimating 1,000,000 free parameters. However if we use a 2^{nd} order tensor model, organize the features into a 1000×1000 matrix $\boldsymbol{\Phi}$, and use just

[1] The form of tensor decomposition defined here is named as CANDECOMP/PARAFAC(CP) decomposition (Kolda and Bader, 2009). Another popular form of tensor decomposition is called Tucker decomposition, which decomposes a tensor into a core tensor multiplied by a matrix along each mode. We focus only on the CP decomposition in this paper.

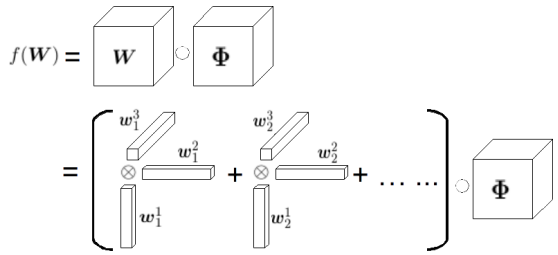

Figure 1: A 3^{rd} order linear tensor model. The feature weight tensor $\boldsymbol{W}$ can be decomposed as the sum of a sequence of rank-1 component tensors.

one rank-1 matrix to approximate the weight tensor, then the linear model becomes

$$f(\boldsymbol{w}_1, \boldsymbol{w}_2) = \boldsymbol{w}_1^T \boldsymbol{\Phi} \boldsymbol{w}_2,$$

where $\boldsymbol{w}_1, \boldsymbol{w}_2 \in \mathbb{R}^{1000}$. That is to say, now we only need to estimate 2000 parameters!

In general, if V features are defined for a learning problem, and we (i) organize the feature set as a tensor $\boldsymbol{\Phi} \in \mathbb{R}^{n_1 \times n_2 \times \ldots n_D}$ and (ii) use H component rank-1 tensors to approximate the corresponding target weight tensor. Then the total number of parameters to be learned for this tensor model is $H \sum_{d=1}^{D} n_d$, which is usually much smaller than $V = \prod_{d=1}^{D} n_d$ for a traditional vector space model. Therefore we expect the tensor model to be more effective in a low-resource training environment.

Specifically, a vector space model assumes each feature weight to be a "free" parameter, and estimating them reliably could therefore be hard when training data are not sufficient or the feature set is huge. By contrast, a linear tensor model only needs to learn $H \sum_{d=1}^{D} n_d$ "bases" of the m feature weights instead of individual weights directly. The weight corresponding to the feature $\Phi_{i_1, i_2, \ldots, i_D}$ in the tensor model is expressed as

$$w_{i_1, i_2, \ldots, i_D} = \sum_{h=1}^{H} w_{h,i_1}^1 w_{h,i_2}^2 \ldots w_{h,i_D}^D, \quad (2)$$

where w_{h,i_j}^j is the i_j^{th} element in the vector $\boldsymbol{w}_h^j$.

In other words, a true feature weight is now approximated by a set of bases. This reminds us of the well-known low-rank matrix approximation of images via SVD, and we are applying similar techniques to approximate target feature weights, which is made possible only after we shift from vector to tensor space models.

This approximation can be treated as a form of model regularization, since the weight tensor is represented in a constrained form and made highly structured via the rank-1 tensor approximation. Of course, as we reduce the model complexity, e.g. by choosing a smaller and smaller H, the model's expressive ability is weakened at the same time. We will elaborate on this point in Section 3.1.

3 Tensor Model Construction

To apply a tensor model, we first need to convert the feature vector into a tensor $\boldsymbol{\Phi}$. Once the structure of $\boldsymbol{\Phi}$ is determined, the structure of $\boldsymbol{W}$ is fixed as well. As mentioned in Section 2.1, a tensor model has many more degrees of "design freedom" than a vector model, which makes the problem of finding a good tensor structure a non-trivial one.

3.1 Tensor Order

The order of a tensor affects the model in two ways: the expressiveness of the model and the number of parameters to be estimated. We assume $H = 1$ in the analysis below, noting that one can always add as many rank-1 component tensors as needed to approximate a tensor with arbitrary precision.

Obviously, the 1^{st} order tensor (vector) model is the most expressive, since it is structureless and any arbitrary set of numbers can always be represented exactly as a vector. The 2^{nd} order rank-1 tensor (rank-1 matrix) is less expressive because not every set of numbers can be organized into a rank-1 matrix. In general, a D^{th} order rank-1 tensor is more expressive than a $(D+1)^{\text{th}}$ order rank-1 tensor, as a lower-order tensor imposes less structural constraints on the set of numbers it can express. We formally state this fact as follows:

Theorem 1. *A set of real numbers that can be represented by a $(D+1)^{\text{th}}$ order tensor $\mathcal{Q}$ can also be represented by a D^{th} order tensor $\mathcal{P}$, provided $\mathcal{P}$ and $\mathcal{Q}$ have the same volume. But the reverse is not true.*

Proof. See appendix. □

On the other hand, tensor order also affects the number of parameters to be trained. Assuming that a D^{th} order has equal size on each mode (we will elaborate on this point in Section 3.2) and the volume (number of entries) of the tensor is fixed as V, then the total number of parameters

of the model is $DV^{\frac{1}{D}}$. This is a convex function of D, and the minimum[2] is reached at either $D^* = \lfloor \ln V \rfloor$ or $D^* = \lceil \ln V \rceil$.

Therefore, as D increases from 1 to D^*, we lose more and more of the expressive power of the model but reduce the number of parameters to be trained. However it would be a bad idea to choose a D beyond D^*. The optimal tensor order depends on the nature of the actual problem, and we tune this hyper-parameter on a held-out set.

3.2 Mode Size

The size n_d of each tensor mode, $d = 1, \ldots, D$, determines the structure of feature weights a tensor model can precisely represent, as well as the number of parameters to estimate (we also assume $H = 1$ in the analysis below). For example, if the tensor order is 2 and the volume V is 12, then we can either choose $n_1 = 3, n_2 = 4$ or $n_1 = 2, n_2 = 6$. For $n_1 = 3, n_2 = 4$, the numbers that can be precisely represented are divided into 3 groups, each having 4 numbers, that are scaled versions of one another. Similarly for $n_1 = 2, n_2 = 6$, the numbers can be divided into 2 groups with different scales. Obviously, the two possible choices of (n_1, n_2) also lead to different numbers of free parameters (7 vs. 8).

Given D and V, there are many possible combinations of $n_d, d = 1, \ldots, D$, and the optimal combination should indeed be determined by the structure of target features weights. However it is hard to know the structure of target feature weights before learning, and it would be impractical to try every possible combination of mode sizes, therefore we choose the criterion of determining the mode sizes as minimization of the total number of parameters, namely we solve the problem:

$$\min_{n_1,\ldots,n_D} \sum_{d=1}^{D} n_d \quad s.t \quad \prod_{d=1}^{D} n_d = V$$

The optimal solution is reached when $n_1 = n_2 = \ldots = n_D = V^{\frac{1}{D}}$. Of course it is not guaranteed that $V^{\frac{1}{D}}$ is an integer, therefore we choose $n_d = \lfloor V^{\frac{1}{D}} \rfloor$ or $\lceil V^{\frac{1}{D}} \rceil, d = 1, \ldots, D$ such that $\prod_{d=1}^{D} n_d \geq V$ and $\left[\prod_{d=1}^{D} n_d\right] - V$ is minimized. The $\left[\prod_{d=1}^{D} n_d\right] - V$ extra entries of the tensor correspond to no features and are used just for padding. Since for each n_d there are only two possible values to choose, we can simply enumerate all the possible 2^D (which is usually a small number) combinations of values and pick the one that matches the conditions given above. This way $n_1, \ldots, n_D$ are fully determined.

Here we are only following the principle of minimizing the parameter number. While this strategy might work well with small amount of training data, it is not guaranteed to be the best strategy in all cases, especially when more data is available we might want to increase the number of parameters, making the model more complex so that the data can be more precisely modeled. Ideally the mode size needs to be adaptive to the amount of training data as well as the property of target weights. A theoretically guaranteed optimal approach to determining the mode sizes remains an open problem, and will be explored in our future work.

3.3 Number of Rank-1 Tensors

The impact of using $H > 1$ rank-1 tensors is obvious: a larger H increases the model complexity and makes the model more expressive, since we are able to approximate target weight tensor with smaller error. As a trade-off, the number of parameters and training complexity will be increased. To find out the optimal value of H for a given problem, we tune this hyper-parameter too on a held-out set.

3.4 Vector to Tensor Mapping

Finally, we need to find a way to map the original feature vector to a tensor, i.e. to associate each feature with an index in the tensor. Assuming the tensor volume V is the same as the number of features, then there are in all $V!$ ways of mapping, which is an intractable number of possibilities even for modest sized feature sets, making it impractical to carry out a brute force search. However while we are doing the mapping, we hope to arrange the features in a way such that the corresponding target weight tensor has approximately a low-rank structure, this way it can be well approximated by very few component rank-1 tensors.

Unfortunately we have no knowledge about the target weights in advance, since that is what we need to learn after all. As a way out, we first run a simple vector-model based learning algorithm (say the Perceptron) on the training data and estimate a weight vector, which serves as a "surro-

[2]The optimal integer solution can be determined simply by comparing the two function values.

gate" weight vector. We then use this surrogate vector to guide the design of the mapping. Ideally we hope to find a permutation of the surrogate weights to map to a tensor in such a way that the tensor has a rank as low as possible. However matrix rank minimization is in general a hard problem (Fazel, 2002). Therefore, we follow an approximate algorithm given in Figure 2a, whose main idea is illustrated via an example in Figure 2b.

Basically, what the algorithm does is to divide the surrogate weights into hierarchical groups such that groups on the same level are approximately proportional to each other. Using these groups as units we are able to "fill" the tensor in a hierarchical way. The resulting tensor will have an approximate low-rank structure, provided that the sorted feature weights have roughly group-wise proportional relations.

For comparison, we also experimented a trivial solution which maps each entry of the feature tensor to the tensor just in sequential order, namely ϕ_0 is mapped to $\Phi_{0,0,\ldots,0}$, ϕ_1 is mapped to $\Phi_{0,0,\ldots,1}$ etc. This of course ignores correlation between features since the original feature order in the vector could be totally meaningless, and this strategy is not expected to be a good solution for vector to tensor mapping.

4 Online Learning Algorithm

We now turn to the problem of learning the feature weight tensor. Here we propose an online learning algorithm similar to MIRA but modified to accommodate tensor models.

Let the model be $f(\boldsymbol{T}) = \boldsymbol{T} \circ \boldsymbol{\Phi}(x, y)$, where $\boldsymbol{T} = \sum_{h=1}^{H} \boldsymbol{w}_h^1 \otimes \boldsymbol{w}_h^2 \otimes, \ldots, \otimes \boldsymbol{w}_h^D$ is the weight tensor, $\boldsymbol{\Phi}(x, y)$ is the feature tensor for an input-output pair (x, y). Training samples $(x_i, y_i), i = 1, \ldots, m$, where x_i is the input and y_i is the reference or oracle hypothesis, are fed to the weight learning algorithm in sequential order. A prediction z_t is made by the model T_t at time t from a set of candidates $\mathcal{Z}(x_t)$, and the model updates the weight tensor by solving the following problem:

$$\min_{\boldsymbol{T} \in \mathbb{R}^{n_1 \times n_2 \times \ldots n_D}} \frac{1}{2}\|\boldsymbol{T} - \boldsymbol{T}_t\|^2 + C\xi \quad (3)$$
$$s.t.$$
$$\mathscr{L}_t \leq \xi, \xi \geq 0$$

where $\boldsymbol{T}$ is a decomposed weight tensor and

$$\mathscr{L}_t = \boldsymbol{T} \circ \boldsymbol{\Phi}(x_t, z_t) - \boldsymbol{T} \circ \boldsymbol{\Phi}(x_t, y_t) + \rho(y_t, z_t)$$

Input:

Tensor order D, tensor volume V, mode size $n_d, d = 1, \ldots, D$, surrogate weight vector $\boldsymbol{v}$

Let

$\boldsymbol{v}^+ = [v_1^+, \ldots, v_p^+]$ be the non-negative part of $\boldsymbol{v}$

$\boldsymbol{v}^- = [v_1^-, \ldots, v_q^-]$ be the negative part of $\boldsymbol{v}$

Algorithm:

$\tilde{\boldsymbol{v}}^+$ = *sort*($\boldsymbol{v}^+$) in descending order

$\tilde{\boldsymbol{v}}^-$ = *sort*($\boldsymbol{v}^-$) in ascending order

$u = V/n_D$

$e = p - mod(p, u)$, $f = q - mod(q, u)$

Construct vector

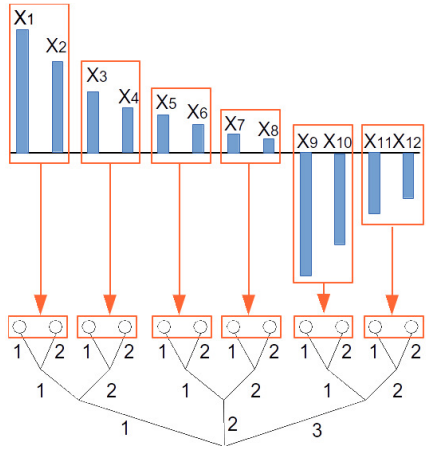
$\mathbf{X} = [\tilde{v}_1^+, \ldots, \tilde{v}_e^+, \tilde{v}_1^-, \ldots, \tilde{v}_f^-,$
$\tilde{v}_{e+1}^+, \ldots, \tilde{v}_p^+, \tilde{v}_{f+1}^-, \ldots, \tilde{v}_q^-]$

Map $X_a, a = 1, \ldots, p + q$ to the tensor entry $\mathcal{T}_{i_1,\ldots,i_D}$, such that

$$a = \sum_{d=1}^{D} (i_d - 1) l_{d-1} + 1$$

where $l_d = l_{d-1} n_d$, and $l_0 = 1$

(a) Mapping a surrogate weight vector to a tensor



(b) Illustration of the algorithm

Figure 2: Algorithm for mapping a surrogate weight vector X to a tensor. (2a) provides the algorithm; (2b) illustrates it by mapping a vector of length $V = 12$ to a $(n_1, n_2, n_3) = (2, 2, 3)$ tensor. The bars X_i represent the surrogate weights — after separately sorting the positive and negative parts — and the labels along a path of the tree correspond to the tensor-index of the weight represented by the leaf resulting from the mapping.

is the structured hinge loss.

This problem setting follows the same "passive-aggressive" strategy as in the original MIRA. To optimize the vectors $\boldsymbol{w}_h^d, h = 1, \ldots, H, d = 1, \ldots, D$, we use a similar iterative strategy as proposed in (Cai et al., 2006b). Basically, the idea is that instead of optimizing $\boldsymbol{w}_h^d$ all together, we optimize $\boldsymbol{w}_1^1, \boldsymbol{w}_1^2, \ldots, \boldsymbol{w}_H^D$ in turn. While we are updating one vector, the rest are fixed. For the problem setting given above, each of the sub-problems that need to be solved is convex, and according to (Cai et al., 2006b) the objective function value will decrease after each individual weight update and eventually this procedure will converge.

We now give this procedure in more detail. Denote the weight vector of the d^{th} mode of the h^{th} tensor at time t as $\boldsymbol{w}_{h,t}^d$. We will update the vectors in turn in the following order: $\boldsymbol{w}_{1,t}^1, \ldots, \boldsymbol{w}_{1,t}^D, \boldsymbol{w}_{2,t}^1, \ldots, \boldsymbol{w}_{2,t}^D, \ldots, \boldsymbol{w}_{H,t}^1, \ldots, \boldsymbol{w}_{H,t}^D$. Once a vector has been updated, it is fixed for future updates.

By way of notation, define

$$\begin{aligned}
&\boldsymbol{W}_{h,t}^d \\
&= \boldsymbol{w}_{h,t+1}^1 \otimes, \ldots, \otimes \boldsymbol{w}_{h,t+1}^{d-1} \otimes \boldsymbol{w}_{h,t}^d \otimes, \ldots, \otimes \boldsymbol{w}_{h,t}^D \\
&\quad \text{(and let } \boldsymbol{W}_{h,t}^{D+1} \triangleq \boldsymbol{w}_{h,t+1}^1 \otimes, \ldots, \otimes \boldsymbol{w}_{h,t+1}^D\text{)}, \\
&\widehat{\boldsymbol{W}}_{h,t}^d \\
&= \boldsymbol{w}_{h,t+1}^1 \otimes, \ldots, \otimes \boldsymbol{w}_{h,t+1}^{d-1} \otimes \boldsymbol{w}^d \otimes, \ldots, \otimes \boldsymbol{w}_{h,t}^D \\
&\quad \text{(where } \boldsymbol{w}^d \in \mathbb{R}^{n_d}\text{)},
\end{aligned}$$

$$\begin{aligned}
\boldsymbol{T}_{h,t}^d &= \sum_{h'=1}^{h-1} \boldsymbol{W}_{h',t}^{D+1} + \boldsymbol{W}_{h,t}^d + \sum_{h'=h+1}^{H} \boldsymbol{W}_{h',t}^1 \quad (4) \\
\widehat{\boldsymbol{T}}_{h,t}^d &= \sum_{h'=1}^{h-1} \boldsymbol{W}_{h',t}^{D+1} + \widehat{\boldsymbol{W}}_{h,t}^d + \sum_{h'=h+1}^{H} \boldsymbol{W}_{h',t}^1
\end{aligned}$$

$$\begin{aligned}
&\boldsymbol{\phi}_{h,t}^d(x, y) \\
&= \boldsymbol{\Phi}(x, y) \times_2 \boldsymbol{w}_{h,t+1}^2 \ldots \times_{d-1} \boldsymbol{w}_{h,t+1}^{d-1} \times_{d+1} \\
&\quad \boldsymbol{w}_{h,t}^{d+1} \ldots \times_D \boldsymbol{w}_{h,t}^D \qquad (5)
\end{aligned}$$

In order to update from $\boldsymbol{w}_{h,t}^d$ to get $\boldsymbol{w}_{h,t+1}^d$, the sub-problem to solve is:

$$\begin{aligned}
&\min_{\boldsymbol{w}^d \in \mathbb{R}^{n_d}} \frac{1}{2} \|\widehat{\boldsymbol{T}}_{h,t}^d - \boldsymbol{T}_{h,t}^d\|^2 + C\xi \\
&= \min_{\boldsymbol{w}^d \in \mathbb{R}^{n_d}} \frac{1}{2} \|\widehat{\boldsymbol{W}}_{h,t}^d - \boldsymbol{W}_{h,t}^d\|^2 + C\xi \\
&= \min_{\boldsymbol{w}^d \in \mathbb{R}^{n_d}} \frac{1}{2} \beta_{h,t+1}^1 \ldots \beta_{h,t+1}^{d-1} \beta_{h,t}^{d+1} \ldots \beta_{h,t}^D \\
&\qquad \|\boldsymbol{w}^d - \boldsymbol{w}_{h,t}^d\|^2 + C\xi \\
&s.t. \qquad \mathscr{L}_{h,t}^d \le \xi, \xi \ge 0.
\end{aligned}$$

where

$$\begin{aligned}
\beta_{h,t}^d &= \|\boldsymbol{w}_{h,t}^d\|^2 \\
\mathscr{L}_{h,t}^d &= \widehat{\boldsymbol{T}}_{h,t}^d \circ \boldsymbol{\Phi}(x_t, z_t) - \widehat{\boldsymbol{T}}_{h,t}^d \circ \boldsymbol{\Phi}(x_t, y_t) \\
&\quad + \rho(y_t, z_t) \\
&= \boldsymbol{w}^d \cdot \left(\boldsymbol{\phi}_{h,t}^d(x_t, z_t) - \boldsymbol{\phi}_{h,t}^d(x_t, y_t) \right) \\
&\quad - \left(\sum_{h'=1}^{h-1} \boldsymbol{W}_{h',t}^{D+1} + \sum_{h'=h+1}^{H} \boldsymbol{W}_{h',t}^1 \right) \circ \\
&\quad (\boldsymbol{\Phi}(x_t, y_t) - \boldsymbol{\Phi}(x_t, z_t)) \\
&\quad + \rho(y_t, z_t)
\end{aligned}$$

Letting

$$\Delta \boldsymbol{\phi}_{h,t}^d \triangleq \boldsymbol{\phi}_{h,t}^d(x_t, y_t) - \boldsymbol{\phi}_{h,t}^d(x_t, z_t)$$

and

$$\begin{aligned}
s_{h,t}^d \triangleq &\left(\sum_{h'=1}^{h-1} \boldsymbol{W}_{h',t}^{D+1} + \sum_{h'=h+1}^{H} \boldsymbol{W}_{h',t}^1 \right) \circ \\
&(\boldsymbol{\Phi}(x_t, y_t) - \boldsymbol{\Phi}(x_t, z_t))
\end{aligned}$$

we may compactly write

$$\mathscr{L}_{h,t}^d = \rho(y_t, z_t) - s_{h,t}^d - \boldsymbol{w}^d \cdot \Delta \boldsymbol{\phi}_{h,t}^d.$$

This convex optimization problem is just like the original MIRA and may be solved in a similar way. The updating strategy for $\boldsymbol{w}_{h,t}^d$ is derived as

$$\begin{aligned}
&\boldsymbol{w}_{h,t+1}^d = \boldsymbol{w}_{h,t}^d + \tau \Delta \boldsymbol{\phi}_{h,t}^d \\
&\tau = \qquad (6) \\
&\min \left\{ C, \frac{\rho(y_t, z_t) - \boldsymbol{T}_{h,t}^d \circ (\boldsymbol{\Phi}(x_t, y_t) - \boldsymbol{\Phi}(x_t, z_t))}{\|\Delta \boldsymbol{\phi}_{h,t}^d\|^2} \right\}
\end{aligned}$$

The initial vectors $\boldsymbol{w}_{h,1}^i$ cannot be made all zero, since otherwise the l-mode product in Equation (5) would yield all zero $\boldsymbol{\phi}_{h,t}^d(x, y)$ and the model would never get a chance to be updated. Therefore, we initialize the entries of $\boldsymbol{w}_{h,1}^i$ uniformly such that the Frobenius-norm of the weight tensor $\boldsymbol{W}$ is unity.

We call the algorithm above "Tensor-MIRA" and abbreviate it as T-MIRA.

5 Experiments

In this section we shows empirical results of the training algorithm on a parsing task. We used the Charniak parser (Charniak et al., 2005) for our experiment, and we used the proposed algorithm to train the reranking feature weights. For comparison, we also investigated training the reranker with Perceptron and MIRA.

5.1 Experimental Settings

To simulate a low-resource training environment, our training sets were selected from sections 2-9 of the Penn WSJ treebank, section 24 was used as the held-out set and section 23 as the evaluation set. We applied the default settings of the parser. There are around $V = 1.33$ million features in all defined for reranking, and the n-best size for reranking is set to 50. We selected the parse with the highest f-score from the 50-best list as the oracle.

We would like to observe from the experiments how the amount of training data as well as different settings of the tensor degrees of freedom affects the algorithm performance. Therefore we tried all combinations of the following experimental parameters:

Parameters	Settings
Training data (m)	Sec. 2, 2-3, 2-5, 2-9
Tensor order (D)	2, 3, 4
# rank-1 tensors (H)	1, 2, 3
Vec. to tensor mapping	approximate, sequential

Here "approximate" and "sequential" means using, respectively, the algorithm given in Figure 2 and the sequential mapping mentioned in Section 3.4. According to the strategy given in 3.2, once the tensor order and number of features are fixed, the sizes of modes and total number of parameters to estimate are fixed as well, as shown in the tables below:

D	Size of modes	Number of parameters
2	1155×1155	2310
3	$110 \times 110 \times 111$	331
4	$34 \times 34 \times 34 \times 34$	136

5.2 Results and Analysis

The f-scores of the held-out and evaluation set given by T-MIRA as well as the Perceptron and MIRA baseline are given in Table 1. From the results, we have the following observations:

1. When very few labeled data are available for training (compared with the number of features), T-MIRA performs much better than the vector-based models MIRA and Perceptron. However as the amount of training data increases, the advantage of T-MIRA fades away, and vector-based models catch up. This is because the weight tensors learned by T-MIRA are highly structured, which significantly reduces model/training complexity and makes the learning process very effective in a low-resource environment, but as the amount of data increases, the more complex and expressive vector-based models adapt to the data better, whereas further improvements from the tensor model is impeded by its structural constraints, making it insensitive to the increase of training data.

2. To further contrast the behavior of T-MIRA, MIRA and Perceptron, we plot the f-scores on both the training and held-out sets given by these algorithms after each training epoch in Figure 3. The plots are for the experimental setting with mapping=surrogate, # rank-1 tensors=2, tensor order=2, training data=sections 2-3. It is clearly seen that both MIRA and Perceptron do much better than T-MIRA on the training set. Nevertheless, with a huge number of parameters to fit a limited amount of data, they tend to over-fit and give much worse results on the held-out set than T-MIRA does.

   As an aside, observe that MIRA consistently outperformed Perceptron, as expected.

3. Properties of linear tensor model: The heuristic vector-to-tensor mapping strategy given by Figure 2 gives consistently better results than the sequential mapping strategy, as expected.

   To make further comparison of the two strategies, in Figure 4 we plot the 20 largest singular values of the matrices which the surrogate weights (given by the Perceptron after running for 1 epoch) are mapped to by both strategies (from the experiment with training data sections 2-5). From the contrast between the largest and the 2^{nd}-largest singular values, it can be seen that the matrix generated

by the first strategy approximates a low-rank structure much better than the second strategy. Therefore, the performance of T-MIRA is influenced significantly by the way features are mapped to the tensor. If the corresponding target weight tensor has internal structure that makes it approximately low-rank, the learning procedure becomes more effective.

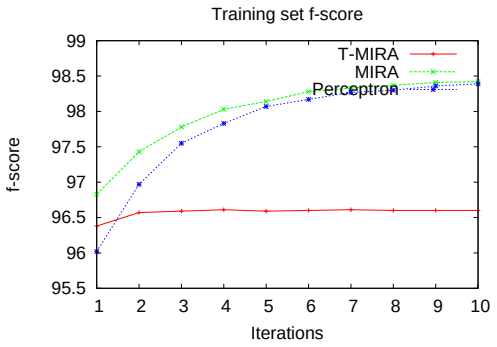
The best results are consistently given by 2^{nd} order tensor models, and the differences between the 3^{rd} and 4^{th} order tensors are not significant. As discussed in Section 3.1, although 3^{rd} and 4^{th} order tensors have less parameters, the benefit of reduced training complexity does not compensate for the loss of expressiveness. A 2^{nd} order tensor has already reduced the number of parameters from the original 1.33 million to only 2310, and it does not help to further reduce the number of parameters using higher order tensors.

4. As the amount of training data increases, there is a trend that the best results come from models with more rank-1 component tensors. Adding more rank-1 tensors increases the model's complexity and ability of expression, making the model more adaptive to larger data sets.

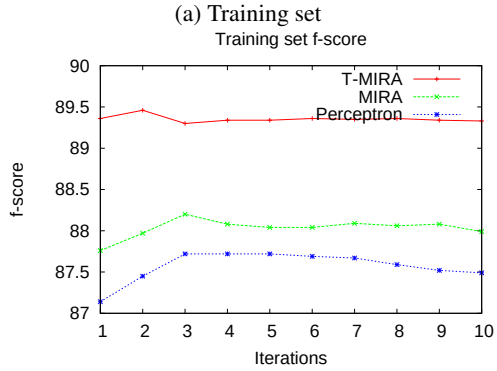
6 Conclusion and Future Work

In this paper, we reformulated the traditional linear vector-space models as tensor-space models, and proposed an online learning algorithm named Tensor-MIRA. A tensor-space model is a compact representation of data, and via rank-1 tensor approximation, the weight tensor can be made highly structured hence the number of parameters to be trained is significantly reduced. This can be regarded as a form of model regularization.Therefore, compared with the traditional vector-space models, learning in the tensor space is very effective when a large feature set is defined, but only small amount of training data is available. Our experimental results corroborated this argument.

As mentioned in Section 3.2, one interesting problem that merits further investigation is how to determine optimal mode sizes. The challenge of applying a tensor model comes from finding a proper tensor structure for a given problem, and



(a) Training set



(b) Held-out set

Figure 3: f-scores given by three algorithms on training and held-out set (see text for the setting).

the key to solving this problem is to find a balance between the model complexity (indicated by the order and sizes of modes) and the number of parameters. Developing a theoretically guaranteed approach of finding the optimal structure for a given task will make the tensor model not only perform well in low-resource environments, but adaptive to larger data sets.

A Proof of Theorem 1

Proof. For $D = 1$, it is obvious that if a set of real numbers $\{x_1, \ldots, x_n\}$ can be represented by a rank-1 matrix, it can always be represented by a vector, but the reverse is not true.

For $D > 1$, if $\{x_1, \ldots, x_n\}$ can be represented by $\mathcal{P} = \mathbf{p}_1 \otimes \mathbf{p}_2 \otimes \ldots \otimes \mathbf{p}_D$, namely $x_i = \mathcal{P}_{i_1,\ldots,i_D} = \prod_{d=1}^{D} p^d_{i_d}$, then for any component vector in mode d,

$$[p^d_1, p^d_2, \ldots, p^d_{n_d}] = [s^d_1 p^d_1, s^d_2 p^d_1, \ldots, s^d_{n^p_d} p^d_1]$$

where n^p_d is the size of mode d of $\mathcal{P}$, s^d_j is a constant and $s^d_j = \frac{p_{i1,\ldots,i_{d-1},j,i_{d+1},\ldots,i_D}}{p_{i1,\ldots,i_{d-1},1,i_{d+1},\ldots,i_D}}$ Therefore

$$x_i = \mathcal{P}_{i_1,\ldots,i_D} = x_{1,\ldots,1} \prod_{d=1}^{D} s^d_{i_d} \tag{7}$$

and this representation is unique for a given D(up to the ordering of $\mathbf{p}_j$ and s^d_j in $\mathbf{p}_j$, which simply assigns $\{x_1, \ldots, x_n\}$ with different indices in the tensor), due to the pairwise proportional constraint imposed by $x_i/x_j, i, j = 1, \ldots, n$.

If x_i can also be represented by $\mathcal{Q}$, then $x_i = \mathcal{Q}_{i_1,\ldots,i_{D+1}} = x_{1,\ldots,1} \prod_{d=1}^{D+1} t^d_{i_d}$, where t^d_j has a similar definition as s^d_j. Then it must be the case that

$$\begin{aligned} &\exists d_1, d_2 \in \{1, \ldots, D+1\}, d \in \{1, \ldots, D\}, d_1 \neq d_2 \\ &s.t. \\ &t^{d_1}_{i_{d_1}} t^{d_2}_{i_{d_2}} = s^d_{i_d}, \\ &t^{d_a}_{i_{d_a}} = s^{d_b}_{i_{d_b}}, \quad d_a \neq d_1, d_2, \quad d_b \neq d \end{aligned} \tag{8}$$

since otherwise $\{x_1, \ldots, x_n\}$ would be represented by a different set of factors than those given in Equation (7).

Therefore, in order for tensor $\mathcal{Q}$ to represent the same set of real numbers that $\mathcal{P}$ represents, there needs to exist a vector $[s^d_1, \ldots, s^d_{n_d}]$ that can be represented by a rank-1 matrix as indicated by Equation (8), which is in general not guaranteed.

On the other hand, if $\{x_1, \ldots, x_n\}$ can be represented by $\mathcal{Q}$, namely

$$x_i = \mathcal{Q}_{i_1,\ldots,i_{D+1}} = \prod_{d=1}^{D+1} q^d_{i_d}$$

then we can just pick $d_1 \in \{1, \ldots, D\}, d_2 = d_1 + 1$ and let

$$\mathbf{q}' = [q^{d_1}_1 q^{d_2}_1, q^{d_1}_1 q^{d_2}_2, \ldots, q^{d_1}_{n^q_{d_2}} q^{d_2}_{n^q_{d_1}}]$$

and

$$\mathcal{Q}' = \mathbf{q}_1 \otimes \ldots \otimes \mathbf{q}_{d_1-1} \otimes \mathbf{q}' \otimes \mathbf{q}_{d_2+1} \otimes \ldots \otimes \mathbf{q}_{D+1}$$

Hence $\{x_1, \ldots, x_n\}$ can also be represented by a D^{th} order tensor $\mathcal{Q}'$. □

Graph-based Semi-Supervised Learning of Translation Models from Monolingual Data

Abstract

Statistical phrase-based translation learns translation rules from bilingual corpora, and has traditionally only used monolingual evidence to construct features that rescore existing translation candidates. In this work, we present a semi-supervised graph-based approach for generating new translation rules that leverages bilingual and monolingual data. The proposed technique first constructs phrase graphs using both source and target language monolingual corpora. Next, graph propagation identifies translations of phrases that were not observed in the bilingual corpus, assuming that similar phrases have similar translations. We report results on a large Arabic-English system and a medium-sized Urdu-English system. Our proposed approach significantly improves the performance of competitive phrase-based systems, leading to consistent improvements between 1 and 4 BLEU points on standard evaluation sets.

1 Introduction

Statistical approaches to machine translation (SMT) use sentence-aligned, parallel corpora to learn translation rules along with their probabilities. With large amounts of data, phrase-based translation systems (Koehn et al., 2003; Chiang, 2007) achieve state-of-the-art results in many typologically diverse language pairs (Bojar et al., 2013). However, the limiting factor in the success of these techniques is parallel data availability. Even in resource-rich languages, learning reliable translations of multiword phrases is a challenge, and an adequate phrasal inventory is crucial for effective translation. This problem is exacerbated in the many language pairs for which parallel resources are either limited or nonexistent. While parallel data is generally scarce, monolingual resources exist in abundance and are being created at accelerating rates. Can we use monolingual data to augment the phrasal translations acquired from parallel data?

The challenge of learning translations from monolingual data is of long standing interest, and has been approached in several ways (Rapp, 1995; Callison-Burch et al., 2006; Haghighi et al., 2008; Ravi and Knight, 2011). Our work introduces a new take on the problem using graph-based semi-supervised learning to acquire translation rules and probabilities by leveraging both monolingual and parallel data resources. On the source side, labeled phrases (those with known translations) are extracted from bilingual corpora, and unlabeled phrases are extracted from monolingual corpora; together they are embedded as nodes in a graph, with the monolingual data determining edge strengths between nodes (§2.2). Unlike previous work (Irvine and Callison-Burch, 2013a; Razmara et al., 2013), we use higher order n-grams instead of restricting to unigrams, since our approach goes beyond OOV mitigation and can enrich the entire translation model by using evidence from monolingual text. This enhancement alone results in an improvement of almost 1.4 BLEU points. On the target side, phrases initially consisting of translations from the parallel data are selectively expanded with generated candidates (§2.1), and are embedded in a target graph.

We then limit the set of translation options for each unlabeled source phrase (§2.3), and using a structured graph propagation algorithm, where translation information is propagated from labeled to unlabeled phrases proportional to *both* source and target phrase similarities, we estimate probability distributions over translations for

*This work was done while the first author was interning at Microsoft Research

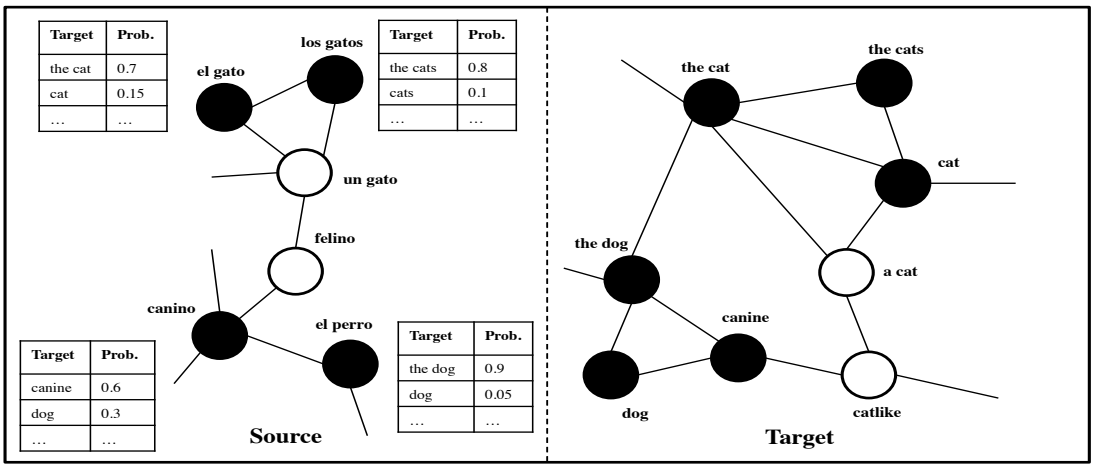

Figure 1: Example source and target graphs used in our approach. Labeled phrases on the source side are black (with their corresponding translations on the target side also black); unlabeled and generated (§2.1) phrases on the source and target sides respectively are white. Labeled phrases also have conditional probability distributions defined over target phrases, which are extracted from the parallel corpora.

the unlabeled source phrases (§2.4). The additional phrases are incorporated in the SMT system through a secondary phrase table (§2.5). We evaluated the proposed approach on both Arabic-English and Urdu-English under a range of scenarios (§3), varying the amount and type of monolingual corpora used, and obtained improvements between 1 and 4 BLEU points, even when using very large language models.

2 Generation & Propagation

Our goal is to obtain translation distributions for source phrases that are not present in the phrase table extracted from the parallel corpus. Both parallel and monolingual corpora are used to obtain these probability distributions over target phrases. We assume that sufficient parallel resources exist to learn a basic translation model using standard techniques, and also assume the availability of larger monolingual corpora in both the source and target languages. Although our technique applies to phrases of any length, in this work we concentrate on unigram and bigram phrases, which provides substantial computational cost savings.

Monolingual data is used to construct *separate* similarity graphs over phrases (word sequences), as illustrated in Fig. 1. The source similarity graph consists of phrase nodes representing sequences of words in the source language. If a source phrase is found in the baseline phrase table it is called a **labeled** phrase: its conditional empirical probability distribution over target phrases (estimated from the parallel data) is used as the label, and is subsequently never changed. Otherwise it is called an **unlabeled** phrase, and our algorithm finds labels (translations) for these unlabeled phrases, with the help of the graph-based representation. The label space is thus the phrasal translation inventory, and like the source side it can also be represented in terms of a graph, initially consisting of target phrase nodes from the parallel corpus.

For the unlabeled phrases, the set of possible target translations could be extremely large (e.g., all target language n-grams). Therefore, we first **generate** and fix a list of possible target translations for each unlabeled source phrase. We then **propagate** by deriving a probability distribution over these target phrases using graph propagation techniques. Next, we will describe the generation, graph construction and propagation steps.

2.1 Generation

The objective of the generation step is to populate the target graph with *additional* target phrases for all unlabeled source phrases, yielding the full set of possible translations for the phrase. Prior to generation, one phrase node for each target phrase occurring in the baseline phrase table is added to the target graph (black nodes in Fig. 1's target graph). We only consider target phrases whose source phrase is a bigram, but it is worth noting that the target phrases are of variable length.

The generation component is based on the observation that for structured label spaces, such as translation candidates for source phrases in SMT, even similar phrases have slightly different labels (target translations). The exponential dependence

of the sizes of these spaces on the length of instances is to blame. Thus, the target phrase inventory from the parallel corpus may be inadequate for unlabeled instances. We therefore need to enrich the target or label space for unknown phrases. A naïve way to achieve this goal would be to extract all n-grams, from $n = 1$ to a maximum n-gram order, from the monolingual data, but this strategy would lead to a combinatorial explosion in the number of target phrases.

Instead, by intelligently expanding the target space using linguistic information such as morphology (Toutanova et al., 2008; Chahuneau et al., 2013), or relying on the baseline system to generate candidates similar to self-training (McClosky et al., 2006), we can tractably propose novel translation candidates (white nodes in Fig. 1's target graph) whose probabilities are then estimated during propagation. We refer to these additional candidates as "generated" candidates.

To generate new translation candidates using the baseline system, we decode each unlabeled source bigram to generate its m-best translations. This set of candidate phrases is filtered to include only n-grams occurring in the target monolingual corpus, and helps to prune passed-through OOV words and invalid translations. To generate new translation candidates using morphological information, we morphologically segment words into prefixes, stem, and suffixes using linguistic resources. We assume that a morphological analyzer which provides context-independent analysis of word types exists, and implements the functions $\text{STEM}(f)$ and $\text{STEM}(e)$ for source and target word types. Based on these functions, source and target sequences of words can be mapped to sequences of stems. The morphological generation step adds to the target graph all target word sequences from the monolingual data that map to the same stem sequence as one of the target phrases occurring in the baseline phrase table. In other words, this step adds phrases that are morphological variants of existing phrases, differing only in their affixes.

2.2 Graph Construction

At this stage, there exists a list of source bigram phrases, both labeled and unlabeled, as well as a list of target language phrases of variable length, originating from both the phrase table and the generation step. To determine pairwise phrase similarities in order to embed these nodes in their graphs, we utilize the monolingual corpora on both the source and target sides to extract distributional features based on the context surrounding each phrase. For a phrase, we look at the p words before and the p words after the phrase, explicitly distinguishing between the two sides, but not distance (i.e., bag of words on each side). Co-occurrence counts for each feature (context word) are accumulated over the monolingual corpus, and these counts are converted to pointwise mutual information (PMI) values, as is standard practice when computing distributional similarities. Cosine similarity between two phrases' PMI vectors is used for similarity, and we take only the k most similar phrases for each phrase, to create a k-nearest neighbor similarity matrix for both source and target language phrases. These graphs are distinct, in that propagation happens within the two graphs but not between them.

While accumulating co-occurrence counts for each phrase, we also maintain an inverted index data structure, which is a mapping from features (context words) to phrases that co-occur with that feature within a window of p.[1] The inverted index structure reduces the graph construction cost from $\theta(n^2)$, by only computing similarities for a subset of all possible pairs of phrases, namely other phrases that have at least one feature in common.

2.3 Candidate Translation List Construction

As mentioned previously, we construct and fix a set of translation candidates, i.e., the label set for each unlabeled source phrase. The probability distribution over these translations is estimated through graph propagation, and the probabilities of items outside the list are assumed to be zero.

We obtain these candidates from two sources:[2]

1. The union of each unlabeled phrase's labeled neighbors' labels, which represents the set of target phrases that occur as translations of source phrases that are similar to the unlabeled source phrase. For *un gato* in Fig. 1, this source would yield *the cat* and *cat*, among others, as candidates.

2. The generated candidates for the unlabeled phrase – the ones from the baseline system's

[1] The q most frequent words in the monolingual corpus were removed as keys from this mapping, as these high entropy features do not provide much information.

[2] We also obtained the k-nearest neighbors of the translation candidates generated through these methods by utilizing the target graph, but this had minimal impact.

decoder output, or from a morphological generator (e.g., *a cat* and *catlike* in Fig. 1).

The morphologically-generated candidates for a given source unlabeled phrase are initially defined as the target word sequences in the monolingual data that have the same stem sequence as one of the baseline's target translations for a source phrase which has the same stem sequence as the unlabeled source phrase. These candidates are scored using stem-level translation probabilities, morpheme-level lexical weighting probabilities, and a language model, and only the top 30 candidates are included.

After obtaining candidates from these two possible sources, the list is sorted by forward lexical score, using the lexical models of the baseline system. The top r candidates are then chosen for each phrase's translation candidate list.

In Figure 2 we provide example outputs of our system for a handful of unlabeled source phrases, and explicitly note the source of the translation candidate ('G' for generated, 'N' for labeled neighbor's label).

2.4 Graph Propagation

A graph propagation algorithm transfers label information from labeled nodes to unlabeled nodes by following the graph's structure. In some applications, a label may consist of class membership information, e.g., each node can belong to one of a certain number of classes. In our problem, the "label" for each node is actually a probability distribution over a set of translation candidates (target phrases). For a given node f, let e refer to a candidate in the label set for node f; then in graph propagation, the probability of candidate e given source phrase f in iteration $t+1$ is:

$$\mathbb{P}^{t+1}(e|f) = \sum_{j \in \mathcal{N}(f)} T_s(j|f)\mathbb{P}^t(e|j) \quad (1)$$

where the set $\mathcal{N}(f)$ contains the (labeled and unlabeled) neighbors of node f, and $T_s(j|f)$ is a term that captures how similar nodes f and j are. This quantity is also known as the propagation probability, and its exact form will depend on the type of graph propagation algorithm used. For our purposes, node f is a source phrasal node, the set $\mathcal{N}(f)$ refers to other source phrases that are neighbors of f (restricted to the k-nearest neighbors as in §2.2), and the aim is to estimate $P(e|f)$, the probability of target phrase e being a phrasal translation of source phrase f.

A classic propagation algorithm that has been suitably modified for use in bilingual lexicon induction (Tamura et al., 2012; Razmara et al., 2013) is the **label propagation** (LP) algorithm of Zhu et al. (2003). In this case, $T_s(f, j)$ is chosen to be:

$$T_s(j|f) = \frac{w^s_{f,j}}{\sum_{j' \in \mathcal{N}(f)} w^s_{f,j'}} \quad (2)$$

where $w^s_{f,j}$ is the cosine similarity (as computed in §2.2) between phrase f and phrase j on side s (the source side).

As evident in Eq. 2, LP only takes into account source language similarity of phrases. To see this observation more clearly, let us reformulate Eq. 1 more generally as:

$$\mathbb{P}^{t+1}(e|f) = \sum_{j \in \mathcal{N}(f)} T_s(j|f) \sum_{e' \in \mathcal{H}(j)} T_t(e'|e)\mathbb{P}^t(e'|j) \quad (3)$$

where $\mathcal{H}(j)$ is the translation candidate set for source phrase j, and $T_t(e'|e)$ is the propagation probability between nodes or phrases e and e' on the *target* side. We have simply replaced $\mathbb{P}^t(e|j)$ with $\sum_{e' \in \mathcal{H}(j)} T_t(e'|e)\mathbb{P}^t(e'|j)$, defining it in terms of j's translation candidate list.

Note that in the original LP formulation the target side information is disregarded, i.e., $T_t(e'|e) = 1$ if and only if $e = e'$ and 0 otherwise. As a result, LP is suboptimal for our needs, since it is unable to appropriately handle generated translation candidates for the unlabeled phrases. These translation candidates are usually not present as translations for the labeled phrases (or for the labeled phrases that neighbor the unlabeled one in question). When propagating information from the labeled phrases, such candidates will obtain no probability mass since $e \neq e'$. Thus, due to the setup of the problem, LP naturally biases away from translation candidates produced during the generation step (§2.1).

2.4.1 Structured Label Propagation

The label set we are considering has a similarity structure encoded by the target graph. How can we exploit this structure in graph propagation on the source graph? In Liu *et al.* (2012), the authors generalize label propagation to **structured label propagation** (SLP) in an effort to work more elegantly with structured labels. In particular, the definition of target similarity is similar to that of source similarity:

$$T_t(e'|e) = \frac{w^t_{e,e'}}{\sum_{e'' \in \mathcal{H}(j)} w^t_{e,e''}} \quad (4)$$

Therefore, the final update equation in SLP is:

$$\mathbb{P}^{t+1}(e|f) = \sum_{j \in \mathcal{N}(f)} T_s(j|f) \sum_{e' \in \mathcal{H}(j)} T_t(e'|e)\mathbb{P}^t(e'|j) \quad (5)$$

With this formulation, even if $e \neq e'$, the similarity $T_t(e'|e)$ as determined by the target phrase graph will dictate propagation probability. We renormalize the probability distributions after each propagation step to sum to one over the fixed list of translation candidates, and run the SLP algorithm to convergence.[3]

2.5 Phrase-based SMT Expansion

After graph propagation, each unlabeled phrase is labeled with a categorical distribution over the set of translation candidates defined in §2.3. In order to utilize these newly acquired phrase pairs, we need to compute their relevant features. The phrase pairs have four log-probability features with two likelihood features and two lexical weighting features. In addition, we use a sophisticated lexicalized hierarchical reordering model (HRM) (Galley and Manning, 2008) with five features for each phrase pair.

We utilize the graph propagation-estimated forward phrasal probabilities $\mathbb{P}(e|f)$ as the forward likelihood probabilities for the acquired phrases; to obtain the backward phrasal probability for a given phrase pair, we make use of Bayes' Theorem:

$$\mathbb{P}(f|e) = \frac{\mathbb{P}(e|f)\mathbb{P}(f)}{\mathbb{P}(e)}$$

where the marginal probabilities of source and target phrases e and f are obtained from the counts extracted from the monolingual data. The baseline system's lexical models are used for the forward and backward lexical scores. The HRM probabilities for the new phrase pairs are estimated from the baseline system by backing-off to the average values for phrases with similar length.

3 Evaluation

We performed an extensive evaluation to examine various aspects of the approach along with overall system performance. Two language pairs were used: Arabic-English and Urdu-English. The Arabic-English evaluation was used to validate the decisions made during the development of our method and also to highlight properties of the technique. With it, in §3.2 we first analyzed the impact of utilizing phrases instead of words and SLP instead of LP; the latter experiment underscores the importance of generated candidates. We also look at how adding morphological knowledge to the generation process can further enrich performance. In §3.3, we then examined the effect of using a very large 5-gram language model training on 7.5 billion English tokens to understand the nature of the improvements in §3.2. The Urdu to English evaluation in §3.4 focuses on how noisy parallel data and completely monolingual (i.e., not even comparable) text can be used for a realistic low-resource language pair, and is evaluated with the larger language model only. We also examine how our approach can learn from noisy parallel data compared to the traditional SMT system.

Baseline phrasal systems are used both for comparison and for generating translation candidates for unlabeled phrases as described in §2.1. The baseline is a state-of-the-art phrase-based system; we perform word alignment using a lexicalized hidden Markov model, and then the phrase table is extracted using the `grow-diag-final` heuristic (Koehn et al., 2003). The 13 baseline features (2 lexical, 2 phrasal, 5 HRM, and 1 language model, word penalty, phrase length feature and distortion penalty feature) were tuned using MERT (Och, 2003), which is also used to tune the 4 feature weights introduced by the secondary phrase table (2 lexical and 2 phrasal, other features being shared between the two tables). For all systems, we use a distortion limit of 4. We use case-insensitive BLEU (Papineni et al., 2002) to evaluate translation quality.

3.1 Datasets

Bilingual corpus statistics for both language pairs are presented in Table 2. For Arabic-English, our training corpus consisted of 685k sentence pairs from standard LDC corpora[4]. The NIST MT06 and MT08 Arabic-English evaluation sets (combining the newswire and weblog domains for both sets), with four references each, were used as tuning and testing sets respectively. For Urdu-English, the training corpus was provided by the LDC for the NIST Urdu-English MT evaluation, and most of the data was automatically acquired from the web, making it quite noisy. After filtering, there are approximately 65k parallel sen-

[3] Empirically within a few iterations and a wall-clock time of less than 10 minutes in total.

[4] LDC2007T08 and LDC2008T09

Parameter	Description	Value
m	m-best candidate list size when bootstrapping candidates in generation stage.	100
p	Window size on each side when extracting features for phrases.	2
q	Filter the q most frequent words when storing the inverted index data structure for graph construction. Both source and target sides share the same value.	25
k	Number of neighbors stored for each phrase for both source and target graphs. This parameter controls the sparsity of the graph.	500
r	Maximum size of translation candidate list for unlabeled phrases.	20

Table 1: Parameters, explanation of their function, and value chosen.

tences; these were supplemented by an additional 100k dictionary entries. Tuning and test data consisted of the MT08 and MT09 evaluation corpora, once again a mixture of news and web text.

Corpus	Sentences	Words (Src)
Ar-En Train	685,502	17,055,168
Ar-En Tune (MT06)	1,664	33,739
Ar-En Test (MT08)	1,360	42,472
Ur-En Train	165,159	1,169,367
Ur-En Tune (MT08)	1,864	39,925
Ur-En Test (MT09)	1,792	39,922

Table 2: Bilingual corpus statistics for the Arabic-English and Urdu-English datasets used.

Table 3 contains statistics for the monolingual corpora used in our experiments. From these corpora, we extracted all sentences that contained at least one source or target phrase match to compute features for graph construction. For the Arabic to English experiments, the monolingual corpora are taken from the AFP Arabic and English Gigaword corpora and are of a similar date range to each other (1994-2010), rendering them comparable but not sentence-aligned or parallel.

Corpus	Sentences	Words
Ar Comparable	10.2m	290m
En I Comparable	29.8m	900m
Ur Noisy Parallel	470k	5m
En II Noisy Parallel	470k	4.7m
Ur Non-Comparable	7m	119m
En II Non-Comparable	17m	510m

Table 3: Monolingual corpus statistics for the Arabic-English and Urdu-English evaluations. The monolingual corpora can be sub-divided into comparable, noisy parallel, and non-comparable components. En I refers to the English side of the Arabic-English corpora, and En II to the English side of the Urdu-English corpora.

For the Urdu-English experiments, completely non-comparable monolingual text was used for graph construction; we obtained the Urdu side through a web-crawler, and a subset of the AFP Gigaword English corpus was used for English. In addition, we obtained a corpus from the ELRA[5], which contains a mix of parallel and monolingual data; based on timestamps, we extracted a comparable English corpus for the ELRA Urdu monolingual data to form a roughly 470k-sentence "noisy parallel" set. We used this set in two ways: either to augment the parallel data presented in Table 2, or to augment the non-comparable monolingual data in Table 3 for graph construction.

For the parameters introduced throughout the text, we present in Table 1 a reminder of their interpretation as well as the values used in this work.

3.2 Experimental Variations

In our first set of experiments, we looked at the impact of choosing bigrams over unigrams as our basic unit of representation, along with performance of LP (Eq. 2) compared to SLP (Eq. 4). Recall that LP only takes into account source similarity; since the vast majority of generated candidates do not occur as labeled neighbors' labels, restricting propagation to the source graph drastically reduces the usage of generated candidates as labels, but does not completely eliminate it. In these experiments, we utilize a reasonably-sized 4-gram language model trained on 900m English tokens, i.e., the English monolingual corpus.

Table 4 presents the results of these variations; overall, by taking into account generated candidates appropriately and using bigrams ("SLP 2-gram"), we obtained a 1.13 BLEU gain on the test set. Using unigrams ("SLP 1-gram") actually does worse than the baseline, indicating the importance of focusing on translations for sparser bigrams. While LP ("LP 2-gram") does reasonably well, its underperformance compared to SLP underlines the importance of enriching the translation space with generated candidates and handling these candidates appropriately.[6] In "SLP-

[5]ELRA-W0038

[6]It is relatively straightforward to combine both unigrams and bigrams in one source graph, but for experimental clarity we did not mix these phrase lengths.

HalfMono", we use only half of the monolingual comparable corpora, and still obtain an improvement of 0.56 BLEU points, indicating that adding more monolingual data is likely to improve the system further. Interestingly, biasing away from generated candidates using all the monolingual data ("LP 2-gram") performs similarly to using half the monolingual corpora and handling generated candidates properly ("SLP-HalfMono").

	BLEU	
Setup	**Tune**	**Test**
Baseline	39.33	38.09
SLP 1-gram	39.47	37.85
LP 2-gram	40.75	38.68
SLP 2-gram	41.00	39.22
SLP-HalfMono 2-gram	40.82	38.65
SLP+Morph 2-gram	41.02	39.35

Table 4: Results for the Arabic-English evaluation. The LP vs. SLP comparison highlights the importance of target side enrichment via translation candidate generation, 1-gram vs. 2-gram comparisons highlight the importance of emphasizing phrases, utilizing half the monolingual data shows sensitivity to monolingual corpus size, and adding morphological information results in additional improvement.

Additional morphologically generated candidates were added in this experiment as detailed in §2.3. We used a simple hand-built Arabic morphological analyzer that segments word types based on regular expressions, and an English lexicon-based morphological analyzer. The morphological candidates add a small amount of improvement, primarily by targeting genuine OOVs.

3.3 Large Language Model Effect

In this set of experiments, we examined if the improvements in §3.2 can be explained primarily through the extraction of language model characteristics during the semi-supervised learning phase, or through orthogonal pieces of evidence. Would the improvement be less substantial had we used a very large language model?

To answer this question we trained a 5-gram language model on 570M sentences (7.6B tokens), with data from various sources including the Gigaword corpus[7], WMT and European Parliamentary Proceedings[8], and web-crawled data from Wikipedia and the web. Only m-best generated candidates from the baseline were considered during generation, along with labeled neighbors' labels.

	BLEU	
Setup	**Tune**	**Test**
Baseline+LargeLM	41.48	39.86
SLP+LargeLM	42.82	41.29

Table 5: Results with the large language model scenario. The gains are even better than with the smaller language model.

Table 5 presents the results of using this language model. We obtained a robust, 1.43-BLEU point gain, indicating that the addition of the newly induced phrases provided genuine translation improvements that cannot be compensated by the language model effect. Further examination of the differences between the two systems yielded that most of the improvements are due to better bigrams and trigrams, as indicated by the breakdown of the BLEU score precision per n-gram, and primarily leverages higher quality generated candidates from the baseline system. We analyze the output of these systems further in the output analysis section below (§3.5).

3.4 Urdu-English

In order to evaluate the robustness of these results beyond one language pair, we looked at Urdu-English, a low resource pair likely to benefit from this approach. In this set of experiments, we used the large language model in §3.3, and only used baseline-generated candidates. We experimented with two extreme setups that differed in the data assumed parallel, from which we built our baseline system, and the data treated as monolingual, from which we built our source and target graphs.

In the first setup, we use the noisy parallel data for graph construction and augment the non-comparable corpora with it:

- parallel: "Ur-En Train"
- Urdu monolingual: "Ur Noisy Parallel"+"Ur Non-Comparable"
- English monolingual: "En II Noisy Parallel"+"En II Non-Comparable"

The results from this setup are presented as "Baseline" and "SLP+Noisy" in Table 6. In the second setup, we train a baseline system using the data in Table 2, augmented with the noisy parallel text:

- parallel: "Ur-En Train"+"Ur Noisy Parallel"+"En II Noisy Parallel"
- Urdu monolingual: "Ur Non-Comparable"
- English monolingual: "En II Non-Comparable"

Ex	Source	Reference	Baseline	System
1 (Ar)	ارسال التعزيزات	sending reinforcements	strong reinforcements	sending reinforcements (N)
2 (Ar)	ل+ الاندثار	with extinction	OOV	with extinction (N)
3 (Ar)	تحبط محاولة	thwarts	address	thwarted (N)
4 (Ar)	نسبت الي	was quoted as saying	attributed to	was quoted as saying (G)
5 (Ar)	أوضح عبد المحمود	abdalmahmood said	he said abdul mahmood	mahmood said (G)
6 (Ar)	تراه منكبا	it deems	OOV	it deems (G)
7 (Ur)	پر امید	I am hopeful	this hope	I am hopeful (N)
8 (Ur)	اپنا دفاع	to defend him	to defend	to defend himself (G)
9 (Ur)	گفتگو کی۔	while speaking	In the	in conversation (N)

Figure 2: Nine example outputs of our system vs. the baseline highlighting the properties of our approach. Each example is labeled (Ar) for Arabic source or (Ur) for Urdu source, and system candidates are labeled with (N) if the candidate unlabeled phrase's labeled neighbor's label, or (G) if the candidate was generated.

The results from this setup are presented as "Baseline+Noisy" and "SLP" in Table 6. The two setups allow us to examine how effectively our method can learn from the noisy parallel data by treating it as monolingual (i.e., for graph construction), compared to treating this data as parallel, and also examines the realistic scenario of using completely non-comparable monolingual text for graph construction as in the second setup.

	BLEU	
Setup	**Tune**	**Test**
Baseline	21.87	21.17
SLP+Noisy	26.42	25.38
Baseline+Noisy	27.59	27.24
SLP	28.53	28.43

Table 6: Results for the Urdu-English evaluation evaluated with BLEU. All experiments were conducted with the larger language model, and generation only considered the m-best candidates from the baseline system.

In the first setup, we get a huge improvement of 4.2 BLEU points ("SLP+Noisy") when using the monolingual data and the noisy parallel data for graph construction. Our method obtained much of the gains achieved by the supervised baseline approach that utilizes the noisy parallel data in conjunction with the NIST-provided parallel data ("Baseline+Noisy"), but with fewer assumptions on the nature of the corpora (monolingual vs. parallel). Furthermore, despite completely unaligned, non-comparable monolingual text on the Urdu and English sides, and a very large language model, we can still achieve gains in excess of 1.2 BLEU points ("SLP") in a difficult evaluation scenario, which shows that the technique adds a genuine translation improvement over and above naïve memorization of n-gram sequences.

3.5 Analysis of Output

Figure 2 looks at some of the sample hypotheses produced by our system and the baseline, along with reference translations. The outputs produced by our system are additionally annotated with the origin of the candidate, i.e., labeled neighbor's label (N) or generated (G).

The Arabic-English examples are numbered 1 to 5. The first example shows a source bigram unknown to the baseline system, resulting in a suboptimal translation, while our system proposes the correct translation of "sending reinforcements". The second example shows a word that was an OOV for the baseline system, while our system got a perfect translation. The third and fourth examples represent bigram phrases with much better translations compared to backing off to the lexical translations as in the baseline. The fifth Arabic-English example demonstrates the pitfalls of over-reliance on the distributional hypothesis: the source bigram corresponding to the name "abd almahmood" is distributional similar to another named entity "mahmood" and the English equivalent is offered as a translation. The distributional hypothesis can sometimes be misleading. The sixth example shows how morphological information can propose novel candidates: an OOV word is broken down to its stem via the analyzer and candidates are generated based on the stem.

The Urdu-English examples are numbered 7 to 9. In example 7, the bigram "par umeed" (corresponding to "hopeful") is never seen in the baseline system, which has only seen "umeed" ("hope"). By leveraging the monolingual corpus to understand the context of this unlabeled bigram, we can utilize the graph structure to propose a syntactically correct form, also resulting in a more fluent and correct sentence as determined by the language model. Examples 8 & 9 show cases where the baseline deletes words or translates them into more common words e.g., "conversation" to "the", while our system proposes reasonable candidates.

4 Related Work

The idea presented in this paper is similar in spirit to bilingual lexicon induction (BLI), where a seed lexicon in two different languages is expanded with the help of monolingual corpora, primarily by extracting distributional similarities from the data using word context. This line of work, initiated by Rapp (1995) and continued by others (Fung and Yee, 1998; Koehn and Knight, 2002) (*inter alia*) is limited from a downstream perspective, as translations for only a small number of words are induced and oftentimes for common or frequently occurring ones only. Recent improvements to BLI (Tamura et al., 2012; Irvine and Callison-Burch, 2013b) have contained a graph-based flavor by presenting label propagation-based approaches using a seed lexicon, but evaluation is once again done on top-1 or top-3 accuracy, and the focus is on unigrams.

Razmara et al. (2013) and Irvine and Callison-Burch (2013a) conduct a more extensive evaluation of their graph-based BLI techniques, where the emphasis and end-to-end BLEU evaluations concentrated on OOVs, i.e., unigrams, and not on enriching the entire translation model. As with previous BLI work, these approaches only take into account source-side similarity of words; only moderate gains (and in the latter work, on a subset of language pairs evaluated) are obtained. Additionally, because of our structured propagation algorithm, our approach is better at handling multiple translation candidates and does not need to restrict itself to the top translation.

Klementiev et al. (2012) propose a method that utilizes a pre-existing phrase table and a small bilingual lexicon, and performs BLI using monolingual corpora. The operational scope of their approach is limited in that they assume a scenario where unknown phrase pairs are provided (thereby sidestepping the issue of translation candidate generation for completely unknown phrases), and what remains is the estimation of phrasal probabilities. In our case, we obtain the phrase pairs from the graph structure (and therefore indirectly from the monolingual data) and a separate generation step, which plays an important role in good performance of the method. Similarly, Zhang and Zong (2013) present a series of heuristics that are applicable in a fairly narrow setting.

The notion of translation consensus, wherein similar sentences on the source side are encouraged to have similar target language translations, has also been explored via a graph-based approach (Alexandrescu and Kirchhoff, 2009). Liu et al. (2012) extend this method by proposing a novel structured label propagation algorithm to deal with the generalization of propagating *sets* of labels instead of single labels, and also integrated information from the graph into the decoder. In fact, we utilize this algorithm in our propagation step (§2.4). However, the former work operates only at the level of sentences, and while the latter does extend the framework to sub-spans of sentences, they do not discover new translation pairs or phrasal probabilities for new pairs at all, but instead re-estimate phrasal probabilities using the graph structure and add this score as an additional feature during decoding.

The goal of leveraging non-parallel data in machine translation has been explored from several different angles. Paraphrases extracted by "pivoting" via a third language (Callison-Burch et al., 2006) can be derived solely from monolingual corpora using distributional similarity (Marton et al., 2009). Snover et al. (2008) use cross-lingual information retrieval techniques to find potential sentence-level translation candidates among comparable corpora. In this case, the goal is to try and construct a corpus as close to parallel as possible from comparable corpora, and is a fairly different take on the problem we are looking at. Decipherment-based approaches (Ravi and Knight, 2011; Dou and Knight, 2012) have generally taken a monolingual view to the problem and combine phrase tables through the log-linear model during feature weight training.

5 Conclusion

In this work, we presented an approach that can expand a translation model extracted from a sentence-aligned, bilingual corpus using a large amount of unstructured, monolingual data in both source and target languages, which leads to improvements of 1.4 and 1.2 BLEU points over strong baselines on evaluation sets, and in some scenarios gains in excess of 4 BLEU points. In the future, we plan to estimate the graph structure through other learned, distributed representations.

Abstract

We present experiments in using discourse structure for improving machine translation evaluation. We first design two discourse-aware similarity measures, which use all-subtree kernels to compare discourse parse trees in accordance with the Rhetorical Structure Theory. Then, we show that these measures can help improve a number of existing machine translation evaluation metrics both at the segment- and at the system-level. Rather than proposing a single new metric, we show that discourse information is complementary to the state-of-the-art evaluation metrics, and thus should be taken into account in the development of future richer evaluation metrics.

1 Introduction

From its foundations, Statistical Machine Translation (SMT) had two defining characteristics: first, translation was modeled as a generative process *at the sentence-level*. Second, it was purely statistical over words or word sequences and made *little to no use of linguistic information*. Although modern SMT systems have switched to a discriminative log-linear framework, which allows for additional sources as features, it is generally hard to incorporate dependencies beyond a small window of adjacent words, thus making it difficult to use linguistically-rich models.

Recently, there have been two promising research directions for improving SMT and its evaluation: (*a*) by using more structured linguistic information, such as syntax (Galley et al., 2004; Quirk et al., 2005), hierarchical structures (Chiang, 2005), and semantic roles (Wu and Fung, 2009; Lo et al., 2012), and (*b*) by going beyond the sentence-level, e.g., translating at the document level (Hardmeier et al., 2012).

Going beyond the sentence-level is important since sentences rarely stand on their own in a well-written text. Rather, each sentence follows smoothly from the ones before it, and leads into the ones that come afterwards. The logical relationship between sentences carries important information that allows the text to express a meaning as a whole beyond the sum of its separate parts.

Note that sentences can be made of several clauses, which in turn can be interrelated through the same logical relations. Thus, in a coherent text, discourse units (sentences or clauses) are logically connected: the meaning of a unit relates to that of the previous and the following units.

Discourse analysis seeks to uncover this coherence structure underneath the text. Several formal theories of discourse have been proposed to describe the coherence structure (Mann and Thompson, 1988; Asher and Lascarides, 2003; Webber, 2004). For example, the Rhetorical Structure Theory (Mann and Thompson, 1988), or RST, represents text by labeled hierarchical structures called Discourse Trees (DTs), which can incorporate several layers of other linguistic information, e.g., syntax, predicate-argument structure, etc.

Modeling discourse brings together the above research directions (a) and (b), which makes it an attractive goal for MT. This is demonstrated by the establishment of a recent workshop dedicated to Discourse in Machine Translation (Webber et al., 2013), collocated with the 2013 annual meeting of the Association of Computational Linguistics.

The area of discourse analysis for SMT is still nascent and, to the best of our knowledge, no previous research has attempted to use rhetorical structure for SMT or machine translation evaluation. One possible reason could be the unavailability of accurate discourse parsers. However, this situation is likely to change given the most recent advances in automatic discourse analysis (Joty et al., 2012; Joty et al., 2013).

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 687–698,
Baltimore, Maryland, USA, June 23-25 2014.

We believe that the semantic and pragmatic information captured in the form of DTs (*i*) can help develop discourse-aware SMT systems that produce coherent translations, and (*ii*) can yield better MT evaluation metrics. While in this work we focus on the latter, we think that the former is also within reach, and that SMT systems would benefit from preserving the coherence relations in the source language when generating target-language translations.

In this paper, rather than proposing yet another MT evaluation metric, we show that discourse information is complementary to many existing evaluation metrics, and thus should not be ignored. We first design two discourse-aware similarity measures, which use DTs generated by a publicly-available discourse parser (Joty et al., 2012); then, we show that they can help improve a number of MT evaluation metrics at the segment- and at the system-level in the context of the WMT11 and the WMT12 metrics shared tasks (Callison-Burch et al., 2011; Callison-Burch et al., 2012).

These metrics tasks are based on sentence-level evaluation, which arguably can limit the benefits of using global discourse properties. Fortunately, several sentences are long and complex enough to present rich discourse structures connecting their basic clauses. Thus, although limited, this setting is able to demonstrate the potential of discourse-level information for MT evaluation. Furthermore, sentence-level scoring (*i*) is compatible with most translation systems, which work on a sentence-by-sentence basis, (*ii*) could be beneficial to modern MT tuning mechanisms such as PRO (Hopkins and May, 2011) and MIRA (Watanabe et al., 2007; Chiang et al., 2008), which also work at the sentence-level, and (*iii*) could be used for re-ranking n-best lists of translation hypotheses.

2 Related Work

Addressing discourse-level phenomena in machine translation is relatively new as a research direction. Some recent work has looked at anaphora resolution (Hardmeier and Federico, 2010) and discourse connectives (Cartoni et al., 2011; Meyer, 2011), to mention two examples.[1] However, so far the attempts to incorporate discourse-related knowledge in MT have been only moderately successful, at best.

[1]We refer the reader to (Hardmeier, 2012) for an in-depth overview of discourse-related research for MT.

A common argument, is that current automatic evaluation metrics such as BLEU are inadequate to capture discourse-related aspects of translation quality (Hardmeier and Federico, 2010; Meyer et al., 2012). Thus, there is consensus that discourse-informed MT evaluation metrics are needed in order to advance research in this direction. Here we suggest some simple ways to create such metrics, and we also show that they yield better correlation with human judgments.

The field of automatic evaluation metrics for MT is very active, and new metrics are continuously being proposed, especially in the context of the evaluation campaigns that run as part of the Workshops on Statistical Machine Translation (WMT 2008-2012), and NIST Metrics for Machine Translation Challenge (MetricsMATR), among others. For example, at WMT12, 12 metrics were compared (Callison-Burch et al., 2012), most of them new.

There have been several attempts to incorporate syntactic and semantic linguistic knowledge into MT evaluation. For instance, at the syntactic level, we find metrics that measure the structural similarity between shallow syntactic sequences (Giménez and Màrquez, 2007; Popovic and Ney, 2007) or between constituency trees (Liu and Gildea, 2005). In the semantic case, there are metrics that exploit the similarity over named entities and predicate-argument structures (Giménez and Màrquez, 2007; Lo et al., 2012).

In this work, instead of proposing a new metric, we focus on enriching current MT evaluation metrics with discourse information. Our experiments show that many existing metrics can benefit from additional knowledge about discourse structure.

In comparison to the syntactic and semantic extensions of MT metrics, there have been very few attempts to incorporate discourse information so far. One example are the semantics-aware metrics of Giménez and Màrquez (2009) and Comelles et al. (2010), which use the Discourse Representation Theory (Kamp and Reyle, 1993) and tree-based discourse representation structures (DRS) produced by a semantic parser. They calculate the similarity between the MT output and references based on DRS subtree matching, as defined in (Liu and Gildea, 2005), DRS lexical overlap, and DRS morpho-syntactic overlap. However, they could not improve correlation with human judgments, as evaluated on the MetricsMATR dataset.

Compared to the previous work, (*i*) we use a different discourse representation (RST), (*ii*) we compare discourse parses using *all-subtree* kernels (Collins and Duffy, 2001), (*iii*) we evaluate on much larger datasets, for several language pairs and for multiple metrics, and (*iv*) we do demonstrate better correlation with human judgments.

Wong and Kit (2012) recently proposed an extension of MT metrics with a measure of document-level *lexical cohesion* (Halliday and Hasan, 1976). Lexical cohesion is achieved using word repetitions and semantically similar words such as synonyms, hypernyms, and hyponyms. For BLEU and TER, they observed improved correlation with human judgments on the MTC4 dataset when linearly interpolating these metrics with their *lexical cohesion* score. Unlike their work, which measures lexical cohesion at the document-level, here we are concerned with *coherence (rhetorical) structure*, primarily at the sentence-level.

3 Our Discourse-Based Measures

Our working hypothesis is that the similarity between the discourse structures of an automatic and of a reference translation provides additional information that can be valuable for evaluating MT systems. In particular, we believe that good translations should tend to preserve discourse relations.

As an example, consider the three discourse trees (DTs) shown in Figure 1: (*a*) for a reference (human) translation, and (*b*) and (*c*) for translations of two different systems on the WMT12 test dataset. The leaves of a DT correspond to contiguous atomic text spans, called *Elementary Discourse Units* or EDUs (three in Figure 1a). Adjacent spans are connected by certain coherence relations (e.g., *Elaboration*, *Attribution*), forming larger discourse units, which in turn are also subject to this relation linking. Discourse units linked by a relation are further distinguished based on their relative importance in the text: *nuclei* are the core parts of the relation while *satellites* are supportive ones. Note that the nuclearity and relation labels in the reference translation are also realized in the system translation in (b), but not in (c), which makes (b) a better translation compared to (c), according to our hypothesis. We argue that existing metrics that only use lexical and syntactic information cannot distinguish well between (b) and (c).

In order to develop a discourse-aware evaluation metric, we first generate discourse trees for the reference and the system-translated sentences using a discourse parser, and then we measure the similarity between the two discourse trees. We describe these two steps below.

3.1 Generating Discourse Trees

In Rhetorical Structure Theory, discourse analysis involves two subtasks: (*i*) *discourse segmentation*, or breaking the text into a sequence of EDUs, and (*ii*) *discourse parsing*, or the task of linking the units (EDUs and larger discourse units) into labeled discourse trees. Recently, Joty et al. (2012) proposed discriminative models for both discourse segmentation and discourse parsing at the sentence level. The segmenter uses a maximum entropy model that achieves state-of-the-art accuracy on this task, having an F_1-score of 90.5%, while human agreement is 98.3%.

The discourse parser uses a dynamic Conditional Random Field (Sutton et al., 2007) as a parsing model in order to infer the probability of all possible discourse tree constituents. The inferred (posterior) probabilities are then used in a probabilistic CKY-like bottom-up parsing algorithm to find the most likely DT. Using the standard set of 18 coarse-grained relations defined in (Carlson and Marcu, 2001), the parser achieved an F_1-score of 79.8%, which is very close to the human agreement of 83%. These high scores allowed us to develop successful discourse similarity metrics.[2]

3.2 Measuring Similarity

A number of metrics have been proposed to measure the similarity between two labeled trees, e.g., Tree Edit Distance (Tai, 1979) and Tree Kernels (Collins and Duffy, 2001; Moschitti and Basili, 2006). Tree kernels (TKs) provide an effective way to integrate arbitrary tree structures in kernel-based machine learning algorithms like SVMs.

In the present work, we use the convolution TK defined in (Collins and Duffy, 2001), which efficiently calculates the number of common subtrees in two trees. Note that this kernel was originally designed for syntactic parsing, where the subtrees are subject to the constraint that their nodes are taken with either all or none of the children. This constraint of the TK imposes some limitations on the type of substructures that can be compared.

[2]The discourse parser is freely available from http://alt.qcri.org/tools/

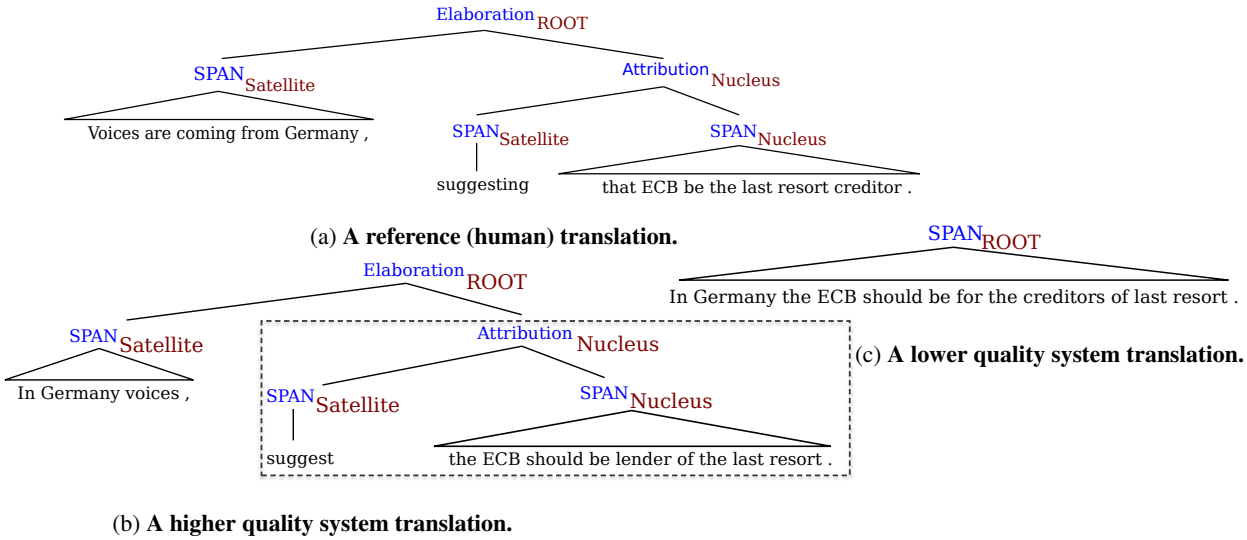

Figure 1: Example of three different discourse trees for the translations of a source sentence. (a) The reference, (b) A higher quality translation, (c) A lower quality translation.

One way to cope with the limitations of the TK is to change the representation of the trees to a form that is suitable to capture the relevant information for our task. We experiment with TKs applied to two different representations of the discourse tree: non-lexicalized (DR), and lexicalized (DR-LEX). In Figure 2 we show the two representations for the subtree that spans the text: *"suggest the ECB should be the lender of last resort"*, which is highlighted in Figure 1b.

As shown in Figure 2a, DR does not include any lexical item, and therefore measures the similarity between two translations in terms of their discourse structures only. On the contrary, DR-LEX includes the lexical items to account for lexical matching; moreover, it separates the structure (the skeleton) of the tree from its labels, i.e. the nuclearity and the relations, in order to allow the tree kernel to give partial credit to subtrees that differ in labels but match in their skeletons. More specifically, it uses the tags SPAN and EDU to build the skeleton of the tree, and considers the nuclearity and/or the relation labels as properties, added as children, of these tags.

For example, a SPAN has two properties (its nuclearity and its relation), and an EDU has one property (its nuclearity). The words of an EDU are placed under the predefined children NGRAM. In order to allow the tree kernel to find subtree matches at the word level, we include an additional layer of *dummy* leaves as was done in (Moschitti et al., 2007); not shown in Figure 2, for simplicity.

4 Experimental Setup

In our experiments, we used the data available for the WMT12 and the WMT11 metrics shared tasks for translations into English.[3] This included the output from the systems that participated in the WMT12 and the WMT11 MT evaluation campaigns, both consisting of 3,003 sentences, for four different language pairs: Czech-English (CS-EN), French-English (FR-EN), German-English (DE-EN), and Spanish-English (ES-EN); as well as a dataset with the English references.

We measured the correlation of the metrics with the human judgments provided by the organizers. The judgments represent rankings of the output of five systems chosen at random, for a particular sentence, also chosen at random. Note that each judgment effectively constitutes 10 pairwise system rankings. The overall coverage, i.e. the number of unique sentences that were evaluated, was only a fraction of the total; the total number of judgments, along with other information of the datasets are shown in Table 1.

4.1 MT Evaluation Metrics

In this study, we evaluate to what extent existing evaluation metrics can benefit from additional discourse information. To do so, we contrast different MT evaluation metrics with and without discourse information. The evaluation metrics we used are described below.

ES-EN	12	1,141	923	45	15	570	207	18
FR-EN	15	1,395	949	44	18	708	249	32

Table 1: Number of systems (systs), judgments (ranks), unique sentences (sents), and different judges (judges) for the different language pairs, for the human evaluation of the WMT12 and WMT11 shared tasks.

Metrics from WMT12. We used the publicly available scores for all metrics that participated in the WMT12 metrics task (Callison-Burch et al., 2012): SPEDE07PP, AMBER, METEOR, TERRORCAT, SIMPBLEU, XENERRCATS, WORDBLOCKEC, BLOCKERRCATS, and POSF.

Metrics from ASIYA. We used the freely available version of the ASIYA toolkit[4] in order to extend the set of evaluation measures contrasted in this study beyond those from the WMT12 metrics task. ASIYA (Giménez and Màrquez, 2010a) is a suite for MT evaluation that provides a large set of metrics that use different levels of linguistic information. For reproducibility, below we explain the individual metrics with the exact names required by the toolkit to calculate them.

First, we used ASIYA's ULC (Giménez and Màrquez, 2010b), which was the best performing metric at the system and the segment levels at the WMT08 and WMT09 metrics tasks. This is a uniform linear combination of 12 individual metrics. From the original ULC, we only replaced TER and Meteor individual metrics by newer versions taking into account synonymy lookup and paraphrasing: TERp-A and METEOR-pa in ASIYA's terminology. We will call this combined metric Asiya-0809 in our experiments.

[4]http://nlp.lsi.upc.edu/asiya/

To complement the set of individual metrics that participated at the WMT12 metrics task, we also computed the scores of other commonly-used evaluation metrics: BLEU (Papineni et al., 2002), NIST (Doddington, 2002), TER (Snover et al., 2006), ROUGE-W (Lin, 2004), and three METEOR variants (Denkowski and Lavie, 2011): METEOR-ex (exact match), METEOR-st (+stemming) and METEOR-sy (+synonyms). The uniform linear combination of the previous 7 individual metrics plus the 12 from Asiya-0809 is reported as Asiya-ALL in the experimental section.

The individual metrics combined in Asiya-ALL can be naturally categorized according to the type of linguistic information they use to compute the quality scores. We grouped them in the following four families and calculated the uniform linear combination of the metrics in each group:[5]

1. Asiya-LEX. Combination of five metrics based on lexical similarity: BLEU, NIST, METEOR-ex, ROUGE-W, and TERp-A.
2. Asiya-SYN. Combination of four metrics ba-sed on syntactic information from constituency and dependency parse trees: 'CP-STM-4', 'DP-HWCM_c-4', 'DP-HWCM_r-4', and 'DP-Or(*)'.
3. Asiya-SRL. Combination of three metric variants based on predicate argument structures (semantic role labeling): 'SR-Mr(*)', 'SR-Or(*)', and 'SR-Or'.
4. Asiya-SEM. Combination of two metrics variants based on semantic parsing:[6] 'DR-Or(*)' and 'DR-Orp(*)'.

[5]A detailed description of every individual metric can be found at (Giménez and Màrquez, 2010b). For a more up-to-date description, see the User Manual from ASIYA's website.

[6]In ASIYA the metrics from this family are referred to as "Discourse Representation" metrics. However, the structures they consider are actually very different from the discourse structures exploited in this paper. See the discussion in Section 2. For clarity, we will refer to them as *semantic parsing* metrics.

All uniform linear combinations are calculated outside ASIYA. In order to make the scores of the different metrics comparable, we performed a $\min$–$\max$ normalization, for each metric, and for each language pair combination.

4.2 Human Judgements and Learning

The human-annotated data from the WMT campaigns encompasses series of rankings on the output of different MT systems for every source sentence. Annotators rank the output of five systems according to perceived translation quality. The organizers relied on a random selection of systems, and a large number of comparisons between pairs of them, to make comparisons across systems feasible (Callison-Burch et al., 2012). As a result, for each source sentence, only relative rankings were available. As in the WMT12 experimental setup, we use these rankings to calculate correlation with human judgments at the sentence-level, i.e. Kendall's Tau; see (Callison-Burch et al., 2012) for details.

For the experiments reported in Section 5.4, we used pairwise rankings to discriminatively learn the weights of the linear combinations of individual metrics. In order to use the WMT12 data for training a learning-to-rank model, we transformed the five-way relative rankings into ten pairwise comparisons. For instance, if a judge ranked the output of systems A, B, C, D, E as $A > B > C > D > E$, this would entail that $A > B$, $A > C$, $A > D$ and $A > E$, etc.

To determine the relative weights for the tuned combinations, we followed a similar approach to the one used by PRO to tune the relative weights of the components of a log-linear SMT model (Hopkins and May, 2011), also using Maximum Entropy as the base learning algorithm. Unlike PRO, (*i*) we use *human judgments*, not automatic scores, and (*ii*) we train on *all pairs*, not on a subsample.

5 Experimental Results

In this section, we explore how discourse information can be used to improve machine translation evaluation metrics. Below we present the evaluation results at the system- and segment-level, using our two basic metrics on discourse trees (Section 3.1), which are referred to as DR and DR-LEX.

5.1 Evaluation

In our experiments, we only consider translation into English, and use the data described in Table 1. For evaluation, we follow the setup of the metrics task of WMT12 (Callison-Burch et al., 2012): at the system-level, we use the official script from WMT12 to calculate the Spearman's correlation, where higher *absolute* values indicate better metrics performance; at the segment-level, we use Kendall's Tau for measuring correlation, where negative values are worse than positive ones.[7]

In our experiments, we combine DR and DR-LEX to other metrics in two different ways: using uniform linear interpolation (at system- and segment-level), and using a tuned linear interpolation for the segment-level. We only present the average results over all four language pairs. For simplicity, in our tables we show results divided into evaluation groups:

1. Group I: contains our evaluation metrics, DR and DR-LEX.

2. Group II: includes the metrics that participated in the WMT12 metrics task, excluding metrics which did not have results for all language pairs.

3. Group III: contains other important evaluation metrics, which were not considered in the WMT12 metrics task: NIST and ROUGE for both system- and segment-level, and BLEU and TER at segment-level.

4. Group IV: includes the metric combinations calculated with ASIYA and described in Section 4.

For each metric in groups II, III and IV, we present the results for the original metric as well for the linear interpolation of that metric with DR and with DR-LEX. The combinations with DR and DR-LEX that improve over the original metrics are shown in **bold**, and those that degrade are in *italic*. Furthermore, we also present overall results for: (*i*) the average score over all metrics, excluding DR and DR-LEX, and (*ii*) the differences in the correlations for the DR/DR-LEX-combined and the original metrics.

[7] We have fixed a bug in the scoring tool from WMT12, which was making all scores positive. This made TERRORCAT's score negative, as we present it in Table 3.

Table 3: Results on WMT12 at the segment-level. Kendall's Tau with human judgments.

5.2 System-level Results

Table 2 shows the system-level experimental results for WMT12. We can see that DR is already competitive by itself: on average, it has a correlation of .807, very close to BLEU and TER scores (.810 and .812, respectively). Moreover, DR yields improvements when combined with 15 of the 19 metrics; worsening only four of the metrics. Overall, we observe an average improvement of +.024, in the correlation with the human judgments. This suggests that DR contains information that is complementary to that used by the other metrics. Note that this is true both for the individual metrics from groups II and III, as well as for the metric combinations in group IV. Combinations in the last group involve several metrics that already use linguistic information at different levels and are hard to improve over; yet, adding DR does improve, which shows that it has some complementary information to offer.

As expected, DR-LEX performs better than DR since it is lexicalized (at the unigram level), and also gives partial credit to correct structures. Individually, DR-LEX outperforms most of the metrics from group II, and ranks as the second best metric in that group. Furthermore, when combined with individual metrics in group II, DR-LEX is able to improve consistently over each one of them.

Note that, even though DR-LEX has better individual performance than DR, it does not yield improvements when combined with most of the metrics in group IV.[8] However, over all metrics and all language pairs, DR-LEX is able to obtain an average improvement in correlation of +.035, which is remarkably higher than that of DR. Thus, we can conclude that at the system-level, adding discourse information to a metric, even using the simplest of the combination schemes, is a good idea for most of the metrics, and can help to significantly improve the correlation with human judgments.

5.3 Segment-level Results: Non-tuned

Table 3 shows the results for WMT12 at the segment-level. We can see that DR performs badly, with a high negative Kendall's Tau of -.433. This should not be surprising: (a) the discourse tree structure alone does not contain enough information for a good evaluation at the segment-level, and (b) this metric is more sensitive to the quality of the DT, which can be wrong or void.

[8] In this work, we have not investigated the reasons behind this phenomenon. We speculate that this might be caused by the fact that the lexical information in DR-LEX is incorporated only in the form of unigram matching at the sentence-level, while the metrics in group IV are already complex combined metrics, which take into account stronger lexical models. Note, however, that the variations are very small and might not be significant.

	Metrics	Orig.	Tuned	+DR	+DR-LEX
I	DR	-.433	–	–	–
	DR-LEX	.133	–	–	–
II	SPEDE07PP	.254	–	*.253*	.254
	METEOR	.247	–	**.250**	**.251**
	AMBER	.229	–	**.230**	**.232**

Table 4: Results on WMT12 at the segment-level: tuning with cross-validation on WMT12. Kendall's Tau with human judgments.

Additionally, DR is more likely to produce a high number of ties, which is harshly penalized by WMT12's definition of Kendall's Tau. Conversely, ties and incomplete discourse analysis were not a problem at the system-level, where evidence from all 3,003 test sentences is aggregated, and allows to rank systems more precisely. Due to the low score of DR as an individual metric, it fails to yield improvements when uniformly combined with other metrics.

Again, DR-LEX is better than DR; with a positive Tau of +.133, yet as an individual metric, it ranks poorly compared to other metrics in group II. However, when linearly combined with other metrics, DR-LEX outperforms 14 of the 19 metrics in Table 3. Across all metrics, DR-LEX yields an average Tau improvement of +.026, i.e. from .165 to .190. This is a large improvement, taking into account that the combinations are just uniform linear combinations. In subsection 5.4, we present the results of tuning the linear combination in a discriminative way.

5.4 Segment-level Results: Tuned

We experimented with tuning the weights of the individual metrics in the metric combinations, using the learning method described in Section 4.2. First, we did this using cross-validation to tune and test on WMT12. Later we tuned on WMT12 and evaluated on WMT11. For cross-validation in WMT12, we used ten folds of approximately equal sizes, each containing about 300 sentences: we constructed the folds by putting together entire documents, thus not allowing sentences from a document to be split over two different folds. During each cross-validation run, we trained our pairwise ranker using the human judgments corresponding to nine of the ten folds. We aggregated the data for different language pairs, and produced a single set of tuning weights for all language pairs.[9] We then used the remaining fold for evaluation

The results are shown in Table 4. As in previous sections we present the average results over all four language pairs. We can see that the tuned combinations with DR-LEX improve over most of the individual metrics in groups II and III. Interestingly, the tuned combinations that include the much weaker metric DR now improve over 12 out of 13 of the individual metrics in groups II and III, and only slightly degrades the score of the 13th one (SPEDE07PP).

Note that the ASIYA metrics are combinations of several metrics, and these combinations (which exclude DR and DR-LEX) can be also tuned; this yields sizable improvements over the untuned versions as column three in the table shows. Compared to this baseline, DR improves for three of the six ASIYA metrics, while DR-LEX improves for four of them. Note that improving over the last two ASIYA metrics is very hard: they have very high scores of .296 and .295; for comparison, the best segment-level system at WMT12 (SPEDE07PP) achieved a Tau of .254.

On average, DR improves Tau from .165 to .201, which is +.036, while DR-LEX improves to .222, or +.057. These much larger improvements highlight the importance of tuning the linear combination when working at the segment-level.

5.4.1 Testing on WMT11

In order to rule out the possibility that the improvement of the tuned metrics on WMT12 comes from over-fitting, and to verify that the tuned metrics do generalize when applied to other sentences, we also tested on a new test set: WMT11.

[9] Tuning separately for each language pair yielded slightly lower results.

Therefore, we tuned the weights on *all* WMT12 pairwise judgments (no cross-validation), and we evaluated on WMT11. Since the metrics that participated in WMT11 and WMT12 are different (and even when they have the same name, there is no guarantee that they have not changed from 2011 to 2012), we only report results for the versions of NIST, ROUGE, TER, and BLEU available in ASIYA, as well as for the ASIYA metrics, thus ensuring that the metrics in the experiments are consistent for 2011 and 2012.

The results are shown in Table 5. Once again, tuning yields sizable improvements over the simple combination for the ASIYA metrics (third column in Table 5). Adding DR and DR-LEX to the combinations manages to improve over five and four of the six tuned ASIYA metrics, respectively. However, some of the differences are very small. On the contrary, DR and DR-LEX significantly improve over NIST, ROUGE, TER, and BLEU. Overall, DR improves the average Tau from .207 to .244, which is +.037, while DR-LEX improves to .267 or +.061. These improvements are very close to those for the WMT12 cross-validation. This shows that the weights learned on WMT12 generalize well, as they are also good for WMT11.

What is also interesting to note is that when tuning is used, DR helps achieve sizeable improvements, even if not as strong as for DR-LEX. This is remarkable given that DR has a strong negative Tau as an individual metric at the sentence-level. This suggests that both DR and DR-LEX contain information that is complementary to that of the individual metrics that we experimented with.

Overall, from the experimental results in this section, we can conclude that discourse structure is an important information source to be taken into account in the automatic evaluation of machine translation output.

6 Conclusions and Future Work

In this paper we have shown that discourse structure can be used to improve automatic MT evaluation. First, we defined two simple discourse-aware similarity metrics (lexicalized and un-lexicalized), which use the all-subtree kernel to compute similarity between discourse parse trees in accordance with the Rhetorical Structure Theory. Then, after extensive experimentation on WMT12 and WMT11 data, we showed that a variety of existing evaluation metrics can benefit from our discourse-based metrics, both at the segment- and the system-level, especially when the discourse information is incorporated in an informed way (i.e. using supervised tuning). Our results show that discourse-based metrics can improve the state-of-the-art MT metrics, by increasing correlation with human judgments, even when only sentence-level discourse information is used.

Addressing discourse-level phenomena in MT is a relatively new research direction. Yet, many of the ongoing efforts have been moderately successful according to traditional evaluation metrics. There is a consensus in the MT community that more discourse-aware metrics need to be proposed for this area to move forward. We believe this work is a valuable contribution towards this longer-term goal.

The tuned combined metrics tested in this paper are just an initial proposal, i.e. a simple adjustment of the relative weights for the individual metrics in a linear combination. In the future, we plan to work on integrated representations of syntactic, semantic and discourse-based structures, which would allow us to train evaluation metrics based on more fine-grained features. Additionally, we propose to use the discourse information for MT in two different ways. First, at the sentence-level, we can use discourse information to re-rank alternative MT hypotheses; this could be applied either for MT parameter tuning, or as a post-processing step for the MT output. Second, we propose to move in the direction of using discourse information beyond the sentence-level.

Learning Continuous Phrase Representations for Translation Modeling

Abstract

This paper tackles the sparsity problem in estimating phrase translation probabilities by learning continuous phrase representations, whose distributed nature enables the sharing of related phrases in their representations. A pair of source and target phrases are projected into continuous-valued vector representations in a low-dimensional latent space, where their translation score is computed by the distance between the pair in this new space. The projection is performed by a neural network whose weights are learned on parallel training data. Experimental evaluation has been performed on two WMT translation tasks. Our best result improves the performance of a state-of-the-art phrase-based statistical machine translation system trained on WMT 2012 French-English data by up to 1.3 BLEU points.

1 Introduction

The phrase translation model, also known as the *phrase table*, is one of the core components of phrase-based statistical machine translation (SMT) systems. The most common method of constructing the phrase table takes a two-phase approach (Koehn et al. 2003). First, the bilingual phrase pairs are extracted heuristically from an automatically word-aligned training data. The second phase, which is the focus of this paper, is parameter estimation where each phrase pair is assigned with some scores that are estimated based on counting these phrases or their words using the same word-aligned training data.

Phrase-based SMT systems have achieved state-of-the-art performance largely due to the fact that long phrases, rather than single words, are used as translation units so that useful context information can be captured in selecting translations. However, longer phrases occur less often in training data, leading to a severe data sparseness problem in parameter estimation. There has been a plethora of research reported in the literature on improving parameter estimation for the phrase translation model (e.g., DeNero et al. 2006; Wuebker et al. 2010; He and Deng 2012; Gao and He 2013).

This paper revisits the problem of scoring a phrase translation pair by developing a Continuous-space Phrase Translation Model (CPTM). The translation score of a phrase pair in this model is computed as follows. First, we represent each phrase as a bag-of-words vector, called *word vector* henceforth. We then project the word vector, in either the source language or the target language, into a respective continuous feature vector in a common low-dimensional space that is language independent. The projection is performed by a multi-layer neural network. The projected feature vector forms the *continuous representation* of a phrase. Finally, the translation score of a source-target phrase pair is computed by the distance between their feature vectors.

The main motivation behind the CPTM is to alleviate the data sparseness problem associated with the traditional counting-based methods by grouping phrases with a similar meaning across different languages. This style of grouping is made possible because of the distributed nature of the continuous-space representations for phrases. No such sharing was possible in the original symbolic space for representing words or phrases. In this model, semantically or grammatically related phrases, in both the source and the target languages, would tend to have similar (close) feature vectors in the continuous space, guided by the training objective. Since the translation score is a smooth function of these feature vectors, a small

change in the features should only lead to a small change in the translation score.

The primary research task in developing the CPTM is learning the continuous representation of a phrase that is effective for SMT. Motivated by recent studies on continuous-space language models (e.g., Bengio et al. 2003; Mikolov et al. 2011; Schwenk et al., 2012), we use a neural network to project a word vector to a feature vector. Ideally, the projection would discover those latent features that are useful to differentiate *good* translations from *bad* ones, for a given source phrase. However, there is no training data with explicit annotation on the quality of phrase translations. The phrase translation pairs are *hidden* in the parallel source-target sentence pairs, which are used to train the traditional translation models. The quality of a phrase translation can only be judged implicitly through the translation quality of the sentences, as measured by BLEU, which contain the phrase pair. In order to overcome this challenge and let the BLEU metric guide the projection learning, we propose a new method to learn the parameters of a neural network. This new method, via the choice of an appropriate objective function in training, automatically forces the feature vector of a source phrase to be closer to the feature vectors of its candidate translations. As a result, the BLEU score is improved when these translations are selected by an SMT decoder to produce final, sentence-level translations. The new learning method makes use of the L-BFGS algorithm and the expected BLEU as the objective function defined on N-best lists.

To the best of our knowledge, the CPTM proposed in this paper is the first continuous-space phrase translation model that makes use of joint representations of a phrase in the source language and its translation in the target language (to be detailed in Section 4) and that is shown to lead to significant improvement over a standard phrase-based SMT system (to be detailed in Section 6).

Like the traditional phrase translation model, the translation score of each bilingual phrase pair is modeled explicitly in our model. However, instead of estimating the phrase translation score on aligned parallel data, our model intends to capture the grammatical and semantic similarity between a source phrase and its paired target phrase by projecting them into a common, continuous space that is language independent.

The rest of the paper is organized as follows. Section 2 reviews previous work. Section 3 reviews the log-linear model for phrase-based SMT and Sections 4 presents the CPTM. Section 5 describes the way the model parameters are estimated, followed by the experimental results in Section 6. Finally, Section 7 concludes the paper.

2 Related Work

Representations of words or documents as continuous vectors have a long history. Most of the earlier latent semantic models for learning such vectors are designed for information retrieval (Deerwester et al. 1990; Hofmann 1999; Blei et al. 2003). In contrast, recent work on continuous space language models, which estimate the probability of a word sequence in a continuous space (Bengio et al. 2003; Mikolov et al. 2010), have advanced the state of the art in language modeling, outperforming the traditional n-gram model on speech recognition (Mikolov et al. 2012; Sundermeyer et al. 2013) and machine translation (Mikolov 2012; Auli et al. 2013).

Because these models are developed for monolingual settings, word embedding from these models is not directly applicable to translation. As a result, variants of such models for cross-lingual scenarios have been proposed so that words in different languages are projected into the shared latent vector space (Dumais et al. 1997; Platt et al. 2010; Vinokourov et al. 2002; Yih et al. 2011; Gao et al. 2011; Huang et al. 2013; Zou et al. 2013). In principle, a phrase table can be derived using any of these cross-lingual models, although decoupling the derivation from the SMT training often results in suboptimal performance (e.g., measured in BLEU), as we will show in Section 6.

Recently, there is growing interest in applying continuous-space models for translation. The most related to this study is the work of continuous space n-gram translation models (Schwenk et al. 2007; Schwenk 2012; Son et al. 2012), where the feed-forward neural network language model is extended to represent translation probabilities. However, these earlier studies focused on the *n-gram translation models*, where the translation probability of a phrase or a sentence is decomposed as a product of n-gram probabilities as in a standard n-gram language model. Therefore, it is not clear how their approaches can be applied to the phrase translation model[1], which is much more

[1] Niehues et al. (2011) use different translation units in order to integrate the n-gram translation model into the phrase-based approach. However, it is not clear how a continuous version of such a model can be trained efficiently because the factor models used by Son et al. cannot be applied directly.

widely used in modern SMT systems. In contrast, our model learns jointly the representations of a phrase in the source language as well as its translation in the target language. The recurrent continuous translation models proposed by Kalchbrenner and Blunsom (2013) also adopt the recurrent language model (Mikolov et al. 2010). But unlike the n-gram translation models above, they make no Markov assumptions about the dependency of the words in the target sentence. Continuous space models have also been used for generating translations for new words (Mikolov et al. 2013a) and ITG reordering (Li et al. 2013).

There has been a lot of research on improving the phrase table in phrase-based SMT (Marcu and Wong 2002; Lamber and Banchs 2005; Denero et al. 2006; Wuebker et al. 2010; Zhang et al., 2011; He and Deng 2012; Gao and He 2013). Among them, (Gao and He 2013) is most relevant to the work described in this paper. They estimate phrase translation probabilities using a discriminative training method under the N-best reranking framework of SMT. In this study we use the same objective function to learn the continuous representations of phrases, integrating the strengths associated with these earlier studies.

3 The Log-Linear Model for SMT

Phrase-based SMT is based on a log-linear model which requires learning a mapping between input $F \in \mathcal{F}$ to output $E \in \mathcal{E}$. We are given

- Training samples (F_i, E_i) for $i = 1 \ldots N$, where each source sentence F_i is paired with a reference translation in target language E_i;
- A procedure GEN to generate a list of N-best candidates $\mathrm{GEN}(F_i)$ for an input F_i, where GEN in this study is the baseline phrase-based SMT system, i.e., an in-house implementation of the Moses system (Koehn et al. 2007) that does not use the CPTM, and each $E \in \mathrm{GEN}(F_i)$ is labeled by the sentence-level BLEU score (He and Deng 2012), denoted by $\mathrm{sBleu}(E_i, E)$, which measures the quality of E with respect to its reference translation E_i;
- A vector of features $\mathbf{h} \in \mathbb{R}^M$ that maps each (F_i, E) to a vector of feature values[2]; and
- A parameter vector $\boldsymbol{\lambda} \in \mathbb{R}^M$, which assigns a real-valued weight to each feature.

The components $\mathrm{GEN}(.)$, $\mathbf{h}$ and $\boldsymbol{\lambda}$ define a log-linear model that maps F_i to an output sentence as follows:

$$E^* = \underset{(E,A)\in \mathrm{GEN}(F_i)}{\operatorname{argmax}} \boldsymbol{\lambda}^{\mathrm{T}} \mathbf{h}(F_i, E, A) \qquad (1)$$

which states that given $\boldsymbol{\lambda}$ and $\mathbf{h}$, argmax returns the highest scoring translation E^*, maximizing over correspondences A. In phrase-based SMT, A consists of a segmentation of the source and target sentences into phrases and an alignment between source and target phrases. Since computing the argmax exactly is intractable, it is commonly performed approximatedly by beam search (Och and Ney 2004). Following Liang et al. (2006), we assume that every translation candidate is always coupled with a corresponding A, called the *Viterbi derivation*, generated by (1).

4 A Continuous-Space Phrase Translation Model (CPTM)

The architecture of the CPTM is shown in Figures 1 and 2, where for each pair of source and target phrases (f_i, e_j) in a source-target sentence pair, we first project them into feature vectors $\mathbf{y}_{f_i}$ and $\mathbf{y}_{e_j}$ in a latent, continuous space via a neural network with one hidden layer (as shown in Figure 2), and then compute the translation score, $\mathrm{score}(f_i, e_j)$, by the distance of their feature vectors in that space.

We start with a bag-of-words representation of a phrase $\mathbf{x} \in \mathbb{R}^d$, where $\mathbf{x}$ is a word vector and d is the size of the vocabulary consisting of words in both source and target languages, which is set to 200K in our experiments. We then learn to project $\mathbf{x}$ to a low-dimensional continuous space $\mathbb{R}^k$:

$$\phi(\mathbf{x}): \mathbb{R}^d \rightarrow \mathbb{R}^k$$

The projection is performed using a fully connected neural network with one hidden layer and tanh activation functions. Let $\mathbf{W}_1$ be the projection matrix from the input layer to the hidden layer and $\mathbf{W}_2$ the projection matrix from the hidden layer to the output layer, we have

$$\mathbf{y} \equiv \phi(\mathbf{x}) = \tanh\left(\mathbf{W}_2{}^{\mathrm{T}}\left(\tanh\left(\mathbf{W}_1{}^{\mathrm{T}}\mathbf{x}\right)\right)\right) \qquad (2)$$

[2] Our baseline system uses a set of standard features suggested in Koehn et al. (2007), which is also detailed in Section 6.

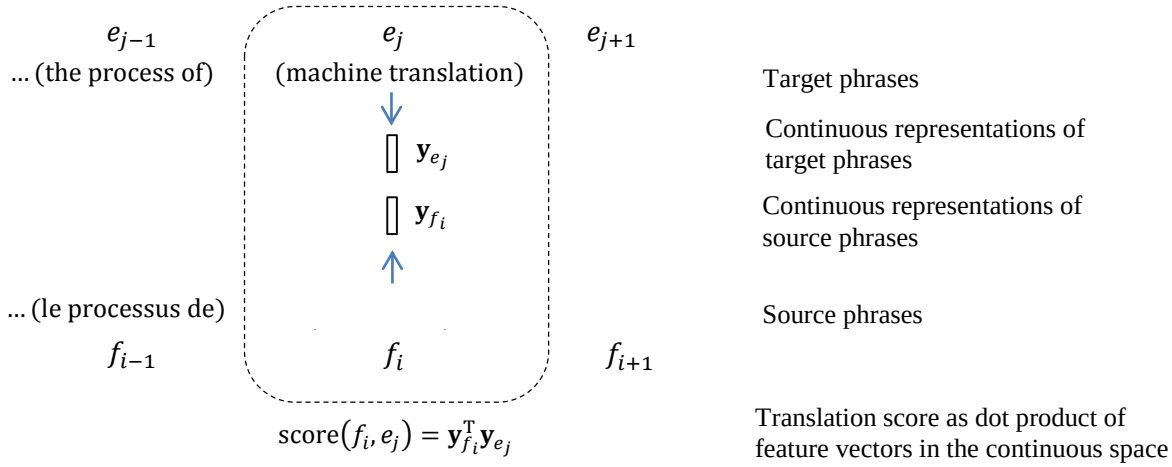

Figure 1. The architecture of the CPTM, where the mapping from a phrase to its continuous representation is shown in Figure 2.

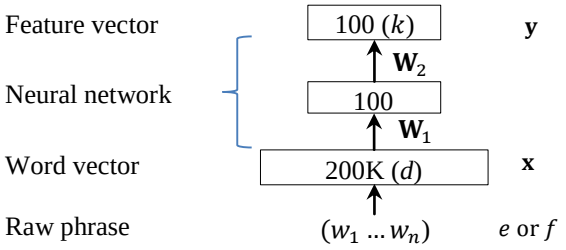

Figure 2. A neural network model for phrases giving rise to their continuous representations. The model with the same form is used for both source and target languages.

The translation score of a source phrase f and a target phrase e can be measured as the similarity (or distance) between their feature vectors. We choose the dot product as the similarity function[3]:

$$\text{score}(f, e) \equiv \text{sim}_{\boldsymbol{\theta}}(\mathbf{x}_f, \mathbf{x}_e) = \mathbf{y}_f^{\mathrm{T}} \mathbf{y}_e \qquad (3)$$

According to (2), we see that the value of the scoring function is determined by the projection matrices $\boldsymbol{\theta} = \{\mathbf{W}_1, \mathbf{W}_2\}$.

The CPTM of (2) and (3) can be incorporated into the log-linear model for SMT (1) by introducing a new feature h_{M+1} and a new feature weight λ_{M+1}. The new feature is defined as

$$h_{M+1}(F_i, E, A) = \sum_{(f,e)\in A} \text{sim}_{\boldsymbol{\theta}}(\mathbf{x}_f, \mathbf{x}_e) \qquad (4)$$

Thus, the phrase-based SMT system, into which the CPTM is incorporated, is parameterized by $(\boldsymbol{\lambda}, \boldsymbol{\theta})$, where $\boldsymbol{\lambda}$ is a vector of a handful of parameters used in the log-linear model of (1), with one weight for each feature; and $\boldsymbol{\theta}$ is the projection matrices used in the CPTM defined by (2) and (3). In our experiments we take three steps to learn $(\boldsymbol{\lambda}, \boldsymbol{\theta})$:

1. We use a baseline phrase-based SMT system to generate for each source sentence in training data an N-best list of translation hypotheses[4].
2. We set $\boldsymbol{\lambda}$ to that of the baseline system and let $\lambda_{M+1} = 1$, and optimize $\boldsymbol{\theta}$ w.r.t. a loss function on training data[5].
3. We fix $\boldsymbol{\theta}$, and optimize $\boldsymbol{\lambda}$ using MERT (Och 2003) to maximize BLEU on dev data.

In the next section, we will describe Step 2 in detail as it is directly related to the CPTM training.

[3] In our experiments, we compare dot product and the cosine similarity functions and find that the former works better for nonlinear multi-layer neural networks, and the latter works better for linear neural networks. For the sake of clarity, we choose dot product when we describe the CPTM and its training in Sections 4 and 5, respectively.

[4] The baseline SMT needs to be reasonably good in the sense that the oracle BLEU score on the generated n-best lists needs to be significantly higher than that of the top-1 translations so that the CPTM can be effectively trained.

[5] The initial value of λ_{M+1} can also be tuned using the dev set. However, we find in a pilot study that it is good enough to set it to 1 when the values of all the baseline feature weights, used in the log-linear model of (1), are properly normalized, such as by setting $\lambda_m = \lambda_m / C$ for $m = 1 \dots M$, where C is the unnormalized weight value of the target language model.

5 Training CPTM

This section describes the loss function we employ with the CPTM and the algorithm to train the neural network weights.

We define the loss function $\mathcal{L}(\boldsymbol{\theta})$ as the negative of the N-best list based expected BLEU, denoted by $\text{xBleu}(\boldsymbol{\theta})$. In the reranking framework of SMT outlined in Section 3, $\text{xBleu}(\boldsymbol{\theta})$ over one training sample (F_i, E_i) is defined as

$$\text{xBleu}(\boldsymbol{\theta}) = \sum_{E \in \text{GEN}(F_i)} P(E|F_i)\text{sBleu}(E_i, E) \quad (5)$$

where $\text{sBleu}(E_i, E)$ is the sentence-level BLEU score, and $P(E|F_i)$ is the translation probability from F_i to E computed using *softmax* as

$$P(E|F_i) = \frac{\exp\left(\gamma \boldsymbol{\lambda}^{\mathrm{T}} \mathbf{h}(F_i, E, A)\right)}{\sum_{E' \in \text{GEN}(F_i)} \exp\left(\gamma \boldsymbol{\lambda}^{\mathrm{T}} \mathbf{h}(F_i, E', A)\right)} \quad (6)$$

where $\boldsymbol{\lambda}^{\mathrm{T}}\mathbf{h}$ is the log-linear model of (1), which also includes the feature derived from the CPTM as defined by (4), and γ is a tuned smoothing factor.

Let $\mathcal{L}(\boldsymbol{\theta})$ be a loss function which is differentiable w.r.t. the parameters of the CPTM, $\boldsymbol{\theta}$. We can compute the gradient of the loss and learn $\boldsymbol{\theta}$ using gradient-based numerical optimization algorithms, such as L-BFGS or stochastic gradient descent (SGD).

5.1 Computing the Gradient

Since the loss does not explicitly depend on $\boldsymbol{\theta}$, we use the chain rule for differentiation:

$$\frac{\partial \mathcal{L}(\boldsymbol{\theta})}{\partial \boldsymbol{\theta}} = \sum_{(f,e)} \frac{\partial \mathcal{L}(\boldsymbol{\theta})}{\partial \text{sim}_{\boldsymbol{\theta}}(\mathbf{x}_f, \mathbf{x}_e)} \frac{\partial \text{sim}_{\boldsymbol{\theta}}(\mathbf{x}_f, \mathbf{x}_e)}{\partial \boldsymbol{\theta}}$$

$$= \sum_{(f,e)} -\delta_{(f,e)} \frac{\partial \text{sim}_{\boldsymbol{\theta}}(\mathbf{x}_f, \mathbf{x}_e)}{\partial \boldsymbol{\theta}} \quad (7)$$

which takes the form of summation over all phrase pairs occurring either in a training sample (stochastic mode) or in the entire training data (batch mode). $\delta_{(f,e)}$ in (7) is known as the *error* term of the phrase pair (f, e), and is defined as

$$\delta_{(f,e)} = -\frac{\partial \mathcal{L}(\boldsymbol{\theta})}{\partial \text{sim}_{\boldsymbol{\theta}}(\mathbf{x}_f, \mathbf{x}_e)} \quad (8)$$

It describes how the overall loss changes with the translation score of the phrase pair (f, e). We will leave the derivation of $\delta_{(f,e)}$ to Section 5.1.2, and will first describe how the gradient of $\text{sim}_{\boldsymbol{\theta}}(\mathbf{x}_f, \mathbf{x}_e)$ w.r.t. $\boldsymbol{\theta}$ is computed.

5.1.1 Computing $\partial \text{sim}_{\boldsymbol{\theta}}(\mathbf{x}_f, \mathbf{x}_e)/\partial \boldsymbol{\theta}$

Without loss of generality, we use the following notations to describe a neural network:

- $\mathbf{W}_l$ is the projection matrix for the *l*-th layer of the neural network;
- $\mathbf{x}$ is the input word vector of a phrase;
- $\mathbf{z}^l$ is the sum vector of the *l*-th layer; and
- $\mathbf{y}^l = \sigma(\mathbf{z}^l)$ is the output vector of the *l*-th layer, where σ is an activation function;

Thus, the CPTM defined by (2) and (3) can be represented as

$$\mathbf{z}^1 = {\mathbf{W}_1}^{\mathrm{T}}\mathbf{x}$$
$$\mathbf{y}^1 = \sigma(\mathbf{z}^1)$$
$$\mathbf{z}^2 = {\mathbf{W}_2}^{\mathrm{T}}\mathbf{y}^1$$
$$\mathbf{y}^2 = \sigma(\mathbf{z}^2)$$
$$\text{sim}_{\boldsymbol{\theta}}(\mathbf{x}_f, \mathbf{x}_e) = \left(\mathbf{y}_f^2\right)^{\mathrm{T}}\mathbf{y}_e^2$$

The gradient of the matrix $\mathbf{W}_2$ which projects the hidden vector to the output vector is computed as:

$$\frac{\partial \text{sim}_{\boldsymbol{\theta}}(\mathbf{x}_f, \mathbf{x}_e)}{\partial \mathbf{W}_2} = \frac{\partial \left(\mathbf{y}_f^2\right)^{\mathrm{T}}}{\partial \mathbf{W}_2}\mathbf{y}_e^2 + \left(\mathbf{y}_f^2\right)^{\mathrm{T}} \frac{\partial \mathbf{y}_e^2}{\partial \mathbf{W}_2}$$

$$= \mathbf{y}_f^1 \left(\mathbf{y}_e^2 \circ \sigma'\left(\mathbf{z}_f^2\right)\right)^{\mathrm{T}} + \mathbf{y}_e^1 \left(\mathbf{y}_f^2 \circ \sigma'\left(\mathbf{z}_e^2\right)\right)^{\mathrm{T}} \quad (9)$$

where $\circ$ is the element-wise multiplication (Hadamard product). Applying the back propagation principle, the gradient of the projection matrix mapping the input vector to the hidden vector $\mathbf{W}_1$ is computed as

$$\frac{\partial \text{sim}_{\boldsymbol{\theta}}(\mathbf{x}_f, \mathbf{x}_e)}{\partial \mathbf{W}_1}$$
$$= \mathbf{x}_f \left(\mathbf{W}_2 \left(\mathbf{y}_e^2 \circ \sigma'\left(\mathbf{z}_f^2\right)\right) \circ \sigma'\left(\mathbf{z}_f^1\right)\right)^{\mathrm{T}}$$
$$+ \mathbf{x}_e \left(\mathbf{W}_2 \left(\mathbf{y}_f^2 \circ \sigma'\left(\mathbf{z}_e^2\right)\right) \circ \sigma'\left(\mathbf{z}_e^1\right)\right)^{\mathrm{T}} \quad (10)$$

The derivation can be easily extended to a neural network with multiple hidden layers.

5.1.2 Computing $\delta_{(f,e)}$

To simplify the notation, we rewrite our loss function of (5) and (6) over one training sample as

$$\mathcal{L}(\boldsymbol{\theta}) = -\mathrm{xBleu}(\boldsymbol{\theta}) = -\frac{\mathrm{G}(\boldsymbol{\theta})}{\mathrm{Z}(\boldsymbol{\theta})} \quad (11)$$

where

$$\mathrm{G}(\boldsymbol{\theta}) = \sum_E \mathrm{sBleu}(E, E_i) \exp\left(\boldsymbol{\lambda}^{\mathrm{T}} \mathbf{h}(F_i, E, A)\right)$$

$$\mathrm{Z}(\boldsymbol{\theta}) = \sum_E \exp\left(\boldsymbol{\lambda}^{\mathrm{T}} \mathbf{h}(F_i, E, A)\right)$$

Combining (8) and (11), we have

$$\delta_{(f,e)} = \frac{\partial \mathrm{xBleu}(\boldsymbol{\theta})}{\partial \mathrm{sim}_{\boldsymbol{\theta}}(\mathbf{x}_f, \mathbf{x}_e)} \quad (12)$$

$$= \frac{1}{\mathrm{Z}(\boldsymbol{\theta})} \left(\frac{\partial \mathrm{G}(\boldsymbol{\theta})}{\partial \mathrm{sim}_{\boldsymbol{\theta}}(\mathbf{x}_f, \mathbf{x}_e)} - \frac{\partial \mathrm{Z}(\boldsymbol{\theta})}{\partial \mathrm{sim}_{\boldsymbol{\theta}}(\mathbf{x}_f, \mathbf{x}_e)} \mathrm{xBleu}(\boldsymbol{\theta}) \right)$$

Because $\boldsymbol{\theta}$ is only relevant to h_{M+1} which is defined in (4), we have

$$\frac{\partial \boldsymbol{\lambda}^{\mathrm{T}} \mathbf{h}(F_i, E, A)}{\partial \mathrm{sim}_{\boldsymbol{\theta}}(\mathbf{x}_f, \mathbf{x}_e)} = \lambda_{M+1} \frac{\partial h_{M+1}(F_i, E, A)}{\partial \mathrm{sim}_{\boldsymbol{\theta}}(\mathbf{x}_f, \mathbf{x}_e)}$$

$$= \lambda_{M+1} N(f, e; A) \quad (13)$$

where $N(f, e; A)$ is the number of times the phrase pair (f, e) occurs in A. Combining (12) and (13), we end up with the following equation

$$\delta_{(f,e)} = \sum_{(E,A) \in GEN(F_i)} \mathrm{U}(\boldsymbol{\theta}, E) P(E|F_i) \lambda_{M+1} N(f, e; A) \quad (14)$$

where

$$\mathrm{U}(\boldsymbol{\theta}, E) = \mathrm{sBleu}(E_i, E) - \mathrm{xBleu}(\boldsymbol{\theta}).$$

5.2 The Training Algorithm

In our experiments we train the parameters of the CPTM, $\boldsymbol{\theta}$, using the L-BFGS optimizer described in Andrew and Gao (2007), together with the loss function described in (5). The gradient is computed as described in Sections 5.1. Although SGD has been advocated for neural network training due to its simplicity and its robustness to local minima (Bengio 2009), we find that in our task that the L-BFGS minimizes the loss in a desirable fashion empirically when iterating over the complete training data (batch mode). For example, the convergence of the algorithm was found to be smooth, despite the non-convexity in our loss. Another merit of batch training is that the gradient over all training data can be computed efficiently. As shown in Section 5.1, computing $\partial \mathrm{sim}_{\theta}(\mathrm{x}_f, \mathrm{x}_e)/\partial\theta$ requires large-scale matrix multiplications, and is expensive for multi-layer neural networks. Eq. (7) suggests that $\partial \mathrm{sim}_{\theta}(\mathrm{x}_f, \mathrm{x}_e)/\partial\theta$ and $\delta_{(f,e)}$ can be computed separately, thus making the computation cost of the former term only depends on the number of phrase pairs in the phrase table, but not the size of training data. Therefore, the training method described here can be used on larger amounts of training data with little difficulty.

As described in Section 4, we take three steps to learn the parameters for both the log-linear model of SMT and the CPTM. While steps 1 and 3 can be easily parallelized on a computer cluster, the CPTM training is performed on a single machine. For example, given a phrase table containing 16M pairs and a 1M-sentence training set, it takes a couple of hours to generate the N-best lists on a cluster, and about 10 hours to train the CPTM on a Xeon E5-2670 2.60GHz machine.

For a non-convex problem, model initialization is important. In our experiments we always initialize $\mathbf{W}_1$ using a bilingual topic model trained on parallel data (see detail in Section 6.2), and $\mathbf{W}_2$ as an identity matrix. In principle, the loss function of (5) can be further regularized (e.g. by adding a term of L_2 norm) to deal with overfitting. However, we did not find clear empirical advantage over the simpler early stop approach in a pilot study, which is adopted in the experiments in this paper.

6 Experiments

This section evaluates the CPTM presented on two translation tasks using WMT data sets. We first describe the data sets and baseline setup. Then we present experiments where we compare different versions of the CPTM and previous models.

6.1 Experimental Setup

Baseline. We experiment with an in-house phrase-based system similar to Moses (Koehn et al. 2007), where the translation candidates are scored by a set of common features including maximum likelihood estimates of source given target phrase mappings $P_{MLE}(e|f)$ and vice versa $P_{MLE}(f|e)$, as well as lexical weighting estimates $P_{LW}(e|f)$ and $P_{LW}(f|e)$, word and phrase penalties, a linear distortion feature, and a lexicalized reordering feature. The baseline includes a standard 5-gram modified Kneser-Ney language model trained on the target side of the parallel corpora described below. Log-linear weights are estimated with the MERT algorithm (Och 2003).

Evaluation. We test our models on two different data sets. First, we train an English to French system based on the data of WMT 2006 shared task (Koehn and Monz 2006). The parallel corpus includes 688K sentence pairs of parliamentary proceedings for training. The development set contains 2000 sentences, and the test set contains other 2000 sentences, all from the official WMT 2006 shared task.

Second, we experiment with a French to English system developed using 2.1M sentence pairs of training data, which amounts to 102M words, from the WMT 2012 campaign. The majority of the training data set is parliamentary proceedings except for 5M words which are newswire. We use the 2009 newswire data set, comprising 2525 sentences, as the development set. We evaluate on four newswire domain test sets from 2008, 2010 and 2011 as well as the 2010 system combination test set, containing 2034 to 3003 sentences.

In this study we perform a detailed empirical comparison using the WMT 2006 data set, and verify our best models and results using the larger WMT 2012 data set.

The metric used for evaluation is case insensitive BLEU score (Papineni et al. 2002). We also perform a significance test using the Wilcoxon signed rank test. Differences are considered statistically significant when the *p*-value is less than 0.05.

6.2 Results of the CPTM

Table 1 shows the results measured in BLEU evaluated on the WMT 2006 data set, where Row 1 is the baseline system. Rows 2 to 4 are the systems enhanced by integrating different versions of the CPTM. Rows 5 to 7 present the results of previous models. Row 8 is our best system. Table 2 shows the main results on the WMT 2012 data set.

CPTM is the model described in Sections 4. As illustrated in Figure 2, the number of the nodes in the input layer is the vocabulary size d. Both the hidden layer and the output layer have 100 nodes[6]. That is, $\mathbf{W}^1$ is a $d \times 100$ matrix and $\mathbf{W}^2$ a 100×100 matrix. The result shows that **CPTM** leads to a substantial improvement over the baseline system with a statistically significant margin of 1.0 BLEU points as in Table 1.

We have developed a set of variants of **CPTM** to investigate two design choices we made in developing the CPTM: (1) whether to use a linear projection or a multi-layer nonlinear projection; and (2) whether to compute the phrase similarity using word-word similarities as suggested by e.g., the lexical weighting model (Koehn et al. 2003). We compare these variants on the WMT 2006 data set, as shown in Table 1.

#	Systems	WMT test2006
1	**Baseline**	33.06
2	**CPTM**	**34.10**$^{\alpha}$
3	**CPTM$_{\mathbf{L}}$**	33.60$^{\alpha\beta}$
4	**CPTM$_{\mathbf{W}}$**	33.25$^{\beta}$
5	**BLTM$_{\mathbf{PR}}$**	33.15$^{\beta}$
6	**DPM**	33.29$^{\beta}$
7	**MRF$_{\mathbf{P}}$**	33.91$^{\alpha}$
8	**Comb (2 + 7)**	**34.39**$^{\alpha\beta}$

Table 1: BLEU results for the English to French task using translation models and systems built on the WMT 2006 data set. The superscripts α and β indicate statistically significant difference ($p < 0.05$) from **Baseline** and **CPTM**, respectively.

CPTM$_{\mathbf{L}}$ (Row 3 in Table 1) uses a linear neural network to project a word vector of a phrase $\mathbf{x}$ to a feature vector $\mathbf{y}$: $\mathbf{y} \equiv \phi(\mathbf{x}) = \mathbf{W}^{\mathrm{T}}\mathbf{x}$, where $\mathbf{W}$ is a $d \times 100$ projection matrix. The translation score of a source phrase f and a target phrase e is measured as the similarity of their feature vectors. We choose cosine similarity because it works better than dot product for linear projection.

CPTM$_{\mathbf{W}}$ (Row 4 in Table 1) computes the phrase similarity using word-word similarity scores. This follows the common smoothing strategy of addressing the data sparseness problem in modeling phrase translations, such as the lexical weighting model (Koehn et al. 2003) and the word factored n-gram translation model (Son et al. 2012). Let w denote a word, and f and e the source and target phrases, respectively. We define

$$\mathrm{sim}(f,e) = \frac{1}{|f|}\sum_{w\in f}\mathrm{sim}_\tau(w,e) + \frac{1}{|e|}\sum_{w\in e}\mathrm{sim}_\tau(w,f)$$

where $\mathrm{sim}_\tau(w,e)$ (or $\mathrm{sim}_\tau(w,f)$) is the word-phrase similarity, and is defined as a smooth approximation of the maximum function

$$\mathrm{sim}_\tau(w,e) = \frac{\sum_{w'\in e}\mathrm{sim}(w,w')\exp\big(\tau\mathrm{sim}(w,w')\big)}{\sum_{w'\in e}\exp\big(\tau\mathrm{sim}(w,w')\big)}$$

[6] We can achieve slightly better results using more nodes in the hidden and output layers, say 500 nodes. But the model training is too slow to perform a detailed study within a reasonable time. Therefore, all the models reported in this paper use 100 nodes.

#	Systems	dev	news2011	news2010	news2008	newssyscomb2010

Table 2: BLEU results for the French to English task using translation models and systems built on the WMT 2012 data set. The superscripts α and β indicate statistically significant difference ($p < 0.05$) from **Baseline** and **MRF$_p$**, respectively.

where $\mathrm{sim}_\tau(w, e)$ (or $\mathrm{sim}_\tau(w, f)$) is the word-phrase similarity, and is defined as a smooth approximation of the maximum function
where τ is the tuned smoothing parameter.

Similar to **CPTM**, **CPTM$_W$** also uses a nonlinear projection to map each word (not a phrase vector as in **CPTM**) to a feature vector.

Two observations can be made by comparing **CPTM** in Row 2 to its variants in Table 1. First of all, it is more effective to model the phrase translation directly than decomposing it into word-word translations in the CPTMs. Second, we see that the nonlinear projection is able to generate more effective features, leading to better results than the linear projection.

We also compare the best version of the CPTM i.e., **CPTM**, with three related models proposed previously. We start the discussion with the results on the WMT 2006 data set in Table 1.

Rows 5 and 6 in Table 1 are two state-of-the-art latent semantic models that are originally trained on clicked query-document pairs (i.e., clickthrough data extracted from search logs) for query-document matching (Gao et al. 2011). To adopt these models for SMT, we view source-target sentence pairs as clicked query-document pairs, and trained both models using the same methods as in Gao et al. (2011) on the parallel bilingual training data described earlier. Specifically, **BTLM$_{PR}$** is an extension to PLSA, and is the best performer among different versions of the Bi-Lingual Topic Model (BLTM) described in Gao et al. (2011). BLTM with Posterior Regularization (**BLTM$_{PR}$**) is trained on parallel training data using the EM algorithm with a constraint enforcing a source sentence and its paralleled target sentence to not only share the same prior topic distribution, but to also have similar fractions of words assigned to each topic. We incorporated the model into the log-linear model for SMT (1) as follows. First of all, the topic distribution of a source sentence F_i, denoted by $P(z|F_i)$, is induced from the learned topic-word distributions using EM. Then, each translation candidate E in the N-best list $\mathrm{GEN}(F_i)$ is scored as

$$P(E|F_i) = \prod_{w \in E} \sum_z P(w|z) P(z|F_i)$$

$P(F_i|E)$ can be similarly computed. Finally, the logarithms of the two probabilities are incorporated into the log-linear model of (1) as two additional features. **DPM** is the Discriminative Projection Model described in Gao et al. (2011), which is an extension of LSA. **DPM** uses a matrix to project a word vector of a sentence to a feature vector. The projection matrix is learned on parallel training data using the S2Net algorithm (Yih et al. 2011). **DPM** can be incorporated into the log-linear model for SMT (1) by introducing a new feature h_{M+1} for each phrase pair, which is defined as the cosine similarity of the phrases in the project space.

As we see from Table 1, both latent semantic models, although leading to some slight improvement over **Baseline**, are much less effective than **CPTM**.

Finally, we compare the CPTM with the Markov Random Field model using phrase features (**MRF$_P$** in Tables 1 and 2), proposed by Gao and He (2013)[7], on both the WMT 2006 and WMT 2012 datasets. **MRF$_p$** is a state-of-the-art large scale discriminative training model that uses the same expected BLEU training criterion, which has proven to give superior performance across a range of MT tasks recently (He and Deng 2012, Setiawan and Zhou 2013, Gao and He 2013).

Unlike **CPTM**, **MRF$_p$** is a linear model that simply treats each phrase pair as a single feature. Therefore, although both are trained using the

[7] Gao and He (2013) reported results of MRF models with different feature sets. We picked the MRF using phrase features only (**MRF$_P$**) for comparison since we are mainly interested in phrase representation.

same expected BLEU based objective function, **CPTM** and **MRF$_p$** model the translation relationship between two phrases from different angles. **MRF$_p$** estimates one translation score for each phrase pair explicitly without parameter sharing, while in **CPTM**, all phrases share the same neural network that projects raw phrases to the continuous space, providing a more smoothed estimation of the translation score for each phrase pair.

The results in Tables 1 and 2 show that **CPTM** outperforms **MRF$_P$** on most of the test sets across the two WMT data sets, but the difference between them is often not significant. Our interpretation is that although **CPTM** provides a better smoothed estimation for low-frequent phrase pairs, which otherwise suffer the data sparsity issue, **MRF$_p$** provides a more precise estimation for those high-frequent phrase pairs. That is, **CPTM** and **MRF$_p$** capture complementary information for translation. We thus combine **CPTM** and **MRF$_P$** (**Comb** in Tables 1 and 2) by incorporating two features, each for one model, into the log-linear model of SMT (1). We observe that for both translation tasks, accuracy improves by up to 0.8 BLEU over **MRF$_P$** alone (e.g., on the news2008 test set in Table 2). The results confirm that **CPTM** captures complementary translation information to **MRF$_p$**. Overall, we improve accuracy by up to 1.3 BLEU over the baseline on both WMT data sets.

7 Conclusions

The work presented in this paper makes two major contributions. First, we develop a novel phrase translation model for SMT, where joint representations are exploited of a phrase in the source language and of its translation in the target language, and where the translation score of the pair of source-target phrases are represented as the distance between their feature vectors in a low-dimensional, continuous space. The space is derived from the representations generated using a multilayer neural network. Second, we present a new learning method to train the weights in the multilayer neural network for the end-to-end BLEU metric directly. The training method is based on L-BFGS. We describe in detail how the gradient in closed form, as required for efficient optimization, is derived. The objective function, which takes the form of the expected BLEU computed from N-best lists, is very different from the usual objective functions used in most existing architectures of neural networks, e.g., cross entropy (Hinton et al. 2012) or mean square error (Deng et al. 2012). We hence have provided details in the derivation of the gradient, which can serve as an example to guide the derivation of neural network learning with other non-standard objective functions in the future.

Our evaluation on two WMT data sets show that incorporating the continuous-space phrase translation model into the log-linear framework significantly improves the accuracy of a state-of-the-art phrase-based SMT system, leading to a gain up to 1.3 BLEU. Careful implementation of the L-BFGS optimization based on the BLEU-centric objective function, together with the associated closed-form gradient, is a key to the success.

A natural extension of this work is to expand the model and learning algorithm from shallow to deep neural networks. The deep models are expected to produce more powerful and flexible semantic representations (e.g., Tur et al., 2012), and thus greater performance gain than what is presented in this paper.

Abstract

The automatic estimation of machine translation (MT) output quality is a hard task in which the selection of the appropriate algorithm and the most predictive features over reasonably sized training sets plays a crucial role. When moving from controlled lab evaluations to real-life scenarios the task becomes even harder. For current MT quality estimation (QE) systems, additional complexity comes from the difficulty to model user and domain changes. Indeed, the instability of the systems with respect to data coming from different distributions calls for adaptive solutions that react to new operating conditions. To tackle this issue we propose an online framework for adaptive QE that targets reactivity and robustness to user and domain changes. Contrastive experiments in different testing conditions involving user and domain changes demonstrate the effectiveness of our approach.

1 Introduction

After two decades of steady progress, research in statistical machine translation (SMT) started to cross its path with translation industry with tangible mutual benefit. On one side, SMT research brings to the industry improved output quality and a number of appealing solutions useful to increase translators' productivity. On the other side, the market needs suggest concrete problems to solve, providing real-life scenarios to develop and evaluate new ideas with rapid turnaround. The evolution of computer-assisted translation (CAT) environments is an evidence of this trend, shown by the increasing interest towards the integration of suggestions obtained from MT engines with those derived from translation memories (TMs).

The possibility to speed up the translation process and reduce its costs by post-editing good-quality MT output raises interesting research challenges. Among others, these include deciding *what* to present as a suggestion, and *how* to do it in the most effective way.

In recent years, these issues motivated research on automatic QE, which addresses the problem of estimating the quality of a translated sentence given the source and without access to reference translations (Blatz et al., 2003; Specia et al., 2009; Mehdad et al., 2012). Despite the substantial progress done so far in the field and in successful evaluation campaigns (Callison-Burch et al., 2012; Bojar et al., 2013), focusing on concrete market needs makes possible to further define the scope of research on QE. For instance, moving from controlled lab testing scenarios to real working environments poses additional constraints in terms of adaptability of the QE models to the variable conditions of a translation job. Such variability is due to two main reasons:

1. **The notion of MT output quality is highly subjective** (Koponen, 2012; Turchi et al., 2013; Turchi and Negri, 2014). Since the quality standards of individual users may vary considerably (*e.g.* according to their knowledge of the source and target languages), the estimates of a static QE model trained with data collected from a group of post-editors might not fit with the actual judgements of a new user;

2. **Each translation job has its own specificities** (domain, complexity of the source text, average target quality). Since data from a new job may differ from those used to train the QE model, its estimates on the new instances might result to be biased or uninformative.

The ability of a system to self-adapt to the be-

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 710–720,
Baltimore, Maryland, USA, June 23-25 2014.

haviour of specific users and domain changes is a facet of the QE problem that so far has been disregarded. To cope with these issues and deal with the erratic conditions of real-world translation workflows, we propose **an adaptive approach to QE** that is sensitive and robust to differences between training and test data. Along this direction, our main contribution is a framework in which QE models can be trained and can continuously evolve over time accounting for knowledge acquired from post editors' work.

Our approach is **based on the online learning paradigm** and exploits a key difference between such framework and the batch learning methods currently used. On one side, the QE models obtained with batch methods are learned exclusively from a predefined set of training examples under the assumption that they have similar characteristics with respect to the test data. This makes them suitable for controlled evaluation scenarios where such condition holds. On the other side, online learning techniques are designed to learn in a stepwise manner (either from scratch, or by refining an existing model) from new, unseen test instances by taking advantage of external feedback. This makes them suitable for real-life scenarios where the new instances to be labelled can considerably differ from the data used to train the QE model.

To develop our approach, different online algorithms have been embedded in the backbone of a QE system. This required the adaptation of its standard batch learning workflow to:

1. Perform online feature extraction from a source–target pair (*i.e.* one instance at a time instead of processing an entire training set);
2. Emit a prediction for the input instance;
3. Gather user feedback for the instance (*i.e.* calculating a "true label" based on the amount of user post-editions);
4. Send the true label back to the model to update its predictions for future instances.

Focusing on the adaptability to user and domain changes, we report the results of comparative experiments with two online algorithms and the standard batch approach. The evaluation is carried out by measuring the global error of each algorithm on test sets featuring different degrees of similarity with the data used for training. Our results show that the sensitivity of online QE models to different distributions of training and test instances makes them more suitable than batch methods for integration in a CAT framework.

Our adaptive QE infrastructure has been released as open source. Its C++ implementation is available at `http://hlt.fbk.eu/technologies/aqet`.

2 Related work

QE is generally cast as a supervised machine learning task, where a model trained from a collection of (*source, target, label*) instances is used to predict labels[1] for new, unseen test items (Specia et al., 2010).

In the last couple of years, research in the field received a strong boost by the shared tasks organized within the WMT workshop on SMT,[2] which is also the framework of our first experiment in §5. Current approaches to the tasks proposed at WMT have mainly focused on three main directions, namely: *i)* feature engineering, as in (Hardmeier et al., 2012; de Souza et al., 2013a; de Souza et al., 2013b; Rubino et al., 2013b), *ii)* model learning with a variety of classification and regression algorithms, as in (Bicici, 2013; Beck et al., 2013; Soricut et al., 2012), and *iii)* feature selection as a way to overcome sparsity and overfitting issues, as in (Soricut et al., 2012).

Being optimized to perform well on specific WMT sub-tasks and datasets, current systems reflect variations along these directions but leave important aspects of the QE problem still partially investigated or totally unexplored.[3] Among these, the necessity to model the diversity of human quality judgements and correction strategies (Koponen, 2012; Koponen et al., 2012) calls for solutions that: *i)* account for annotator-specific behaviour, thus being capable of learning from inherently noisy datasets produced by multiple annotators, and *ii)* self-adapt to changes in data distribution, learning from user feedback on new, unseen test items.

[1] Possible label types include *post-editing effort scores* (*e.g.* 1-5 Likert scores indicating the estimated percentage of MT output that has to be corrected), *HTER values* (Snover et al., 2006), and post-editing *time* (*e.g.* seconds per word).

[2] `http://www.statmt.org/wmt13/`

[3] For a comprehensive overview of the QE approaches proposed so far we refer the reader to the WMT12 and WMT13 QE shared task reports (Callison-Burch et al., 2012; Bojar et al., 2013).

These interconnected issues are particularly relevant in the CAT framework, where translation jobs from different domains are routed to professional translators with different idiolect, background and quality standards.

The first aspect, modelling annotators' individual behaviour and interdependences, has been addressed by Cohn and Specia (2013), who explored multi-task Gaussian Processes as a way to jointly learn from the output of multiple annotations. This technique is suitable to cope with the unbalanced distribution of training instances and yields better models when heterogeneous training datasets are available.

The second problem, the adaptability of QE models, has not been explored yet. A common trait of all current approaches, in fact, is the reliance on batch learning techniques, which assume a "static" nature of the world where new unseen instances that will be encountered will be similar to the training data.[4] However, similarly to translation memories that incrementally store translated segments and evolve over time incorporating users style and terminology, all components of a CAT tool (the MT engine and the mechanisms to assign quality scores to the suggested translations) should take advantage of translators feedback.

On the MT system side, research on adaptive approaches tailored to interactive SMT and CAT scenarios explored the online learning protocol (Littlestone, 1988) to improve various aspects of the decoding process (Cesa-Bianchi et al., 2008; Ortiz-Martínez et al., 2010; Martínez-Gómez et al., 2011; Martínez-Gómez et al., 2012; Mathur et al., 2013; Bertoldi et al., 2013).

As regards QE models, our work represents the first investigation on incremental adaptation by exploiting users feedback to provide targeted (system, user, or project specific) quality judgements.

3 Online QE for CAT environments

When operating with advanced CAT tools, translators are presented with suggestions (either matching fragments from a translation memory or automatic translations produced by an MT system) for each sentence of a source document. Before being approved and published, translation suggestions may require different amounts of post-editing operations depending on their quality.

[4]This assumption holds in the WMT evaluation scenario, but it is not necessarily valid in real operating conditions.

Each post-edition brings a wealth of dynamic knowledge about the whole translation process and the involved actors. For instance, adaptive QE components could exploit information about the distance between automatically assigned scores and the quality standards of individual translators (inferred from the amount of their corrections) to "profile" their behaviour.

The online learning paradigm fits well with this research objective. In the online framework, differently from the batch mode, the learning algorithm sequentially processes an unknown sequence of instances $X = x_1, x_2, ..., x_n$, returning a prediction $p(x_i)$ as output at each step. Differences between $p(x_i)$ and the true label $\hat{p}(x_i)$ obtained as feedback are used by the learner to refine the next prediction $p(x_{i+1})$.

In our experiments on adaptive QE we aim to predict the quality of the suggested translations in terms of HTER, which measures the minimum edit distance between the MT output and its manually post-edited version in the [0,1] interval.[5] In this scenario:

- The set of instances X is represented by (*source, target*) pairs;
- The prediction $p(x_i)$ is the automatically estimated HTER score;
- The true label $\hat{p}(x_i)$ is the actual HTER score calculated over the target and its post-edition.

At each step of the process, the goal of the learner is to exploit user post-editions to reduce the difference between the predicted HTER values and the true labels for the following (*source, target*) pairs.

As depicted in Figure 1, this is done as follows:

1. At step *i*, an unlabelled (*source, target*) pair x_i is sent to a feature extraction component. To this aim, we used an adapted version (Shah et al., 2014) of the open-source QuEst[6] tool (Specia et al., 2013). The tool, which implements a large number of features proposed by participants in the WMT QE shared tasks, has been modified to process one sentence at a time as requested for integration in a CAT environment;

[5]Edit distance is calculated as the number of edits (word insertions, deletions, substitutions, and shifts) divided by the number of words in the reference. Lower HTER values indicate better translations.

[6]`http://www.quest.dcs.shef.ac.uk/`

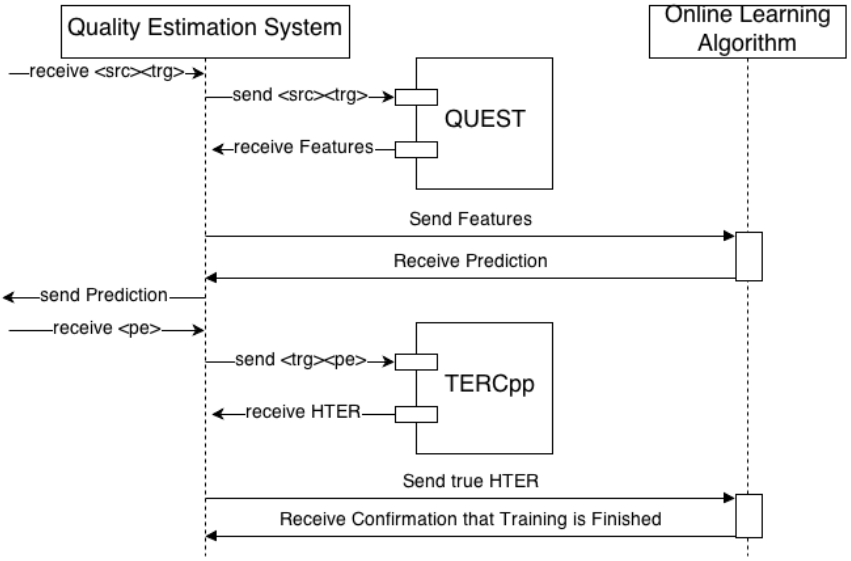

Figure 1: Online QE workflow. <src>, <trg> and <pe> respectively stand for the source sentence, the target translation and the post-edited target.

2. The extracted features are sent to an online regressor, which returns a QE prediction score $p(x_i)$ in the [0,1] interval (set to 0 at the first round of the iteration);

3. Based on the post-edition done by the user, the true HTER label $\hat{p}(x_i)$ is calculated by means of the TERCpp[7] open source tool;

4. The true label is sent back to the online algorithm for a stepwise model improvement. The updated model is then ready to process the following instance x_{i+1}.

This new paradigm for QE makes it possible to: *i)* let the QE system learn from one point at a time without complete re-training from scratch, *ii)* customize the predictions of an existing QE model with respect to a specific situation (post-editor or domain), or even *iii)* build a QE model from scratch when training data is not available.

For the sake of clarity it is worth observing that, at least in principle, a model built in a batch fashion could also be adapted to new test data. For instance, this could be done by running periodic re-training routines once a certain amount of new labelled instances has been collected (*de facto* mimicking an online process). Such periodic updates, however, would not represent a viable solution in the CAT framework where post-editors' work cannot be slowed by time-consuming procedures to re-train core system components from scratch.

[7] goo.gl/nkh2rE

4 Evaluation framework

To measure the adaptation capability of different QE models, we experiment with a range of conditions defined by variable degrees of similarity between training and test data.

The degree of similarity depends on several factors: the MT engine used, the domain of the documents to be translated, and the post-editing style of individual translators. In our experiments, the degree of similarity is measured in terms of ΔHTER, which is computed as the absolute value of the difference between the average HTER of the training and test sets. Large values indicate a low similarity between training and test data and a more challenging scenario for the learning algorithms.

4.1 Experimental setup

In the range of possible evaluation scenarios, our experiments cover:

- One artificial setting (§5) obtained from the WMT12 QE shared task data, in which training/test instances are arranged to reflect homogeneous distributions of the HTER labels.

- Two settings obtained from data collected with a CAT tool in real working conditions, in which different facets of the adaptive QE problem interact with each other. In the first (`user_change`, §6.1), training and test data from the same domain are obtained from different users. In the sec-

ond (user+domain_change, §6.2), training and test data are obtained from different users and domains.

For each setting, we compare an *adaptive* and an *empty* model against a system trained in *batch* mode. The *adaptive* model is built on top of an existing model created from the training data and exploits the new test instances to refine its predictions in a stepwise manner. The *empty* model only learns from the test set, simulating the worst condition where training data is not available. The *batch* model is built by learning only from the training data and is evaluated on the test set without exploiting information from the test instances.

Each model is also compared against a common baseline for regression tasks, which is particularly relevant in settings featuring different data distributions between training and test sets. This baseline (μ henceforth) is calculated by labelling each instance of the test set with the mean HTER score of the training set. Previous works (Rubino et al., 2013a) demonstrated that its results can be particularly hard to beat.

4.2 Performance indicator and feature set

To measure the adaptability of our model to a given test set we compute the Mean Absolute Error (MAE), a metric for regression problems also used in the WMT QE shared tasks. The MAE is the average of the absolute errors $e_i = |f_i - y_i|$, where f_i is the prediction of the model and y_i is the true value for the i^{th} instance.

As our focus is on the algorithmic aspect, in all experiments we use the same feature set, which consists of the seventeen features proposed in (Specia et al., 2009). This feature set, fully described in (Callison-Burch et al., 2012), takes into account the complexity of the source sentence (*e.g.* number of tokens, number of translations per source word) and the fluency of the target translation (*e.g.* language model probabilities). The results of previous WMT QE shared tasks have shown that these baseline features are particularly competitive in the regression task (with only few systems able to beat them at WMT12).

4.3 Online algorithms

In our experiments we evaluate two online algorithms, OnlineSVR (Parrella, 2007)[8] and Passive-Aggressive Perceptron (Crammer et al., 2006),[9] by comparing their performance with a batch learning strategy based on the Scikit-learn implementation of Support Vector Regression (SVR).[10]

The choice of the OnlineSVR and Passive-Aggressive (OSVR and PA henceforth) is motivated by different considerations. From a **performance** point of view, as an adaptation of ϵ-SVR which proved to be one of the top performing algorithms in the regression QE tasks at WMT, OSVR seems to be the best candidate. For this reason, we use the online adaptation of ϵ-SVR proposed by (Ma et al., 2003). The goal of OnlineSVR is to find a way to add each new sample to one of three sets (support, empty, error) maintaining the consistency of a set of conditions known as Karush-Kuhn Tucker (KKT) conditions. For each new point, OSVR starts a cycle where the samples are moved across the three sets until the KKT conditions are verified and the new point is assigned to one of the sets. If the point is identified as a support vector, the parameters of the model are updated. This allows OSVR to benefit from the prediction capability of ϵ-SVR in an online setting.

From a **practical** point of view, providing the best trade off between accuracy and computational time (He and Wang, 2012), PA represents a good solution to meet the demand of efficiency posed by the CAT framework. For each instance *i*, after emitting a prediction and receiving the true label, PA computes the ϵ-insensitive hinge loss function. If its value is larger than the tolerance parameter (ϵ), the weights of the model are updated as much as the aggressiveness parameter C allows. In contrast with OSVR, which keeps track of the most important points seen in the past (support vectors), the update of the weights is done without considering the previously processed *i-1* instances. Although it makes PA faster than OSVR, this is a riskier strategy because it may lead the algorithm to change the model to adapt to outlier points.

5 Experiments with WMT12 data

The motivations for experiments with training and test data featuring homogeneous label distributions are twofold. First, since in this artificial scenario adaptation capabilities are not required for the QE component, batch methods operate in the ideal conditions (as training and test are indepen-

Table 1: MAE of the best performing *batch*, *adaptive* and *empty* models on WMT12 data. Training sets of different size and the test set have been arranged to reflect homogeneous label distributions.

dent and identically distributed). This makes possible to obtain from batch models the best possible performance to compare with. Second, this scenario provides the fairest conditions for such comparison because, in principle, online algorithms are not favoured by the possibility to learn from the diversity of the test instances.

For our controlled experiments we use the WMT12 English-Spanish corpus, which consists of 2,254 source-target pairs (1,832 for training, 422 for test). The HTER labels for our regression task are calculated from the post-edited version and the target sentences provided in the dataset.

To avoid biases in the label distribution, the WMT12 training and test data have been merged, shuffled, and eventually separated to generate three training sets of different size (200, 600, and 1500 instances), and one test set with 754 instances. For each algorithm, the training sets are used for learning the QE models, optimizing parameters (*i.e.* C, ϵ, the kernel and its parameters for SVR and OSVR; tolerance and aggressiveness for PA) through grid search in 10-fold cross-validation.

Evaluation is carried out by measuring the performance of the *batch* (learning only from the training set), the *adaptive* (learning from the training set and adapting to the test set), and the *empty* (learning from scratch from the test set) models in terms of global MAE scores on the test set.

Table 1 reports the results achieved by the best performing algorithm for each type of model (*batch*, *adaptive*, *empty*). As can be seen, close MAE values show a similar behaviour for the three types of models.[11] With the same amount of training data, the performance of the batch and the adaptive models (in this case always obtained with OSVR) is almost identical. This demonstrates that, as expected, the online algorithms do not take advantage of test data with a label distribution similar to the training set. All the models outperform the baseline, even if the minimal differences confirm the competitiveness of such a simple approach.

Overall, these results bring some interesting indications about the behaviour of the different online algorithms. First, the good results achieved by the empty models (less than one MAE point separates them from the best ones built on the largest training set) suggest their high potential when training data are not available. Second, our results show that OSVR is always the best performing algorithm for the adaptive and empty models. This suggests a lower capability of PA to learn from instances similar to the training data.

6 Experiments with CAT data

To experiment with adaptive QE in more realistic conditions we used a CAT tool[12] to collect two datasets of (*source*, *target*, *post_edited target*) English-Italian tuples.The source sentences in the datasets come from two documents from different domains, respectively legal (L) and information technology (IT). The L document, which was extracted from a European Parliament resolution published on the EUR-Lex platform,[13] contains 164 sentences. The IT document, which was taken from a software user manual, contains 280 sentences. The source sentences were translated with two SMT systems built by training the Moses toolkit (Koehn et al., 2007) on parallel data from the two domains (about 2M sentences for IT and 1.5M for L). Post-editions were collected from eight professional translators (four for each document) operating with the CAT tool in real working conditions.

According to the way they are created, the two datasets allow us to evaluate the adaptability of different QE models with respect to user changes

[11] Results marked with the "*" symbol are NOT statistically significant compared to the corresponding batch model. The others are always statistically significant at $p \leq 0.005$, calculated with approximate randomization (Yeh, 2000).

within the same domain (§6.1), as well as user and domain changes at the same time (§6.2).

For each document *D* (L or IT), these two scenarios are obtained by dividing *D* into two parts of equal size (80 instances for L and 140 for IT). The result is one training set and one test set for each post-editor within the same domain. For the `user_change` experiments, training and test sets are selected from different post-editors within the same domain. For the `user+domain_change` experiments, training and test sets are selected from different post-editors in different domains.

On each combination of training and test sets, the *batch*, *adaptive*, and *empty* models are trained and evaluated in terms of global MAE scores on the test set.

6.1 Dealing with user changes

Among the possible combinations of training and test data from different post-editors in the same domain, Table 2 refers to two opposite scenarios. For each domain, these respectively involve the most dissimilar and the most similar post-editors according to the ΔHTER. Also in this case, for each model (*batch*, *adaptive* and *empty*) we only report the MAE of the best performing algorithm.

The first scenario defines a challenging situation where two post-editors (*rad* and *cons*) are characterized by opposite behaviour. As evidenced by the high ΔHTER values, one of them (*rad*) is the most "radical" post-editor (performing more corrections) while the other (*cons*) is the most "conservative" one. As shown in Table 2, global MAE scores for the online algorithms (both *adaptive* and *empty*) indicate their good adaptation capabilities. This is evident from the significant improvements both over the baseline (μ) and the batch models. Interestingly, the best results are always achieved by the *empty* models (with MAE reductions up to 10 points when tested on *rad* in the L domain, and 3.2 points when tested on *rad* in the IT domain). These results (MAE reductions are always statistically significant) suggest that, when dealing with datasets with very different label distributions, the evident limitations of batch methods are more easily overcome by learning from scratch from the feedback of a new post-editor. This also holds when the amount of test points to learn from is limited, as in the L domain where the test set contains only 80 instances. From the application-oriented perspective that motivates our work, considering the high costs of acquiring large and representative QE training data, this is an important finding.

The second scenario defines a less challenging situation where the two post-editors (*sim1* and *sim2*) are characterized by the most similar behaviour (small ΔHTER). This scenario is closer to the situation described in Section §5. Also in this case MAE results for the *adaptive* and *empty* models are slightly worse, but not significantly, than those of the batch models and the baseline. However, considering the very small amount of "uninformative" instances to learn from (especially for the *empty* models), these lower results are not surprising.

A closer look at the behaviour of the online algorithms in the two domains leads to other observations. First, OSVR always outperforms PA for the *empty* models and when post-editors have sim-

Table 3: MAE of the best performing *batch*, *adaptive* and *empty* models on CAT data collected from different users and domains.

ilar behaviour, which are situations where the algorithm does not have to quickly adapt or react to sudden changes.

Second, PA seems to perform better for the *adaptive* models when the post-editors have significantly different behaviour and a quick adaptation to the incoming points is required. This can be motivated by the fact that PA relies on a simpler and less robust learning strategy that does not keep track of all the information coming from the previously processed instances, and can easily modify its weights taking into consideration the last seen point (see Section §3). For OSVR the addition of new points to the support set may have a limited effect on the whole model, in particular if the number of points in the set is large. This also results in a different processing time for the two algorithms.[14] For instance, in the *empty* configurations on IT data, OSVR devotes $6.0\ ms$ per instance to update the model, while PA devotes $4.8\ ms$, which comes at the cost of lower performance.

6.2 Dealing with user and domain changes

In the last round of experiments we evaluate the reactivity of different online models to simultaneous user and domain changes. To this aim, our QE models are created using a training set coming from one domain (L or IT), and then used to predict the HTER labels for the test instances coming from the other domain (*e.g.* training on L, testing on IT).

Among the possible combinations of training and test data, Table 3 refers to scenarios involving the most conservative and radical post-editors in each domain (previously identified with *cons* and *rad*)[15]. In the table, results are ordered according to the ΔHTER computed between the selected post-editor in the training domain (*e.g. L cons*) and the selected post-editor in the test domain (*e.g. IT rad*). For the sake of comparison, we also report (grey rows) the results of the experiments within the same domain presented in §6.1. For each type of model (*batch*, *adaptive* and *empty*) we only show the MAE obtained by the best performing algorithm.

Intuitively, dealing with simultaneous user and domain changes represents a more challenging problem compared to the previous setting where only post-editors changes were considered. Such intuition is confirmed by the results of the *adaptive* models that outperform both the baseline (μ) and the *batch* models even for low ΔHTER values. Although in these cases the distance between training and test data is comparable to the experiments with similar post-editors working in the same domain (*sim1* and *sim2*), here the predictive power of the *batch* models seems in fact to be lower. The same holds also for the *empty* models except in two cases where the ΔHTER is the smallest (2.2 and 5.0). This is a strong evidence of the fact that, in case of domain changes, online models can still learn from new test instances even if they have a label distribution similar to the training set.

When the distance between training and test increases, our results confirm our previous findings

[14] Their complexity depends on the number of features (*f*) and the number of previously seen instances (*n*). While for PA it is linear in *f*, *i.e. O(f)*, for OSVR it is quadratic in *n*, *i.e.* $O(n^2 * f)$.

[15] For brevity, we omit the results for the other post-editors which, however, show similar trends with respect to the previous experiments.

about the potential of the *empty* models. The observed MAE reductions range in fact from 10.4 to 12.9 points for the two combinations with the highest ΔHTER.

From the algorithmic point of view, our results indicate that OSVR achieves the best performance for all the combinations involving user and domain changes. This contrasts with the results of most of the combinations involving only user changes with post-editors characterized by opposite behaviour (grey rows in Table 3). However, it has to be remarked that in the case of heterogeneous datasets the difference between the two algorithms is always very high. In our experiments, when PA outperforms OSVR, its MAE results are significantly lower and vice-versa (respectively up to 1.5 and 1.7 MAE points). This suggests that, although PA is potentially capable of achieving higher results and better adapt to the new test points, its instability makes it less reliable for practical use.

As a final analysis of our results, we investigated how the performance of the different types of models (*batch*, *adaptive*, *empty*) relates to the distance between training and test sets. To this aim, we computed the Pearson correlation between the ΔHTER (column 3 in Table 3) and the MAE of each model (columns 5, 6 and 8), which respectively resulted in 0.9 for the *batch*, 0.63 for the *adaptive* and -0.07 for the *empty* model. These values confirm that *batch* models are heavily affected by the dissimilarity between training and test data: large differences in the label distribution imply higher MAE results and vice-versa. This is in line with our previous findings about *batch* models that, learning only from the training set, cannot leverage possible dissimilarities of the test set. The lower correlation observed for the *adaptive* models also confirms our intuitions: adapting to the new test points, these models are in fact more robust to differences with the training data. As expected, the results of the *empty* models are completely uncorrelated with the ΔHTER since they only use the test set.

This analysis confirms that, even when dealing with different domains, the similarity between the training and test data is one of the main factors that should drive the choice of the QE model. When this distance is minimal, *batch* models can be a reasonable option, but when the gap between training and test data increases, *adaptive* or *empty* models are a preferable choice to achieve good results.

7 Conclusion

In the CAT scenario, each translation job can be seen as a complex situation where the user (his personal style and background), the source document (the language and the domain) and the underlying technology (the translation memory and the MT engine that generate translation suggestions) contribute to make the task unique. So far, the adaptability to such specificities (a major challenge for CAT technology) has been mainly supported by the evolution of translation memories, which incrementally store translated segments incorporating the user style. The wide adoption of translation memories demonstrates the importance of capitalizing on such information to increase translators productivity.

While this lesson recently motivated research on adaptive MT decoders that learn from user corrections, nothing has been done to develop adaptive QE components. In the first attempt to address this problem, we proposed the application of the online learning protocol to leverage users feedback and to tailor QE predictions to their quality standards. Besides highlighting the limitations of current batch methods to adapt to user and domain changes, we performed an application-oriented analysis of different online algorithms focusing on specific aspects relevant to the CAT scenario. Our results show that the wealth of dynamic knowledge brought by user corrections can be exploited to refine in a stepwise fashion the quality judgements in different testing conditions (user changes as well as simultaneous user and domain changes).

As an additional contribution, to spark further research on this facet of the QE problem, our adaptive QE infrastructure (integrating all the components and the algorithms described in this paper) has been released as open source. Its C++ implementation is available at `http://hlt.fbk.eu/technologies/aqet`.

Abstract

In this paper we address the problem of grounding distributional representations of lexical meaning. We introduce a new model which uses stacked autoencoders to learn higher-level embeddings from textual and visual input. The two modalities are encoded as vectors of attributes and are obtained automatically from text and images, respectively. We evaluate our model on its ability to simulate similarity judgments and concept categorization. On both tasks, our approach outperforms baselines and related models.

1 Introduction

Recent years have seen a surge of interest in single word vector spaces (Turney and Pantel, 2010; Collobert et al., 2011; Mikolov et al., 2013) and their successful use in many natural language applications. Examples include information retrieval (Manning et al., 2008), search query expansions (Jones et al., 2006), document classification (Sebastiani, 2002), and question answering (Yih et al., 2013). Vector spaces have been also popular in cognitive science figuring prominently in simulations of human behavior involving semantic priming, deep dyslexia, text comprehension, synonym selection, and similarity judgments (see Griffiths et al., 2007). In general, these models specify mechanisms for constructing semantic representations from text corpora based on the *distributional hypothesis* (Harris, 1970): words that appear in similar linguistic contexts are likely to have related meanings.

Word meaning, however, is also tied to the physical world. Words are *grounded* in the external environment and relate to sensorimotor experience (Regier, 1996; Landau et al., 1998; Barsalou, 2008). To account for this, new types of perceptually grounded distributional models have emerged. These models learn the meaning of words based on textual and perceptual input. The latter is approximated by feature norms elicited from humans (Andrews et al., 2009; Steyvers, 2010; Silberer and Lapata, 2012), visual information extracted automatically from images, (Feng and Lapata, 2010; Bruni et al., 2012a; Silberer et al., 2013) or a combination of both (Roller and Schulte im Walde, 2013). Despite differences in formulation, most existing models conceptualize the problem of meaning representation as one of learning from multiple views corresponding to different modalities. These models still represent words as vectors resulting from the combination of representations with different statistical properties that do not necessarily have a natural correspondence (e.g., text and images).

In this work, we introduce a model, illustrated in Figure 1, which learns grounded meaning representations by mapping words and images into a common embedding space. Our model uses stacked autoencoders (Bengio et al., 2007) to induce semantic representations integrating visual and textual information. The literature describes several successful approaches to multimodal learning using different variants of deep networks (Ngiam et al., 2011; Srivastava and Salakhutdinov, 2012) and data sources including text, images, audio, and video. Unlike most previous work, our model is defined at a finer level of granularity — it computes meaning representations for *individual* words and is unique in its use of *attributes* as a means of representing the textual and visual modalities. We follow Silberer et al. (2013) in arguing that an attribute-centric representation is expedient for several reasons.

Firstly, attributes provide a natural way of expressing salient properties of word meaning as demonstrated in norming studies (e.g., McRae et al., 2005) where humans often employ attributes when asked to describe a concept. Secondly, from

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 721–732,
Baltimore, Maryland, USA, June 23-25 2014.

a modeling perspective, attributes allow for easier integration of different modalities, since these are rendered in the same medium, namely, language. Thirdly, attributes are well-suited to describing visual phenomena (e.g., objects, scenes, actions). They allow to generalize to new instances for which there are no training examples available and to transcend category and task boundaries whilst offering a generic description of visual data (Farhadi et al., 2009).

Our model learns multimodal representations from attributes which are automatically inferred from text and images. We evaluate the embeddings it produces on two tasks, namely word similarity and categorization. In the first task, model estimates of word similarity (e.g., *gem–jewel* are similar but *glass–magician* are not) are compared against elicited similarity ratings. We performed a large-scale evaluation on a new dataset consisting of human similarity judgments for 7,576 word pairs. Unlike previous efforts such as the widely used WordSim353 collection (Finkelstein et al., 2002), our dataset contains ratings for visual and textual similarity, thus allowing to study the two modalities (and their contribution to meaning representation) together and in isolation. We also assess whether the learnt representations are appropriate for categorization, i.e., grouping a set of objects into meaningful semantic categories (e.g., *peach* and *apple* are members of FRUIT, whereas *chair* and *table* are FURNITURE). On both tasks, our model outperforms baselines and related models.

2 Related Work

The presented model has connections to several lines of work in NLP, computer vision research, and more generally multimodal learning. We review related work in these areas below.

Grounded Semantic Spaces Grounded semantic spaces are essentially distributional models augmented with perceptual information. A model akin to Latent Semantic Analysis (Landauer and Dumais, 1997) is proposed in Bruni et al. (2012b) who concatenate two independently constructed textual and visual spaces and subsequently project them onto a lower-dimensional space using Singular Value Decomposition.

Several other models have been extensions of Latent Dirichlet Allocation (Blei et al., 2003) where topic distributions are learned from words *and* other perceptual units. Feng and Lapata (2010) use visual words which they extract from a corpus of multimodal documents (i.e., BBC news articles and their associated images), whereas others (Steyvers, 2010; Andrews et al., 2009; Silberer and Lapata, 2012) use feature norms obtained in longitudinal elicitation studies (see McRae et al. (2005) for an example) as an approximation of the visual environment. More recently, topic models which combine both feature norms and visual words have also been introduced (Roller and Schulte im Walde, 2013). Drawing inspiration from the successful application of attribute classifiers in object recognition, Silberer et al. (2013) show that automatically predicted visual attributes act as substitutes for feature norms without any critical information loss.

The visual and textual modalities on which our model is trained are decoupled in that they are not derived from the same corpus (we would expect co-occurring images and text to correlate to some extent) but unified in their representation by natural language attributes. The use of stacked autoencoders to extract a shared lexical meaning representation is new to our knowledge, although, as we explain below related to a large body of work on deep learning.

Multimodal Deep Learning Our work employs deep learning (a.k.a deep networks) to project linguistic and visual information onto a unified representation that fuses the two modalities together. The goal of deep learning is to learn multiple levels of representations through a hierarchy of network architectures, where higher-level representations are expected to help define higher-level concepts.

A large body of work has focused on projecting words and images into a common space using a variety of deep learning methods ranging from deep and restricted Boltzman machines (Srivastava and Salakhutdinov, 2012; Feng et al., 2013), to autoencoders (Wu et al., 2013), and recursive neural networks (Socher et al., 2013b). Similar methods have been employed to combine other modalities such as speech and video (Ngiam et al., 2011) or images (Huang and Kingsbury, 2013). Although our model is conceptually similar to these studies (especially those applying stacked autoencoders), it differs considerably from them in at least two aspects. Firstly, most of these approaches aim to learn a shared representation between modalities

so as to infer some missing modality from others (e.g., to infer text from images and vice versa); in contrast, we aim to learn an optimal representation for each modality and their optimal combination. Secondly, our problem setting is different from the former studies, which usually deal with classification tasks and fine-tune the deep neural networks using training data with explicit class labels; in contrast we fine-tune our autoencoders using a semi-supervised criterion. That is, we use indirect supervision in the form of object classification in addition to the objective of reconstructing the attribute-centric input representation.

3 Autoencoders for Grounded Semantics

3.1 Background

Our model learns higher-level meaning representations for single words from textual and visual input in a joint fashion. We first briefly review autoencoders in Section 3.1 with emphasis on aspects relevant to our model which we then describe in Section 3.2.

Autoencoders An autoencoder is an unsupervised neural network which is trained to reconstruct a given input from its latent representation (Bengio, 2009). It consists of an encoder f_θ which maps an input vector $\mathbf{x^{(i)}}$ to a latent representation $\mathbf{y^{(i)}} = f_\theta(\mathbf{x^{(i)}}) = s(\mathbf{W}\mathbf{x^{(i)}} + \mathbf{b})$, with s being a non-linear activation function, such as a sigmoid function. A decoder $g_{\theta'}$ then aims to reconstruct input $\mathbf{x^{(i)}}$ from $\mathbf{y^{(i)}}$, i.e., $\hat{\mathbf{x}}^{(\mathbf{i})} = g_{\theta'}(\mathbf{y^{(i)}}) = s(\mathbf{W}'\mathbf{y^{(i)}} + \mathbf{b}')$. The training objective is the determination of parameters $\hat{\theta} = \{\mathbf{W}, \mathbf{b}\}$ and $\hat{\theta}' = \{\mathbf{W}', \mathbf{b}'\}$ that minimize the average reconstruction error over a set of input vectors $\{\mathbf{x^{(1)}}, ..., \mathbf{x^{(n)}}\}$:

$$\hat{\theta}, \hat{\theta}' = \arg\min_{\theta,\theta'} \frac{1}{n} \sum_{i=1}^{n} L(\mathbf{x^{(i)}}, g_{\theta'}(f_\theta(\mathbf{x^{(i)}}))), \quad (1)$$

where L is a loss function, such as cross-entropy. Parameters θ and θ' can be optimized by gradient descent methods.

Autoencoders are a means to learn representations of some input by retaining useful features in the encoding phase which help to reconstruct the input, whilst discarding useless or noisy ones. To this end, different strategies have been employed to guide parameter learning and constrain the hidden representation. Examples include imposing a bottleneck to produce an under-complete representation of the input, using sparse representations, or *denoising*.

Denoising Autoencoders The training criterion with denoising autoencoders is the reconstruction of clean input $\mathbf{x^{(i)}}$ given a corrupted version $\tilde{\mathbf{x}}^{(\mathbf{i})}$ (Vincent et al., 2010). The underlying idea is that the learned latent representation is good if the autoencoder is capable of reconstructing the actual input from its corruption. The reconstruction error for an input $\mathbf{x^{(i)}}$ with loss function L then is:

$$L(\mathbf{x^{(i)}}, g_{\theta'}(f_\theta(\tilde{\mathbf{x}}^{(\mathbf{i})}))) \quad (2)$$

One possible corruption process is *masking noise*, where the corrupted version $\tilde{\mathbf{x}}^{(\mathbf{i})}$ results from randomly setting a fraction v of $\mathbf{x^{(i)}}$ to 0.

Stacked Autoencoders Several (denoising) autoencoders can be used as building blocks to form a deep neural network (Bengio et al., 2007; Vincent et al., 2010). For that purpose, the autoencoders are pre-trained layer by layer, with the current layer being fed the latent representation of the previous autoencoder as input. Using this unsupervised pre-training procedure, initial parameters are found which approximate a good solution. Subsequently, the original input layer and hidden representations of all the autoencoders are stacked and all network parameters are fine-tuned with backpropagation.

To further optimize the parameters of the network, a supervised criterion can be imposed on top of the last hidden layer such as the minimization of a prediction error on a supervised task (Bengio, 2009). Another approach is to unfold the stacked autoencoders and fine-tune them with respect to the minimization of the global reconstruction error (Hinton and Salakhutdinov, 2006). Alternatively, a semi-supervised criterion can be used (Ranzato and Szummer, 2008; Socher et al., 2011) through combination of the unsupervised training criterion (global reconstruction) with a supervised criterion (prediction of some target given the latent representation).

3.2 Semantic Representations

To learn meaning representations of single words from textual and visual input, we employ stacked (denoising) autoencoders (SAEs). Both input modalities are vector-based representations of words, or, more precisely, the objects they refer to (e.g., *canary*, *trolley*). The vector dimensions correspond to textual and visual attributes, examples of which are shown in Table 1. We explain how these representations are obtained in more detail

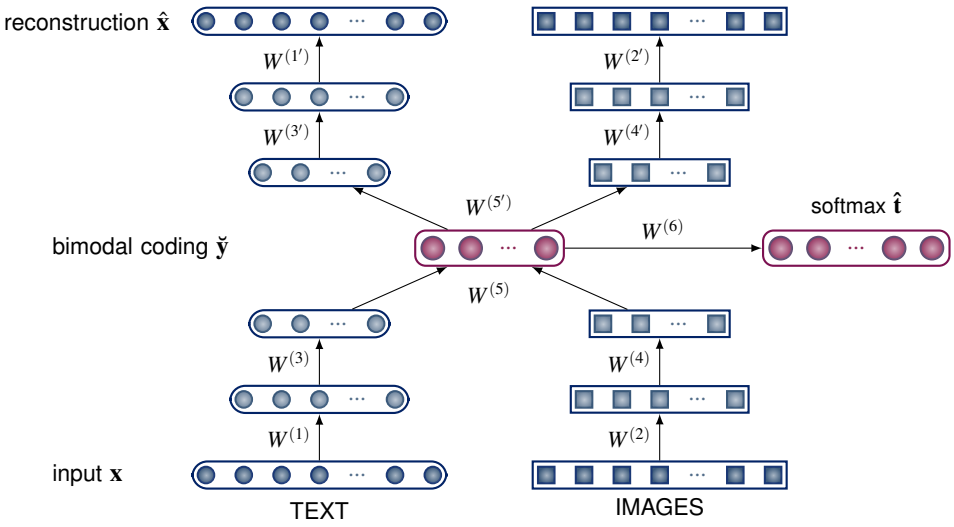

Figure 1: Stacked autoencoder trained with semi-supervised objective. Input to the model are single-word vector representations obtained from text and images. Vector dimensions correspond to textual and visual attributes, respectively (see Table 1).

in Section 4.1. We first train SAEs with two hidden layers (codings) for each modality separately. Then, we join these two SAEs by feeding their respective second coding simultaneously to another autoencoder, whose hidden layer thus yields the fused meaning representation. Finally, we stack all layers and unfold them in order to fine-tune the SAE. Figure 1 illustrates the model.

Unimodal Autoencoders For both modalities, we use the hyperbolic tangent function as activation function for encoder f_θ and decoder $g_{\theta'}$ and an entropic loss function for L. The weights of each autoencoder are tied, i.e., $\mathbf{W}' = \mathbf{W}^T$. We employ denoising autoencoders (DAEs) for pre-training the textual modality. Regarding the visual autoencoder, we derive a new ('denoised') target vector to be reconstructed for each input vector $\mathbf{x^{(i)}}$, and treat $\mathbf{x^{(i)}}$ itself as corrupted input. The unimodal autoencoder is thus trained to denoise a given input. The target vector is derived as follows: each object o in our data is represented by multiple images, and each image is in turn represented by a visual attribute vector $\mathbf{x^{(i)}}$. The target vector is the sum of $\mathbf{x^{(i)}}$ and the centroid $\mathbf{x^{(j)}}$ of the remaining attribute vectors representing object o.

Bimodal Autoencoder The bimodal autoencoder is fed with the concatenated final hidden codings of the visual and textual modalities as input and maps these inputs to a joint hidden layer $\check{\mathbf{y}}$ with B units. We normalize both unimodal input codings to unit length. Again, we use tied weights for the bimodal autoencoder. We also encourage the autoencoder to detect dependencies between the two modalities while learning the mapping to the bimodal hidden layer. We therefore apply masking noise to one modality with a masking factor v (see Section 3.1), so that the corrupted modality optimally has to rely on the other modality in order to reconstruct its missing input features.

Stacked Bimodal Autoencoder We finally build a stacked bimodal autoencoder (SAE) with all pre-trained layers and fine-tune them with respect to a semi-supervised criterion. That is, we unfold the stacked autoencoder and furthermore add a softmax output layer on top of the bimodal layer $\check{\mathbf{y}}$ that outputs predictions $\hat{\mathbf{t}}$ with respect to the inputs' object labels (e.g., *boat*):

$$\hat{\mathbf{t}}^{(\mathbf{i})} = \frac{\exp(\mathbf{W^{(6)}}\check{\mathbf{y}}^{(\mathbf{i})} + \mathbf{b^{(6)}})}{\sum_{k=1}^{O} \exp(\mathbf{W}^{(\mathbf{6})}_{\mathbf{k}.}\check{\mathbf{y}}^{(\mathbf{i})} + \mathbf{b}^{(\mathbf{6})}_{\mathbf{k}})}, \quad (3)$$

with weights $\mathbf{W^{(6)}} \in \mathbb{R}^{O\times B}$, $\mathbf{b^{(6)}} \in \mathbb{R}^{O\times 1}$, where O is the number of unique object labels. The overall objective to be minimized is therefore the weighted sum of the reconstruction error L_r and the classification error L_c:

$$L = \frac{1}{n}\sum_{i=1}^{n}\left(\delta_r L_r(\mathbf{x^{(i)}}, \hat{\mathbf{x}}^{(\mathbf{i})}) + \delta_c L_c(\mathbf{t^{(i)}}, \hat{\mathbf{t}}^{(\mathbf{i})})\right) + \lambda R \quad (4)$$

where δ_r and δ_c are weighting parameters that give different importance to the partial objectives,

		eats_seeds	has_beak	has_claws	has_handlebar	has_wheels	has_wings	is_yellow	made_of_wood
Visual	*canary*	0.05	0.24	0.15	0.00	–0.10	0.19	0.34	0.00
	trolley	0.00	0.00	0.00	0.30	0.32	0.00	0.00	0.25

		bird:n	breed:v	cage:n	chirp:v	fly:v	track:n	ride:v	run:v	rail:n	wheel:n
Textual	*canary*	0.16	0.19	0.39	0.13	0.13	0.00	0.00	0.00	0.00	–0.05
	trolley	–0.40	0.00	0.00	0.00	0.00	0.14	0.16	0.33	0.17	0.20

Table 1: Examples of attribute-based representations provided as input to our autoencoders.

L_c and L_r are entropic loss functions, and R is a regularization term with $R = \sum_{j=1}^{5} 2||\mathbf{W^{(j)}}||^2 + ||\mathbf{W^{(6)}}||^2$. Finally, $\hat{\mathbf{t}}^{(\mathbf{i})}$ is the object label vector predicted by the softmax layer for input vector $\mathbf{x}^{(\mathbf{i})}$, and $\mathbf{t}^{(\mathbf{i})}$ is the correct object label, represented as a O-dimensional one-hot vector[1].

The additional supervised criterion drives the learning towards a representation capable of discriminating between different objects. Furthermore, the semi-supervised setting affords flexibility, allowing to adapt the architecture to specific tasks. For example, by setting the corruption parameter v for the textual modality to one and δ_r to zero, a standard object classification model for images can be trained. Setting v close to one for either modality enables the model to infer the other (missing) modality. As our input consists of natural language attributes, the model would infer textual attributes given visual attributes and vice versa.

4 Experimental Setup

In this section we present our experimental setup for assessing the performance of our model. We give details on the tasks and datasets used for evaluation, we explain how the textual and visual inputs were constructed, how the SAE model was trained, and describe the approaches used for comparison with our own work.

4.1 Data

We learn meaning representations for the nouns contained in McRae et al.'s (2005) feature norms. These are 541 concrete animate and inanimate objects (e.g., animals, clothing, vehicles, utensils, fruits, and vegetables). The norms were elicited by asking participants to list properties (e.g., barks, an_animal, has_legs) describing the nouns they were presented with.

As shown in Figure 1, our model takes as input two (real-valued) vectors representing the visual and textual modalities. Vector dimensions correspond to textual and visual attributes, respectively. Textual attributes were extracted by running Strudel (Baroni et al., 2010) on a 2009 dump of the English Wikipedia.[2] Strudel is a fully automatic method for extracting weighted word-attribute pairs (e.g., *bat–species:n*, *bat–bite:v*) from a lemmatized and POS-tagged corpus. Weights are log-likelihood ratio scores expressing how strongly an attribute and a word are associated. We only retained the ten highest scored attributes for each target word. This returned a total of 2,362 dimensions for the textual vectors. Association scores were scaled to the $[-1,1]$ range.

To obtain visual vectors, we followed the methodology put forward in Silberer et al. (2013). Specifically, we used an updated version of their dataset to train SVM-based attribute classifiers that predict visual attributes for images (Farhadi et al., 2009). The dataset is a taxonomy of 636 visual attributes (e.g., has_wings, made_of_wood) and nearly 700K images from ImageNet (Deng et al., 2009) describing more than 500 of McRae et al.'s (2005) nouns. The classifiers perform reasonably well with an interpolated average precision of 0.52. We only considered attributes assigned to at least two nouns in the dataset, obtaining a 414 dimensional vector for each noun. Analogously to the textual representations, visual vectors were scaled to the $[-1,1]$ range.

We follow Silberer et al.'s (2013) partition of the dataset into training, validation, and test set and acquire visual vectors for each of the sets. We use the visual vectors of the training and development set for training the autoencoders, and the vectors for the test set for evaluation.

[1] In a one-hot vector, the element corresponding to the object label is one and the others are zero.

[2] The corpus is downloadable from `http://wacky.sslmit.unibo.it/doku.php?id=corpora`.

4.2 Model Architecture

Model parameters were optimized on a subset of the word association norms collected by Nelson et al. (1998).[3] These were established by presenting participants with a cue word (e.g., *canary*) and asking them to name an associate word in response (e.g., *bird, sing, yellow*). For each cue, the norms provide a set of associates and the frequencies with which they were named. The dataset contains a very large number of cue-associate pairs (63,619 in total) some of which luckily are covered in McRae et al. (2005).[4] During training we used correlation analysis (Spearman's ρ) to monitor the degree of linear relationship between model cue-associate (cosine) similarities and human probabilities.

The best autoencoder on the word association task obtained a correlation coefficient of 0.33. This performance is superior to the results reported in Silberer et al. (2013) (their correlation coefficients range from 0.16 to 0.28). This model has the following architecture: the textual autoencoder (see Figure 1, left-hand side) consists of 700 hidden units which are then mapped to the second hidden layer with 500 units (the corruption parameter was set to $v = 0.1$); the visual autoencoder (see Figure 1, right-hand side) has 170 and 100 hidden units, in the first and second layer, respectively. The 500 textual and 100 visual hidden units were fed to a bimodal autoencoder containing 500 latent units, and masking noise was applied to the textual modality with $v = 0.2$. The weighting parameters for the joint training objective of the stacked autoencoder were set to $\delta_r = 0.8$ and $\delta_c = 1$ (see Equation (4)).

We used the model described above and the meaning representations obtained from the output of the bimodal latent layer for all the evaluation tasks detailed below. Some performance gains could be expected if parameter optimization took place separately for each task. However, we wanted to avoid overfitting, and show that our parameters are robust across tasks and datasets.

4.3 Evaluation Tasks

Word Similarity We first evaluated how well our model predicts word similarity ratings. Although several relevant datasets exist, such as the widely used WordSim353 (Finkelstein et al., 2002) or the more recent Rel-122 norms (Szumlanski et al., 2013), they contain many abstract words, (e.g., *love–sex* or *arrest–detention*) which are not covered in McRae et al. (2005). This is for a good reason, as most abstract words do not have discernible attributes, or at least attributes that participants would agree upon. We thus created a new dataset consisting exclusively of McRae et al. (2005) nouns which we hope will be useful for the development and evaluation of grounded semantic space models.[5]

Initially, we created all possible pairings over McRae et al.'s (2005) nouns and computed their semantic relatedness using Patwardhan and Pedersen (2006)'s WordNet-based measure. We opted for this specific measure as it achieves high correlation with human ratings and has a high coverage on our nouns. Next, for each word we randomly selected 30 pairs under the assumption that they are representative of the full variation of semantic similarity. This resulted in 7,576 word pairs for which we obtained similarity ratings using Amazon Mechanical Turk (AMT). Participants were asked to rate a pair on two dimensions, visual and semantic similarity using a Likert scale of 1 (highly dissimilar) to 5 (highly similar). Each task consisted of 32 pairs covering examples of weak to very strong semantic relatedness. Two control pairs from Miller and Charles (1991) were included in each task to potentially help identify and eliminate data from participants who assigned random scores. Examples of the stimuli and mean ratings are shown in Table 2.

The elicitation study comprised overall 255 tasks, each task was completed by five volunteers. The similarity data was post-processed so as to identify and remove outliers. We considered an outlier to be any individual whose mean pairwise correlation fell outside two standard deviations from the mean correlation. 11.5% of the annotations were detected as outliers and removed. After outlier removal, we further examined how well the participants agreed in their similarity judgments. We measured inter-subject agreement as the average pairwise correlation coefficient (Spearman's ρ) between the ratings of all annotators for each task. For semantic similarity, the mean correlation was 0.76 (Min =0.34, Max

[3] http://w3.usf.edu/Freeassociation.

[4] 435 word pairs constitute the overlap between Nelson et al.'s norms (1998) and McRae et al.'s (2005) nouns.

Table 2: Mean semantic and visual similarity ratings for the McRae et al. (2005) nouns using a scale of 1 (highly dissimilar) to 5 (highly similar).

=0.97, StD =0.11) and for visual similarity 0.63 (Min =0.19, Max =0.90, SD =0.14). These results indicate that the participants found the task relatively straightforward and produced similarity ratings with a reasonable level of consistency. For comparison, Patwardhan and Pedersen's (2006) measure achieved a coefficient of 0.56 on the dataset for semantic similarity and 0.48 for visual similarity. The correlation between the average ratings of the AMT annotators and the Miller and Charles (1991) dataset was $\rho = 0.91$. In our experiments (see Section 5), we correlate model-based cosine similarities with mean similarity ratings (again using Spearman's ρ).

Categorization The task of categorization (i.e., grouping objects into meaningful categories) is a classic problem in the field of cognitive science, central to perception, learning, and the use of language. We evaluated model output against a gold standard set of categories created by Fountain and Lapata (2010). The dataset contains a classification, produced by human participants, of McRae et al.'s (2005) nouns into (possibly multiple) semantic categories (40 in total).[6]

To obtain a clustering of nouns, we used Chinese Whispers (Biemann, 2006), a randomized graph-clustering algorithm. In the categorization setting, Chinese Whispers (CW) produces a hard clustering over a weighted graph whose nodes correspond to words and edges to cosine similarity scores between vectors representing their meaning. CW is a non-parametric model, it induces the number of clusters (i.e., categories) from the data as well as which nouns belong to these clusters. In our experiments, we initialized Chinese Whispers with different graphs resulting from different vector-based representations of the McRae et al. (2005) nouns. We also transformed the dataset into hard categorizations by assigning each noun to its most typical category as extrapolated from human typicality ratings (for details see Fountain and Lapata, 2010). CW can optionally apply a minimum weight threshold which we optimized using the categorization dataset from Baroni et al. (2010). The latter contains a classification of 82 McRae et al. (2005) nouns into 10 categories. These nouns were excluded from the gold standard (Fountain and Lapata, 2010) in our final evaluation.

We evaluated the clusters produced by CW using the F-score measure introduced in the SemEval 2007 task (Agirre and Soroa, 2007); it is the harmonic mean of precision and recall defined as the number of correct members of a cluster divided by the number of items in the cluster and the number of items in the gold-standard class, respectively.

4.4 Comparison with Other Models

Throughout our experiments we compare a bimodal stacked autoencoder against unimodal autoencoders based solely on textual and visual input (left- and right-hand sides in Figure 1, respectively). We also compare our model against two approaches that differ in their fusion mechanisms. The first one is based on kernelized canonical correlation (kCCA, Hardoon et al., 2004) with a linear kernel which was the best performing model in Silberer et al. (2013). The second one emulates Bruni et al.'s (2014) fusion mechanism. Specifically, we concatenate the textual and visual vectors and project them onto a lower dimensional latent space using SVD (Golub and Reinsch, 1970). All these models run on the same datasets/items and are given input identical to our model, namely attribute-based textual and visual representations.

We furthermore report results obtained with Bruni et al.'s (2014) bimodal distributional model, which employs SVD to integrate co-occurrence-based textual representations with visual repre-

sentations constructed from low-level image features. In their model, the textual modality is represented by the 30K-dimensional vectors extracted from UKWaC and WaCkypedia.[7] The visual modality is represented by bag-of-visual-words histograms built on the basis of clustered SIFT features (Lowe, 2004). We rebuilt their model on the ESP image dataset (von Ahn and Dabbish, 2004) using Bruni et al.'s (2013) publicly available system.

Finally, we also compare to the word embeddings obtained using Mikolov et al.'s (2011) recurrent neural network based language model. These were pre-trained on Broadcast news data (400M words) using the word2vec tool.[8] We report results with the 640-dimensional embeddings as they performed best.

5 Results

Table 3 presents our results on the word similarity task. We report correlation coefficients of model predictions against similarity ratings. As an indicator to how well automatically extracted attributes can approach the performance of clean human generated attributes, we also report results of a distributional model induced from McRae et al.'s (2005) norms (see the row labeled McRae in the table). Each noun is represented as a vector with dimensions corresponding to attributes elicited by participants of the norming study. Vector components are set to the (normalized) frequency with which participants generated the corresponding attribute. We show results for three models, using all attributes except those classified as visual (T), only visual attributes (V), and all available attributes (V+T).[9] As baselines, we also report the performance of a model based solely on textual attributes (which we obtain from Strudel), visual attributes (obtained from our classifiers), and their concatenation (see row Attributes in Table 3, and columns T, V, and T+V, respectively). The automatically obtained textual and visual attribute vectors serve as input to SVD, kCCA, and our stacked autoencoder (SAE). The third row in the table presents three variants of our model trained on textual and visual attributes only (T and V, respectively) and on both modalities jointly (T+V).

Recall that participants were asked to provide ratings on two dimensions, namely semantic and visual similarity. We would expect the textual modality to be more dominant when modeling semantic similarity and conversely the perceptual modality to be stronger with respect to visual similarity. This is borne out in our unimodal SAEs. The textual SAE correlates better with semantic similarity judgments ($\rho = 0.65$) than its visual equivalent ($\rho = 0.60$). And the visual SAE correlates better with visual similarity judgments ($\rho = 0.60$) compared to the textual SAE ($\rho = 0.52$). Interestingly, the bimodal SAE is better than the unimodal variants on both types of similarity judgments, semantic and visual. This suggests that both modalities contribute complementary information and that the SAE model is able to extract a shared representation which improves generalization performance across tasks by learning them

[7] We thank Elia Bruni for providing us with their data.

Models	T	V	T+V
McRae	0.52	0.31	0.42
Attributes	0.35	0.37	0.33
SAE	0.36	0.35	0.43
SVD	—	—	0.39
kCCA	—	—	0.37
Bruni	—	—	0.34
RNN-640	0.32	—	—

Table 5: F-score results on concept categorization.

jointly. The bimodal autoencoder (SAE, T+V) outperforms all other bimodal models on both similarity tasks. It yields a correlation coefficient of $\rho = 0.70$ on semantic similarity and $\rho = 0.64$ on visual similarity. Human agreement on the former task is 0.76 and 0.63 on the latter. Table 4 shows examples of word pairs with highest semantic and visual similarity according to the SAE model.

We also observe that simply concatenating textual and visual attributes (Attributes, T+V) performs competitively with SVD and better than kCCA. This indicates that the attribute-based representation is a powerful predictor on its own. Interestingly, both Bruni et al. (2013) and Mikolov et al. (2011) which do not make use of attributes are out-performed by all other attribute-based systems (see columns T and T+V in Table 3).

Our results on the categorization task are given in Table 5. In this task, simple concatenation of visual and textual attributes does not yield improved performance over the individual modalities (see row Attributes in Table 5). In contrast, all bimodal models (SVD, kCCA, and SAE) are better than their unimodal equivalents and RNN-640. The SAE outperforms both kCCA and SVD by a large margin delivering clustering performance similar to the McRae et al.'s (2005) norms. Table 6 shows examples of clusters produced by Chinese Whispers when using vector representations provided by the SAE model.

In sum, our experiments show that the bimodal SAE model delivers superior performance across the board when compared against competitive baselines and related models. It is interesting to note that the unimodal SAEs are in most cases better than the raw textual or visual attributes. This indicates that higher level embeddings may be beneficial to NLP tasks in general, not only to those requiring multimodal information.

6 Conclusions

In this paper, we presented a model that uses stacked autoencoders to learn grounded meaning representations by simultaneously combining textual and visual modalities. The two modalities are encoded as vectors of *natural language attributes* and are obtained automatically from *decoupled* text and image data. To the best of our knowledge, our model is novel in its use of attribute-based input in a deep neural network. Experimental results in two tasks, namely simulation of word similarity and word categorization, show that our model outperforms competitive baselines and related models trained on the same attribute-based input. Our evaluation also reveals that the bimodal models are superior to their unimodal counterparts and that higher-level unimodal representations are better than the raw input. In the future, we would like to apply our model to other tasks, such as image and text retrieval (Hodosh et al., 2013; Socher et al., 2013b), zero-shot learning (Socher et al., 2013a), and word learning (Yu and Ballard, 2007).

Acknowledgment We would like to thank Vittorio Ferrari, Iain Murray and members of the ILCC at the School of Informatics for their valuable feedback. We acknowledge the support of EPSRC through project grant EP/I037415/1.

Abstract

We propose three improvements to address the drawbacks of state-of-the-art transition-based constituent parsers. First, to resolve the error propagation problem of the traditional pipeline approach, we incorporate POS tagging into the syntactic parsing process. Second, to alleviate the negative influence of size differences among competing action sequences, we align parser states during beam-search decoding. Third, to enhance the power of parsing models, we enlarge the feature set with non-local features and semi-supervised word cluster features. Experimental results show that these modifications improve parsing performance significantly. Evaluated on the Chinese TreeBank (CTB), our final performance reaches 86.3% (F1) when trained on CTB 5.1, and 87.1% when trained on CTB 6.0, and these results outperform all state-of-the-art parsers.

1 Introduction

Constituent parsing is one of the most fundamental tasks in Natural Language Processing (NLP). It seeks to uncover the underlying recursive phrase structure of sentences. Most of the state-of-the-art parsers are based on the PCFG paradigm and chart-based decoding algorithms (Collins, 1999; Charniak, 2000; Petrov et al., 2006). Chart-based parsers perform exhaustive search with dynamic programming, which contributes to their high accuracy, but they also suffer from higher runtime complexity and can only exploit simple local structural information.

Transition-based constituent parsing (Sagae and Lavie, 2005; Wang et al., 2006; Zhang and Clark, 2009) is an attractive alternative. It utilizes a series of deterministic shift-reduce decisions to construct syntactic trees. Therefore, it runs in linear time and can take advantage of arbitrarily complex structural features from already constructed subtrees. The downside is that they only search a tiny fraction of the whole space and are therefore commonly considered to be less accurate than chart-based parsers. Recent studies (Zhu et al., 2013; Zhang et al., 2013) show, however, that this approach can also achieve the state-of-the-art performance with improved training procedures and the use of additional source of information as features.

However, there is still room for improvement for these state-of-the-art transition-based constituent parsers. First, POS tagging is typically performed separately as a preliminary step, and POS tagging errors will propagate to the parsing process. This problem is especially severe for languages where the POS tagging accuracy is relatively low, and this is the case for Chinese where there are fewer contextual clues that can be used to inform the tagging process and some of the tagging decisions are actually influenced by the syntactic structure of the sentence. This creates a chicken and egg problem that needs to be addressed when designing a parsing model. Second, due to the existence of unary rules in constituent trees, competing candidate parses often have different number of actions, and this increases the disambiguation difficulty for the parsing model. Third, transition-based parsers have the freedom to define arbitrarily complex structural features, but this freedom has not fully been taken advantage of and most of the present approaches only use simple structural features.

In this paper, we address these drawbacks to improve the transition-based constituent parsing for Chinese. First, we integrate POS tagging into the parsing process and jointly optimize these two processes simultaneously. Because non-local syntactic information is now available to POS tag

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 733–742,
Baltimore, Maryland, USA, June 23-25 2014.

determination, the accuracy of POS tagging improves, and this will in turn improve parsing accuracy. Second, we propose a novel state alignment strategy to align candidate parses with different action sizes during beam-search decoding. With this strategy, parser states and their unary extensions are put into the same beam, therefore the parsing model could decide whether or not to use unary actions within local decision beams. Third, we take into account two groups of complex structural features that have not been previously used in transition-based parsing: *non-local* features (Charniak and Johnson, 2005) and semi-supervised *word cluster* features (Koo et al., 2008). With the help of the non-local features, our transition-based parsing system outperforms all previous single systems in Chinese. After integrating semi-supervised word cluster features, the parsing accuracy is further improved to 86.3% when trained on CTB 5.1 and 87.1% when trained on CTB 6.0, and this is the best reported performance for Chinese.

The remainder of this paper is organized as follows: Section 2 introduces the standard transition-based constituent parsing approach. Section 3 describes our three improvements to standard transition-based constituent parsing. We discuss and analyze the experimental results in Section 4. Section 5 discusses related work. Finally, we conclude this paper in Section 6.

2 Transition-based Constituent Parsing

This section describes the transition-based constituent parsing model, which is the basis of Section 3 and the baseline model in Section 4.

2.1 Transition-based Constituent Parsing Model

A transition-based constituent parsing model is a quadruple $C = (S, T, s_0, S_t)$, where S is a set of parser *states* (sometimes called *configurations*), T is a finite set of *actions*, s_0 is an initialization function to map each input sentence into a unique *initial state*, and $S_t \in S$ is a set of *terminal states*. Each action $t \in T$ is a transition function to transit a state into a new state. A parser state $s \in S$ is defined as a tuple $s = (\sigma, \beta)$, where σ is a *stack* which is maintained to hold partial subtrees that are already constructed, and β is a *queue* which is used for storing word-POS pairs that remain unprocessed. In particular, the initial state has an empty stack σ and a queue β containing the entire input sentence (word-POS pairs), and the terminal states have an empty queue β and a stack σ containing only one complete parse tree. The task of transition-based constituent parsing is to scan the input POS-tagged sentence from left to right and perform a sequence of actions to transform the initial state into a terminal state.

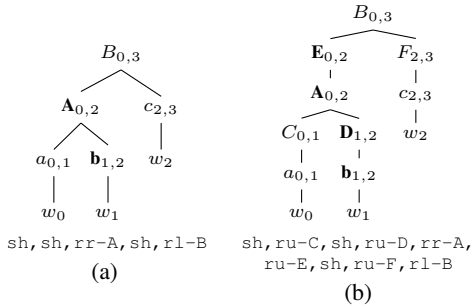

Figure 1: Two constituent trees for an example sentence $w_0w_1w_2$ with POS tags abc. The corresponding action sequences are given below, the spans of each nodes are annotated and the head nodes are written with **Bold** font type.

In order to construct lexicalized constituent parse trees, we define the following actions for the action set T according to (Sagae and Lavie, 2005; Wang et al., 2006; Zhang and Clark, 2009):

- SHIFT (`sh`): remove the first word-POS pair from β, and push it onto the top of σ;
- REDUCE-UNARY-X (`ru-x`): pop the top subtree from σ, construct a new unary node labeled with X for the subtree, then push the new subtree back onto σ. The head of the new subtree is inherited from its child;
- REDUCE-BINARY-{L/R}-X (`rl/rr-x`): pop the top two subtrees from σ, combine them into a new tree with a node labeled with X, then push the new subtree back onto σ. The left (L) and right (R) versions of the action indicate whether the head of the new subtree is inherited from its left or right child.

With these actions, our parser can process trees with unary and binary branches easily. For example, in Figure 1, for the input sentence $w_0w_1w_2$ and its POS tags abc, our parser can construct two parse trees using action sequences given below these trees. However, parse trees in Treebanks often contain an arbitrary number of branches. To

Table 1: Baseline features, where p_i represents the i_{th} subtree in the stack σ and q_i denotes the i_{th} item in the queue β. w refers to the head lexicon, t refers to the head POS, and c refers to the constituent label. p_{il} and p_{ir} refer to the left and right child for a binary subtree p_i, and p_{iu} refers to the child of a unary subtree p_i.

process such trees, we employ binarization and debinarization processes described in Zhang and Clark (2009) to transform multi-branch trees into binary-branch trees and restore the generated binary trees back to their original forms.

2.2 Modeling, Training and Decoding

To determine which action $t \in T$ should the parser perform at a state $s \in S$, we use a linear model to score each possible $\langle s, t \rangle$ combination:

$$score(s,t) = \vec{w} \cdot \phi(s,t) = \sum_i w_i f_i(s,t) \quad (1)$$

where $\phi(s,t)$ is the feature function used for mapping a state-action pair into a feature vector, and $\vec{w}$ is the weight vector. The score of a parser state s is the sum of the scores for all state-action pairs in the transition path from the initial state to the current state. Table 1 lists the feature templates used in our baseline parser, which is adopted from Zhang and Clark (2009). To train the weight vector $\vec{w}$, we employ the averaged perceptron algorithm with early update (Collins and Roark, 2004).

We employ the beam search decoding algorithm (Zhang and Clark, 2009) to balance the trade-off between accuracy and efficiency. Algorithm 1 gives details of the process. In the algorithm, we maintain a $beam$ (sometimes called $agenda$) to keep k best states at each step. The first $beam_0$

Algorithm 1 Beam-search Constituent Parsing

Input: A POS-tagged sentence, beam size k.
Output: A constituent parse tree.

```
1:  beam_0 ← {s_0}                          ▷ initialization
2:  i ← 0                                   ▷ step index
3:  loop
4:      P ← {}                              ▷ a priority queue
5:      while beam_i is not empty do
6:          s ← POP(beam_i)
7:          for all possible t ∈ T do
8:              s_new ← apply t to s
9:              score s_new with E.q (1)
10:             insert s_new into P
11:     beam_{i+1} ← k best states of P
12:     s_best ← best state in beam_{i+1}
13:     if s_best ∈ S_t then
14:         return s_best
15:     i ← i + 1
```

is initialized with the initial state s_0 (line 1). At step i, each of the k states in $beam_i$ is extended by applying all possible actions (line 5-10). For all newly generated states, only the k best states are preserved for $beam_{i+1}$ (line 11). The decoding process repeats until the highest scored state in $beam_{i+1}$ reaches a terminal state (line 12-14).

3 Joint POS Tagging and Parsing with Non-local Features

To address the drawbacks of the standard transition-based constituent parsing model (described in Section 1), we propose a model to jointly solve POS tagging and constituent parsing with non-local features.

3.1 Joint POS Tagging and Parsing

POS tagging is often taken as a preliminary step for transition-based constituent parsing, therefore the accuracy of POS tagging would greatly affect parsing performance. In our experiment (described in Section 4.2), parsing accuracy would decrease by 8.5% in F_1 in Chinese parsing when using automatically generated POS tags instead of gold-standard ones. To tackle this issue, we integrate POS tagging into the transition-based constituent parsing process and jointly optimize these two processes simultaneously. Inspired from Hatori et al. (2011), we modify the `sh` action by assigning a POS tag for the word when it is shifted:

- SHIFT-X (`sh-x`): remove the first word from

β, assign POS tag X to the word and push it onto the top of σ.

With such an action, POS tagging becomes a natural part of transition-based parsing. However, some feature templates in Table 1 become unavailable, because POS tags for the look-ahead words are not specified yet under the joint framework. For example, for the template q_0wt , the POS tag of the first word q_0 in the queue β is required, but it is not specified yet at the present state.

To overcome the lack of look-ahead POS tags, we borrow the concept of *delayed features* originally developed for dependency parsing (Hatori et al., 2011). Features that require look-ahead POS tags are defined as delayed features. In these features, look-ahead POS tags are taken as variables. During parsing, delayed features are extracted and passed from one state to the next state. When a `sh-x` action is performed, the look-ahead POS tag of some delayed features is specified, therefore these delayed features can be transformed into normal features (by replacing variable with the newly specified POS tag). The remaining delayed features will be transformed similarly when their look-ahead POS tags are specified during the following parsing steps.

3.2 State Alignment

Assuming an input sentence contains n words, in order to reach a terminal state, the initial state requires n `sh-x` actions to consume all words in β, and $n-1$ `rl`/`rr-x` actions to construct a complete parse tree by consuming all the subtrees in σ. However, `ru-x` is a very special action. It only constructs a new unary node for the subtree on top of σ, but does not consume any items in σ or β. As a result, the number of `ru-x` actions varies among terminal states for the same sentence. For example, the parse tree in Figure 1a contains no `ru-x` action, while the parse tree for the same input sentence in Figure 1b contains four `ru-x` actions. This makes the lengths of complete action sequences very different, and the parsing model has to disambiguate among terminal states with varying action sizes. Zhu et al. (2013) proposed a *padding* method to align terminal states containing different number of actions. The idea is to append some *IDLE* actions to terminal states with shorter action sequence, and make sure all terminal states contain the same number of actions (including *IDLE* actions).

Algorithm 2 Beam-search with State Alignment

Input: A word-segmented sentence, beam size k.
Output: A constituent parse tree.

1: $beam_0 \leftarrow \{s_0\}$ ▷ initialization
2: **for** $i \leftarrow 0$ to $2n-1$ **do** ▷ n is sentence length
3: $P_0 \leftarrow \{\}$, $P_1 \leftarrow \{\}$ ▷ two priority queues
4: **while** $beam_i$ is not empty **do**
5: $s \leftarrow$ POP($beam_i$)
6: **for** $t \in \{$`sh-x`, `rl-x`, `rr-x`$\}$ **do**
7: $s_{new} \leftarrow$ apply t to s
8: score s_{new} with E.q (1)
9: insert s_{new} into P_0
10: **for** all state s in P_0 **do**
11: **for** all possible $t \in \{$`ru-x`$\}$ **do**
12: $s_{new} \leftarrow$ apply t to s
13: score s_{new} with E.q (1)
14: insert s_{new} into P_1
15: insert all states of P_1 into P_0
16: $beam_{i+1} \leftarrow k$ best states of P_0
17: **return** the best state in $beam_{2n-1}$

We propose a novel method to align states during the parsing process instead of just aligning terminal states like Zhu et al. (2013). We classify all the actions into two groups according to whether they consume items in σ or β. `sh-x`, `rl-x`, and `rr-x` belong to *consuming* actions, and `ru-x` belongs to *non-consuming* action. Algorithm 2 gives the details of our method. It is based on the beam search decoding algorithm described in Algorithm 1. Different from Algorithm 1, Algorithm 2 is guaranteed to perform $2n-1$ parsing steps for an input sentence containing n words (line 2), and divides each parsing step into two parsing phases. In the first phase (line 4-9), each of the k states in $beam_i$ is extended by consuming actions. In the second phase (line 10-14), each of the newly generated states is further extended by non-consuming actions. Then, all these states extended by both consuming and non-consuming actions are considered together (line 15), and only the k highest-scored states are preserved for $beam_{i+1}$ (line 16). After these $2n-1$ parsing steps, the highest scored state in $beam_{2n-1}$ is returned as the final result (line 17). Figure 2 shows the states aligning process for the two trees in Figure 1. We find that our new method aligns states with their `ru-x` extensions in the same $beam$, therefore the parsing model could make decisions on whether using `ru-x` actions or not within local decision

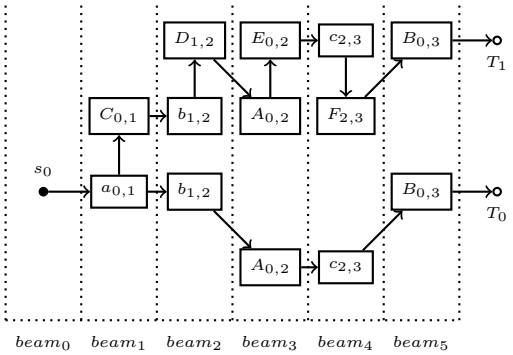

Figure 2: State alignment for the two trees in Figure 1, where s_0 is the initial state, T_0 and T_1 are terminal states corresponding to the two trees in Figure 1. For clarity, we represent each state as a rectangle with the label of top subtree in the stack σ. We also denote `sh-x` with $\rightarrow$, `ru-x` with $\uparrow$ or $\downarrow$, `rl-x` with $\nearrow$, and `rr-x` with $\searrow$.

beams.

3.3 Feature Extension

One advantage of transition-based constituent parsing is that it is capable of incorporating arbitrarily complex structural features from the already constructed subtrees in σ and unprocessed words in β. However, all the feature templates given in Table 1 are just some simple structural features. To further improve the performance of our transition-based constituent parser, we consider two group of complex structural features: *non-local* features (Charniak and Johnson, 2005; Collins and Koo, 2005) and semi-supervised *word cluster* features (Koo et al., 2008).

Table 2 lists all the non-local features we want to use. These features have been proved very helpful for constituent parsing (Charniak and Johnson, 2005; Collins and Koo, 2005). But almost all previous work considered non-local features only in parse reranking frameworks. Instead, we attempt to extract non-local features from newly constructed subtrees during the decoding process as they become incrementally available and score newly generated parser states with them. One difficulty is that the subtrees built by our baseline parser are binary trees (only the complete parse tree is debinarized into its original multi-branch form), but most of the non-local features need to be extracted from their original multi-branch forms. To resolve this conflict, we integrate the debinarization process into the parsing process, i.e., when a new subtree is constructed during parsing, we debinarize it immediately if it is not rooted with an *intermediate* node [1]. The other subtrees for subsequent parsing steps will be built based on these debinarized subtrees. After the modification, our parser can extract non-local features incrementally during the parsing process.

Table 2: Non-local features for constituent parsing.

Semi-supervised word cluster features have been successfully applied to many NLP tasks (Miller et al., 2004; Koo et al., 2008; Zhu et al., 2013). Here, we adopt such features for our transition-based constituent parser. Given a large-scale unlabeled corpus (word segmentation should be performed), we employ the Brown cluster algorithm (Liang, 2005) to cluster all words into a binary tree. Within this binary tree, words appear as leaves, left branches are labeled with 0 and right branches are labeled with 1. Each word can be uniquely identified by its path from the root, and represented as a bit-string. By using various length of prefixes of the bit-string, we can produce word clusters of different granularities (Miller et al., 2004). Inspired from Koo et al. (2008), we employ two types of word clusters: (1) taking 4 bit-string prefixes of word clusters as replacements of POS tags, and (2) taking 8 bit-string prefixes as replacements of words. Using these two types of clusters, we construct semi-supervised word cluster features by mimicking the template structure of the original baseline features in Table 1.

4 Experiment

4.1 Experimental Setting

We conducted experiments on the Penn Chinese Treebank (CTB) version 5.1 (Xue et al., 2005): Articles 001-270 and 400-1151 were used as the training set, Articles 301-325 were used as the development set, and Articles 271-300 were used

[1] Intermediate nodes are produced by binarization process.

as the test set. Standard corpus preparation steps were performed before our experiments: empty nodes and functional tags were removed, and the unary chains were collapsed to single unary rules as Harper and Huang (2011). To build word clusters, we used the unlabeled Chinese Gigaword (LDC2003T09) and conducted Chinese word segmentation using a CRF-based segmenter.

We used EVALB [2] tool to evaluate parsing performance. The metrics include labeled precision (LP), labeled recall (LR), bracketing F_1 and POS tagging accuracy. We set the beam size k to 16, which brings a good balance between efficiency and accuracy. We tuned the optimal number of iterations of perceptron training algorithm on the development set.

4.2 Pipeline Approach *vs* Joint POS Tagging and Parsing

In this subsection, we conducted some experiments to illustrate the drawbacks of the pipeline approach and the advantages of our joint approach. We built three parsing systems: *Pipeline-Gold* system is our baseline parser (described in Section 2) taking gold-standard POS tags as input; *Pipeline* system is our baseline parser taking as input POS tags automatically assigned by Stanford POS Tagger [3]; and *JointParsing* system is our joint POS tagging and transition-based parsing system described in subsection 3.1. We trained these three systems on the training set and evaluated them on the development set. The second, third and forth rows in Table 3 show the parsing performances. We can see that the parsing F_1 decreased by about 8.5 percentage points in F_1 score when using automatically assigned POS tags instead of gold-standard ones, and this shows that the pipeline approach is greatly affected by the quality of its preliminary POS tagging step. After integrating the POS tagging step into the parsing process, our *JointParsing* system improved the POS tagging accuracy to 94.8% and parsing F_1 to 85.8%, which are significantly better than the *Pipeline* system. Therefore, the joint parsing approach is much more effective for transition-based constituent parsing.

4.3 State Alignment Evaluation

We built two new systems to verify the effectiveness of our state alignment strategy proposed in Subsection 3.2. The first system *Padding* extends our *JointParsing* system by aligning terminal states with the padding strategy proposed in Zhu et al. (2013), and the second system *StateAlign* extends the *JointParsing* system with our state alignment strategy. The fifth and sixth rows of Table 3 give the performances of these two systems. Compared with the *JointParsing* system which does not employ any alignment strategy, the *Padding* system only achieved a slight improvement on parsing F_1 score, but no improvement on POS tagging accuracy. In contrast, our *StateAlign* system achieved an improvement of 0.6% on parsing F_1 score and 0.4% on POS tagging accuracy. All these results show us that our state alignment strategy is more helpful for beam-search decoding.

System	LP	LR	F_1	POS
Pipeline-Gold	92.2	92.5	92.4	100
Pipeline	83.9	83.8	83.8	93.0
JointParsing	85.1	86.6	85.8	94.8
Padding	85.4	86.4	85.9	94.8
StateAlign	86.9	85.9	86.4	95.2
Nonlocal	88.0	86.5	87.2	95.3
Cluster	89.0	88.3	88.7	96.3
Nonlocal&Cluster	89.4	88.7	89.1	96.2

Table 3: Parsing performance on Chinese development set.

4.4 Feature Extension Evaluation

In this subsection, we examined the usefulness of the new non-local features and the semi-supervised word cluster features described in Subsection 3.3. We built three new parsing systems based on the *StateAlign* system: *Nonlocal* system extends the feature set of *StateAlign* system with non-local features, *Cluster* system extends the feature set with semi-supervised word cluster features, and *Nonlocal&Cluster* system extend the feature set with both groups of features. Parsing performances of the three systems are shown in the last three rows of Table 3. Compared with the *StateAlign* system which takes only the baseline features, the non-local features improved parsing F_1 by 0.8%, while the semi-supervised word cluster features result in an improvement of 2.3% in parsing F_1 and an 1.1% improvement on POS tagging accuracy. When integrating both groups of features, the final parsing F_1 reaches 89.1%. Al-

l these results show that both the non-local features and the semi-supervised features are helpful for our transition-based constituent parser.

4.5 Final Results on Test Set

In this subsection, we present the performances of our systems on the CTB test set. The corresponding results are listed in the top rows of Table 4. We can see that all these systems maintain a similar relative relationship as they do on the development set, which shows the stability of our systems.

To further illustrate the effectiveness of our systems, we compare them with some state-of-the-art systems. We group parsing systems into three categories: single systems, reranking systems and semi-supervised systems. Our *Pipeline*, *JointParsing*, *Padding*, *StateAlign* and *Nonlocal* systems belong to the category of single systems, because they don't utilize any extra processing steps or resources. Our *Cluster* and *Nonlocal&Cluster* systems belong to semi-supervised systems, because both of them have employed semi-supervised word cluster features. The parsing performances of state-of-the-art systems are shown in the bottom rows of Table 4. We can see that the final F_1 of our *Nonlocal* system reached 84.9%, and it outperforms state-of-the-art single systems by more than 1.6%. As far as we know, this is the best result on the CTB test set acquired by single systems. Our *Nonlocal&Cluster* system further improved the parsing F_1 to 86.3%, and it outperforms all reranking systems and semi-supervised systems. To our knowledge, this is the best reported performance in Chinese parsing.

System	F_1
Huang and Harper (2009)	85.2
Nonlocal&Cluster	**87.1**

Table 5: Parsing performance based on CTB 6.

All previous experiments were conducted on CTB 5. To check whether more labeled data can further improve our parsing system, we evaluated our *Nonlocal&Cluster* system on the Chinese TreeBank version 6.0 (CTB6), which is a super set of CTB5 and contains more annotated data. We used the same development set and test set as CTB5, and took all the remaining data as the new training set. Table 5 shows the parsing performances on CTB6. Our *Nonlocal&Cluster* system improved the final F_1 to 87.1%, which is 1.9% better than the state-of-the-art performance on CTB6 (Huang and Harper, 2009). Compared with its performance on CTB5 (in Table 4), our *Nonlocal&Cluster* system also got 0.8% improvement. All these results show that our approach can become more powerful when given more labeled training data.

4.6 Error Analysis

To better understand the linguistic behavior of our systems, we employed the berkeley-parser-analyser tool [4] (Kummerfeld et al., 2013) to categorize the errors. Table 6 presents the average

[4] http://code.google.com/p/berkeley-parser-analyser/

System	NP Int.	Unary	1-Word Span	Coord	Mod. Attach	Verb Args	Diff Label	Clause Attach	Noun Edge
Worst	1.75	0.74	0.44	0.49	0.39	0.37	0.29	0.15	0.14
Pipeline

Best	1.33	0.42	0.28	0.29	0.19	0.21	0.17	0.07	0.09

Table 6: Parse errors on Chinese test set. The shaded area of each bar indicates average number of that error type per sentence, and the completely full bar indicates the number in the *Worst* row.

System	VV→NN	NN→VV	DEC→DEG	JJ→NN	NR→NN	DEG→DEC	NN→NR	NN→JJ
Worst	0.26	0.18	0.15	0.09	0.08	0.07	0.06	0.05
Pipeline								
JointParsing								
Padding								
StateAlign								
Nonlocal								
Cluster								
Nonlocal&Cluster								
Best	0.14	0.10	0.03	0.07	0.05	0.03	0.03	0.02

Table 7: POS tagging error patterns on Chinese test set. For each error pattern, the left hand side tag is the gold-standard tag, and the right hand side is the wrongly assigned tag.

number of errors for each error type by our parsing systems. We can see that almost all the *Worst* numbers are produced by the *Pipeline* system. The *JointParsing* system reduced errors of all types produced by the *Pipeline* system except for the coordination error type (Coord). The *StateAlign* system corrected a lot of the NP-internal errors (NP Int.). The *Nonlocal* system and the *Cluster* system produced similar numbers of errors for all error types. The *Nonlocal&Cluster* system produced the *Best* numbers for all the error types. NP-internal errors are still the most frequent error type in our parsing systems.

Table 7 presents the statistics of frequent POS tagging error patterns. We can see that *JointParsing* system disambiguates {VV, NN} and {DEC, DEG} better than *Pipeline* system, but cannot deal with the NN→JJ pattern very well. *StateAlign* system got better results in most of the patterns, but cannot disambiguate {NR, NN} well. *Nonlocal&Cluster* system got the best results in disambiguating the most ambiguous POS tag pairs of {VV, NN}, {DEC, DEG}, {JJ, NN} and {NN, NR}.

5 Related Work

Joint POS tagging with parsing is not a new idea. In PCFG-based parsing (Collins, 1999; Charniak, 2000; Petrov et al., 2006), POS tagging is considered as a natural step of parsing by employing lexical rules. For transition-based parsing, Hatori et al. (2011) proposed to integrate POS tagging with *dependency* parsing. Our joint approach can be seen as an adaption of Hatori et al. (2011)'s approach for *constituent* parsing. Zhang et al. (2013) proposed a transition-based constituent parser to process an input sentence from the character level. However, manual annotation of the word-internal structures need to be added to the original Treebank in order to train such a parser.

Non-local features have been successfully used for constituent parsing (Charniak and Johnson, 2005; Collins and Koo, 2005; Huang, 2008). However, almost all of the previous work use non-local features at the parse reranking stage. The reason is that the single-stage chart-based parser cannot use non-local structural features. In contrast, the transition-based parser can use arbitrarily complex structural features. Therefore, we can concisely utilize non-local features in a single-

stage parsing system.

6 Conclusion

In this paper, we proposed three improvements to transition-based constituent parsing for Chinese. First, we incorporated POS tagging into transition-based constituent parsing to resolve the error propagation problem of the pipeline approach. Second, we proposed a state alignment strategy to align competing decision sequences that have different number of actions. Finally, we enhanced our parsing model by enlarging the feature set with non-local features and semi-supervised word cluster features. Experimental results show that all these methods improved the parsing performance substantially, and the final performance of our parsing system outperformed all state-of-the-art systems.

Abstract

In this paper, we investigate various strategies to predict both syntactic dependency parsing and contiguous multiword expression (MWE) recognition, testing them on the dependency version of French Treebank (Abeillé and Barrier, 2004), as instantiated in the SPMRL Shared Task (Seddah et al., 2013). Our work focuses on using an alternative representation of syntactically regular MWEs, which captures their syntactic internal structure. We obtain a system with comparable performance to that of previous works on this dataset, but which predicts both syntactic dependencies and the internal structure of MWEs. This can be useful for capturing the various degrees of semantic compositionality of MWEs.

1 Introduction

A real-life parsing system should comprise the recognition of multi-word expressions (MWEs[1]), first because downstream semantic-oriented applications need some marking in order to distinguish between regular semantic composition and the typical semantic non-compositionality of MWEs. Second, MWE information, is intuitively supposed to help parsing.

That intuition is confirmed in a classical but non-realistic setting in which *gold* MWEs are pregrouped (Arun and Keller, 2005; Nivre and Nilsson, 2004; Eryiğit et al., 2011). But the situation is much less clear when switching to automatic MWE prediction. While Cafferkey et al. (2007) report a small improvement on the pure parsing task when using external MWE lexicons to help English parsing, Constant et al. (2012) report results on the joint MWE recognition and parsing task, in which errors in MWE recognition alleviate their positive effect on parsing performance.

While the realistic scenario of syntactic parsing with automatic MWE recognition (either done jointly or in a pipeline) has already been investigated in constituency parsing (Green et al., 2011; Constant et al., 2012; Green et al., 2013), the French dataset of the SPMRL 2013 Shared Task (Seddah et al., 2013) only recently provided the opportunity to evaluate this scenario within the framework of dependency syntax.[2] In such a scenario, a system predicts dependency trees with marked groupings of tokens into MWEs. The trees show syntactic dependencies between semantically sound units (made of one or several tokens), and are thus particularly appealing for downstream semantic-oriented applications, as dependency trees are considered to be closer to predicate-argument structures.

In this paper, we investigate various strategies for predicting from a tokenized sentence both MWEs and syntactic dependencies, using the French dataset of the SPMRL 13 Shared Task. We focus on the use of an alternative representation for those MWEs that exhibit regular internal syntax. The idea is to represent these using regular syntactic internal structure, while keeping the semantic information that they are MWEs.

We devote section 2 to related work. In section 3, we describe the French dataset, how MWEs are originally represented in it, and we present and motivate an alternative representation. Section 4 describes the different architectures we test

[1] Multiword expressions can be roughly defined as continuous or discontinuous sets of tokens, which either do not exhibit full freedom in lexical selection or whose meaning is not fully compositional. We focus in this paper on *contiguous* multiword expressions, also known as "words with spaces".

[2] The main focus of the Shared Task was on predicting both morphological and syntactic analysis for morphologically-rich languages. The French dataset is the only one containing MWEs: the French treebank has the particularity to contain a high ratio of tokens belonging to a MWE (12.7% of non numerical tokens).

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 743–753,
Baltimore, Maryland, USA, June 23-25 2014.

for predicting both syntax and MWEs. Section 5 presents the external resources targeted to improve MWE recognition. We describe experiments and discuss their results in section 6 and conclude in section 7.

2 Related work

We gave in introduction references to previous work on predicting MWEs and constituency parsing. To our knowledge, the first works[3] on *predicting* both MWEs and *dependency trees* are those presented to the SPMRL 2013 Shared Task that provided scores for French (which is the only dataset containing MWEs). Constant et al. (2013) proposed to combine pipeline and joint systems in a reparser (Sagae and Lavie, 2006), and ranked first at the Shared Task. Our contribution with respect to that work is the representation of the internal syntactic structure of MWEs, and use of MWE-specific features for the joint system. The system of Björkelund et al. (2013) ranked second on French, though with close UAS/LAS scores. It is a less language-specific system that reranks n-best dependency parses from 3 parsers, informed with features from predicted constituency trees. It uses no feature nor treatment specific to MWEs as it focuses on the general aim of the Shared Task, namely coping with prediction of morphological and syntactic analysis.

Concerning related work on the representation of MWE internal structure, we can cite the Prague Dependency Bank, which captures both regular syntax of non-compositional MWEs and their MWE status, in two distinct annotation layers (Bejček and Stranak, 2010). Our representation also resembles that of light-verb constructions (LVC) in the hungarian dependency treebank (Vincze et al., 2010): the construction has regular syntax, and a suffix is used on labels to express it is a LVC (Vincze et al., 2013).

3 Data: MWEs in Dependency Trees

The data we use is the SPMRL 13 dataset for French, in dependency format. It contains projective dependency trees that were automatically derived from the latest status of the French Treebank (Abeillé and Barrier, 2004), which consists of constituency trees for sentences from the newspaper *Le Monde*, manually annotated with phrase structures, morphological information, and grammatical functional tags for dependents of verbs. The Shared Task used an enhanced version of the constituency-to-dependency conversion of Candito et al. (2010), with different handling of MWEs. The dataset consists of 18535 sentences, split into 14759, 1235 and 2541 sentences for training, development, and final evaluation respectively.

We describe below the flat representation of MWEs in this dataset, and the modified representation for regular MWEs that we propose.

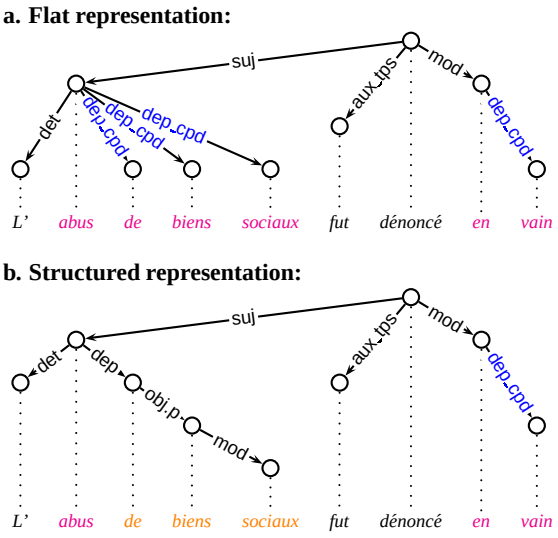

Figure 1: French dependency tree for *L'abus de biens sociaux fut dénoncé en vain* (literally *the misuse of assets social was denounced in vain*, meaning *The misuse of corporate assets was denounced in vain*), containing two MWEs (in red). Top: original flat representation. Bottom: Tree after regular MWEs structuring.

3.1 MWEs in Gold Data: Flat representation

In gold data, the MWEs appear in an expanded flat format: each MWE bears a part-of-speech and consists of a sequence of tokens (hereafter the "components" of the MWE), each having their proper POS, lemma and morphological features. In the dependency trees, there is no "node" for a MWE as a whole, but one node per MWE component (more generally one node per token). The first component of a MWE is taken as the head of the MWE. All subsequent components of the MWE depend on the first one, with the special label `dep_cpd` (hence the name *flat represen-*

[3] Concerning non contiguous MWEs, we can cite the work of Vincze et al. (2013), who experimented joint dependency parsing and light verb construction identification.

tation). Furthermore, the first MWE component bears a feature `mwehead` equal to the POS of the MWE. An example is shown in Figure 1. The MWE *en vain* (*pointlessly*) is an adverb, containing a preposition and an adjective. The latter depends on former, which bears `mwehead=ADV+`.

The algorithm to recover MWEs is: any node having dependents with the `dep_cpd` label forms a MWE with such dependents.

3.2 Alternative representation for regular MWEs

In the alternative representation we propose, irregular MWEs are unchanged and appear as flat MWEs (e.g. *en vain* in Figure 1 has pattern preposition+adjective, which is not considered regular for an adverb, and is thus unchanged). Regular MWEs appear with 'structured' syntax: we modify the tree structure to recover the regular syntactic dependencies. For instance, in the bottom tree of the figure, *biens* is attached to the preposition, and the adjective *sociaux* is attached to *biens*, with regular labels. Structured MWEs cannot be spotted using the tree topology and labels only. Features are added for that purpose: the syntactic head of the structured MWE bears a `regmwehead` for the POS of the MWE (*abus* in Figure 1), and the other components of the MWE bear a `regcomponent` feature (the orange tokens in Figure 1).[4] With this representation, the algorithm to recover regular MWEs is: any node bearing `regmwehead` forms a MWE with the set of direct or indirect dependents bearing a `regcomponent` feature.

3.2.1 Motivations

Our first motivation is to increase the quantity of information conveyed by the dependency trees, by distinguishing syntactic regularity and semantic regularity. Syntactically regular MWEs (hereafter regular MWEs) show various degrees of semantic non-compositionality. For instance, in the French Treebank, *population active* (lit. *active population*, meaning *'working population'*) is a partially compositional MWE. Furthermore, some sequences are both syntactically and semantically regular, but encoded as MWE due to frozen lexical selection. This is the case for *déficit budgétaire* (lit. *budgetary deficit*, meaning *'budget deficit'*), because it is not possible to use *déficit du budget* (*budget deficit*). Our alternative representation distinguishes between syntactic internal regularity and semantic regularity. This renders the syntactic description more uniform and it provides an internal structure for regular MWEs, which is meaningful if the MWE is fully or partially compositional. For instance, it is meaningful to have the adjective *sociaux* attach to *biens* instead of on the first component *abus*. Moreover, such a distinction opens the way to a non-binary classification of MWE status: the various criteria leading to classify a sequence as MWE could be annotated separately and using nominal or scaled categories for each criteria. For instance, *déficit budgétaire* could be marked as fully compositional, but with frozen lexical selection. Further, annotation is often incoherent for the MWEs with both regular syntax and a certain amount of semantic compositionality, the same token sequence (with same meaning) being sometimes annotated as MWE and sometimes not.

More generally, keeping a regular representation would allow to better deal with the interaction between idiomatic status and regular syntax, such as the insertion of modifiers on MWE subparts (e.g. *make a **quick** decision*).

Finally, using regular syntax for MWEs provides a more uniform training set. For instance for a sequence *N1 preposition N2*, though some *external* attachments might vary depending on whether the sequence forms a MWE or not, some may not, and the internal dependency structure $(N1 \rightarrow (preposition \rightarrow N2))$ is quite regular. One objective of the current work is to investigate whether this increased uniformity eases parsing or whether it is mitigated by the additional difficulty of finding the internal structure of a MWE.

	Total nb of MWEs	Nb of regular MWEs *(% of nouns, adverbs, prepositions, verbs)*
train	23658	12569 *(64.7, 19.2, 14.6, 1.5)*
dev	2120	1194 *(66.7, 17.7, 14.7, 0.8)*
test	4049	2051 *(64.5, 19.9, 13.6, 2.0)*

Table 1: Total number of MWEs and number of regular MWEs in training, development and test set (and broken down by POS of MWE).

[4] The syntactic head of a structured MWE may not be the first token, whereas the head token of a flat MWE is always the first one.

3.2.2 Implementation

We developed an ad hoc program for structuring the regular MWEs in gold data. MWEs are first classified as regular or irregular, using regular expressions over the sequence of parts-of-speech within the MWE. To define the regular expressions, we grouped gold MWEs according to the pair [global POS of the MWE + sequence of POS of the MWE components], and designed regular expressions to match the most frequent patterns that looked regular according to our linguistic knowledge. The internal structure for the matching MWEs was built deterministically, using heuristics favoring local attachments.[5] Table 1 shows the proportions of MWEs classified as regular, and thus further structured. About half MWEs are structured, and about two thirds of structured MWEs are nouns.

For predicted parses with structured MWEs, we use an inverse transformation of structured MWEs into flat MWEs, for evaluation against the gold data. When a predicted structured MWE is flattened, all the dependents of any token of the MWE that are not themselves belonging to the MWE are attached to the head component of the MWE.

3.3 Integration of MWE features into labels

In some experiments, we make use of alternative representations, which we refer later as "labeled representation", in which the MWE features are incorporated in the dependency labels, so that MWE composition and/or the POS of the MWE be totally contained in the tree topology and labels, and thus predictable via dependency parsing. Figure shows the labeled representation for the sentence of Figure 1.

For flat MWEs, the only missing information is the MWE part-of-speech: we concatenate it to the `dep_cpd` labels. For instance, the arc from *en* to *vain* is relabeled `dep_cpd_ADV`. For structured MWEs, in order to get full MWE account within the tree structure and labels, we need to incorporate both the MWE POS, and to mark it as

[5]The six regular expressions that we obtained cover nominal, prepositional, adverbial and verbal compounds. We manually evaluated both the regular versus irregular classification and the structuring of regular MWEs on the first 200 MWEs of the development set. 113 of these were classified as regular, and we judged that all of them were actually regular, and were correctly structured. Among the 87 classified as irregular, 7 should have been tagged as regular and structured. For 4 of them, the classification error is due to errors on the (gold) POS of the MWE components.

c. Labeled representation:

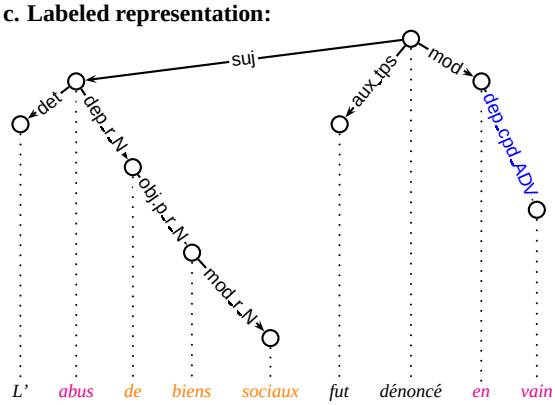

Figure 2: Integration of all MWE information into labels for the example of Figure 1.

belonging to a MWE. The suffixed label has the form `FCT_r_POS`. For instance, in bottom tree of Figure 1, arcs pointing to the non-head components (*de*, *biens*, *sociaux*) are suffixed with `_r` to mark them as belonging to a structured MWE, and with `_N` since the MWE is a noun.

In both cases, this label suffixing is translated back into features for evaluation against gold data.

4 Architectures for MWE Analysis and Parsing

The architectures we investigated vary depending on whether the MWE status of sequences of tokens is predicted via dependency parsing or via an external tool (described in section 5), and this dichotomy applies both to structured MWEs and flat MWEs. More precisely, we consider the following alternative for irregular MWEs:

- IRREG-MERGED: gold irregular MWEs are merged for training; for parsing, irregular MWEs are predicted externally, merged into one token at parsing time, and re-expanded into several tokens for evaluation;

- IRREG-BY-PARSER: the MWE status, flat topology and POS are all predicted via dependency parsing, using representations for training and parsing, with all information for irregular MWEs encoded in topology and labels (as for *in vain* in Figure 2).

For regular MWEs, their internal structure is always predicted by the parser. For instance the unlabeled dependencies for *abus de biens sociaux* are the same, independently of predicting whether it

forms a MWE or not. But we use two kinds of predictions for their MWE status and POS:

- REG-POST-ANNOTATION: the regular MWEs are encoded/predicted as shown for *abus de biens sociaux* in bottom tree of Figure 1, and their MWE status and POS is predicted after parsing, by an external tool.
- REG-BY-PARSER: all regular MWE information (topology, status, POS) is predicted via dependency parsing, using representations with all information for regular MWEs encoded in topology and labels (Figure 2).

Name	prediction of reg MWEs	prediction of irreg MWEs
JOINT	irreg-by-parser	reg-by-parser
JOINT-REG	irreg-merged	reg-by-parser
JOINT-IRREG	irreg-by-parser	reg-post-annot
PIPELINE	irreg-merged	reg-post-annot

Table 2: The four architectures, depending on how regular and irregular MWEs are predicted.

We obtain four architectures, schematized in table 2. We describe more precisely two of them, the other two being easily inferable:

JOINT-REG architecture:

- **training set**: irregular MWEs merged into one token, regular MWEs are structured, and integration of regular MWE information into the labels (`FCT_r_POS`).
- **parsing**: **(i)** MWE analysis with classification of MWEs into regular or irregular, **(ii)** merge of predicted irregular MWEs, **(iii)** tagging and morphological prediction, **(iv)** parsing

JOINT-IRREG architecture:

- **training set**: flat representation of irregular MWEs, with label suffixing (`dep_cpd_POS`), structured representation of regular MWEs without label suffixing.
- **parsing**: **(i)** MWE analysis and classification into regular or irregular, used for MWE-specific features, **(ii)** tagging and morphological prediction, **(iii)** parsing,

We compare these four architectures between them and also with two simpler architectures used by (Constant et al., 2013) within the SPMRL 13 Shared Task, in which regular and irregular MWEs are not distinguished:

Uniform joint architecture: The joint systems perform syntactic parsing and MWE analysis via a single dependency parser, using representations as in 3.3.

Uniform pipeline architecture:

- **training set**: MWEs merged into one token
- **parsing**: **(i)** MWE analysis, **(ii)** merge of predicted MWEs, **(iii)** tagging and morphological prediction, **(iv)** parsing

For each architecture, we apply the appropriate normalization procedures on the predicted parses, in order to evaluate against (i) the pseudo-gold data in structured representation, and (ii) the gold data in flat representation.

5 Use of external MWE resources

In order to better deal with MWE prediction, we use external MWE resources, namely MWE lexicons and an MWE analyzer. Both resources help to predict MWE-specific features (section 5.3) to guide the MWE-aware dependency parser. Moreover, in some of the architectures, the external MWE analyzer is used either to pre-group irregular MWEs (for the architectures using IRREG-MERGED), or to post-annotate regular MWEs.

5.1 MWE lexicons

MWE lexicons are exploited as sources of features for both the dependency parser and the external MWE analyzer. In particular, two large-coverage general-language lexicons are used: the Lefff[6] lexicon (Sagot, 2010), which contains approximately half a million inflected word forms, among which approx. $25,000$ are MWEs; and the DELA[7] (Courtois, 2009; Courtois et al., 1997) lexicon, which contains approx. one million inflected forms, among which about $110,000$ are MWEs. These resources are completed with specific lexicons freely available in the platform Unitex[8]: the toponym dictionary Prolex (Piton et al., 1999) and a dictionary of first names. Note that the lexicons do not include any information on the irregular or the regular status of the MWEs. In order to compare the MWEs present in the lexicons and those encoded in the French treebank, we applied the following procedure (hereafter called lexicon

[6] We use the version available in the POS tagger MElt (Denis and Sagot, 2009).

[7] We use the version in the platform Unitex (http://igm.univ-mlv.fr/~unitex). We had to convert the DELA POS tagset to that of the French Treebank.

[8] http://igm.univ-mlv.fr/~unitex

lookup): in a given sentence, the maximum number of non overlapping MWEs according to the lexicons are systematically marked as such. We obtain about 70% recall and 50% precision with respect to MWE spanning.

5.2 MWE Analyzer

The MWE analyzer is a CRF-based sequential labeler, which, given a tokenized text, jointly performs MWE segmentation and POS tagging (of simple tokens and of MWEs), both tasks mutually helping each other[9]. The MWE analyzer integrates, among others, features computed from the external lexicons described in section 5.1, which greatly improve POS tagging (Denis and Sagot, 2009) and MWE segmentation (Constant and Tellier, 2012). The MWE analyzer also jointly classifies its predicted MWEs as regular or irregular (the distinction being learnt on gold training set, with structured MWEs cf. section 3.2).

5.3 MWE-specific features

We introduce information from the external MWE resources in different ways:

Flat MWE features: MWE information can be integrated as features to be used by the dependency parser. We tested to incorporate the MWE-specific features as defined in the gold flat representation (section 3.1): the *mwehead=POS* feature for the MWE head token, POS being the part-of-speech of the MWE; the *component=y* feature for the non-first MWE component.

Switch: instead or on top of using the `mwehead` feature, we use the POS of the MWE instead of the POS of the first component of a flat MWE. For instance in Figure 1, the token *en* gets `pos=ADV` instead of `pos=P`. The intuition behind this feature is that for an irregular MWE, the POS of the linearly first component, which serves as head, is not always representative of the external distribution of the MWE. For regular MWEs, the usefulness of such a trick is less obvious. The first component of a regular MWE is not necessarily its head (for instance for a nominal MWE with internal pattern adjective+noun), so the switch trick could be detrimental in such cases.[10]

[9]Note that in our experiments, we use this analyzer for MWE analysis only, and discard the POS tagging prediction. Tagging is performed along with lemmatization with the Morfette tool (section 6.1).

[10]We also experimented to use POS of MWE plus suffixes to force disjoint tagsets for single words, irregular MWEs and regular MWEs, but this showed comparable results.

6 Experiments

6.1 Settings and evaluation metrics

MWE Analysis and Tagging: For the MWE analyzer, we used the tool *lgtagger*[11] (version 1.1) with its default set of feature templates, and a 10-fold jackknifing on the training corpus.

Parser: We used the second-order graph-based parser available in *Mate-tools*[12] (Bohnet, 2010). We used the *Anna3.3* version, in projective mode, with default feature sets and parameters proposed in the documentation, augmented or not with MWE-specific features, depending on the experiments.

Morphological prediction: Predicted lemmas, POS and morphology features are computed with Morfette version 0.3.5 (Chrupała et al., 2008; Seddah et al., 2010)[13], using 10 iterations for the tagging perceptron, 3 iterations for the lemmatization perceptron, default beam size for the decoding of the joint prediction, and the Lefff (Sagot, 2010) as external lexicon used for out-of-vocabulary words. We performed a 10-fold jackknifing on the training corpus.

Evaluation metrics: we evaluate our parsing systems by using the standard metrics for dependency parsing: Labeled Attachment Score (LAS) and Unlabeled Attachment Score (UAS), computed using all tokens including punctuation. To evaluate statistical significance of parsing performance differences, we use eval07.pl[14] with -b option, and then Dan Bikel's comparator.[15] For MWEs, we use the Fmeasure for recognition of untagged MWEs (hereafter FUM) and for recognition of tagged MWEs (hereafter FTM).

6.2 MWE-specific feature prediction

In all our experiments, for the switch trick (section 5.3), the POS of MWE is always predicted using the MWE analyzer. For the flat MWE features, we experimented both with features predicted by the MWE analyzer, and with features predicted using the external lexicons mentioned in section 5.1 (using the lexicon lookup procedure). Both kinds of

prediction lead to fairly comparable results, so in all the following, the MWE features, when used, are predicted using the external lexicons.

6.3 Tuning features for each architecture

We ran experiments for all value combinations of the following parameters: (i) the architecture, (ii) whether MWE features are used, whether the switch trick is applied or not (iii) for irregular MWEs and (iv) for regular MWEs.

We performed evaluation of the predicted parses using the three representations described in section 3, namely flat, structured and labeled representations. In the last two cases, the evaluation is performed against an instance of the gold data automatically transformed to match the representation type. Moreover, for the "labeled representation" evaluation, though the MWE information in the predicted parses is obtained in various ways, depending on the architecture, we always map all this information in the dependency labels, to obtain predicted parses matching the "labeled representation". While the evaluation in flat representation is the only one comparable to other works on this dataset, the other two evaluations provide useful information. In the "labeled representation" evaluation, the UAS provides a measure of syntactic attachments for sequences of words, independently of the (regular) MWE status of subsequences. For the sequence *abus de biens sociaux*, suppose that the correct internal structure is predicted, but not the MWE status. The UAS for labeled representation will be maximal, whereas for the flat representation, the last two tokens will count as incorrect for UAS. For LAS, in both cases the three last tokens will count as incorrect if the wrong MWE status is predicted. So to sum up on the "labeled evaluation", we obtain a LAS evaluation for the whole task of parsing plus MWE recognition, but an UAS evaluation that penalizes less errors on MWE status, while keeping a representation that is richer: predicted parses contain not only the syntactic dependencies and MWE information, but also a classification of MWEs into regular and irregular, and the internal syntactic structure of regular MWEs.

The evaluation on "structured representation" can be interpreted as an evaluation of the parsing task plus the recognition of irregular MWEs only: both LAS and UAS are measured independently of errors on regular MWE status (note the UAS is exactly the same than in the "labeled" case).

For each architecture, Table 3 shows the results for two systems: first the baseline system without any MWE features nor switches and immediately below the best settings for the architecture. The JOINT baseline corresponds to a "pure" joint system without external MWE resources (hence the minus sign for the first three columns). For each architecture except the PIPELINE one, differences between the baseline and the best setting are statistically significant ($p < 0.01$). Differences between best PIPELINE and best JOINT-REG are not. Best JOINT has statistically significant difference ($p < 0.01$) over both best JOINT-REG and best PIPELINE. The situation for best JOINT-IRREG with respect to the other three is borderline (with various p-values depending on the metrics).

Concerning the tuning of parameters, it appears that the best setting is to use MWE-features, and switch for both regular and irregular MWEs, except for the pipeline architecture for which results without MWE features are slightly better. So overall, informing the parser with independently pre-

Table 4: Final results on test set for baseline and the best system for each architecture.

dicted POS of MWE has positive impact. The best architectures are JOINT and JOINT-IRREG, with the former slightly better than the latter for parsing metrics, though only some of the differences are significant between the two. It can be noted though, that JOINT-IRREG performs overall better on MWEs (last two columns of table 3), whereas JOINT performs better on irregular MWEs: the latter seems to be beneficial for parsing, but is less efficient to correctly spot the regular MWEs.

Concerning the three distinct representations, evaluating on structured representation (hence without looking at regular MWE status) leads to a rough 2 point performance increase for the LAS and a one point increase for the UAS, with respect to the evaluation against flat representation. This quantifies the additional difficulty of deciding for a regular sequence of tokens whether it forms a MWE or not. The evaluation on the labeled representation provides an evaluation of the full task (parsing, regular/irregular MWE recognition and regular MWEs structuring), with a UAS that is less impacted by errors on regular MWE status, while LAS reflects the full difficulty of the task.[16]

6.4 Results on test set and comparison

We provide the final results on the test set in table 4. We compare the baseline JOINT system with the best system for all four reg/irreg architectures (cf. section 6.3). We observe the same general trend as in the development corpus, but with tinier differences. JOINT and JOINT-IRREG significantly outperform the baseline and the PIPELINE, on labeled representation and flat representation. We can see that there is no significant difference between JOINT and JOINT-IRREG and between JOINT-REG and JOINT-IRREG. JOINT slightly outperforms JOINT-REG ($p < 0.05$). On the structured representation, the two best systems (JOINT and JOINT-IRREG) significantly outperform the other systems ($p < 0.01$ for all; $p < 0.05$ for JOINT-REG).

[16]The slight differences in LAS between the labeled and the flat representations are due to side effects of errors on MWE status: some wrong reattachments performed to obtain flat representation decrease the UAS, but also in some cases the LAS.

	DEV		TEST

uniform joint	**88.81**	**85.42**	87.96	84.59

Table 5: Comparison on dev set of our best architecture with reg/irregular MWE distinction (first row), with the single-parser architectures of (Constant et al., 2013) (Const13) and (Björkelund et al., 2013) (Bjork13). Uniform joint is our reimplementation of Const13 joint, enhanced with mwe-features and switch.

Moreover, we provide in table 5 a comparison of our best architecture with reg/irregular MWE distinction with other architectures that do not make this distinction, namely the two best comparable systems designed for the SPMRL Shared Task (Seddah et al., 2013): the pipeline simple parser based on Mate-tools of Constant et al. (2013) (Const13) and the Mate-tools system (without reranker) of Björkelund et al. (2013) (Bjork13). We also reimplemented and improved the uniform joint architecture of Constant et al. (2013), by adding MWE features and switch. Results can only be compared on the flat representation, because the other systems output poorer linguistic information. We computed statistical significance of differences between our systems and Const13. On dev, the best system is the enhanced uniform joint, but differences are not significant between that and the best reg/irreg joint (1st row) and the Const13 pipeline. But on the test corpus (which is twice bigger), the best system is Const13

Table 6: Comparison with simpler tasks on the flat representation of the development set.

pipeline, with statistically significant differences over our joint systems. So the first observation is that our architectures that distinguish between reg/irreg MWEs do not outperform uniform architectures. But we note that the differences are slight, and the output we obtain is enhanced with regular MWE internal structure. It can thus be noted that the increased syntactic uniformity obtained by our MWE representation is mitigated so far by the additional complexity of the task. The second observation is that currently the best system on this dataset is a pipeline system, as results on test set show (and somehow contrary to results on dev set). The joint systems that integrate MWE information in the labels seem to suffer from increased data sparseness.

6.5 Evaluating the double task with respect to simpler tasks

In this section, we propose to better evaluate the difficulty of combining the tasks of MWE analysis and dependency parsing by comparing our systems with systems performing simpler tasks: i.e. MWE recognition without parsing, and parsing with no or limited MWE recognition, simulated by using gold MWEs. We also provide a finer evaluation of the MWE recognition task, in particular with respect to their regular/irregular status.

We first compare our best system with a parser where all MWEs have been perfectly pre-grouped, in order to quantify the difficulty that MWEs add to the parsing task. We also compare the performance on MWEs of our best system with that achieved by the CRF-based analyzer described in section 5.2. Next, we compare the best JOINT-REG system with the one based on the same architecture but where the irregular MWEs are perfectly pre-identified, in order to quantify the difficulty added by the irregular MWEs. Results are given in table 6. Without any surprise, the task is much easier without considering MWE recognition. We can see that without considering MWE analysis the parsing accuracy is about 2.5 points better in terms of LAS. In the JOINT-REG architecture, assuming gold irregular MWE identification, increases LAS by 1.3 point. In terms of MWE recognition, as compared with the CRF-based analyzer, our best system is around 2 points below. But the situation is quite different when breaking the evaluation by MWE type. Our system is 1 point better than the CRF-based analyzer for irregular MWEs. This shows that considering a larger syntactic context helps recognition of irregular MWEs. The ”weak point” of our system is therefore the identification of regular MWEs.

7 Conclusion

We experimented strategies to predict both MWE analysis and dependency structure, and tested them on the dependency version of French Treebank (Abeillé and Barrier, 2004), as instantiated in the SPMRL Shared Task (Seddah et al., 2013). Our work focused on using an alternative representation of syntactically regular MWEs, which captures their syntactic internal structure. We obtain a system with comparable performance to that of previous works on this dataset, but which predicts both syntactic dependencies and the internal structure of MWEs. This can be useful for capturing the various degrees of semantic compositionality of MWEs. The main weakness of our system comes from the identification of regular MWEs, a property which is highly lexical. Our current use of external lexicons does not seem to suffice, and the use of data-driven external information to better cope with this identification can be envisaged.

Abstract

This paper presents a novel framework called *error case frames* for correcting preposition errors. They are case frames specially designed for describing and correcting preposition errors. Their most distinct advantage is that they can correct errors with feedback messages explaining why the preposition is erroneous. This paper proposes a method for automatically generating them by comparing learner and native corpora. Experiments show (i) automatically generated error case frames achieve a performance comparable to conventional methods; (ii) error case frames are intuitively interpretable and manually modifiable to improve them; (iii) feedback messages provided by error case frames are effective in language learning assistance. Considering these advantages and the fact that it has been difficult to provide feedback messages by automatically generated rules, error case frames will likely be one of the major approaches for preposition error correction.

1 Introduction

This paper presents a novel framework for correcting preposition errors. Its most significant advantage over previous methods is that it can provide learners with feedback messages, that is, explanatory notes describing why the detected preposition is erroneous and should be corrected as indicated, as shown in Fig. 1. Despite the fact that appropriate feedback messages are essential in language learning assistance (Ferris and Roberts, 2001; Robb et al., 1986), which is one of the immediate applications of grammatical error correction, almost all previous methods are incapable of providing feedback messages.

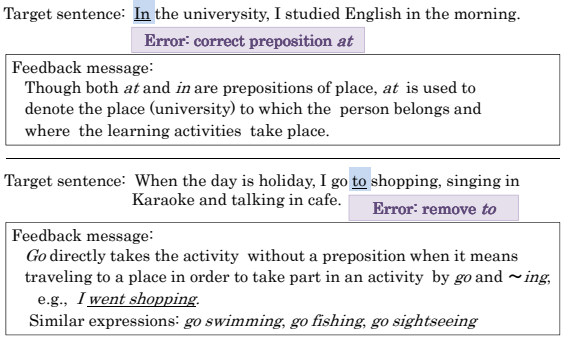

Figure 1: Error correction and feedback messages provided by the proposed method.

Grammatical error correction has been intensively studied in recent years. Current methods mostly exploit machine learning-based classifiers to correct target errors; examples are errors in article (Han et al., 2006; Nagata et al., 2006; Rozovskaya and Roth, 2011), preposition (Chodorow et al., 2007; Felice and Pulman, 2008; Rozovskaya and Roth, 2011; Tetreault et al., 2010), and tense (Nagata and Kawai, 2011; Tajiri et al., 2012), to name a few. Recently, Wu and Ng (2013) and Rozovskaya and Roth (2013) proposed methods for simultaneously correcting multiple types of errors using integer linear programming. Another major approach is to use a language model (LM) for predicting correct words or phrases for a given context. Some researchers (Brockett et al., 2006; Yoshimoto et al., 2013) use statistical machine translation (SMT) for the same purpose, which can be regarded as the mixture of a classifier and an LM. With these diverse techniques, correction performance has dramatically improved against a wide variety of target errors.

As noted above, however, one of the crucial limitations of these previous methods is that they

*Part of this work was performed while the author was a visiting researcher at LIMSI, Orsay (France).

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 754–764,
Baltimore, Maryland, USA, June 23-25 2014.

are not capable of providing feedback messages. They are not suitable for generating open-class text such as feedback messages by their nature. Some researchers (Kakegawa et al., 2000; McCoy et al., 1996) made an attempt to develop hand-crafted rules for correcting errors with feedback messages. However, this approach encounters the tremendous difficulty of covering a wide variety of errors using hand-crafted rules.

In view of this background, this paper presents a novel error correction framework called *error case frames* an example of which is shown in Fig. 2. They are case frames specially designed for describing and correcting errors in preposition attached to a verb; the reader may be able to see that it describes preposition errors such as **John often goes shopping to the market with his family.* and that the preposition *to* should be replaced with *at*. This paper proposes a method for automatically generating them by comparing learner and native corpora. Achieving a comparable correction performance, they have the following two advantages over the conventional approaches: (i) they are intuitively interpretable and manually modifiable to enrich them; (ii) they are capable of providing feedback messages.

The rest of this paper is structured as follows. Sect. 2 introduces the definition of error case frames. Sect. 3 discusses the method for generating error case frames. Sect. 4 describes how to correct preposition errors with feedback messages by error case frames. Sect. 5 describes experiments conducted to evaluate error case frames. Sect. 6 discusses the experimental results.

2 Error Case Frame

An error case frame consists of a verb, cases, and a feedback message as shown in Fig. 2[1]. The following explains error case frames in detail based on this example; occasionally consulting it may help understanding the following sections.

An error case frame always has a verb. In Fig. 2, the verb is *go*.

Cases are arguments the verb takes in an error case frame. A case consists of a case tag and case elements. A case tag and case elements describe, respectively, the role that the case plays in the error case frame and a set of words that are allowed

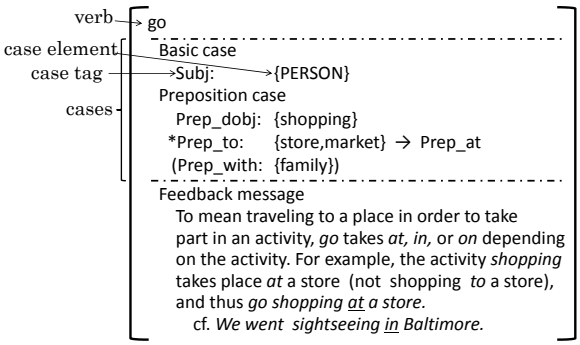

Figure 2: Example of an error case frame.

to appear as the argument. For instance, in Fig. 2, "Subj: {PERSON}" is a case where its case tag and element are "Subj:" and "{PERSON}," respectively, denoting that a person such as *John* plays a role of the subject of the verb. Note that tokens in all upper case such as "PERSON" refer to a group of words such as {john,he,$\cdots$} in this paper.

Cases are classified into two categories: basic and preposition cases. Basic cases are either a subject or a particle, whose case tags are "Subj:" and "Ptr:", respectively. The "Subj:" case is obligatory while the "Ptr:" is optional. Preposition cases correspond to the prepositions the verb takes as its arguments. Its case tag has the form of "Prep_x" where x ranges over the target prepositions. It should be emphasized that direct and indirect objects are included in the preposition cases for efficiency; their case tags are denoted as "Prep_dobj" and "Prep_iobj", respectively. Preposition cases are classified into those obligatory and optional. *Optional* here means that the verb can constitute a sentence with or without the preposition. Optional prepositions are written in parentheses as in "(Prep_with:{family})".

Preposition cases describe the information about an error. An error case frame is constrained to contain only one erroneous preposition case. It is marked with the symbol "*". So, the preposition case "*Prep_to:{store,market}" is erroneous in Fig. 2. The correct preposition is described after the symbol "→" as in "→ Prep_at".

Error case frames are furnished with feedback messages. Unlike verbs and cases, which are automatically filled based on corpus data, they are manually edited. A human annotator interprets error case frames and adds explanatory notes to them. This may seem time-consuming. How-

[1]Fig. 2 shows an example of error case frames for illustration purposes. They are formally expressed in a machine-readable format such as XML.

ever, the editing is far more efficient than manually creating correction rules with feedback messages from scratch because error case frames are highly abstracted as explained in Sect. 3. Above all, it is a significant advantage over the previous classifier-/LM-based methods considering that there exists no effective technique for augmenting these methods with feedback messages.

3 Generating Error Case Frames

The method proposed here exploits two sources of corpus data: native and learner corpora. Case frames (error case frames without the information about an error and a feedback message) can be automatically extracted from parsed sentences as Kawahara and Uchimoto (2008) show. The proposed method generates error case frames by comparing case frames generated from the learner corpus with those from the native corpus. The basic approach is to extract, as error case frames, case frames which appear in the learner corpus but not in the native corpus. However, this approach is so simple that it extracts undesirable false error case frames which do not actually correspond to preposition errors. To overcome the problem, the following procedures are applied:
(1) Filtering input sentences
(2) Extracting case frames
(3) Recognizing optional cases
(4) Grouping case frames
(5) Selecting candidate error case frames
(6) Determining correct prepositions
(7) Enriching error case frames
(8) Manually editing error case frames

(1) Filtering input sentences: This is a pre-process to filter out unsuitable input sentences for case frame generation. Accurate parsing is essential for accurate case frame generation. Parsing errors tend to occur in longer sentences. To reduce parsing errors, Kawahara and Uchimoto (2008) propose filtering out sentences which are longer than 20 words. We adopt this filtering in our method. We also filter out sentences containing commas, which often introduce complex structures. We apply the filtering pre-process only to the native corpus; the availability of learner corpora is still somewhat limited and therefore we use all the sentences available in the learner corpus for better coverage of preposition errors.

(2) Extracting case frames: This procedure can be viewed as a slot filling task where the slots are the verb and the cases in a case frame. To achieve this, the corpus data are first parsed by a parser. Then, for each verb, the predicate-argument structures are extracted from the parses as shown in Fig. 3. Here, only head words are extracted as arguments. They are reduced to their base form when extracted. Certain classes of words are replaced with their corresponding sense (e.g., *John* to *PERSON*); the mapping between words and their senses is shown in Appendix A. In the case of the learner corpus, mis-spelt words are automatically corrected using a spell-checker. Finally, a case frame is created by filling its slots with the extracted predicate-argument structures. Hereafter, case frames generated from the native and learner corpora will be referred to as the native and learner case frames, respectively.

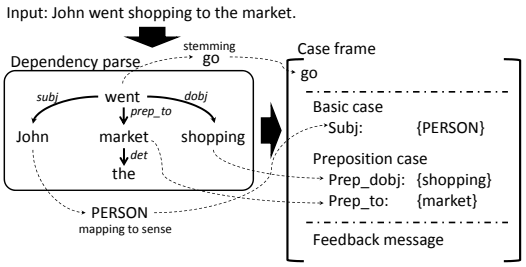

Figure 3: Example of case frame extraction.

(3) Recognizing optional cases: it is crucial for generating flexible error case frames to recognize optional preposition cases. Optional preposition cases are determined by the following heuristic rules: (a) Objects are always obligatory; (b) The number of obligatory preposition cases (except objects) is at most one; (c) Prepositions appearing left of the verb are optional; (d) Prepositions appearing right of the verb are optional except the one which is nearest to the verb. Rule (a) states that objects are always recognized as obligatory[2]. Rule (b) constrains an error case frame to have at most one obligatory preposition. Certain verbs sometimes have more than one obligatory preposition as in *range from A to B*. However, the large majority of verbs satisfy rule (b). Rule (c) states that prepositions appearing left of the verb

[2]A sentence can be constituted without objects as in *We sing.* Rule (a) always mistakenly recognizes such objects as obligatory. However, preposition errors never appear in sentences consisting of no object nor prepositions, and thus, the objects mistakenly recognized as obligatory never cause any problems in preposition error correction in practice.

in the input sentence are optional preposition cases as in *In the morning, he went shopping.* Rule (c) is based on the assumption that obligatory cases are tied to the verb more strongly than optional cases. In other words, obligatory cases cannot easily change their position. Conversely, optional cases have more freedom of their position, which enables them to appear left of a verb. Admittedly, obligatory prepositions can appear left of a verb as in *To school, he went* in certain circumstances such as in poetry. However, this usage is not so frequent in corpora normally used as training data such as newspaper articles. Rule (d), together with rule (b), states that if more than one preposition appears right of the verb, the one nearest to the verb is obligatory and the rest are optional. Rule (d) is based on the same reasoning as in rule (c).

Optional preposition cases are sometimes determined naturally by comparing two case frames. In this case, one of them must consist of only the object(s) as its preposition case(s) as in "[go Subj:{PERSON} Prep_dobj:{shopping}]." Then, the other case frame must consist of the same verb, the same basic cases, and the same object(s). The only difference between them is preposition cases (except the object(s)) (e.g., [go Subj:{PERSON} Prep_dobj:{shopping} Prep_at:{market}]). The case frame only with the object(s) proves the other to be valid without the preposition case(s). Thus, these preposition cases are recognized as optional (e.g., [go Subj:{PERSON} Prep_dobj:{shopping} (Prep_at:{market})]).

(4) Grouping case frames: Similar case frames in the native case frames are grouped into one, which will play an important role in **(7) Enriching error case frames**. Case frames comprising similar cases tend to denote similar usage of a verb. Considering this, case frames are merged into one if they consist of the same verb, the same basic cases, and the same case tags of the obligatory preposition cases. The grouping procedure is illustrated in Fig. 4. When preposition cases are obligatory in one case frame and optional in the other, the discrepancy is resolved by setting the preposition case to optional in the merged case frame. Note that this grouping procedure is not applied to the learner case frames so that erroneous usages in the learner case frames do not propagate to other (correct) learner case frames.

(5) Selecting candidate error case frames: Candidates for error case frames are selected from the learner case frames. If a learner case frame does not match, ignoring optional preposition cases, any native case frame, it is selected as a candidate for an error case frame on the assumption that case frames corresponding to erroneous usages do not appear in the native corpus.

Alternatively, an error-annotated learner corpus can be used to select error case frames; simply extracting case frames of which preposition is marked as an error gives error case frames. In this case[3], procedure (6) may be omitted and procedure (7) is directly applied after procedure (5).

(6) Determining correct prepositions: Now, correct prepositions for the candidate error case frames are explored. Each case tag of the preposition cases in a candidate is replaced, one at a time, with one of the other target prepositions. This replacement can be interpreted as error correction. Take as an example the following candidate error case frame: [go Subj:{PERSON} Prep_dobj:{shopping} Prep_to:{market}]. Replacing the case tag "Prep_to" with "Prep_at" corresponds to correct expressions such as *John often goes shopping at the market.* Note that replacing a direct object with one of the prepositions corresponds to correcting an omission error as in "Prep_dobj" with "Prep_to" in "[go Subj:{PERSON} Prep_dobj:{market}]". Similarly, replacing a preposition with an object corresponds to correcting an extra-preposition error (e.g., "Prep_to" with "Prep_dobj" in "[go Subj:{PERSON} Prep_to:{shopping}])".

To examine whether each correction is valid or not, the native case frames are again used; if the replaced case frame matches one of the native case frames, the correction is determined to be valid. Here, we define the match as the two case frames consisting of the same verb, the same basic cases, the same obligatory preposition cases, and the same preposition case to which the correction is applied (if it is an optional one). If the condition is satisfied, the information on the error and correction is added to the candidate error case frame. If a valid correction is found, the candidate is determined to be a valid error case frame. In total, their validity is double-checked, once in (5) and once in (6), by comparing them with the

[3] We do not make use of error-annotated learner corpora in this paper in order to reveal how well the proposed methods perform without such corpora. In practice, one can use error-annotated learner corpora together with raw learner corpora to achieve better performance.

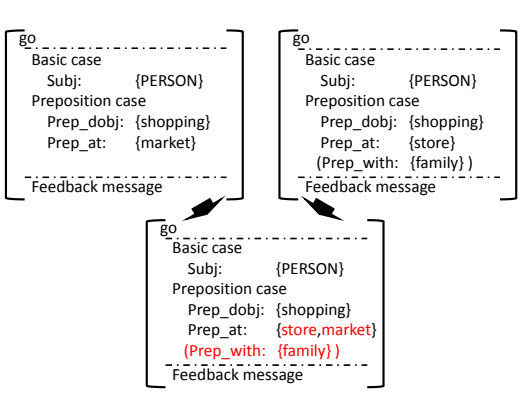

Figure 4: Example of grouping case frames.

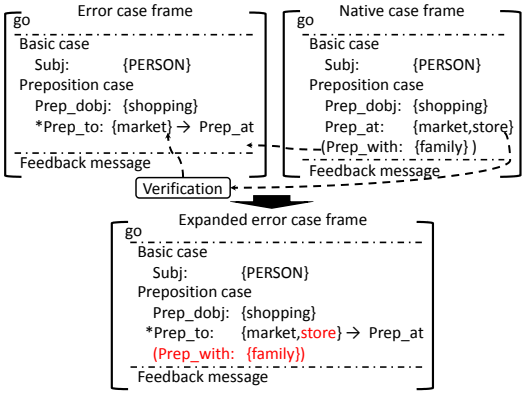

Figure 5: Enriching an error case frame.

native case frames.

(7) Enriching error case frames: The generated error cases are limited in error coverage because the procedures so far solely rely on preposition errors appearing in the learner corpus. In other words, it is impossible to generate error case frames corresponding to preposition errors which do not appear in the learner corpus. To overcome this limitation, the generated error case frames are enriched using the native case frames. For each error case frame, we already know the corresponding native (thus, correct) case frame, which is obtained in (6). The corresponding native case frame is normally much richer in preposition cases because of the optional cases and grouping given by procedures (3) and (4), as shown at the top of Fig. 5. These additional cases are useful to enrich error case frames.

For the preposition case which is determined to be erroneous, its correct preposition is found in the error case frame (e.g., "→ Prep_at" at the top-left of Fig. 5). Also, its correct preposition case is found in the corresponding native case frame (e.g., "Prep_at:{market,store}" at the top-right). Replacing the case element of the erroneous case by one of the case elements of the correct preposition case gives a new candidate for an error case frame (e.g., replacing *market* of "*Prep_to:{market}" by *store* gives "[go Subj:{PERSON} Prep_dobj:{shopping} *Prep_to:{store}]." It should be emphasized that this new error case frame is still a candidate at this point and the usage might be correct. To verify if it really describes an erroneous preposition use, the native case frames are searched for; if it matches one of them, that means that the use of the preposition actually appears in the native corpus. Therefore, it should be discarded. Only if a match is not found, is the case element added to the erroneous preposition case in the original error case frame. This process is illustrated in the box denoted as *Verification* in Fig. 5.

For the other preposition cases which are not erroneous, the enriching procedure is much simpler. They are simply added to the error case frame as shown in Fig. 5. One thing we should take care of is that there might be a discrepancy in obligatory/optional between the cases of the error case frame and the native case frame. This discrepancy is solved by setting the preposition case in the error case frame to optional. The resulting expanded error case frame after procedure (7) is shown at the bottom of Fig. 5 where the enriched cases are shown in red.

(8) Manually Editing Error Case Frames: The most important editing is the addition of feedback messages. A human annotator interprets the generated error case frames and adds explanatory notes to them. Although this basically requires manual editing, part of feedback messages can be automatically created to facilitate the procedure. For example, example sentences corresponding to an error case frame can be automatically added to it, whether correct or error examples, because the original sentences from which the (error) case frames extracted are available in the native and learner corpora. Besides, setting a variable to the feedback message allows it to be adaptable to correction results as shown in Fig. 6. In Fig. 6, $X_{\text{Prep\_to}}$ is a variable. It is replaced with one of the case elements of "Prep_to:" depending on correction results. Also, it will be beneficial to link similar error case frames each other, which allows the user to obtain additional information.

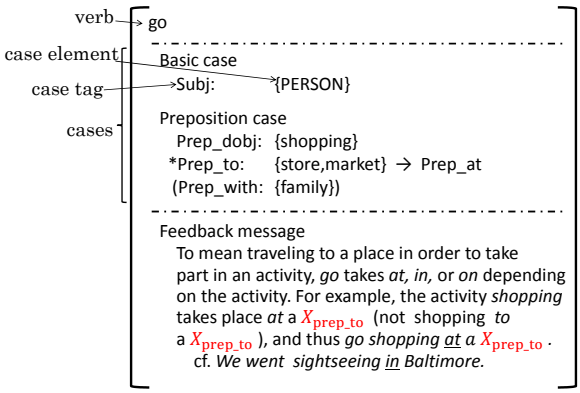

Figure 6: Error case frame with a variable.

For example, the example error case frame in Fig. 6 may be linked to similar case frames such as "[go Subj:{PERSON} Prep_dobj:{sightseeing} *Prep_to:{Baltimore} → Prep_in]." One can retrieve similar error case frames from the generated error case frames where the similarity between two error case frames are defined by the overlap in the verb, the basic cases, and the case tags of the preposition cases.

The generated error case frames may be further edited to enrich them. As we can see in Fig. 5, the generated error case frames are easy to interpret. This property enables us to manually edit them to enrich their preposition cases. For example, one might add a case element such as *supermarket* to the preposition case "Prep_to:{market,store}" in the example error case frame. Conversely, one might discard unnecessary case elements, cases, or even error case frames.

4 Correcting Preposition Errors

Preposition errors are corrected by applying the generated error case frames to the target text. Case frames are first extracted from the target text by the same procedures (2) and (3) in Sect. 3. Then, each extracted case frame is examined if it matches one of the error case frames. If a match is found, the preposition is detected as an error and the correct preposition is suggested with the feedback message according to the matched error case frame. The match between a case frame and an error case frame is defined in the exact same manner as in procedure (4) in Sect. 3. Sometimes, a case frame matches more than one error case frame suggesting different corrections. In this case, the most frequent correction among the candidates is chosen to correct the error, which was applied in the evaluation described in Sect. 5[4].

One of the advantages of error case frames is that they do not require an error-annotated corpus as explained in the previous section. This means that the target text itself can be used as part of a learner corpus for generating error case frames at the time of error correction. Applying procedures (2) to (7) to the target text generates additional error case frames[5]. Although feedback messages are not available in these additional error case frames, they are still useful for improving correction performance, especially in recall. Hereafter, this way of error case frame generation will be referred to as *active generation*.

A pre-experiment using a development data set revealed that there were some preposition errors for which error case frames were not generated even though the corresponding erroneous and correct preposition usages appeared in the learner and native corpora, respectively. They are preposition errors where the preposition is incorrectly used with an adverb as in **John went to there*. To be precise, they are either an adverb denoting a place (e.g., *there*) with a preposition concerning a place (*at*, *in*, *on*, and *to*) or a noun denoting time, frequency, and duration with a preposition concerning time, frequency, and duration (*at*, *for*, *in*, and *on*). In the native corpus, these adverbs or nouns are correctly used without a preposition and thus they are not recognized as a prepositional phrase by a parser. Therefore, corresponding native case frames are never found for these types of errors in procedure (6), and in turn error case frames are never generated for them.

Considering that they are limited in number because they are independent of verbs and basic cases, we decided to manually create error case frames describing these types of errors. In these error case frames, the verb and the basic cases are filled with ANY denoting any word. The preposition cases are manually filled based on the linguistic knowledge known as *absence of preposition* (Quirk et al., 1985). For example, an error case frame for the above error would be "[ANY Subj:{ANY} *Prep_to:{here,somewhere,there} → Prep_dobj]." Certain errors involve a phrase such as **John goes shopping in every morning*. To handle these cases,

[4]Ties are broken by random selection.

[5]Recall that procedure (1) is only applied to the native corpus.

these manually created error case frames are allowed to have phrases as their case elements (e.g., [ANY Subj:{ANY} *Prep_in:{every morning} → Prep_dobj]).

5 Evaluation

We evaluated the proposed method from two points of view: correction performance and usefulness of feedback messages. We measured correction performance by recall, precision, and F-measure. In the evaluation on usefulness of feedback messages, three human raters (a teacher of English at college and two who have a master degree in TESOL) separately examined whether each feedback message was useful for learning the correct usage of the preposition. We defined usefulness by the ratio of feedback messages evaluated as useful to the total number of feedback messages.

We used the following data sets in the evaluation. We selected the Konan-JIEM (KJ) learner corpus (Nagata et al., 2011) as the target texts. The KJ learner corpus is fully annotated with grammatical errors. In addition, it includes error correction results of several benchmark systems. This means that one can directly compare correction results of a new method with those of the benchmark systems, which reveals where the method is strong and weak compared to the benchmark systems. The KJ corpus consists of training and test sets. We used the training set to generate error case frames and evaluated correction performance on the test set. In addition to these data sets, we created a development set, which we had collected to develop the proposed method. We did not use it in the final evaluation. As a native corpus, we used the EDR corpus (Japan electronic dictionary research institute Ltd, 1993), the Reuters-21578 corpus[6], and the LOCNESS corpus[7]. We used the lexicalized dependency parser in the Stanford Statistical Natural Language Parser (ver.2.0.3) (de Marneffe et al., 2006) to obtain parses for the data sets. Table 1 shows the statistics on the data sets.

Using these data sets, we implemented three versions of the proposed method. The first one was based on error case frames generated from the training set of the KJ corpus. The second one was the first one with active generation. To implement the third one, we manually edited the error case frames of the first version to remove unnecessary error case frames and case elements (but no addition) and to add feedback messages to them. After this, active generation was applied to augment the edited error case frames. In implementing the proposed methods, we selected as target prepositions the ten most frequent prepositions, the same as in previous work (Rozovskaya and Roth, 2011): *about*, *at*, *by*, *for*, *from*, *in*, *of*, *on*, *to*, *with*.

Name	# of tokens	# of errors
KJ training	22,701	327
KJ test	8,065	131
Dev. set	47,217	774
EDR	1,745,863	—
Reuters	28,431,228	—
LOCNESS	294,325	—

Table 1: Statistics on the data sets for evaluation.

For comparison, we selected two conventional methods. One was the best-performing system among the benchmark systems, which is the classifier-based method (Sakaguchi et al., 2012) which had participated in the HOO 2012 shared task (Dale et al., 2012). The other was the SMT-based method (Yoshimoto et al., 2013) which was the best-performing system in preposition error correction in the CoNLL 2013 shared task (Ng et al., 2013). In addition, we evaluated performance of hybrid methods combining the correction results of the third version of the proposed method with those of the classifier-/SMT-based method; we simply took the union of the two.

Table 2 shows the evaluation results. The simple error case frame-based method achieves an F-measure of 0.189. It improves recall when combined with active generation, which shows the effectiveness of active generation for augmenting error case frames. It further improves precision without decreasing recall by manual editing; note that manual editing was only applied to the error case frames generated from the training data but not to those generated by active generation. The performance is comparable to both classifier-/SMT-based methods. The hybrid methods achieve the best performances in F-measure.

In the usefulness evaluation, the third version of the proposed method was able to provide 20 feedback messages for the target texts. The three human raters evaluated 80%, 80%, and 85% of the

20 feedback messages as useful (82% on average). The agreement among the raters was $\kappa = 0.67$ in Fleiss's κ.

6 Discussion

As the experimental results show, the proposed method achieves a comparable correction performance with the classifier-/SMT-based methods. A closer look at the correction results reveals the differences in correction tendencies between these methods, which explains well why the hybrid methods achieve better performance.

One of the tendencies is that the proposed method performs better on preposition errors where relatively wider contexts are required to correct them. Error case frames naturally exploit wider contexts based on the cases which are extracted by parsing. In contrast, classifier-/SMT-based methods rely on narrower contexts such as a few words surrounding the preposition in question. Take as an example the following sentence which appeared in the test set: **In the univerysity, I studied English in the morning*[8]. To confirm that the preposition *In* is erroneous requires the verb *studied* and the object *English*. The proposed method successfully corrected this error by the error case frame "[study Subj:{PERSON} Prep_dobj:{english,math,$\cdots$} *Prep_in:{university} $\rightarrow$ at]" in the evaluation. This would be difficult for methods relying on only a few words surrounding the preposition *In*.

It is also difficult for classifier-/SMT-based methods to correct missing preposition errors. Classifier-based methods need to be informed of the position of the preposition to predict a correct preposition. Because the position of a missing preposition is implicit, classifier-based methods would have to make a prediction at every single position between words, which would be inefficient. Because of this, the classifier-based method used in the evaluation (and often other classifier-based methods) excludes missing preposition errors from its target. SMT-based methods do not perform well either on missing preposition errors because of the fact that they implicitly, but not directly, handle missing preposition errors. In contrast, error case frames directly model missing prepositions by treating objects as one of the preposition cases (i.e., *Prep_dobj*).

Grammatical errors other than preposition errors influence both the proposed and classifier-/SMT-based methods, but differently. Grammatical errors appearing around the preposition in question seem to influence the previous methods more significantly than the proposed method because they rely on words surrounding the preposition. On the other hand, structural errors such as errors in voice tend to degrade performance of the proposed method. For instance, if an error in voice occurs as in **I excited _ this*, correctly, *I was excited by this*, error case frames are not properly applied.

The precisions of the proposed methods are high compared to those of the previous methods. To be precise, the number of false positives is only seven in the third version of the proposed method. Out of seven, four false positives are due to problems with the used error case frames themselves. Two are the influence of other grammatical errors (e.g., **I like to look beautiful view.* was corrected as *look at beautiful view* by the proposed method but as *see beautiful view* in the error annotation).

Unlike false positives, it is difficult to precisely point out causes for false negatives, which often involve several factors. One cause which is theoretically clear is errors in preposition attached to a noun phrase (NP), which amounts to 11 % of all false negatives. Since error case frames describe errors in preposition attached to a verb, they do not target these types of errors. Extending error case frames to general frames might overcome this limitation, which will require further investigation. Similarly, error case frames are not generated for preposition errors where prepositions are incorrectly used with words other than a noun as

[8]The word *univerysity* is a mis-spelt word of *university*. Note that mis-spelt words are automatically corrected by a spell-checker when case frames are extracted.

in **make me to happy* (5 % of all). Although error case frames can describe these types of errors, case frames are not extracted for their corresponding correct usages from the native corpus. This is because the word in question (e.g., *happy*) correctly appears without the erroneous preposition in the native corpus, and thus it is not recognized as a preposition case. This means that a corresponding correct case frame is never found for any error of these types in the generation procedure (6). Accordingly, error case frames are never generated for these types of errors. The most influential cause of false negatives, which is also a major cause of false negatives in the previous methods, is other grammatical errors (at least 22 % of all). One of such errors is errors in voice as already explained (4%). Another is the omission of the object of a verb (4%). In these cases, even if an appropriate error case frame exists, it is not applied because of the grammatical error.

In addition to correction performance, error case frames are effective in providing feedback messages; Fig. 1 (on the first page) shows excerpts of the feedback messages provided in the evaluation. The evaluation shows that 82% of the provided feedback messages were actually rated as useful for language learning on average (the rest were mostly evaluated as not-useful due to false positive corrections). With the feedback messages of error case frames, we now have the following three choices as the way of error correction: (a) just indicating the correct preposition (as in previous methods); (b) indicating the correction preposition with a feedback message; (c) displaying only a feedback message. In (a), the learner might just copy the correct preposition to correct his or her writing, which would result in little or no learning effect. This suggests that the ultimate goal of grammatical error correction for language learning assistance is not to correct all errors in the given text but to maximize learning effect for the learner. (b) might give a similar result because the learner can copy the correct preposition without reading the feedback message. In (c), the learner has to actually read and understand the feedback message to select the correct preposition. Taking these into consideration, (c) will likely give the learner better learning effect than the other two. Therefore, we propose applying the feedback (c) to language learning assistance. To the best of our knowledge, it is only the error case frame-based method that is capable of this manner of error correction.

7 Conclusions

This paper presented a novel framework called error case frames for correcting preposition errors with feedback messages. The evaluation showed that (i) automatically generated error case frames achieve a performance comparable to conventional methods; (ii) they are intuitively interpretable and manually modifiable to improve them; (iii) feedback messages provided by error case frames are effective in language learning assistance. Considering these advantages and the fact that it has been difficult to provide feedback messages by automatically generated rules, error case frames will likely be one of the major approaches for preposition error correction.

Appendix A. Sense mapping

The following list shows the mapping between words and senses developed based on the WordNet (Miller, 1995) and GSK dictionary of places and facilities (2nd Ed.)[9]. Each line consists of a token for a sense, its definition, examples of its member. DRINK (drink): tea, coffee
FOOD (food): cake, sandwich
MONTH (names of months): January, February
MINST (musical instruments): guitar, piano
PERSON (persons): John, he
PLACE (place names): Canada, Paris
SPORT (sports): football, tennis
SPORTING (sporting activities): swimming
WEEK (the days of the week): Monday
VEHICLE (vehicles): train, bus

Acknowledgments

We would like to thank Daisuke Kawahara for his advice on case frame generation. We also would like to thank Keisuke Sakaguchi and Mamoru Komachi for providing the authors with their system outputs. Finally, we would acknowledge the help from the members of the ILES group at LIMSI, Orsay (France) where the first author performed part of this work. This work was partly supported by Kaken Grant-in-Aid for Young Scientists (B) (26750091).

Abstract

Widely used in speech and language processing, Kneser-Ney (KN) smoothing has consistently been shown to be one of the best-performing smoothing methods. However, KN smoothing assumes integer counts, limiting its potential uses—for example, inside Expectation-Maximization. In this paper, we propose a generalization of KN smoothing that operates on fractional counts, or, more precisely, on *distributions* over counts. We rederive all the steps of KN smoothing to operate on count distributions instead of integral counts, and apply it to two tasks where KN smoothing was not applicable before: one in language model adaptation, and the other in word alignment. In both cases, our method improves performance significantly.

1 Introduction

In speech and language processing, smoothing is essential to reduce overfitting, and Kneser-Ney (KN) smoothing (Kneser and Ney, 1995; Chen and Goodman, 1999) has consistently proven to be among the best-performing and most widely used methods. However, KN smoothing assumes integer counts, whereas in many NLP tasks, training instances appear with possibly fractional weights. Such cases have been noted for language modeling (Goodman, 2001; Goodman, 2004), domain adaptation (Tam and Schultz, 2008), grapheme-to-phoneme conversion (Bisani and Ney, 2008), and phrase-based translation (Andrés-Ferrer, 2010; Wuebker et al., 2012).

For example, in Expectation-Maximization (Dempster et al., 1977), the Expectation (E) step computes the posterior distribution over possible completions of the data, and the Maximization (M) step reestimates the model parameters as if that distribution had actually been observed. In most cases, the M step is identical to estimating the model from complete data, except that counts of observations from the E step are fractional. It is common to apply add-one smoothing to the M step, but we cannot apply KN smoothing.

Another example is instance weighting. If we assign a weight to each training instance to indicate how important it is (say, its relevance to a particular domain), and the counts are not integral, then we again cannot train the model using KN smoothing.

In this paper, we propose a generalization of KN smoothing (called *expected KN* smoothing) that operates on fractional counts, or, more precisely, on *distributions* over counts. We rederive all the steps of KN smoothing to operate on count distributions instead of integral counts. We demonstrate how to apply expected KN to two tasks where KN smoothing was not applicable before. One is language model domain adaptation, and the other is word alignment using the IBM models (Brown et al., 1993). In both tasks, expected KN smoothing improves performance significantly.

2 Smoothing on integral counts

Before presenting our method, we review KN smoothing on integer counts as applied to language models, although, as we will demonstrate in Section 7, KN smoothing is applicable to other tasks as well.

2.1 Maximum likelihood estimation

Let $\mathbf{u}w$ stand for an n-gram, where $\mathbf{u}$ stands for the $(n-1)$ context words and w, the predicted word. Let $c(\mathbf{u}w)$ be the number of occurrences of $\mathbf{u}w$. We use a bullet ($\bullet$) to indicate summation over words, that is, $c(\mathbf{u}\bullet) = \sum_w c(\mathbf{u}w)$. Under maximum-likelihood estimation (MLE), we max-

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 765–774,
Baltimore, Maryland, USA, June 23-25 2014.

imize

$$L = \sum_{\mathbf{u}w} c(\mathbf{u}w) \log p(w \mid \mathbf{u}),$$

obtaining the solution

$$p_{\text{mle}}(w \mid \mathbf{u}) = \frac{c(\mathbf{u}w)}{c(\mathbf{u}\bullet)}. \tag{1}$$

2.2 Absolute discounting

Absolute discounting (Ney et al., 1994) – on which KN smoothing is based – tries to generalize better to unseen data by subtracting a *discount* from each seen n-gram's count and distributing the subtracted discounts to unseen n-grams. For now, we assume that the discount is a constant D, so that the smoothed counts are

$$\tilde{c}(\mathbf{u}w) = \begin{cases} c(\mathbf{u}w) - D & \text{if } c(\mathbf{u}w) > 0 \\ n_{1+}(\mathbf{u}\bullet) D q_{\mathbf{u}}(w) & \text{otherwise} \end{cases}$$

where $n_{1+}(\mathbf{u}\bullet) = |\{w \mid c(\mathbf{u}w) > 0\}|$ is the number of word types observed after context $\mathbf{u}$, and $q_{\mathbf{u}}(w)$ specifies how to distribute the subtracted discounts among unseen n-gram types. Maximizing the likelihood of the smoothed counts $\tilde{c}$, we get

$$p(w \mid \mathbf{u}) = \begin{cases} \dfrac{c(\mathbf{u}w) - D}{c(\mathbf{u}\bullet)} & \text{if } c(\mathbf{u}w) > 0 \\ \dfrac{n_{1+}(\mathbf{u}\bullet) D q_{\mathbf{u}}(w)}{c(\mathbf{u}\bullet)} & \text{otherwise.} \end{cases} \tag{2}$$

How to choose D and $q_{\mathbf{u}}(w)$ are described in the next two sections.

2.3 Estimating D by leaving-one-out

The discount D can be chosen by various means; in absolute discounting, it is chosen by the method of *leaving one out*. Given N training instances, we form the probability of each instance under the MLE using the other $(N-1)$ instances as training data; then we maximize the log-likelihood of all those instances. The probability of an n-gram token $\mathbf{u}w$ using the other tokens as training data is

$$p_{\text{loo}}(w \mid \mathbf{u}) = \begin{cases} \dfrac{c(\mathbf{u}w) - 1 - D}{c(\mathbf{u}\bullet) - 1} & c(\mathbf{u}w) > 1 \\ \dfrac{(n_{1+}(\mathbf{u}\bullet) - 1) D q_{\mathbf{u}}(w)}{c(\mathbf{u}\bullet) - 1} & c(\mathbf{u}w) = 1. \end{cases}$$

We want to find the D that maximizes the leaving-one-out log-likelihood

$$\begin{aligned} L_{\text{loo}} &= \sum_{\mathbf{u}w} c(\mathbf{u}w) \log p_{\text{loo}}(w \mid \mathbf{u}) \\ &= \sum_{\mathbf{u}w \mid c(\mathbf{u}w) > 1} c(\mathbf{u}w) \log \frac{c(\mathbf{u}w) - 1 - D}{c(\mathbf{u}\bullet) - 1} \\ &\quad + \sum_{\mathbf{u}w \mid c(\mathbf{u}w) = 1} \log \frac{(n_{1+}(\mathbf{u}\bullet) - 1) D q_{\mathbf{u}}(w)}{c(\mathbf{u}\bullet) - 1} \\ &= \sum_{r>1} r n_r \log(r - 1 - D) + n_1 \log D + C, \end{aligned} \tag{3}$$

where $n_r = |\{\mathbf{u}w \mid c(\mathbf{u}w) = r\}|$ is the number of n-gram types appearing r times, and C is a constant not depending on D. Setting the partial derivative with respect to D to zero, we have

$$\begin{aligned} \frac{\partial L_{\text{loo}}}{\partial D} &= -\sum_{r>1} \frac{r n_r}{r - 1 - D} + \frac{n_1}{D} \\ \frac{n_1}{D} &= \sum_{r>1} \frac{r n_r}{r - 1 - D} \geq \frac{2 n_2}{1 - D}. \end{aligned}$$

Solving for D, we have

$$D \leq \frac{n_1}{n_1 + 2 n_2}. \tag{4}$$

Theoretically, we can use iterative methods to optimize D. But in practice, setting D to this upper bound is effective and simple (Ney et al., 1994; Chen and Goodman, 1999).

2.4 Estimating the lower-order distribution

Finally, $q_{\mathbf{u}}(w)$ is defined to be proportional to an $(n-1)$-gram model $p'(w \mid \mathbf{u}')$, where $\mathbf{u}'$ is the $(n-2)$-gram suffix of $\mathbf{u}$. That is,

$$q_{\mathbf{u}}(w) = \gamma(\mathbf{u}) p'(w \mid \mathbf{u}'),$$

where $\gamma(\mathbf{u})$ is an auxiliary function chosen to make the distribution $p(w \mid \mathbf{u})$ in (2) sum to one.

Absolute discounting chooses $p'(w \mid \mathbf{u}')$ to be the maximum-likelihood unigram distribution; under KN smoothing (Kneser and Ney, 1995), it is chosen to make p in (2) satisfy the following constraint for all $(n-1)$-grams $\mathbf{u}'w$:

$$p_{\text{mle}}(\mathbf{u}'w) = \sum_{v} p(w \mid v\mathbf{u}') p_{\text{mle}}(v\mathbf{u}'). \tag{5}$$

Substituting in the definition of p_{mle} from (1) and p from (2) and canceling terms, we get

$$\begin{aligned} c(\mathbf{u}'w) &= \sum_{v \mid c(v\mathbf{u}'w) > 0} (c(v\mathbf{u}'w) - D) \\ &\quad + \sum_{v \mid c(v\mathbf{u}'w) = 0} n_{1+}(v\mathbf{u}'\bullet) D \gamma(v\mathbf{u}') p'(w \mid \mathbf{u}'). \end{aligned}$$

Solving for $p'(w \mid \mathbf{u}')$, we have

$$p'(w \mid \mathbf{u}') = \frac{\sum_{v|c(v\mathbf{u}'w)>0} 1}{\sum_{v|c(v\mathbf{u}'w)=0} n_{1+}(v\mathbf{u}'\bullet)\gamma(v\mathbf{u}')}.$$

Kneser and Ney assume the denominator is constant in w and renormalize to get an approximation

$$p'(w \mid \mathbf{u}') \approx \frac{n_{1+}(\bullet\mathbf{u}'w)}{n_{1+}(\bullet\mathbf{u}'\bullet)}, \tag{6}$$

where

$$n_{1+}(\bullet\mathbf{u}'w) = |\{v \mid c(v\mathbf{u}'w) > 0\}|$$
$$n_{1+}(\bullet\mathbf{u}'\bullet) = \sum_w n_{1+}(\bullet\mathbf{u}'w).$$

3 Count distributions

The computation of D and p' above made use of n_r and n_{r+}, which presupposes integer counts. But in many applications, the counts are not integral, but fractional. How do we apply KN smoothing in such cases? In this section, we introduce *count distributions* as a way of circumventing this problem.

3.1 Definition

In the E step of EM, we compute a probability distribution (according to the current model) over all possible completions of the observed data, and the expected counts of all types, which may be fractional. However, note that in each completion of the data, the counts are integral. Although it does not make sense to compute n_r or n_{r+} on fractional counts, it does make sense to compute them on possible completions.

In other situations where fractional counts arise, we can still think of the counts as expectations under some distribution over possible "realizations" of the data. For example, if we assign a weight between zero and one to every instance in a corpus, we can interpret each instance's weight as the probability of that instance occurring or not, yielding a distribution over possible subsets of the data.

Let X be a random variable ranging over possible realizations of the data, and let $c_X(\mathbf{u}w)$ be the count of $\mathbf{u}w$ in realization X. The expectation $E[c_X(\mathbf{u}w)]$ is the familiar fractional expected count of $\mathbf{u}w$, but we can also compute the probabilities $p(c_X(\mathbf{u}w) = r)$ for any r. From now on, for brevity, we drop the subscript X and understand $c(\mathbf{u}w)$ to be a random variable depending on X. The $n_r(\mathbf{u}\bullet)$ and $n_{r+}(\mathbf{u}\bullet)$ and related quantities also become random variables depending on X.

For example, suppose that our data consists of the following bigrams, with their weights:

(a)	fat cat	0.3
(b)	fat cat	0.8
(c)	big dog	0.9

We can interpret this as a distribution over eight subsets (not all distinct), with probabilities:

$\emptyset$	$0.7 \cdot 0.2 \cdot 0.1 = 0.014$
{a}	$0.3 \cdot 0.2 \cdot 0.1 = 0.006$
{b}	$0.7 \cdot 0.8 \cdot 0.1 = 0.056$
{a, b}	$0.3 \cdot 0.8 \cdot 0.1 = 0.024$
{c}	$0.7 \cdot 0.2 \cdot 0.9 = 0.126$
{a, c}	$0.3 \cdot 0.2 \cdot 0.9 = 0.054$
{b, c}	$0.7 \cdot 0.8 \cdot 0.9 = 0.504$
{a, b, c}	$0.3 \cdot 0.8 \cdot 0.9 = 0.216$

Then the count distributions and the $E[n_r]$ are:

	$r = 1$	$r = 2$	$r > 0$
$p(c(\text{fat cat}) = r)$	0.62	0.24	0.86
$p(c(\text{big dog}) = r)$	0.9	0	0.9
$E[n_r]$	1.52	0.24	

3.2 Efficient computation

How to compute these probabilities and expectations depends in general on the structure of the model. If we assume that all occurrences of $\mathbf{u}w$ are independent (although in fact they are not always), the computation is very easy. If there are k occurrences of $\mathbf{u}w$, each occurring with probability p_i, the count $c(\mathbf{u}w)$ is distributed according to the *Poisson-binomial distribution* (Hong, 2013). The expected count $E[c(\mathbf{u}w)]$ is just $\sum_i p_i$, and the distribution of $c(\mathbf{u}w)$ can be computed as follows:

$$p(c(\mathbf{u}w) = r) = s(k, r)$$

where $s(k, r)$ is defined by the recurrence

$$s(k, r) = \begin{cases} s(k-1, r)(1 - p_k) & \\ \quad + s(k-1, r-1)p_k & \text{if } 0 \le r \le k \\ 1 & \text{if } k = r = 0 \\ 0 & \text{otherwise.} \end{cases}$$

We can also compute

$$p(c(\mathbf{u}w) \ge r) = \max\left\{s(m, r), 1 - \sum_{r'<r} s(m, r')\right\},$$

the floor operation being needed to protect against rounding errors, and we can compute

$$E[n_r(\mathbf{u}\bullet)] = \sum_w p(c(\mathbf{u}w) = r)$$
$$E[n_{r+}(\mathbf{u}\bullet)] = \sum_w p(c(\mathbf{u}w) \ge r).$$

Since, as we shall see, we only need to compute these quantities up to a small value of r (2 or 4), this takes time linear in k.

4 Smoothing on count distributions

We are now ready to describe how to apply KN smoothing to count distributions. Below, we recapitulate the derivation of KN smoothing presented in Section 2, using the expected log-likelihood in place of the log-likelihood and applying KN smoothing to each possible realization of the data.

4.1 Maximum likelihood estimation

The MLE objective function is the expected log-likelihood,

$$\begin{aligned} E[L] &= E\left[\sum_{\mathbf{u}w} c(\mathbf{u}w) \log p(w \mid \mathbf{u})\right] \\ &= \sum_{\mathbf{u}w} E[c(\mathbf{u}w)] \log p(w \mid \mathbf{u}) \end{aligned}$$

whose maximum is

$$p_{\text{mle}}(w \mid \mathbf{u}) = \frac{E[c(\mathbf{u}w)]}{E[c(\mathbf{u}\bullet)]}. \tag{7}$$

4.2 Absolute discounting

If we apply absolute discounting to every realization of the data, the expected smoothed counts are

$$\begin{aligned} E[\tilde{c}(\mathbf{u}w)] &= \sum_{r>0} p(c(\mathbf{u}w) = r)(r - D) \\ &\quad + p(c(\mathbf{u}w) = 0) E[n_{1+}(\mathbf{u}\bullet)] D q_{\mathbf{u}}(w) \\ &= E[c(\mathbf{u}w)] - p(c(\mathbf{u}w) > 0) D \\ &\quad + p(c(\mathbf{u}w) = 0) E[n_{1+}(\mathbf{u}\bullet)] D q_{\mathbf{u}}(w) \end{aligned} \tag{8}$$

where, to be precise, the expectation $E[n_{1+}(\mathbf{u}\bullet)]$ should be conditioned on $c(\mathbf{u}w) = 0$; in practice, it seems safe to ignore this. The MLE is then

$$p(w \mid \mathbf{u}) = \frac{E[\tilde{c}(\mathbf{u}w)]}{E[\tilde{c}(\mathbf{u}\bullet)]}. \tag{9}$$

4.3 Estimating D by leaving-one-out

It would not be clear how to perform leaving-one-out estimation on fractional counts, but here we have a distribution over realizations of the data, each with integral counts, and we can perform leaving-one-out estimation on each of these. In other words, our goal is to find the D that maximizes the *expected* leaving-one-out log-likelihood, which is just the expected value of (3):

$$\begin{aligned} E[L_{\text{loo}}] &= E\Big[n_1 \log D + \sum_{r>1} r n_r \log(r - 1 - D) + C\Big] \\ &= E[n_1] \log D \\ &\quad + \sum_{r>1} r E[n_r] \log(r - 1 - D) + C, \end{aligned}$$

where C is a constant not depending on D. We have made the assumption that the n_r are independent.

By exactly the same reasoning as before, we obtain an upper bound for D:

$$D \leq \frac{E[n_1]}{E[n_1] + 2E[n_2]}. \tag{10}$$

In our example above, $D = \frac{1.52}{1.52+2\cdot 0.24} = 0.76$.

4.4 Estimating the lower-order distribution

We again require p' to satisfy the marginal constraint (5). Substituting in (7) and solving for p' as in Section 2.4, we obtain the solution

$$p'(w \mid \mathbf{u}') = \frac{E[n_{1+}(\bullet \mathbf{u}' w)]}{E[n_{1+}(\bullet \mathbf{u}' \bullet)]}. \tag{11}$$

For the example above, the estimates for the unigram model $p'(w)$ are

$$\begin{aligned} p'(\text{cat}) &= \tfrac{0.86}{0.86+0.9} \approx 0.489 \\ p'(\text{dog}) &= \tfrac{0.9}{0.86+0.9} \approx 0.511. \end{aligned}$$

4.5 Extensions

Chen and Goodman (1999) introduce three extensions to Kneser-Ney smoothing which are now standard. For our experiments, we used all three, for both integral counts and count distributions.

4.5.1 Interpolation

In interpolated KN smoothing, the subtracted discounts are redistributed not only among unseen events but also seen events. That is,

$$\tilde{c}(\mathbf{u}w) = \max\{0, c(\mathbf{u}w) - D\} + n_{1+}(\mathbf{u}\bullet) D p'(w \mid \mathbf{u}').$$

In this case, $\gamma(\mathbf{u})$ is always equal to one, so that $q_{\mathbf{u}}(w) = p'(w \mid \mathbf{u}')$. (Also note that (6) becomes an exact solution to the marginal constraint.) Theoretically, this requires us to derive a new estimate for D. However, as this is not trivial, nearly all implementations simply use the original estimate (4).

On count distributions, the smoothed counts become

$$\begin{aligned} E[\tilde{c}(\mathbf{u}w)] &= E[c(\mathbf{u}w)] - p(c(\mathbf{u}w) > 0) D \\ &\quad + E[n_{1+}(\mathbf{u}\bullet)] D p'(w \mid \mathbf{u}'). \end{aligned} \tag{12}$$

In our example, the smoothed counts are:

$\mathbf{u}w$	$E[\tilde{c}]$
fat cat	$1.1 - 0.86 \cdot 0.76 + 0.86 \cdot 0.76 \cdot 0.489 \approx 0.766$
fat dog	$0 \quad - 0 \cdot 0.76 \quad + 0.86 \cdot 0.76 \cdot 0.511 \approx 0.334$
big cat	$0 \quad - 0 \cdot 0.76 \quad + 0.9 \cdot 0.76 \cdot 0.489 \approx 0.334$
big dog	$0.9 - 0.9 \cdot 0.76 \quad + 0.9 \cdot 0.76 \cdot 0.511 \approx 0.566$

which give the smoothed probability estimates:

$$p(\text{cat} \mid \text{fat}) = \tfrac{0.766}{0.766+0.334} = 0.696$$
$$p(\text{dog} \mid \text{fat}) = \tfrac{0.334}{0.766+0.334} = 0.304$$
$$p(\text{dog} \mid \text{big}) = \tfrac{0.334}{0.334+0.556} = 0.371$$
$$p(\text{cat} \mid \text{big}) = \tfrac{0.556}{0.334+0.556} = 0.629.$$

4.5.2 Modified discounts

Modified KN smoothing uses a different discount D_r for each count $r < 3$, and a discount D_{3+} for counts $r \geq 3$. On count distributions, a similar argument to the above leads to the estimates:

$$\begin{aligned} D_1 &\leq 1 - 2Y\frac{E[n_2]}{E[n_1]} \\ D_2 &\leq 2 - 3Y\frac{E[n_3]}{E[n_2]} \\ D_{3+} &\approx 3 - 4Y\frac{E[n_4]}{E[n_3]} \\ Y &= \frac{E[n_1]}{E[n_1] + 2E[n_2]}. \end{aligned} \tag{13}$$

One side-effect of this change is that (6) is no longer the correct solution to the marginal constraint (Teh, 2006; Sundermeyer et al., 2011). Although this problem can be fixed, standard implementations simply use (6).

4.5.3 Recursive smoothing

In the original KN method, the lower-order model p' was estimated using (6); recursive KN smoothing applies KN smoothing to p'. To do this, we need to reconstruct counts whose MLE is (6). On integral counts, this is simple: we generate, for each n-gram type $v\mathbf{u}'w$, an $(n-1)$-gram token $\mathbf{u}'w$, for a total of $n_{1+}(\bullet\mathbf{u}'w)$ tokens. We then apply KN smoothing to these counts.

Analogously, on count distributions, for each n-gram type $v\mathbf{u}'w$, we generate an $(n-1)$-gram token $\mathbf{u}'w$ with probability $p(c(v\mathbf{u}'w) > 0)$. Since

$$E[c(\mathbf{u}'w)] = \sum_v p(c(v\mathbf{u}'w) > 0) = E[n_{1+}(\bullet\mathbf{u}'w)],$$

this has (11) as its MLE and therefore satisfies the marginal constraint. We then apply expected KN smoothing to these count distributions.

For the example above, the count distributions used for the unigram distribution would be:

	$r=0$	$r=1$
$p(c(\text{cat}) = r)$	0.14	0.86
$p(c(\text{dog}) = r)$	0.1	0.9

4.6 Summary

In summary, to perform expected KN smoothing (either the original version or Chen and Goodman's modified version), we perform the steps listed below:

	orig.	mod.
compute count distributions	§3.2	
estimate discount D	(10)	(13)
estimate lower-order model p'	(11)	§4.5.3
compute smoothed counts $\tilde{c}$	(8)	(12)
compute probabilities p	(9)	

The computational complexity of expected KN is almost identical to KN on integral counts. The main addition is computing and storing the count distributions. Using the dynamic program in Section 3.2, computing the distributions for each r is linear in the number of n-gram types, and we only need to compute the distributions up to $r = 2$ (or $r = 4$ for modified KN), and store them for $r = 0$ (or up to $r = 2$ for modified KN).

5 Related Work

Witten-Bell (WB) smoothing is somewhat easier than KN to adapt to fractional counts. The SRILM toolkit (Stolcke, 2002) implements a method which we call *fractional WB*:

$$p(w \mid \mathbf{u}) = \lambda(\mathbf{u})p_{\text{mle}}(w \mid \mathbf{u}) + (1 - \lambda(\mathbf{u}))p'(w \mid \mathbf{u}')$$
$$\lambda(\mathbf{u}) = \frac{E[c(\mathbf{u})]}{E[c(\mathbf{u})] + n_{1+}(\mathbf{u}\bullet)},$$

where $n_{1+}(\mathbf{u}\bullet)$ is the number of word types observed after context $\mathbf{u}$, computed by ignoring all weights. This method, although simple, inconsistently uses weights for counting tokens but not types. Moreover, as we will see below, it does not perform as well as expected KN.

The only previous adaptation of KN smoothing to fractional counts that we are aware of is that of Tam and Schultz (2008) and Bisani and Ney (2008), called *fractional KN*. This method subtracts D directly from the fractional counts, zeroing out counts that are smaller than D. The discount D must be set by minimizing an error metric on held-out data using a line search (Tam, p. c.) or Powell's method (Bisani and Ney, 2008), requiring repeated estimation and evaluation of the language model. By contrast, we choose D by leaving-one-out. Like KN on integral counts, our method has a closed-form approximation and requires neither held-out data nor trial and error.

6 Language model adaptation

N-gram language models are widely used in applications like machine translation and speech recognition to select fluent output sentences. Although they can easily be trained on large amounts of data, in order to perform well, they should be trained on data containing the right kind of language. For example, if we want to model spoken language, then we should train on spoken language data. If we train on newswire, then a spoken sentence might be regarded as ill-formed, because the distribution of sentences in these two domains are very different. In practice, we often have limited-size training data from a specific domain, and large amounts of data consisting of language from a variety of domains (we call this *general-domain* data). How can we utilize the large general-domain dataset to help us train a model on a specific domain?

Many methods (Lin et al., 1997; Gao et al., 2002; Klakow, 2000; Moore and Lewis, 2010; Axelrod et al., 2011) rank sentences in the general-domain data according to their similarity to the in-domain data and select only those with score higher than some threshold. Such methods are effective and widely used. However, sometimes it is hard to say whether a sentence is totally in-domain or out-of-domain; for example, quoted speech in a news report might be partly in-domain if the domain of interest is broadcast conversation. Here, we propose to assign each sentence a probability to indicate how likely it is to belong to the domain of interest, and train a language model using expected KN smoothing. We show that this approach yields models with much better perplexity than the original sentence-selection approach.

6.1 Method

One of the most widely used sentence-selection approaches is that of Moore and Lewis (2010). They first train two language models, p_{in} on a set of in-domain data, and p_{out} on a set of general-domain data. Then each sentence $\mathbf{w}$ is assigned a score

$$H(\mathbf{w}) = \frac{\log(p_{\text{in}}(\mathbf{w})) - \log(p_{\text{out}}(\mathbf{w}))}{|\mathbf{w}|}.$$

They set a threshold on the score to select a subset.

We adapt this approach as follows. After selection, for each sentence in the subset, we use a sigmoid function to map the scores into probabilities:

$$p(\mathbf{w} \text{ is in-domain}) = \frac{1}{1 + \exp(-H(\mathbf{w}))}.$$

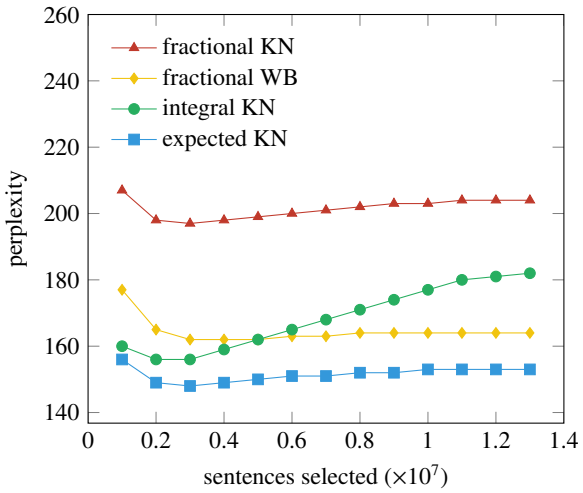

Figure 1: On the language model adaptation task, expected KN outperforms all other methods across all sizes of selected subsets. Integral KN is applied to unweighted instances, while fractional WB, fractional KN and expected KN are applied to weighted instances.

Then we use the weighted subset to train a language model with expected KN smoothing.

6.2 Experiments

Moore and Lewis (2010) test their method by partitioning the in-domain data into training data and test data, both of which are disjoint from the general-domain data. They use the in-domain training data to select a subset of the general-domain data, build a language model on the selected subset, and evaluate its perplexity on the in-domain test data. Here, we follow this experimental framework and compare Moore and Lewis's unweighted method to our weighted method.

For our experiments, we used all the English data allowed for the BOLT Phase 1 Chinese-English evaluation. We took 60k sentences (1.7M words) of web forum data as in-domain data, further subdividing it into 54k sentences (1.5M words) for training, 3k sentences (100k words) for testing, and 3k sentences (100k words) for future use. The remaining 12.7M sentences (268M words) we treated as general-domain data.

We trained trigram language models and compared expected KN smoothing against integral KN smoothing, fractional WB smoothing, and fractional KN smoothing, measuring perplexity across various subset sizes (Figure 1). For fractional KN, for each subset size, we optimized D to mini-

mize perplexity on the *test* set to give it the greatest possible advantage; nevertheless, it is clearly the worst performer. Expected KN consistently gives the best perplexity, and, at the optimal subset size, obtains better perplexity (148) than the other methods (156 for integral KN, 162 for fractional WB and 197 for fractional KN). Finally, we note that integral KN is very sensitive to the subset size, whereas expected KN and the other methods are more robust.

7 Word Alignment

In this section, we show how to apply expected KN to the IBM word alignment models (Brown et al., 1993). This illustrates both how to use expected KN inside EM and how to use it beyond language modeling. Of course, expected KN can be applied to other instances of EM besides word alignment.

7.1 Problem

Given a French sentence $\mathbf{f} = f_1 f_2 \cdots f_m$ and its English translation $\mathbf{e} = e_1 e_2 \cdots e_n$, an alignment $\mathbf{a}$ is a sequence $a_1, a_2, \ldots, a_m$, where a_i is the index of the English word which generates the French word f_i, or NULL. As is common, we assume that each French word can only be generated from one English word or from NULL (Brown et al., 1993; Och and Ney, 2003; Vogel et al., 1996).

The IBM models and related models define probability distributions $p(\mathbf{a}, \mathbf{f} \mid \mathbf{e}, \theta)$, which model how likely a French sentence $\mathbf{f}$ is to be generated from an English sentence $\mathbf{e}$ with word alignment $\mathbf{a}$. Different models parameterize this probability distribution in different ways. For example, Model 1 only models the lexical translation probabilities:

$$p(\mathbf{a}, \mathbf{f} \mid \mathbf{e}, \theta) \propto \prod_{j=1}^{m} p(f_j \mid e_{a_j}).$$

Models 2–5 and the HMM model introduce additional components to model word order and fertility. All, however, have the lexical translation model $p(f_j \mid e_i)$ in common. It also contains most of the model's parameters and is where overfitting occurs most. Thus, here we only apply KN smoothing to the lexical translation probabilities, leaving the other model components for future work.

7.2 Method

The $\mathbf{f}$ and $\mathbf{e}$ are observed, while $\mathbf{a}$ is a latent variable. Normally, in the E step, we collect expected counts $E[c(e, f)]$ for each e and f. Then, in the M step, we find the parameter values that maximize their likelihood. However, MLE is prone to overfitting, one symptom of which is the "garbage collection" phenomenon where a rare English word is wrongly aligned to many French words.

To reduce overfitting, we use expected KN smoothing during the M step. That is, during the E step, we calculate the distribution of $c(e, f)$ for each e and f, and during the M step, we train a language model on bigrams ef using expected KN smoothing (that is, with $\mathbf{u} = e$ and $w = f$). This gives a smoothed probability estimate for $p(f \mid e)$.

One question that arises is: what distribution to use as the lower-order distribution p'? Following common practice in language modeling, we use the unigram distribution $p(f)$ as the lower-order distribution. We could also use the uniform distribution over word types, or a distribution that assigns zero probability to all known word types. (The latter case is equivalent to a backoff language model, where, since all bigrams are known, the lower-order model is never used.) Below, we compare the performance of all three choices.

7.3 Alignment experiments

We modified GIZA++ (Och and Ney, 2003) to perform expected KN smoothing as described above. Smoothing is enabled or disabled with a command-line switch, making direct comparisons simple. Our implementation is publicly available as open-source software.[1]

We carried out experiments on two language pairs: Arabic to English and Czech to English. For Arabic-English, we used 5.4+4.3 million words of parallel text from the NIST 2009 constrained task,[2] and 346 word-aligned sentence pairs (LDC2006E86) for evaluation. For Czech-English, we used all 2.0+2.2 million words of training data from the WMT 2009 shared task, and 515 word-aligned sentence pairs (Bojar and Prokopová, 2006) for evaluation.

For all methods, we used five iterations of IBM Models 1, 2, and HMM, followed by three iterations of IBM Models 3 and 4. We applied expected KN smoothing to all iterations of all models. We aligned in both the foreign-to-English

Smoothing	p'	Alignment F1		B	
		Ara-Eng	Cze-Eng	Ara-Eng	Cze-Eng
none (baseline)	–	66.5	67.2	37.0	16.6
variational Bayes	uniform	65.7	65.5	36.5	16.6
fractional WB	unigram	60.1	63.7	–	–
	uniform	60.8	66.5	37.8	16.9
	zero	60.8	65.2	–	–
fractional KN	unigram	67.7	70.2	37.2	16.5
expected KN	unigram	**69.7**	**71.9**	**38.2**	**17.0**
	uniform	69.4	71.3	–	–
	zero	69.2	**71.9**	–	–

Table 1: Expected KN (interpolating with the unigram distribution) consistently outperforms all other methods. For variational Bayes, we followed Riley and Gildea (2012) in setting α to zero (so that the choice of p' is irrelevant). For fractional KN, we chose D to maximize F1 (see Figure 2).

and English-to-foreign directions and then used the *grow-diag-final* method to symmetrize them (Koehn et al., 2003), and evaluated the alignments using F-measure against gold word alignments.

As shown in Table 1, for KN smoothing, interpolation with the unigram distribution performs the best, while for WB smoothing, interestingly, interpolation with the uniform distribution performs the best. The difference can be explained by the way the two smoothing methods estimate p'. Consider again a training example with a word e that occurs nowhere else in the training data. In WB smoothing, $p'(f)$ is the empirical unigram distribution. If $\mathbf{f}$ contains a word that is much more frequent than the correct translation of e, then smoothing may actually encourage the model to wrongly align e with the frequent word. This is much less of a problem in KN smoothing, where p' is estimated from bigram types rather than bigram tokens.

We also compared with variational Bayes (Riley and Gildea, 2012) and fractional KN. Overall, expected KN performs the best. Variational Bayes is not consistent across different language pairs. While fractional KN does beat the baseline for both language pairs, the value of D, which we optimized D to maximize F1, is not consistent across language pairs: as shown in Figure 2, on Arabic-English, a smaller D is better, while for Czech-English, a larger D is better. By contrast, expected KN uses a closed-form expression for D that outperforms the best performance of fractional KN.

Table 2 shows that, if we apply expected KN smoothing to only selected stages of training, adding smoothing always brings an improvement,

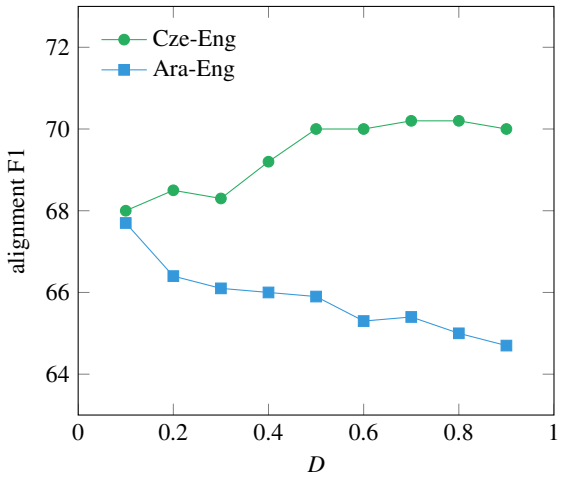

Figure 2: Alignment F1 vs. D of fractional KN smoothing for word alignment.

Smoothed models					Alignment F1	
1	2	H	3	4	Ara-Eng	Cze-Eng
○	○	○	○	○	66.5	67.2
●	○	○	○	○	67.3	67.9
○	●	○	○	○	68.0	68.7
○	○	●	○	○	68.6	70.0
○	○	○	●	○	66.9	68.4
○	○	○	○	●	67.0	68.6
●	●	●	●	●	**69.7**	**71.9**

Table 2: Smoothing more stages of training makes alignment accuracy go up. For each row, we smoothed all iterations of the models indicated. Key: H = HMM model; ● = smoothing enabled; ○ = smoothing disabled.

with the best setting being to smooth all stages. This shows that expected KN smoothing is consistently effective. It is also interesting to note that smoothing is less helpful for the fertility-based Models 3 and 4. Whether this is because modeling fertility makes them less susceptible to "garbage collection," or the way they approximate the E step makes them less amenable to smoothing, or another reason, would require further investigation.

7.4 Translation experiments

Finally, we ran MT experiments to see whether the improved alignments also lead to improved translations. We used the same training data as before. For the Arabic-English tasks, we used the NIST 2008 test set as development data and the NIST 2009 test set as test data; for the Czech-English tasks, we used the WMT 2008 test set as development data and the WMT 2009 test set as test data.

We used the Moses toolkit (Koehn et al., 2007) to build MT systems using various alignments (for expected KN, we used the one interpolated with the unigram distribution, and for fractional WB, we used the one interpolated with the uniform distribution). We used a trigram language model trained on Gigaword (AFP, AP Worldstream, CNA, and Xinhua portions), and minimum error-rate training (Och, 2003) to tune the feature weights.

Table 1 shows that, although the relationship between alignment F1 and B is not very consistent, expected KN smoothing achieves the best B among all these methods and is significantly better than the baseline ($p < 0.01$).

8 Conclusion

For a long time, and as noted by many authors, the usage of KN smoothing has been limited by its restriction to integer counts. In this paper, we addressed this issue by treating fractional counts as distributions over integer counts and generalizing KN smoothing to operate on these distributions. This generalization makes KN smoothing, widely considered to be the best-performing smoothing method, applicable to many new areas. We have demonstrated the effectiveness of our method in two such areas and showed significant improvements in both.

Robust Entity Clustering via Phylogenetic Inference

Nicholas Andrews and **Jason Eisner** and **Mark Dredze**

Abstract

Entity clustering must determine when two named-entity mentions refer to the same entity. Typical approaches use a pipeline architecture that clusters the mentions using fixed or learned measures of name and context similarity. In this paper, we propose a model for cross-document coreference resolution that achieves robustness by learning similarity from unlabeled data. The generative process assumes that each entity mention arises from copying and optionally mutating an earlier name from a similar context. Clustering the mentions into entities depends on recovering this copying tree jointly with estimating models of the mutation process and parent selection process. We present a block Gibbs sampler for posterior inference and an empirical evaluation on several datasets.

1 Introduction

Variation poses a serious challenge for determining who or what a name refers to. For instance, Wikipedia contains more than 100 variations of the name Barack Obama as redirects to the U.S. President article, including:

President Obama	Barack H. Obama, Jr.
Barak Obamba	Barry Soetoro

To relate different names, one solution is to use specifically tailored measures of name similarity such as Jaro-Winkler similarity (Winkler, 1999; Cohen et al., 2003). This approach is brittle, however, and fails to adapt to the test data. Another option is to train a model like stochastic edit distance from known pairs of similar names (Ristad and Yianilos, 1998; Green et al., 2012), but this requires supervised data in the test domain.

Even the best model of name similarity is not enough by itself, since two names that are similar—even identical—do not *necessarily* corefer. Document context is needed to determine whether they may be talking about two different people.

In this paper, we propose a method for jointly (1) learning similarity between names and (2) clustering name mentions into entities, the two major components of cross-document coreference resolution systems (Baron and Freedman, 2008; Finin et al., 2009; Rao et al., 2010; Singh et al., 2011; Lee et al., 2012; Green et al., 2012). Our model is an evolutionary generative process based on the name variation model of Andrews et al. (2012), which stipulates that names are often copied from previously generated names, perhaps with mutation (spelling edits). This can deduce that rather than being names for different entities, Barak Obamba and Barock obama more likely arose from the frequent name Barack Obama as a common ancestor, which accounts for most of their letters. This can also relate seemingly dissimilar names via multiple steps in the generative process:

Taylor Swift → T-Swift → T-Swizzle

Our model learns without supervision that these all refer to the the same entity. Such creative spellings are especially common on Twitter and other social media; we give more examples of coreferents learned by our model in Section 8.4.

Our primary contributions are improvements on Andrews et al. (2012) for the entity clustering task. Their inference procedure only clustered types (distinct names) rather than tokens (mentions in context), and relied on expensive matrix inversions for learning. Our novel approach features:

- §4.1 A topical model of which entities from previously written text an author tends to mention from previously written text.
- §4.2 A name mutation model that is sensitive to features of the input and output characters and takes a reader's comprehension into account.
- §5 A scalable Markov chain Monte Carlo sampler used in training and inference.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 775–785,
Baltimore, Maryland, USA, June 23-25 2014.

§7 A minimum Bayes risk decoding procedure to pick an output clustering. The procedure is applicable to any model capable of producing a posterior over coreference decisions.

We evaluate our approach by comparing to several baselines on datasets from three different genres: Twitter, newswire, and blogs.

2 Overview and Related Work

Cross-document coreference resolution (CDCR) was first introduced by Bagga and Baldwin (1998b). Most approaches since then are based on the intuitions that coreferent names tend to have "similar" spellings and tend to appear in "similar" contexts. The distinguishing feature of our system is that both notions of similarity are learned together without supervision.

We adopt a "phylogenetic" generative model of coreference. The basic insight is that coreference is created when an author thinks of an entity that was mentioned earlier in a similar context, and mentions it again in a similar way. The author may alter the name mention string when copying it, but both names refer to the same entity. Either name may later be copied further, leading to an evolutionary tree of mentions—a phylogeny. Phylogenetic models are new to information extraction. In computational historical linguistics, Bouchard-Côté et al. (2013) have also modeled the mutation of strings along the edges of a phylogeny; but for them the phylogeny is observed and most mentions are not, while we observe the mentions only.

To apply our model to the CDCR task, we observe that the probability that two name mentions are coreferent is the probability that they arose from a common ancestor in the phylogeny. So we design a Monte Carlo sampler to reconstruct likely phylogenies. A phylogeny must explain every observed name. While our model is capable of generating each name independently, *a phylogeny will generally achieve higher probability if it explains similar names as being similar by mutation (rather than by coincidence)*. Thus, our sampled phylogenies tend to make similar names coreferent—especially long or unusual names that would be expensive to generate repeatedly, and especially in contexts that are topically similar and therefore have a higher prior probability of coreference.

For learning, we iteratively adjust our model's parameters to better explain our samples. That is, we do unsupervised training via Monte Carlo EM.

What is learned? An important component of a CDCR system is its model of name similarity (Winkler, 1999; Porter and Winkler, 1997), which is often fixed up front. This role is played in our system by the name mutation model, which we take to be a variant of stochastic edit distance (Ristad and Yianilos, 1996). Rather than fixing its parameters before we begin CDCR, we *learn* them (without supervision) as part of CDCR, by training from samples of reconstructed phylogenies.

Name similarity is also an important component of *within*-document coreference resolution, and efforts in that area bear resemblance to our approach. Haghighi and Klein (2010) describe an "entity-centered" model where a distance-dependent Chinese restaurant process is used to pick previous coreferent mentions *within* a document. Similarly, Durrett and Klein (2013) learn a mention similarity model based on labeled data. Our *cross*-document setting has no observed mention ordering and no observed entities: we must sum over all possibilities, a challenging inference problem.

The second major component of CDCR is context-based disambiguation of similar or identical names that refer to the same entity. Like Kozareva and Ravi (2011) and Green et al. (2012) we use topics as the contexts, but learn mention topics *jointly* with other model parameters.

3 Generative Model of Coreference

Let $\boldsymbol{x} = (x_1, \ldots, x_N)$ denote an ordered sequence of distinct named-entity mentions in documents $\boldsymbol{d} = (d_1, \ldots, d_D)$. We assume that each document has a (single) known language, and that its mentions and their types have been identified by a named-entity recognizer. We use the object-oriented notation $x.v$ for attribute v of mention x.

Our model generates an ordered sequence $\boldsymbol{x}$ although we do not observe its order. Thus each mention x has *latent* position $x.i$ (e.g., $x_{729}.i = 729$). The entire corpus, including these entities, is generated according to standard topic model assumptions; we first generate a topic distribution for a document, then sample topics and words for the document (Blei et al., 2003). However, any topic may generate an entity type, e.g. PERSON, which is then replaced by a specific name: when PERSON is generated, the model chooses a *previous* mention of any person and copies it, perhaps mutating its name.[1] Alternatively, the model may manufacture

[1] We make the closed-world assumption that the author is

a name for a new person, though the name itself may not be new.

If all previous *mentions* were equally likely, this would be a Chinese Restaurant Process (CRP) in which frequently mentioned *entities* are more likely to be mentioned again ("the rich get richer"). We refine that idea by saying that the current topic, language, and document influence the choice of which previous mention to copy, similar to the distance-dependent CRP (Blei and Frazier, 2011).[2] This will help distinguish multiple John Smith entities if they tend to appear in different contexts.

Formally, each mention x is derived from a parent mention $x.p$ where $x.p.i < x.i$ (the parent came first), $x.e = x.p.e$ (same entity) and $x.n$ is a copy or mutation of $x.p.n$. In the special case where x is a first mention of $x.e$, $x.p$ is the special symbol $\diamondsuit$, $x.e$ is a newly allocated entity of some appropriate type, and the name $x.n$ is generated from scratch.

Our goal is to reconstruct mappings $\boldsymbol{p}, \boldsymbol{i}, \boldsymbol{z}$ that specify the latent properties of the mentions x. The mapping $\boldsymbol{p} : x \mapsto x.p$ forms a phylogenetic tree on the mentions, with root $\diamondsuit$. Each entity corresponds to a subtree that is rooted at some child of $\diamondsuit$. The mapping $\boldsymbol{i} : x \mapsto x.i$ gives an ordering consistent with that tree in the sense that $(\forall x) x.p.i < x.i$. Finally, the mapping $\boldsymbol{z} : x \mapsto x.z$ specifies, for each mention, the topic that generated it. While $\boldsymbol{i}$ and $\boldsymbol{z}$ are not necessary for creating coref clusters, they are needed to produce $\boldsymbol{p}$.

4 Detailed generative story

Given a few constants that are referenced in the main text, we assume that the corpus $\boldsymbol{d}$ was generated as follows.

First, for each topic $z = 1, \ldots K$ and each language ℓ, choose a multinomial $\boldsymbol{\beta}_{z\ell}$ over the word vocabulary, from a symmetric Dirichlet with concentration parameter η. Then set $m = 0$ (entity count), $i = 0$ (mention count), and for each document index $d = 1, \ldots, D$:

1. Choose the document's length L and language ℓ. (The distributions used to choose these are unimportant because these variables are always observed.)
2. Choose its topic distribution $\boldsymbol{\psi}_d$ from an asymmetric Dirichlet prior with parameters $\boldsymbol{m}$ (Wallach et al., 2009).[3]
3. For each token position $k = 1, \ldots, L$:
   (a) Choose a topic $z_{dk} \sim \boldsymbol{\psi}_d$.
   (b) Choose a word conditioned on the topic and language, $w_{dk} \sim \boldsymbol{\beta}_{z_{dk}\ell}$.
   (c) If w_{dk} is a named entity type (PERSON, PLACE, ORG, ...) rather than an ordinary word, then increment i and:
      i. create a new mention x with
      $x.e.t = w_{dk} \quad x.d = d \quad x.\ell = \ell$
      $x.i = i \quad x.z = z_{dk} \quad x.k = k$
      ii. Choose the parent $x.p$ from a distribution conditioned on the attributes just set (see §4.1).
      iii. If $x.p = \diamondsuit$, increment m and set $x.e =$ a new entity e_m. Else set $x.e = x.p.e$.
      iv. Choose $x.n$ from a distribution conditioned on $x.p.n$ and $x.\ell$ (see §4.2).

Notice that the tokens w_{dk} in document d are exchangeable: by collapsing out $\boldsymbol{\psi}_d$, we can regard them as having been generated from a CRP. Thus, for fixed values of the non-mention tokens and their topics, the probability of generating the mention sequence $\boldsymbol{x}$ is proportional to the product of the probabilities of the choices in step 3 at the positions dk where mentions were generated. These choices generate a topic $x.z$ (from the CRP for document d), a type $x.e.t$ (from $\beta_{x.z}$), a parent mention (from the distribution over previous mentions), and a name string (conditioned on the parent's name if any). §5 uses this fact to construct an MCMC sampler for the latent parts of $\boldsymbol{x}$.

4.1 Sub-model for parent selection

To select a parent for a mention x of type $t = x.e.t$, a simple model (as mentioned above) would be a CRP: each previous mention of the same type is selected with probability proportional to 1, and $\diamondsuit$ is

only aware of previous mentions *from our corpus*. This means that two mentions cannot be derived from a common ancestor outside our corpus. To mitigate this unrealistic assumption, we allow any ordering $\boldsymbol{x}$ of the observed mentions, not respecting document timestamps or forcing the mentions from a given document to be generated as a contiguous subsequence of $\boldsymbol{x}$.

[2] Unlike the ddCRP, our generative story is careful to prohibit derivational cycles: each mention is copied from a *previous* mention in the latent ordering. This is why our phylogeny is a *tree*, and why our sampler is more complex. Also unlike the ddCRP, we permit asymmetric "distances": if a certain topic or language likes to copy mentions from another, the compliment is not necessarily returned.

[3] Extension: This choice could depend on the language $d.\ell$.

selected with probability proportional to $\alpha_t > 0$. A larger choice of α_t results in smaller entity clusters, because it prefers to create new entities of type t rather than copying old ones.

We modify this story by re-weighting $\diamondsuit$ and previous mentions according to their relative suitability as the parent of x:

$$\Pr_{\boldsymbol{\phi}}(x.p \mid x) = \frac{\exp\left(\boldsymbol{\phi} \cdot \mathbf{f}(x.p, x)\right)}{Z(x)} \quad (1)$$

where $x.p$ ranges over $\diamondsuit$ and all previous mentions of the same type as x, that is, mentions p such that $p.i < x.i$ and $p.e.t = x.e.t$. The normalizing constant $Z(x) \stackrel{\text{def}}{=} \sum_p \exp\left(\boldsymbol{\phi} \cdot \mathbf{f}(x.p, x)\right)$ is chosen so that the probabilities sum to 1.

This is a conditional log-linear model parameterized by $\boldsymbol{\phi}$, where $\phi_k \sim \mathcal{N}(0, \sigma_k^2)$. The features $\mathbf{f}$ are extracted from the attributes of x and $x.p$. Our most important feature tests whether $x.p.z = x.z$. This binary feature has a high weight if authors mainly choose mentions from the same topic. To model which (other) topics tend to be selected, we also have a binary feature for each parent topic $x.p.z$ and each topic pair $(x.p.z, x.z)$.[4]

4.2 Sub-model for name mutation

Let x denote a mention with parent $p = x.p$. As in Andrews et al. (2012), its name $x.n$ is a stochastic transduction of its parent's name $p.n$. That is,

$$\Pr_{\boldsymbol{\theta}}(x.n \mid p.n) \quad (2)$$

is given by the probability that applying a random sequence of edits to the characters of $p.n$ would yield $x.n$. The contextual probabilities of different edits depend on learned parameters $\boldsymbol{\theta}$.

(2) is the total probability of *all* edit sequences that derive $x.n$ from $p.n$. It can be computed in time $O(|x.n| \cdot |p.n|)$ by dynamic programming.

The probability of a *single* edit sequence, which corresponds to a monotonic alignment of $x.n$ to $p.n$, is a product of individual edit probabilities of the form $\Pr_{\boldsymbol{\theta}}(\binom{a}{b} \mid \hat{a})$, which is conditioned on the next input character $\hat{a}$. The edit $\binom{a}{b}$ replaces input $a \in \{\epsilon, \hat{a}\}$ with output $b \in \{\epsilon\} \cup \Sigma$ (where ϵ is the empty string and Σ is the alphabet of language $x.\ell$). Insertions and deletions are the cases where respectively $a = \epsilon$ or $b = \epsilon$—we do not allow both at once. All other edits are substitutions. When $\hat{a}$ is the special end-of-string symbol $\#$, the only allowed edits are the insertion $\binom{\epsilon}{b}$ and the substitution $\binom{\#}{\#}$. We define the edit probability using a locally normalized log-linear model:

$$\Pr_{\boldsymbol{\theta}}(\binom{a}{b} \mid \hat{a}) = \frac{\exp(\boldsymbol{\theta} \cdot \mathbf{f}(\hat{a}, a, b))}{\sum_{a', b'} \exp(\boldsymbol{\theta} \cdot \mathbf{f}(\hat{a}, a', b'))} \quad (3)$$

We use a small set of simple feature functions $\mathbf{f}$, which consider conjunctions of the attributes of the characters $\hat{a}$ and b: character, character class (letter, digit, etc.), and case (upper vs. lower).

More generally, the probability (2) may also be conditioned on other variables such as on the languages $p.\ell$ and $x.\ell$—this leaves room for a transliteration model when $x.\ell \neq p.\ell$—and on the entity type $x.t$. The features in (3) may then depend on these variables as well.

Notice that we use a locally normalized probability for each edit. This enables faster and simpler training than the similar model of Dreyer et al. (2008), which uses a globally normalized probability for the whole edit sequence.

When $p = \diamondsuit$, we are generating a new name $x.n$. We use the same model, taking $\diamondsuit.n$ to be the empty string (but with $\#_\diamondsuit$ rather than $\#$ as the end-of-string symbol). This yields a feature-based unigram language model (whose character probabilities may differ from usual insertion probabilities because they see $\#_\diamondsuit$ as the lookahead character).

Pragmatics. We can optionally make the model more sophisticated. Authors tend to *avoid* names $x.n$ that readers would misinterpret (given the previously generated names). The edit model thinks that $\Pr_{\boldsymbol{\theta}}(\textsf{CIA} \mid \diamondsuit)$ is relatively high (because CIA is a short string) and so is $\Pr_{\boldsymbol{\theta}}(\textsf{CIA} \mid \textsf{Chuck's Ice Art})$. But in fact, if CIA has already been frequently used to refer to the Central Intelligence Agency, then an author is unlikely to use it for a different entity.

To model this pragmatic effect, we multiply our definition of $\Pr_{\boldsymbol{\theta}}(x.n \mid p.n)$ by an extra factor $\Pr(x.e \mid x)^\gamma$, where $\gamma \geq 0$ is the effect strength.[5] Here $\Pr(x.e \mid x)$ is the probability that a reader correctly identifies the entity $x.e$. We take this to be the probability that a reader who knows our sub-models would guess some parent

[4] Many other features could be added. In a multilingual setting, one would similarly want to model whether English authors select Arabic mentions. One could also imagine features that reward proximity in the generative order ($x.p.i \approx x.i$), local linguistic relationships (when $x.p.d = x.d$ and $x.p.k \approx x.k$), or social information flow (e.g., from mainstream media to Twitter). One could also make more specific versions of any feature by conjoining it with the entity type t.

[5] Currently we omit the step of renormalizing this deficient model. Our training procedure also ignores the extra factor.

having the correct entity (or $\diamondsuit$ if x is a first mention): $\sum_{p':p'.e=x.e} w(p', x) / \sum_{p'} w(p', x)$. Here p' ranges over mentions (including $\diamondsuit$) that precede x in the ordering $\boldsymbol{i}$, and $w(p', x)$—defined later in sec. 5.3—is proportional to the posterior probability that $x.p = p'$, given name $x.n$ and topic $x.z$.[6]

5 Inference by Block Gibbs Sampling

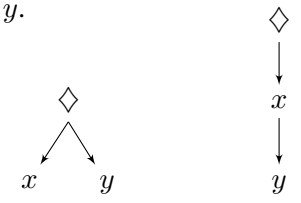
We use a block Gibbs sampler, which from an initial state $(\boldsymbol{p}_0, \boldsymbol{i}_0, \boldsymbol{z}_0)$ repeats these steps:

1. Sample the ordering $\boldsymbol{i}$ from its conditional distribution given all other variables.
2. Sample the topic vector $\boldsymbol{z}$ likewise.
3. Sample the phylogeny $\boldsymbol{p}$ likewise.
4. Output the current sample $s_t = (\boldsymbol{p}, \boldsymbol{i}, \boldsymbol{z})$.

It is difficult to draw exact samples at steps 1 and 2. Thus, we sample $\boldsymbol{i}$ or $\boldsymbol{z}$ from a simpler proposal distribution, but correct the discrepancy using the Independent Metropolis-Hastings (IMH) strategy: with an appropriate probability, reject the proposed new value and instead use another copy of the current value (Tierney, 1994).

5.1 Resampling the ordering i

We resample the ordering $\boldsymbol{i}$ of the mentions $\boldsymbol{x}$, conditioned on the other variables. The current phylogeny $\boldsymbol{p}$ already defines a partial order on $\boldsymbol{x}$, since each parent must precede its children. For instance, phylogeny (a) below requires $\diamondsuit \prec x$ and $\diamondsuit \prec y$. This partial order is compatible with 2 total orderings, $\diamondsuit \prec x \prec y$ and $\diamondsuit \prec y \prec x$. By contrast, phylogeny (b) requires the total ordering $\diamondsuit \prec x \prec y$.



We first sample an ordering $\boldsymbol{i}_\diamondsuit$ (the ordering of mentions with parent $\diamondsuit$, i.e. all mentions) *uniformly* at random from the set of orderings compatible with the current $\boldsymbol{p}$. (We provide details about this procedure in Appendix A.)[7] However, such orderings are not in fact equiprobable given the other variables—some orderings better explain why that phylogeny was chosen in the first place, according to our competitive parent selection model (§4.1). To correct for this bias using IMH, we accept the proposed ordering $\boldsymbol{i}_\diamondsuit$ with probability

$$a = \min\left(1, \frac{\Pr(\boldsymbol{p}, \boldsymbol{i}_\diamondsuit, \boldsymbol{z}, \boldsymbol{x} \mid \boldsymbol{\theta}, \boldsymbol{\phi})}{\Pr(\boldsymbol{p}, \boldsymbol{i}, \ \boldsymbol{z}, \boldsymbol{x} \mid \boldsymbol{\theta}, \boldsymbol{\phi})}\right) \quad (4)$$

where $\boldsymbol{i}$ is the current ordering. Otherwise we reject $\boldsymbol{i}_\diamondsuit$ and reuse $\boldsymbol{i}$ for the new sample.

5.2 Resampling the topics z

Each context word and each named entity is associated with a latent topic. The topics of *context words* are assumed exchangeable, and so we resample them using Gibbs sampling (Griffiths and Steyvers, 2004).

Unfortunately, this is prohibitively expensive for the (non-exchangeable) topics of the *named mentions* x. A Gibbs sampler would have to choose a new value for $x.z$ with probability proportional to the resulting joint probability of the full sample. This probability is expensive to evaluate because changing $x.z$ will change the probability of *many* edges in the current phylogeny $\boldsymbol{p}$. (Equation (1) puts x is in competition with other parents, so *every* mention y that follows x must recompute how happy it is with its current parent $y.p$.)

Rather than resampling one topic at a time, we resample $\boldsymbol{z}$ as a block. We use a proposal distribution for which block sampling is efficient, and use IMH to correct the error in this proposal distribution.

Our proposal distribution is an undirected graphical model whose random variables are the topics $\boldsymbol{z}$ and whose graph structure is given by the current phylogeny $\boldsymbol{p}$:

$$Q(\boldsymbol{z}) \propto \prod_{x \neq \diamondsuit} \Psi_x(x.z) \Psi_{x.p,x}(x.p.z, x.z) \quad (5)$$

$Q(\boldsymbol{z})$ is an approximation to the posterior distribution over $\boldsymbol{z}$. As detailed below, a proposal can be sampled from $Q(\boldsymbol{z})$ in time $O(|\boldsymbol{z}|K^2)$ where K is the number of topics, because the only interactions among topics are along the edges of the tree $\boldsymbol{p}$. The unary factor Ψ_x gives a weight for each possible value of $x.z$, and the binary factor $\Psi_{x.p,x}$ gives a weight for each possible value of the pair $(x.p.z, x.z)$.

The $\Psi_x(x.z)$ factors in (5) approximate the topic model's prior distribution over $\boldsymbol{z}$. $\Psi_x(x.z)$ is proportional to the probability that a Gibbs sampling step for an ordinary topic model would choose this value of $x.z$. This depends on whether—in the

[6] Better, one could integrate over the reader's *guess* of $x.z$.

[7] The full version of this paper is available at `http://cs.jhu.edu/~noa/publications/phylo-acl-14.pdf`

current sample—$x.z$ is currently common in x's document and $x.t$ is commonly generated by $x.z$. It ignores the fact that we will also be resampling the topics of the other mentions.

The $\Psi_{x.p,x}$ factors in (5) approximate $\Pr(\boldsymbol{p} \mid \boldsymbol{z}, \boldsymbol{i})$ (up to a constant factor), where $\boldsymbol{p}$ is the current phylogeny. Specifically, $\Psi_{x.p,x}$ approximates the probability of a single edge. It ought to be given by (1), but we use only the numerator of (1), which avoids modeling the competition among parents.

We sample from Q using standard methods, similar to sampling from a linear-chain CRF by running the backward algorithm followed by forward sampling. Specifically, we run the sum-product algorithm from the leaves up to the root $\diamondsuit$, at each node x computing the following for each topic z:

$$\beta_x(z) \stackrel{\text{def}}{=} \Psi_x(z) \cdot \prod_{y \in \text{children}(x)} \sum_{z'} \Psi_{x,y}(z, z') \cdot \beta_y(z')$$

Then we sample from the root down to the leaves, first sampling $\diamondsuit.z$ from $\beta_\diamondsuit$, then at each $x \neq \diamondsuit$ sampling the topic $x.z$ to be z with probability proportional to $\Psi_{x.p,x}(x.p.z, z) \cdot \beta_x(z)$.

Again we use IMH to correct for the bias in Q: we accept the resulting proposal $\hat{\boldsymbol{z}}$ with probability

$$\min\left(1, \frac{\Pr(\boldsymbol{p}, \boldsymbol{i}, \hat{\boldsymbol{z}}, \boldsymbol{x} \mid \boldsymbol{\theta}, \boldsymbol{\phi})}{\Pr(\boldsymbol{p}, \boldsymbol{i}, \boldsymbol{z}, \boldsymbol{x} \mid \boldsymbol{\theta}, \boldsymbol{\phi})} \cdot \frac{Q(\boldsymbol{z})}{Q(\hat{\boldsymbol{z}})}\right) \quad (6)$$

While $\Pr(\boldsymbol{p}, \boldsymbol{i}, \hat{\boldsymbol{z}}, \boldsymbol{x} \mid \boldsymbol{\theta}, \boldsymbol{\phi})$ might seem slow to compute because it contains many factors (1) with different denominators $Z(x)$, one can share work by visiting the mentions x in their order $\boldsymbol{i}$. Most summands in $Z(x)$ were already included in $Z(x')$, where x' is the latest previous mention having the same attributes as x (e.g., same topic).

5.3 Resampling the phylogeny $\boldsymbol{p}$

It is easy to resample the phylogeny. For each x, we must choose a parent $x.p$ from among the possible parents p (having $p.i < x.i$ and $p.e.t = x.e.t$). Since the ordering $\boldsymbol{i}$ prevents cycles, the resulting phylogeny $\boldsymbol{p}$ is indeed a tree.

Given the topics $\boldsymbol{z}$, the ordering $\boldsymbol{i}$, and the observed names, we choose an $x.p$ value according to its posterior probability. This is proportional to $w(x.p, x) \stackrel{\text{def}}{=} \Pr_{\boldsymbol{\phi}}(x.p \mid x) \cdot \Pr_{\boldsymbol{\theta}}(x.n \mid x.p.n)$, independent of any other mention's choice of parent. The two factors here are given by (1) and (2) respectively. As in the previous section, the denominators $Z(x)$ in the $\Pr(x.p \mid x)$ factors can be computed efficiently with shared work.

With the pragmatic model (section 4.2), the parent choices are no longer independent; then the samples of $\boldsymbol{p}$ should be corrected by IMH as usual.

5.4 Initializing the sampler

The initial sampler state $(\boldsymbol{z}_0, \boldsymbol{p}_0, \boldsymbol{i}_0)$ is obtained as follows. (1) We fix topics $\boldsymbol{z}_0$ via collapsed Gibbs sampling (Griffiths and Steyvers, 2004). The sampler is run for 1000 iterations, and the final sampler state is taken to be $\boldsymbol{z}_0$. This process treats all topics as exchangeable, including those associated with named entities.(2) Given the topic assignment $\boldsymbol{z}_0$, initialize $\boldsymbol{p}_0$ to the phylogeny rooted at $\diamondsuit$ that maximizes $\sum_x \log w(x.p, x)$. This is a maximum rooted directed spanning tree problem that can be solved in time $O(n^2)$ (Tarjan, 1977). The weight $w(x.p, x)$ is defined as in section 5.3—except that since we do not yet have an ordering $\boldsymbol{i}$, we do not restrict the possible values of $x.p$ to mentions p with $p.i < x.p.i$. (3) Given $\boldsymbol{p}_0$, sample an ordering $\boldsymbol{i}_0$ using the procedure described in §5.1.

6 Parameter Estimation

Evaluating the likelihood and its partial derivatives with respect to the parameters of the model requires marginalizing over our latent variables. As this marginalization is intractable, we resort to Monte Carlo EM procedure (Levine and Casella, 2001) which iterates the following two steps:

E-step: Collect samples by MCMC simulation as in §5, given current model parameters $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$.

M-step: Improve $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$ to increase[8]

$$\mathcal{L} \stackrel{\text{def}}{=} \frac{1}{S} \sum_{s=1}^{S} \log \Pr_{\boldsymbol{\theta},\boldsymbol{\phi}}(\boldsymbol{x}, \boldsymbol{p}_s, \boldsymbol{i}_s, \boldsymbol{z}_s) \quad (7)$$

It is not necessary to locally maximize $\mathcal{L}$ at each M-step, merely to improve it if it is not already at a local maximum (Dempster et al., 1977). We improve it by a single update: at the tth M-step, we update our parameters to $\Phi_t = (\boldsymbol{\theta}_t, \boldsymbol{\phi}_t)$

$$\Phi_t = \Phi_{t-1} + \varepsilon \Sigma_t \nabla_\Phi \mathcal{L}(\boldsymbol{x}, \Phi_{t-1}) \quad (8)$$

where ε is a fixed scaling term and Σ_t is an adaptive learning rate given by AdaGrad (Duchi et al., 2011).

We now describe how to compute the gradient $\nabla_\Phi \mathcal{L}$. The gradient with respect to the parent se-

[8] We actually do MAP-EM, which augments (7) by adding the log-likelihoods of θ and ϕ under a Gaussian prior.

lection parameters $\boldsymbol{\phi}$ is

$$\sum \frac{1}{S} \left(\mathbf{f}(p, x) - \sum_{p'} \Pr_{\boldsymbol{\phi}}(p' \mid x) \mathbf{f}(p', x) \right) \quad (9)$$

The outer summation ranges over all edges in the S samples. The other variables in (9) are associated with the edge being summed over. That edge explains a mention x as a mutation of some parent p in the context of a particular sample $(\boldsymbol{p}_s, \boldsymbol{i}_s, \boldsymbol{z}_s)$. The possible parents p' range over $\diamondsuit$ and the mentions that precede x according to the ordering $\boldsymbol{i}_s$, while the features $\boldsymbol{f}$ and distribution $\Pr_{\boldsymbol{\phi}}$ depend on the topics $\boldsymbol{z}_s$.

As for the mutation parameters, let $c_{p,x}$ be the fraction of samples in which p is the parent of x. This is the expected number of times that the string $p.n$ mutated into $x.n$. Given this weighted set of string pairs, let $c_{\hat{a},a,b}$ be the expected number of times that edit $\binom{a}{b}$ was chosen in context $\hat{a}$: this can be computed using dynamic programming to marginalize over the latent edit sequence that maps $p.n$ to $x.n$, for each (p, x). The gradient of $\mathcal{L}$ with respect to $\boldsymbol{\theta}$ is

$$\sum_{\hat{a},a,b} c_{\hat{a},a,b} (\mathbf{f}(\hat{a}, a, b) - \sum_{a',b'} \Pr_{\boldsymbol{\theta}}(a', b' \mid \hat{a}) \mathbf{f}(\hat{a}, a', b')) \quad (10)$$

7 Consensus Clustering

From a single phylogeny $\boldsymbol{p}$, we deterministically obtain a clustering $\boldsymbol{e}$ by removing the root $\diamondsuit$. Each of the resulting connected components corresponds to a cluster of mentions. Our model gives a distribution over phylogenies $\boldsymbol{p}$ (given observations $\boldsymbol{x}$ and learned parameters Φ)—and thus gives a posterior distribution over clusterings $\boldsymbol{e}$, which can be used to answer various queries.

A traditional query is to request a *single* clustering $\boldsymbol{e}$. We prefer the clustering $\boldsymbol{e}^*$ that minimizes Bayes risk (MBR) (Bickel and Doksum, 1977):

$$\boldsymbol{e}^* = \operatorname*{argmin}_{\boldsymbol{e}'} \sum_{\boldsymbol{e}} L(\boldsymbol{e}', \boldsymbol{e}) \Pr(\boldsymbol{e} \mid \boldsymbol{x}, \boldsymbol{\theta}, \boldsymbol{\phi}) \quad (11)$$

This minimizes our expected loss, where $L(\boldsymbol{e}', \boldsymbol{e})$ denotes the loss associated with picking $\boldsymbol{e}'$ when the true clustering is $\boldsymbol{e}$. In practice, we again estimate the expectation by sampling $\boldsymbol{e}$ values.

The Rand index (Rand, 1971)—unlike our actual evaluation measure—is an *efficient* choice of loss function L for use with (11):

$$R(\boldsymbol{e}', \boldsymbol{e}) \stackrel{\text{def}}{=} \frac{\text{TP} + \text{TN}}{\text{TP} + \text{FP} + \text{TN} + \text{FN}} = \frac{\text{TP} + \text{TN}}{\binom{N}{2}}$$

where the true positives (TP), true negatives (TN), false positives (FP), and false negatives (FN) use the clustering $\boldsymbol{e}$ to evaluate how well $\boldsymbol{e}'$ classifies the $\binom{N}{2}$ mention pairs as coreferent or not. More similar clusterings achieve larger R, with $R(\boldsymbol{e}', \boldsymbol{e}) = 1$ iff $\boldsymbol{e}' = \boldsymbol{e}$. In all cases, $0 \leq R(\boldsymbol{e}', \boldsymbol{e}) = R(\boldsymbol{e}, \boldsymbol{e}') \leq 1$.

The MBR decision rule for the (negated) Rand index is easily seen to be equivalent to

$$\begin{aligned} \boldsymbol{e}^* &= \operatorname*{argmax}_{\boldsymbol{e}'} \mathbb{E}[\text{TP}] + \mathbb{E}[\text{TN}] \quad (12) \\ &= \operatorname*{argmax}_{\boldsymbol{e}'} \sum_{i,j:\, x_i \sim x_j} s_{ij} + \sum_{i,j:\, x_i \not\sim x_j} (1 - s_{ij}) \end{aligned}$$

where $\sim$ denotes coreference according to $\boldsymbol{e}'$. As explained above, the s_{ij} are coreference probabilities s_{ij} that can be estimated from a sample of clusterings $\boldsymbol{e}$.

This objective corresponds to min-max graph cut (Ding et al., 2001), an NP-hard problem with an approximate solution (Nie et al., 2010).[9]

8 Experiments

In this section, we describe experiments on three different datasets. Our main results are described first: Twitter features many instances of name variation that we would like our model to be able to learn. We also report the performance of different ablations of our full approach, in order to see which consistently helped across the different splits. We report additional experiments on the ACE 2008 corpus, and on a political blog corpus, to demonstrate that our approach is applicable in different settings.

For Twitter and ACE 2008, we report the standard B^3 metric (Bagga and Baldwin, 1998a). For the political blog dataset, the reference does not consist of entity annotations, and so we follow the evaluation procedure of Yogatama et al. (2012).

8.1 Twitter

Data. We use a novel corpus of Twitter posts discussing the 2013 Grammy Award ceremony. This is a challenging corpus, featuring many instances

[9] In our experiments, we run the clustering algorithm five times, initialized from samples chosen at random from the last 10% of the sampler run, and keep the clustering that achieved highest expected Rand score.

of name variation. The dataset consists of five splits (by entity), the smallest of which is 604 mentions and the largest is 1374. We reserve the largest split for development purposes, and report our results on the remaining four. Appendix B provides more detail about the dataset.

Baselines. We use the discriminative entity clustering algorithm of Green et al. (2012) as our baseline; their approach was found to outperform another generative model which produced a flat clustering of mentions via a Dirichlet process mixture model. Their method uses Jaro-Winkler string similarity to match names, then clusters mentions with matching names (for disambiguation) by comparing their unigram context distributions using the Jenson-Shannon metric. We also compare to the EXACT-MATCH baseline, which assigns all strings with the same name to the same entity.

Procedure. We run four test experiments in which one split is used to pick model hyperparameters and the remaining three are used for test. For the discriminative baseline, we tune the string match threshold, context threshold, and the weight of the context model prior (all via grid search). For our model, we tune *only* the fixed weight of the root feature, which determines the precision/recall tradeoff (larger values of this feature result in more attachments to $\diamondsuit$ and hence more entities). We leave other hyperparameters fixed: 16 latent topics, and Gaussian priors $\mathcal{N}(0, 1)$ on all log-linear parameters. For PHYLO, the entity clustering is the result of (1) training the model using EM, (2) sampling from the posterior to obtain a distribution over clusterings, and (3) finding a consensus clustering. We use 20 iterations of EM with 100 samples per E-step for training, and use 1000 samples after training to estimate the posterior. We report results using three variations of our model: PHYLO does not consider mention context (all mentions effectively have the same topic) and determines mention entities from a single sample of $\boldsymbol{p}$ (the last); PHYLO+TOPIC adds context (§5.2); PHYLO+TOPIC+MBR uses the full posterior and consensus clustering to pick the output clustering (§7). Our results are shown in Table 1.[10]

[10]Our single-threaded implementation took around 15 minutes per fold of the Twitter corpus on a personal laptop with a 2.3 Ghz Intel Core i7 processor (including time required to parse the data files). Typical acceptance rates for ordering and topic proposals ranged from 0.03 to 0.08.

	Mean Test B^3		
	P	R	F1
EXACT-MATCH	99.6	53.7	69.8
Green et al. (2012)	92.1	69.8	79.3
PHYLO	85.3	91.4	88.7
PHYLO+TOPIC	92.8	90.8	91.8
PHYLO+TOPIC+MBR	92.9	90.9	91.9

Table 1: Results for the Twitter dataset. Higher B^3 scores are better. Note that each number is averaged over four different test splits. In three out of four experiments, PHYLO+TOPIC+MBR achieved the highest F1 score; in one case PHYLO+TOPIC won by a small margin.

		Test B^3		
		P	R	F1
PER	EXACT-MATCH	98.0	81.2	88.8
	Green et al. (2012)	95.0	88.9	91.9
	PHYLO+TOPIC+MBR	97.2	88.6	92.7
ORG	EXACT-MATCH	98.2	78.3	87.1
	Green et al. (2012)	92.1	88.5	90.3
	PHYLO+TOPIC+MBR	95.5	80.9	87.6

Table 2: Results for the ACE 2008 newswire dataset.

8.2 Newswire

Data. We use the ACE 2008 dataset, which is described in detail in Green et al. (2012). It is split into a development portion and a test portion. The baseline system took the first mention from each (gold) within-document coreference chain as the canonical mention, ignoring other mentions in the chain; we follow the same procedure in our experiments.[11]

Baselines & Procedure. We use the same baselines as in §8.1. On development data, modeling pragmatics as in §4.2 gave large improvements for organizations (8 points in F-measure), correcting the tendency to assume that short names like CIA were coincidental homonyms. Hence we allowed $\gamma > 0$ and tuned it on development data.[12] Results are in Table 2.

8.3 Blogs

Data. The CMU political blogs dataset consists of 3000 documents about U.S. politics (Yano et al., 2009). Preprocessed as described in Yogatama et al. (2012), the data consists of 10647 entity mentions.

[11]That is, each within-document coreference chain is mapped to a single mention as a preprocessing step.

[12]We used only a simplified version of the pragmatic model, approximating $w(p', x)$ as 1 or 0 according to whether $p'.n = x.n$. We also omitted the IMH step from section 5.3. The other results we report do not use pragmatics at all, since we found that it gave only a slight improvement on Twitter.

Unlike our other datasets, mentions are not annotated with entities: the reference consists of a table of 126 entities, where each row is the *canonical name* of one entity.

Baselines. We compare to the system results reported in Figure 2 of Yogatama et al. (2012). This includes a baseline hierarchical clustering approach, the "EEA" name canonicalization system of Eisenstein et al. (2011), as well the model proposed by Yogatama et al. (2012). Like the output of our model, the output of their hierarchical clustering baseline is a mention clustering, and therefore must be mapped to a table of canonical entity names to compare to the reference table.

Procedure & Results We tune our method as in previous experiments, on the initialization data used by Yogatama et al. (2012) which consists of a subset of 700 documents of the full dataset. The tuned model then produced a mention clustering on the full political blog corpus. As the mapping from clusters to a table is not fully detailed in Yogatama et al. (2012), we used a simple heuristic: the *most frequent* name in each cluster is taken as the canonical name, augmented by any titles from a predefined list appearing in any other name in the cluster. The resulting table is then evaluated against the reference, as described in Yogatama et al. (2012). We achieved a response score of 0.17 and a reference score of 0.61. Though not state-of-the-art, this result is close to the score of the "EEA" system of Eisenstein et al. (2011), as reported in Figure 2 of Yogatama et al. (2012), which is specifically designed for the task of canonicalization.

8.4 Discussion

On the Twitter dataset, we obtained a 12.6-point F1 improvement over the baseline. To understand our model's behavior, we looked at the sampled phylogenetic trees on development data. One reason our model does well in this noisy domain is that it is able to relate seemingly dissimilar names via successive steps. For instance, our model learned to relate many variations of LL Cool J:

Cool James	LLCoJ	El-El Cool John
LL	LL COOL JAMES	LLCOOLJ

In the sample we inspected, these mentions were also assigned the same topic, further boosting the probability of the configuration.

The ACE dataset, consisting of editorialized newswire, naturally contains less name variation than Twitter data. Nonetheless, we find that the variation that does appear is often properly handled by our model. For instance, we see several instances of variation due to transliteration that were all correctly grouped together, such as Megawati Soekarnoputri and Megawati Sukarnoputri. The pragmatic model was also effective in grouping common acronyms into the same entity.

We found that multiple samples tend to give different phylogenies (so the sampler is mobile), but essentially the same clustering into entities (which is why consensus clustering did not improve much over simply using the last sample). Random restarts of EM might create more variety by choosing different locally optimal parameter settings. It may also be beneficial to explore other sampling techniques (Bouchard-Côté, 2014).

Our method assembles observed names into an evolutionary tree. However, the true tree must include many names that fall outside our small observed corpora, so our model would be a more appropriate fit for a far larger corpus. Larger corpora also offer stronger signals that might enable our Monte Carlo methods to mix faster and detect regularities more accurately.

A common error of our system is to connect mentions that share long substrings, such as different PERSONs who share a last name, or different ORGANIZATIONs that contain University of. A more powerful name mutation than the one we use here would recognize entire words, for example inserting a common title or replacing a first name with its common nickname. Modeling the *internal structure* of names (Johnson, 2010; Eisenstein et al., 2011; Yogatama et al., 2012) in the mutation model is a promising future direction.

9 Conclusions

Our primary contribution consists of new modeling ideas, and associated inference techniques, for the problem of cross-document coreference resolution. We have described how writers systematically plunder (ϕ) and then systematically modify (θ) the work of past writers. Inference under such models could also play a role in tracking evolving memes and social influence, not merely in establishing strict coreference. Our model also provides an alternative to the distance-dependent CRP.[2]

Our implementation is available for research use at: `https://bitbucket.org/noandrews/phyloinf`.

Abstract

We introduce three linguistically motivated structured regularizers based on parse trees, topics, and hierarchical word clusters for text categorization. These regularizers impose linguistic bias in feature weights, enabling us to incorporate prior knowledge into conventional bag-of-words models. We show that our structured regularizers consistently improve classification accuracies compared to standard regularizers that penalize features in isolation (such as lasso, ridge, and elastic net regularizers) on a range of datasets for various text prediction problems: topic classification, sentiment analysis, and forecasting.

1 Introduction

What is the best way to exploit linguistic information in statistical text processing models? For tasks like text classification, sentiment analysis, and text-driven forecasting, this is an open question, as cheap "bag-of-words" models often perform well. Much recent work in NLP has focused on linguistic feature engineering (Joshi et al., 2010) or representation learning (Glorot et al., 2011; Socher et al., 2013).

In this paper, we propose a radical alternative. We embrace the conventional bag-of-words representation of text, instead bringing linguistic bias to bear on *regularization*. Since the seminal work of Chen and Rosenfeld (2000), the importance of regularization in discriminative models of text—including language modeling, structured prediction, and classification—has been widely recognized. The emphasis, however, has largely been on one specific kind of inductive bias: avoiding large weights (i.e., coefficients in a linear model).

Recently, *structured* (or composite) regularization has been introduced; simply put, it reasons about different weights jointly. The most widely explored variant, group lasso (Yuan and Lin, 2006) seeks to avoid large ℓ_2 norms for *groups* of weights. Group lasso has been shown useful in a range of applications, including computational biology (Kim and Xing, 2008), signal processing (Lv et al., 2011), and NLP (Eisenstein et al., 2011; Martins et al., 2011; Nelakanti et al., 2013). For text categorization problems, Yogatama and Smith (2014) proposed groups based on sentences, an idea generalized here to take advantage of richer linguistic information.

In this paper, we show how linguistic information of various kinds—parse trees, thematic topics, and hierarchical word clusterings—can be used to construct group lasso variants that impose linguistic bias without introducing any new features. Our experiments demonstrate that structured regularizers can squeeze higher performance out of conventional bag-of-words models on seven out of eight of text categorization tasks tested, in six cases with more compact models than the best-performing unstructured-regularized model.

2 Notation

We represent each document as a feature vector $\mathbf{x} \in \mathbb{R}^V$, where V is the vocabulary size. x_v is the frequency of the vth word (i.e., this is a "bag of words" model).

Consider a linear model that predicts a binary response $y \in \{-1, +1\}$ given $\mathbf{x}$ and weight vector $\mathbf{w} \in \mathbb{R}^V$. We denote our training data of D documents in the corpus by $\{\mathbf{x}_d, y_d\}_{d=1}^D$. The goal of the learning procedure is to estimate $\mathbf{w}$ by minimizing the regularized training data loss:

$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w}} \Omega(\mathbf{w}) + \textstyle\sum_{d=1}^D \mathcal{L}(\mathbf{x}_d, \mathbf{w}, y_d),$$

where $\mathcal{L}(\mathbf{x}, \mathbf{w}, y)$ is the loss function for document d and $\Omega(\mathbf{w})$ is the regularizer.

In this work, we use the log loss:

$$\mathcal{L}(\mathbf{x}_d, \mathbf{w}, y_d) = -\log(1 + \exp(-y_d \mathbf{w}^\top \mathbf{x}_d)),$$

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 786–796,
Baltimore, Maryland, USA, June 23-25 2014.

Other loss functions (e.g., hinge loss, squared loss) can also be used with any of the regularizers discussed in this paper.

Our focus is on the regularizer, $\Omega(\mathbf{w})$. For high dimensional data such as text, regularization is crucial to avoid overfitting.[1]

The usual starting points for regularization are the "lasso" (Tibshirani, 1996) and the "ridge" (Hoerl and Kennard, 1970), based respectively on the ℓ_1 and squared ℓ_2 norms:

$$\Omega_{las}(\mathbf{w}) = \lambda_{las}\|\mathbf{w}\|_1 = \lambda \sum_j |w_j|$$
$$\Omega_{rid}(\mathbf{w}) = \lambda_{rid}\|\mathbf{w}\|_2^2 = \lambda \sum_j w_j^2$$

Both methods disprefer weights of large magnitude; smaller (relative) magnitude means a feature (here, a word) has a smaller effect on the prediction, and zero means a feature has no effect.[2] The hyperparameter λ in each case is typically tuned on a development dataset. A linear combination of ridge and lasso is known as the elastic net (Zou and Hastie, 2005). The lasso, ridge, and elastic net are three strong baselines in our experiments.

3 Group Lasso

Structured regularizers penalize estimates of $\mathbf{w}$ in which collections of weights are penalized jointly. For example, in the group lasso (Yuan and Lin, 2006), predefined groups of weights (subvectors of $\mathbf{w}$) are encouraged to either go to zero (as a group) or not (as a group)—this is known as "group sparsity."[3]

The variant of group lasso we explore here uses an $\ell_{1,2}$ norm. Let g index the G predefined groups of weights and $\mathbf{w}_g$ denote the subvector of $\mathbf{w}$ containing weights for group g:

$$\Omega_{glas}(\mathbf{w}) = \lambda_{glas} \sum_{g=1}^{G} \lambda_g \|\mathbf{w}_g\|_2,$$

where λ_{glas} is a hyperparameter tuned on a development data, and λ_g is a group specific weight. Typically the groups are non-overlapping, which offers computational advantages, but this need not be the case (Jacob et al., 2009; Jenatton et al., 2011).

4 Structured Regularizers for Text

Past work applying the group lasso to NLP problems has considered four ways of defining the groups. Eisenstein et al. (2011) defined groups of coefficients corresponding to the same independent variable applied to different (continuous) output variables in multi-output regression. Martins et al. (2011) defined groups based on feature templates used in chunking and parsing tasks. Nelakanti et al. (2013) defined groups based on n-gram histories for language modeling. In each of these cases, the groups were defined based on information from feature *types* alone; given the features to be used, the groups were known.

Here we build on a fourth approach that exploits structure in the data.[4] Yogatama and Smith (2014) introduced the *sentence regularizer*, which uses patterns of word cooccurrence in the training data to define groups. We review this method, then apply the idea to three more linguistically informed structure in text data.

4.1 Sentence Regularizer

The sentence regularizer exploits sentence boundaries in each training document. The idea is to define a group $g_{d,s}$ for every sentence s in every training document d. The group contains coefficients for words that occur in its sentence. This means that a word is a member of one group for every distinct (training) sentence it occurs in, and that the regularizer is based on word tokens, not types as in the approach of Martins et al. (2011) and Nelakanti et al. (2013). The regularizer is:

$$\Omega_{sen}(\mathbf{w}) = \sum_{d=1}^{D} \sum_{s=1}^{S_d} \lambda_{d,s} \|\mathbf{w}_{d,s}\|_2,$$

where S_d is the number of sentences in document d. This regularizer results in tens of thousands to millions of heavily *overlapping* groups, since a standard corpus typically contains thousands to millions of sentences and many words that appear in more than one sentence.

[1] A Bayesian interpretation of regularization is as a prior on the weight vector $\mathbf{w}$; in many cases Ω can be understood as a log-prior representing beliefs about the model held before exposure to data. For lasso regression, the prior is a zero-mean Laplace distribution, whereas for ridge regression the prior is a zero-mean Gaussian distribution. For non-overlapping group lasso, the prior is a two-level hierarchical Bayes model (Figueiredo, 2002). The Bayesian interpretation of overlapping group lasso is not yet well understood.

[2] The lasso leads to strongly sparse solutions, in which many elements of the estimated $\mathbf{w}$ are actually zero. This is an attractive property for efficiency and (perhaps) interpretability. The ridge encourages weights to go toward zero, but usually not all the way *to* zero; for this reason its solutions are known as "weakly" sparse.

[3] Other structured regularizers include the fused lasso (Tibshirani et al., 2005) and the elitist lasso (Kowalski and Torresani, 2009).

[4] This provides a compelling reason *not* to view such methods in a Bayesian framework: if the regularizer is informed by the data, then it does not truly correspond to a prior.

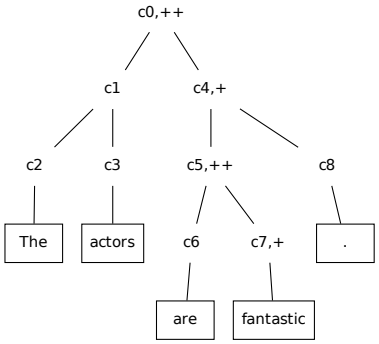

Figure 1: An example of a parse tree from the Stanford sentiment treebank, which annotates sentiment at the level of every constituent (indicated here by + and ++; no marking indicates neutral sentiment). The sentence is The actors are fantastic. Our regularizer constructs nine groups for this sentence, corresponding to $c_0, c_1, \ldots, c_8$. g_{c_0} consists of 5 weights—$\langle w_{the}, w_{actors}, w_{are}, w_{fantastic}, w_. \rangle$, exactly the same as the group in the sentence regularizer—g_{c_1} consists of 2 words, g_{c_4} of 3 words, etc. Notice that c_2, c_3, c_6, c_7, and c_8 each consist of only 1 word. The Stanford sentiment treebank has an annotation of sentiments at the constituent level. As in this example, most constituents are annotated as neutral.

If the norm of $\mathbf{w}_{g_{d,s}}$ is driven to zero, then the learner has deemed the corresponding sentence irrelevant to the prediction. It is important to point out that, while the regularizer prefers to zero out the weights for all words in irrelevant sentences, it also prefers *not* to zero out weights for words in relevant sentences. Since the groups overlap and may work against each other, the regularizer may not be able to drive many weights to zero on its own. Yogatama and Smith (2014) used a linear combination of the sentence regularizer and the lasso (a kind of *sparse group lasso*; Friedman et al., 2010) to also encourage weights of irrelevant word types to go to zero.[5]

4.2 Parse Tree Regularizer

Sentence boundaries are a rather superficial kind of linguistic structure; syntactic parse trees provide more fine-grained information. We introduce a new regularizer, the parse tree regularizer, in which groups are defined for every constituent in every parse of a training data sentence.

Figure 1 illustrates the group structures derived from an example sentence from the Stanford sentiment treebank (Socher et al., 2013). This regularizer captures the idea that *phrases* might be selected as relevant or (in most cases) irrelevant to a task, and is expected to be especially useful in sentence-level prediction tasks.

The parse-tree regularizer (omitting the group coefficients and λ) for one sentence with the parse tree shown in Figure 1 is:

$$\Omega_{tree}(\mathbf{w}) = \sqrt{|w_{the}|^2 + |w_{actors}|^2 + |w_{are}|^2 + |w_{fantastic}|^2 + |w_.|^2} + \sqrt{|w_{are}|^2 + |w_{fantastic}|^2 + |w_.^2|} + \sqrt{|w_{the}|^2 + |w_{actors}|^2} + \sqrt{|w_{are}|^2 + |w_{fantastic}|^2} + |w_{the}| + |w_{actors}| + |w_{are}| + |w_{fantastic}| + |w_.|$$

The groups have a tree structure, in that assigning zero values to the weights in a group corresponding to a higher-level constituent implies the same for those constituents that are dominated by it. This resembles the tree-guided group lasso in Kim and Xing (2008), although the leaf nodes in their tree represent tasks in multi-task regression.

Of course, in a corpus there are many parse trees (one per sentence, so the number of parse trees is the number of sentences). The parse-tree regularizer is:

$$\Omega_{tree}(\mathbf{w}) = \sum_{d=1}^{D} \sum_{s=1}^{S_d} \sum_{c=1}^{C_{d,s}} \lambda_{d,s,c} \|\mathbf{w}_{d,s,c}\|_2,$$

where $\lambda_{d,s,c} = \lambda_{glas} \times \sqrt{size(g_{d,s,c})}$, d ranges over (training) documents and c ranges over constituents in the parse of sentence s in document d. Similar to the sentence regularizer, the parse-tree regularizer operates on word tokens. Note that, since each word token is itself a constituent, the parse tree regularizer includes terms just like the lasso naturally, penalizing the absolute value of each word's weight in isolation. For the lasso-like penalty on each word, instead of defining the group weights to be $1 \times$ the number of tokens for each word type, we tune one group weight for all word types on a development data. As a result, besides λ_{glas}, we have an additional hyperparameter, denoted by λ_{las}.

To gain an intuition for this regularizer, consider the case where we apply the penalty only for a single tree (sentence), which for ease of exposition is assumed not to use the same word more than once (i.e., $\|\mathbf{x}\|_\infty = 1$). Because it instantiates the tree-structured group lasso, the regularizer will require bigger constituents to be "included" (i.e., their words given nonzero weight) before smaller constituents can be included. The result is that some words may not be included. Of course, in some sentences, some words will occur more than once, and the parse tree regularizer instantiates groups for constituents in every sentence in the training corpus, and these groups may work against each other. The parse tree regularizer should therefore

[5] Formally, this is equivalent to including one additional group for each word type.

be understood as encouraging group behavior of syntactically grouped words, or sharing of information by syntactic neighbors.

In sentence level prediction tasks, such as sentence-level sentiment analysis, it is known that most constituents (especially those that correspond to shorter phrases) in a parse tree are uninformative (neutral sentiment). This was verified by Socher et al. (2013) when annotating phrases in a sentence for building the Stanford sentiment treebank. Our regularizer incorporates our prior expectation that most constituents should have no effect on prediction.

4.3 LDA Regularizer

Another type of structure to consider is topics. For example, if we want to predict whether a paper will be cited or not (Yogatama et al., 2011), the model can perform better if it knows beforehand the collections of words that represent certain themes (e.g., in ACL papers, these might include machine translation, parsing, etc.). As a result, the model can focus on which topics will increase the probability of getting citations, and penalize weights for words in the same topic together, instead of treating each word separately.

We do this by inferring topics in the training corpus by estimating the latent Dirichlet allocation (LDA) model (Blei et al., 2003)). Note that LDA is an unsupervised method, so we can infer topical structures from *any* collection of documents that are considered related to the target corpus (e.g., training documents, text from the web, etc.). This contrasts with typical semi-supervised learning methods for text categorization that combine unlabeled and labeled data within a generative model, such as multinomial naïve Bayes, via expectation-maximization (Nigam et al., 2000) or semi-supervised frequency estimation (Su et al., 2011). Our method does not use unlabeled data to obtain more training documents or estimate the joint distributions of words better, but it allows the use of unlabeled data to induce topics. We leave comparison with other semi-supervised methods for future work.

There are many ways to associate inferred topics with group structure. In our experiments, we choose the R most probable words given a topic and create a group for them.[6] The LDA regularizer can be written as:

$$\Omega_{lda}(\mathbf{w}) = \sum_{k=1}^{K} \lambda_k \|\mathbf{w}_k\|_2,$$

where k ranges over the K topics. Similar to our earlier notations, $\mathbf{w}_k$ corresponds to the subvector of $\mathbf{w}$ such that the corresponding features are present in topic k. Note that in this case we can also have overlapping groups, since words can appear in the top R of many topics.

$k=1$	$k=2$	$k=3$	$k=4$
soccer	injury	physics	monday
striker	knee	gravity	tuesday
midfielder	ligament	moon	april
goal	shoulder	sun	june
defender	cruciate	relativity	sunday

Table 1: A toy example of $K = 4$ topics. The top $R = 5$ words in each topics are displayed. The LDA regularizer will construct four groups from these topics. The first group is $\langle w_{soccer}, w_{striker}, w_{midfielder}, w_{goal}, w_{defender} \rangle$, the second group is $\langle w_{injury}, w_{knee}, w_{ligament}, w_{shoulder}, w_{cruciate} \rangle$, etc. In this example, there are no words occurring in the top R of more than one topic, but that need not be the case in general.

To gain an intuition for this regularizer, consider the toy example in Table 1. the case where we have $K = 4$ topics and we select $R = 5$ top words from each topic. Supposed that we want to classify whether an article is a sports article or a science article. The regularizer might encourage the weights for the fourth topics' words toward zero, since they are less useful for the task. Additionally, the regularizer will penalize words in each of the other three groups collectively. Therefore, if (for example) *ligament* is deemed a useful feature for classifying an article to be about sports, then the other words in that topic will have a smaller effective penalty for getting nonzero weights—even weights of the opposite sign as $w_{ligament}$. It is important to distinguish this from unstructured regularizers such as the lasso, which penalize each word's weight on its own without regard for related word types.

Unlike the parse tree regularizer, the LDA regularizer is not tree structured. Since the lasso-like penalty does not occur naturally in a non tree-structured regularizer, we add an additional lasso penalty for each word type (with hyperparameter λ_{las}) to also encourage weights of irrelevant words to go to zero. Our LDA regularizer is an instance of sparse group lasso (Friedman et al., 2010).

[6] Another possibility is to group the smallest set of words whose total probability given a topic amounts to P (e.g., 0.99). mass of a topic. Preliminary experiments found this not to work well.

4.4 Brown Cluster Regularizer

Brown clustering is a commonly used unsupervised method for grouping words into a hierarchy of clusters (Brown et al., 1992). Because it uses local information, it tends to discover words with similar syntactic behavior, though semantic groupings are often evident, especially at the more fine-grained end of the hierarchy.

We incorporate Brown clusters into a regularizer in a similar way to the topical word groups inferred using LDA in §4.3, but here we make use of the hierarchy. Specifically, we construct tree-structured groups, one per cluster (i.e., one per node in the hierarchy). The Brown cluster regularizer is:

$$\Omega_{brown}(\mathbf{w}) = \sum_{v=1}^{N} \lambda_v \|\mathbf{w}_v\|_2,$$

where v ranges over the N nodes in the Brown cluster tree. As a tree structured regularizer, this regularizer enforces constraints that a node v's group is given nonzero weights only if those nodes that dominate v (i.e., are on a path from v to the root) have their groups selected.

Consider a similar toy example to the LDA regularizer (sports vs. science) and the hierarchical clustering of words in Figure 2. In this case, the Brown cluster regularizer will create 17 groups, one for every node in the clustering tree. The regularizer for this tree (omitting the group coefficients and λ) is:

$$\begin{aligned}\Omega_{brown}(\mathbf{w}) = \sum_{i=0}^{7} \|\mathbf{w}_{v_i}\|_2 + |w_{goal}| + |w_{striker}| \\ + |w_{midfielder}| + |w_{knee}| + |w_{injury}| \\ + |w_{gravity}| + |w_{moon}| + |w_{sun}|\end{aligned}$$

The regularizer penalizes words in a cluster together, exploiting discovered syntactic relatedness. Additionally, the regularizer can zero out weights of words corresponding to any of the internal nodes, such as v_7 if the words `monday` and `sunday` are deemed irrelevant to prediction.

Note that the regularizer already includes terms like the lasso naturally. Similar to the parse tree regularizer, for the lasso-like penalty on each word, we tune one group weight for all word types on a development data with a hyperparameter λ_{las}.

A key difference between the Brown cluster regularizer and the parse tree regularizer is that there is only one tree for Brown cluster regularizer, whereas the parse tree regularizer can have millions (one per sentence in the training data). The

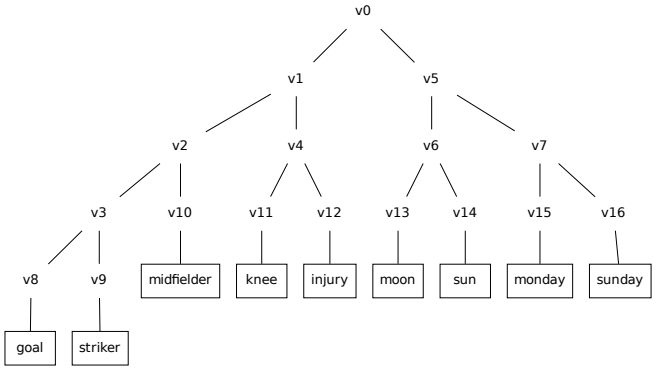

Figure 2: An illustrative example of Brown clusters for $N = 9$. The Brown cluster regularizer constructs 17 groups, one per node in for this tree, $v_0, v_1, \ldots, v_{16}$. v_0 contains 8 words, v_1 contains 5, etc. Note that the leaves, $v_8, v_9, \ldots, v_{16}$, each contain one word.

LDA and Brown cluster regularizers offer ways to incorporate unlabeled data, if we believe that the unlabeled data can help us infer better topics or clusters. Note that the processes of learning topics or clusters, or parsing training data sentences, are a separate stage that precedes learning our predictive model.

5 Learning

There are many optimization methods for learning models with structured regularizers, particulary group lasso (Jacob et al., 2009; Jenatton et al., 2011; Chen et al., 2011; Qin and Goldfarb, 2012; Yuan et al., 2013). We choose the optimization method of Yogatama and Smith (2014) since it handles millions of overlapping groups effectively. The method is based on the alternating directions method of multipliers (ADMM; Hestenes, 1969; Powell, 1969). We review it here in brief, for completeness, and show how it can be applied to tree-structured regularizers (such as the parse tree and Brown cluster regularizers in §4) in particular.

Our learning problem is, generically:

$$\min_{\mathbf{w}} \Omega(\mathbf{w}) + \sum_{d=1}^{D} \mathcal{L}(\mathbf{x}_d, \mathbf{w}, y_d).$$

Separating the lasso-like penalty for each word type from our group regularizers, we can rewrite this problem as:

$$\begin{aligned}\min_{\mathbf{w},\mathbf{v}} \Omega_{las}(\mathbf{w}) + \Omega_{glas}(\mathbf{v}) + \sum_{d=1}^{D} \mathcal{L}(\mathbf{x}_d, \mathbf{w}, y_d) \\ \text{s.t. } \mathbf{v} = \mathbf{M}\mathbf{w}\end{aligned}$$

where $\mathbf{v}$ consists of copies of the elements of $\mathbf{w}$. Notice that we work directly on $\mathbf{w}$ instead of the copies for the lasso-like penalty, since it does not have overlaps and has its own hyperparameters λ_{las}. For the remaining groups with size greater than one, we create copies $\mathbf{v}$ of size

$L = \sum_{g=1}^{G} \text{size}(g)$. $\mathbf{M} \in \{0,1\}^{L \times V}$ is a matrix whose 1s link elements of $\mathbf{w}$ to their copies.[7] We now have a constrained optimization problem, from which we can create an augmented Lagrangian problem; let $\mathbf{u}$ be the Lagrange variables:

$$\Omega_{las}(\mathbf{w}) + \Omega_{glas}(\mathbf{v}) + \mathcal{L}(\mathbf{w}) + \mathbf{u}^\top(\mathbf{v} - \mathbf{M}\mathbf{w}) + \frac{\rho}{2}\|\mathbf{v} - \mathbf{M}\mathbf{w}\|_2^2$$

ADMM proceeds by iteratively updating each of $\mathbf{w}$, $\mathbf{v}$, and $\mathbf{u}$, amounting to the following subproblems:

$$\min_{\mathbf{w}} \Omega_{las}(\mathbf{w}) + \mathcal{L}(\mathbf{w}) - \mathbf{u}^\top\mathbf{M}\mathbf{w} + \frac{\rho}{2}\|\mathbf{v} - \mathbf{M}\mathbf{w}\|_2^2 \quad (1)$$

$$\min_{\mathbf{v}} \Omega_{glas}(\mathbf{v}) + \mathbf{u}^\top\mathbf{v} + \frac{\rho}{2}\|\mathbf{v} - \mathbf{M}\mathbf{w}\|_2^2 \quad (2)$$

$$\mathbf{u} = \mathbf{u} + \rho(\mathbf{v} - \mathbf{M}\mathbf{w}) \quad (3)$$

Yogatama and Smith (2014) show that Eq. 1 can be rewritten in a form quite similar to ℓ_2-regularized loss minimization.[8]

Eq. 2 is the proximal operator of $\frac{1}{\rho}\Omega_{glas}$ applied to $\mathbf{M}\mathbf{w} - \frac{\mathbf{u}}{\rho}$. As such, it depends on the form of $\mathbf{M}$. Note that when applied to the collection of "copies" of the parameters, $\mathbf{v}$, Ω_{glas} no longer has overlapping groups. Defined $\mathbf{M}_g$ as the rows of $\mathbf{M}$ corresponding to weight copies assigned to group g. Let $\mathbf{z}_g \triangleq \mathbf{M}_g\mathbf{w} - \frac{\mathbf{u}_g}{\rho}$. Denote $\lambda_g = \lambda_{glas}\sqrt{\text{size}(g)}$. The problem can be solved by applying the proximal operator used in non-overlapping group lasso to each subvector:

$$\mathbf{v}_g = \text{prox}_{\Omega_{glas}, \frac{\lambda_g}{\rho}}(\mathbf{z}_g) = \begin{cases} \mathbf{0} & \text{if } \|\mathbf{z}_\mathbf{g}\|_2 \leq \frac{\lambda_g}{\rho} \\ \frac{\|\mathbf{z}_g\|_2 - \frac{\lambda_g}{\rho}}{\|\mathbf{z}_g\|_2}\mathbf{z}_g & \text{otherwise.} \end{cases}$$

For a tree structured regularizer, we can get speedups by working from the root node towards the leaf nodes when applying the proximal operator in the second step. If g is a node in a tree which is driven to zero, all of its children h that has $\lambda_h \leq \lambda_g$ will also be driven to zero.

Eq. 3 is a simple update of the dual variable $\mathbf{u}$. Algorithm 1 summarizes our learning procedure.[9]

[7] For the parse tree regularizer, L is the sum, over all training-data word tokens t, of the number of constituents t belongs to. For the LDA regularizer, $L = R \times K$. For the Brown cluster regularizer, $L = V - 1$.

[8] The difference lies in that the squared ℓ_2 norm in the penalty penalizes the difference between $\mathbf{w}$ and a vector that depends on the current values of $\mathbf{u}$ and $\mathbf{v}$. This does not affect the algorithm or its convergence in any substantive way.

[9] We use relative changes in the ℓ_2 norm of the parameter vector $\mathbf{w}$ as our convergence criterion (threshold of 10^{-3}), and set the maximum number of iterations to 100. Other criteria can also be used.

Algorithm 1 ADMM for overlapping group lasso

    $\mathbf{v}_g = \text{prox}_{\Omega_{glas}, \frac{\lambda_g}{\rho}}(\mathbf{z}_g)$
  end for
  $\mathbf{u} = \mathbf{u} + \rho(\mathbf{v} - \mathbf{M}\mathbf{w})$
end while

6 Experiments

6.1 Datasets

We use publicly available datasets to evaluate our model described in more detail below.

Topic classification. We consider four binary categorization tasks from the 20 Newsgroups dataset.[10] Each task involves categorizing a document according to two related categories: comp.sys: ibm.pc.hardware vs. mac.hardware; rec.sport: baseball vs. hockey; sci: med vs. space; and alt.atheism vs. soc.religion.christian.

Sentiment analysis. One task in sentiment analysis is predicting the polarity of a piece of text, i.e., whether the author is favorably inclined toward a (usually known) subject of discussion or proposition (Pang and Lee, 2008). Sentiment analysis, even at the coarse level of polarity we consider here, can be confused by negation, stylistic use of irony, and other linguistic phenomena. Our sentiment analysis datasets consist of movie reviews from the Stanford sentiment treebank (Socher et al., 2013),[11] and floor speeches by U.S. Congressmen alongside "yea"/"nay" votes on the bill under discussion (Thomas et al., 2006).[12] For the Stanford sentiment treebank, we only predict binary classifications (positive or negative) and exclude neutral reviews.

Text-driven forecasting. Forecasting from text requires identifying textual correlates of a response variable revealed in the future, most of which will be weak and many of which will be spurious (Kogan et al., 2009). We consider two such problems. The first one is predicting whether a scientific paper will be cited or not within three years of its publication (Yogatama et al., 2011);

Table 2: Descriptive statistics about the datasets.

the dataset comes from the ACL Anthology and consists of research papers from the Association for Computational Linguistics and citation data (Radev et al., 2009). The second task is predicting whether a legislative bill will be recommended by a Congressional committee (Yano et al., 2012).[13]

Table 2 summarizes statistics about the datasets used in our experiments. In total, we evaluate our method on eight binary classification tasks.

6.2 Setup

In all our experiments, we use unigram features plus an additional bias term which is not regularized. We compare our new regularizers with state-of-the-art methods for document classification: lasso, ridge, and elastic net regularization, as well as the sentence regularizer discussed in §4.1 (Yogatama and Smith, 2014).[14]

We parsed all corpora using the Berkeley parser (Petrov and Klein, 2007).[15] For the LDA regularizers, we ran LDA[16] on training documents with $K = 1,000$ and $R = 10$. For the Brown cluster regularizers, we ran Brown clustering[17] on training documents with $5,000$ clusters for the topic classification and sentiment analysis datasets, and $1,000$ for the larger text forecasting datasets (since they are bigger datasets that took more time).

[13] http://www.ark.cs.cmu.edu/bills

[14] Hyperparameters are tuned on a separate development dataset, using accuracy as the evaluation criterion. For lasso and ridge models, we choose λ from $\{10^{-2}, 10^{-1}, 1, 10, 10^2, 10^3\}$. For elastic net, we perform grid search on the same set of values as ridge and lasso experiments for λ_{rid} and λ_{las}. For the sentence, Brown cluster, and LDA regularizers, we perform grid search on the same set of values as ridge and lasso experiments for $\rho, \lambda_{glas}, \lambda_{las}$. For the parse tree regularizer, because there are many more groups than other regularizers, we choose λ_{glas} from $\{10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}, 10\}$, ρ and λ_{las} from the same set of values as ridge and lasso experiments. If there is a tie on development data we choose the model with the smallest number of nonzero weights.

6.3 Results

Table 3 shows the results of our experiments on the eight datasets. The results demonstrate the superiority of structured regularizers. One of them achieved the best result on all but one dataset.[18] It is also worth noting that in most cases all variants of the structured regularizers outperformed lasso, ridge, and elastic net. In four cases, the new regularizers in this paper outperform the sentence regularizer.

We can see that the parse tree regularizer performed the best for the movie review dataset. The task is to predict sentence-level sentiment, so each training example is a sentence. Since constituent-level annotations are available for this dataset, we only constructed groups for neutral constituents (i.e., we drive neutral constituents to zero during training). It has been shown that syntactic information is helpful for sentence-level predictions (Socher et al., 2013), so the parse tree regularizer is naturally suitable for this task.

The Brown cluster and LDA regularizers performed best for the forecasting scientific articles dataset. The task is to predict whether an article will be cited or not within three years after publication. Regularizers that exploit the knowledge of semantic relations (e.g., topical categories), such as the Brown cluster and LDA regularizers, are therefore suitable for this type of prediction.

Table 4 shows model sizes obtained by each of the regularizers for each dataset. While lasso prunes more aggressively, it almost always performs worse. Our structured regularizers were able to obtain a significantly smaller model (27%, 34%, 19% as large on average for parse tree, Brown, and LDA regularizers respectively) compared to the ridge model.

Topic and cluster features. Another way to incorporate LDA topics and Brown clusters into a linear model is by adding them as additional features. For the 20N datasets, we also ran lasso, ridge, and elastic net with *additional* LDA topic and Brown cluster features.[19] Note that these new baselines use more features than our model. We can also add these additional features to our model

[18] This "bill" dataset, where they offered no improvement, is the largest by far (37,850 documents), and therefore the one where regularizers should matter the least. Note that the differences are small across regularizers for this dataset.

[19] For LDA, we took the top 10 words in a topic as a feature. For Brown clusters, we add a cluster as an additional feature if its size is less than 50.

Table 5: Classification accuracies on the 20N datasets for lasso, ridge, and elastic net models with additional LDA features (top) and Brown cluster features (bottom). The last column shows structured regularized models from Table 3.

and treat them as regular features (i.e., they do not belong to any groups and are regularized with standard regularizer such as the lasso penalty). The results in Table 5 show that for these datasets, models that incorporate this information through structured regularizers outperformed models that encode this information as additional features in 4 out 4 of cases (LDA) and 2 out of 4 cases (Brown). Sparse models with Brown clusters appear to overfit badly; recall that the clusters were learned on only the training data—clusters from a larger dataset would likely give stronger results. Of course, better performance might also be achieved by incorporating new features as well as using structured regularizers.

6.4 Examples

To gain an insight into the models, we inspect group sparsity patterns in the learned models by looking at the parameter copies $\mathbf{v}$. This lets us see which groups are considered important (i.e., "selected" vs. "removed"). For each of the proposed regularizers, we inspect the model a task in which it performed well.

For the parse tree regularizer, we inspect the model for the 20N:religion task. We observed that the model included most of the sentences (root node groups), but in some cases removed phrases from the parse trees, such as *ozzy osbourne* in the sentence *ozzy osbourne , ex-singer and main character of the black sabbath of good ole days past , is and always was a devout catholic .*

For the LDA regularizer, we inspect zero and nonzero groups (topics) in the forecasting scientific articles task. In this task, we observed that 642 out of 1,000 topics are driven to zero by our model. Table 6 shows examples of zero and nonzero topics for the dev.-tuned hyperparameter values. We can see that in this particular case, the model kept meaningful topics such as parsing and speech processing, and discarded general topics that are not correlated with the content of the papers (e.g., acknowledgment, document metadata, equation, etc.). Note that most weights for non-selected groups, even in $\mathbf{w}$, are near zero.

For the Brown cluster regularizer, we inspect the model from the 20N:science task. 771 out of 5,775 groups were driven to zero for the best model tuned on the development set. Examples of zero and nonzero groups are shown in Table 7. Similar to the LDA example, the groups that were driven to zero tend to contain generic words that are not relevant to the predictions. We can also see the tree structure effect in the regularizer. The group {*underwater*, *industrial*} was

driven to zero, but not once it combined with other words such as *hpr*, *std*, *obsessive*. Note that we ran Brown clustering only on the training documents; running it on a larger collection of (unlabeled) documents relevant to the prediction task (i.e., semi-supervised learning) is worth exploring in future work.

7 Related and Future Work

Overall, our results demonstrate that linguistic structure in the data can be used to improve bag-of-words models, through structured regularization. State-of-the-art approaches to some of these problems have used additional features and representations (Yessenalina et al., 2010; Socher et al., 2013). For example, for the vote sentiment analysis datasets, latent variable models of Yessenalina et al. (2010) achieved a superior result of 77.67%. To do so, they sacrificed convexity and had to rely on side information for initialization. Our experimental focus has been on a controlled comparison between regularizers for a fixed model family (the simplest available, linear with bag-of-words features). However, the improvements offered by our regularization methods can be applied in future work to other model families with more carefully engineered features, metadata features (especially important in forecasting), latent variables, etc. In particular, note that other kinds of weights (e.g., metadata) can be penalized conventionally, or incorporated into the structured regularization where it makes sense to do so (e.g., n-grams, as in Nelakanti et al., 2013).

8 Conclusion

We introduced three data-driven, linguistically informed structured regularizers based on parse trees, topics, and hierarchical word clusters. We empirically showed that models regularized using our methods consistently outperformed standard regularizers that penalize features in isolation such as lasso, ridge, and elastic net on a range of datasets for various text prediction problems: topic classification, sentiment analysis, and forecasting.

Abstract

This paper studies the idea of removing low-frequency words from a corpus, which is a common practice to reduce computational costs, from a theoretical standpoint. Based on the assumption that a corpus follows Zipf's law, we derive trade-off formulae of the perplexity of k-gram models and topic models with respect to the size of the reduced vocabulary. In addition, we show an approximate behavior of each formula under certain conditions. We verify the correctness of our theory on synthetic corpora and examine the gap between theory and practice on real corpora.

1 Introduction

Removing low-frequency words from a corpus (often called *cutoff*) is a common practice to save on the computational costs involved in learning language models and topic models. In the case of language models, we often have to remove low-frequency words because of a lack of computational resources, since the feature space of k-grams tends to be so large that we sometimes need cutoffs even in a distributed environment (Brants et al., 2007). In the case of topic models, the intuition is that low-frequency words do not make a large contribution to the statistics of the models. Actually, when we try to roughly analyze a corpus with topic models, a reduced corpus is enough for the purpose (Steyvers and Griffiths, 2007).

A natural question arises: How many low-frequency words can we remove while maintaining sufficient performance? Or more generally, by how much can we reduce a corpus/model using a certain strategy and still keep a sufficient level of performance? There have been many studies addressing the question as it pertains to different strategies (Stolcke, 1998; Buchsbaum et al., 1998; Goodman and Gao, 2000; Gao and Zhang, 2002; Ha et al., 2006; Hirsimaki, 2007; Church et al., 2007). Each of these studies experimentally discusses trade-off relationships between the size of the reduced corpus/model and its performance measured by perplexity, word error rate, and other factors. To our knowledge, however, there is no theoretical study on the question and no evidence for such a trade-off relationship, especially for topic models.

In this paper, we first address the question from a theoretical standpoint. We focus on the cutoff strategy for reducing a corpus, since a cutoff is simple but powerful method that is worth studying; as reported in (Goodman and Gao, 2000; Gao and Zhang, 2002), a cutoff is competitive with sophisticated strategies such as entropy pruning. As the basis of our theory, we assume Zipf's law (Zipf, 1935), which is an empirical rule representing a long-tail property of words in a corpus. Our approach is essentially the same as those in physics, in the sense of constructing a theory while believing experimentally observed results. For example, we can derive the distance to the landing point of a ball thrown up in the air with initial speed v_0 and angle θ as ${v_0}^2 \sin(2\theta)/g$ by believing in the experimentally observed gravity acceleration g. In a similar fashion, we will try to clarify the trade-off relationship by believing Zipf's law.

The rest of the paper is organized as follows. In Section 2, we define the notation and briefly explain Zipf's law and perplexity. In Section 3, we theoretically derive the trade-off formulae of the cutoff for unigram models, k-gram models, and topic models, each of which represents its perplexity with respect to a reduced vocabulary, under the assumption that the corpus follows Zipf's law. In addition, we show an approximate behavior of each formula under certain conditions. In

Baltimore, Maryland, USA, June 23-25 2014.

Section 4, we verify the correctness of our theory on synthetic corpora and examine the gap between theory and practice on several real corpora. Section 5 concludes the paper.

2 Preliminaries

Let us consider a corpus $\mathbf{w} := w_1 \cdots w_N$ of corpus size N and vocabulary size W. We use an abridged notation $\{\mathbf{w}\} := \{w \in \mathbf{w}\}$ to represent the vocabulary of $\mathbf{w}$. Clearly, $N = |\mathbf{w}|$ and $W = |\{\mathbf{w}\}|$ hold. When $\mathbf{w}$ has additional notations, N and W inherit them. For example, we will use N' as the size of $\mathbf{w}'$ without its definition.

2.1 Power law and Zipf's law

A power law is a mathematical relationship between two quantities x and y, where y is proportional to the c-th power of x, i.e., $y \propto x^c$, and c is a real number. Zipf's law (Zipf, 1935) is a power law discovered on real corpora, wherein for any word $w \in \mathbf{w}$ in a corpus $\mathbf{w}$, its frequency (or word count) $f(w)$ is inversely proportional to its frequency ranking $r(w)$, i.e.,

$$f(w) = \frac{C}{r(w)}.$$

Here, $f(w) := |\{w' \in \mathbf{w} \mid w' = w\}|$, and $r(w) := |\{w' \in \mathbf{w} \mid f(w') \geq f(w)\}|$. From the definition, the constant C is the maximum frequency in the corpus. Taking the natural logarithms $\ln(\cdot)$ of both sides of the above equation, we find that its plot becomes linear on a log-log graph of $r(w)$ and $f(w)$. In fact, the result based on a statistical test in (Clauset et al., 2009) reports that the frequencies of words in a corpus completely follow a power law, whereas many datasets with long-tail properties, such as networks, actually do not follow power laws.

2.2 Perplexity

Perplexity is a widely used evaluation measure of k-gram models and topic models. Let p be a predictive distribution over words, which was learned from a training corpus $\mathbf{w}$ based on a certain model. Formally, perplexity *PP* is defined as the geometric mean of the inverse of the per-word likelihood on the held-out test corpus $\mathbf{w}_\tau$, i.e.,

$$PP := \left(\prod_{w \in \mathbf{w}_\tau} \frac{1}{p(w)} \right)^{\frac{1}{N_\tau}}.$$

Intuitively, *PP* means how many possibilities one has for estimating the next word in a test corpus. According to the definition, a lower perplexity means better generalization performance of p. Another well-known evaluation measure is cross-entropy. Since cross-entropy is easily calculated as $\log_2 PP$, we can apply many of the results of this paper to cross-entropy.

3 Perplexity on Reduced Corpora

Now let us consider what a cutoff is. In our study, we simply define a corpus that has been reduced by removing low-frequency words from the original corpus with a certain threshold. Formally, we say $\mathbf{w}'$ is a *corpus reduced from the original corpus* $\mathbf{w}$, if $\mathbf{w}'$ is the longest subsequence of $\mathbf{w}$ such that $\max_{w' \in \mathbf{w}'} r(w') = W'$. Note that a subsequence can include gaps in contrast to a substring. For example, supposing we have a corpus $\mathbf{w} = abcaba$ with a vocabulary $\{\mathbf{w}\} = \{a, b, c\}$, $\mathbf{w}'_1 = ababa$ is a reduced corpus, while $\mathbf{w}'_2 = aba$ and $\mathbf{w}'_3 = acaa$ are not.

After learning a distribution p' from a reduced corpus $\mathbf{w}'$, we need to infer the distribution p learned from the original corpus $\mathbf{w}$. Here, we use *constant restoring* (defined below), which assumes the frequencies of the reduced low-frequency words are a constant.

Definition 1 (Constant Restoring)**.** *Given a positive constant λ, a distribution p' over a reduced corpus $\mathbf{w}'$, and a corpus $\mathbf{w}$, we say that $\hat{p}$ is a λ-*restored distribution of p' from $\mathbf{w}'$ to $\mathbf{w}$*, if $\sum_{w \in \{\mathbf{w}\}} \hat{p}(w) = 1$, and for any $w \in \mathbf{w}$,*

$$\hat{p}(w) \propto \begin{cases} p'(w) & (w \in \mathbf{w}') \\ \lambda & (w \notin \mathbf{w}'). \end{cases}$$

Constant restoring is similar to the additive smoothing defined by $\hat{p}(w) \propto p'(w) + \lambda$, which is used to solve the zero-frequency problem of language models (Chen and Goodman, 1996). The only difference is the addition of a constant λ only to zero-frequency words. We think constant restoring is theoretically natural in our setting, since we can derive the above equation by letting each frequency of reduced words be $\lambda N'$ and defining a restored frequency function as follows:

$$\hat{f}(w) = \begin{cases} f(w) & (w \in \mathbf{w}') \\ \lambda N' & (w \notin \mathbf{w}'). \end{cases}$$

Informally, constant restoring involves padding the vocabulary, while additive smoothing involves padding the corpus. Smoothing should be carried out after restoring.

3.1 Perplexity of Unigram Models

Let us consider the perplexity of a unigram model learned from a reduced corpus. In unigram models, a predictive distribution p' on a reduced corpus $\mathbf{w}'$ can be simply calculated as $p'(w') = f(w')/N'$. We shall start with an analysis of training-set perplexity, since we can derive an exact formula for it, which will give us a sufficient idea for making an approximate analysis of test-set perplexity.

Let $\hat{PP}_1 := \left(\prod_{w\in\mathbf{w}} \frac{1}{\hat{p}(w)}\right)^{\frac{1}{N}}$ be the perplexity of a λ-restored distribution $\hat{p}$ on a unigram model. The next lemma gives the optimal restoring constant λ^* minimizing $\hat{PP}_1$.

Lemma 2. *For any λ-restored distribution $\hat{p}$ of a distribution p' from a reduced corpus $\mathbf{w}'$ to the original corpus $\mathbf{w}$, its perplexity is minimized by*

$$\lambda^* = \frac{N - N'}{(W - W')N'}.$$

Proof. Let $\mathbf{w}_\mathcal{R}$ be the longest subsequence such that $\min_{w'\in\mathbf{w}'} r(w') = W' + 1$. Since $\mathbf{w}_\mathcal{R}$ is the remainder of $\mathbf{w}'$, $N_\mathcal{R} = N - N'$ and $W_\mathcal{R} = W - W'$ hold. After substituting the normalized form of $\hat{p}$ of Definition 1 into $\hat{PP}_1$, we have

$$\begin{aligned}\hat{PP}_1 &= \left(\prod_{w'\in\mathbf{w}'} \frac{1}{\hat{p}(w')} \prod_{w_\mathcal{R}\in\mathbf{w}_\mathcal{R}} \frac{1}{\hat{p}(w_\mathcal{R})}\right)^{\frac{1}{N}} \\ &= \left(\prod_{w'\in\mathbf{w}'} \frac{1 + W_\mathcal{R}\lambda}{p'(w')} \prod_{w_\mathcal{R}\in\mathbf{w}_\mathcal{R}} \frac{1 + W_\mathcal{R}\lambda}{\lambda}\right)^{\frac{1}{N}} \\ &= \frac{1 + W_\mathcal{R}\lambda}{\lambda^{\frac{N_\mathcal{R}}{N}}} \left(\prod_{w'\in\mathbf{w}'} \frac{1}{p'(w')}\right)^{\frac{1}{N}}.\end{aligned}$$

We obtain the optimal smoothing factor λ^* when $\frac{\partial}{\partial\lambda}\hat{PP}_1 \propto \frac{\partial}{\partial\lambda}(1 + W_\mathcal{R}\lambda)/\lambda^{\frac{N_\mathcal{R}}{N}} = 0$. □

By using a similar argument to the one in the above lemma, we can obtain the optimal constant of additive smoothing as $\lambda^* \approx \frac{N-N'}{WN'}$, when N is sufficiently large.

The next theorem gives the exact formula of the training-set perplexity of a unigram model learned from a reduced corpus.

Theorem 3. *For any distribution p' on a unigram model learned from a corpus $\mathbf{w}'$ reduced from the original corpus $\mathbf{w}$ following Zipf's law, the perplexity $\hat{PP}_1$ of the λ^*-restored distribution $\hat{p}$ of p' from $\mathbf{w}'$ to $\mathbf{w}$ is calculated by*

$$\begin{aligned}\hat{PP}_1(W') =& H(W) \exp\left(\frac{B(W')}{H(W)}\right) \\ & \left(\frac{W - W'}{H(W) - H(W')}\right)^{1 - \frac{H(W')}{H(W)}},\end{aligned}$$

where $H(X) := \sum_{x=1}^{X} \frac{1}{x}$ and $B(X) := \sum_{x=1}^{X} \frac{\ln x}{x}$.

Proof. We expand the first part of $\hat{PP}_1$ in the proof of Lemma 2 using λ^* as follows:

$$\begin{aligned}\frac{1 + W_\mathcal{R}\lambda^*}{{\lambda^*}^{\frac{N_\mathcal{R}}{N}}} &= \left(1 + \frac{N_\mathcal{R}}{N'}\right)\left(\frac{W_\mathcal{R}N'}{N_\mathcal{R}}\right)^{\frac{N_\mathcal{R}}{N}} \\ &= \left(\frac{N}{N'}\right)\left(\frac{(W - W')N'}{N - N'}\right)^{1 - \frac{N'}{N}}.\end{aligned}$$

The second part of $\hat{PP}_1$ is as follows:

$$\begin{aligned}\left(\prod_{w'\in\mathbf{w}'} \frac{1}{p'(w')}\right)^{\frac{1}{N}} &= \prod_{w'\in\{\mathbf{w}'\}} \left(\frac{1}{p'(w')}\right)^{\frac{f(w')}{N}} \\ &= \prod_{r=1}^{W'} \left(\frac{rN'}{C}\right)^{\frac{C}{rN}} \\ &= \prod_{r=1}^{W'} \left(\frac{N'}{C}\right)^{\frac{C}{rN}} \prod_{r=1}^{W'} r^{\frac{C}{rN}} \\ &= \left(\frac{N'}{C}\right)^{\frac{N'}{N}} \exp\left(\frac{C}{N}\sum_{r=1}^{W'} \frac{\ln r}{r}\right).\end{aligned}$$

We obtain the objective formula by putting the above two formulae together with $N = CH(W)$ and $N' = CH(W')$, which are derived from Zipf's law. □

The functions $H(X)$ and $B(X)$ are the X-th partial sum of the harmonic series and Bertrand series (special form), respectively. An approximation by definite integrals yields $H(X) \approx \ln X + \gamma$, where γ is the Euler-Mascheroni constant, and $B(X) \approx \frac{1}{2}\ln^2 X$. We may omit γ from the approximate analysis.

Now let us consider an approximate form of $\hat{PP}_1(W')$ in Theorem 3. For further discussion,

we define the last part of $\hat{PP}_1(W')$ as follows:

$$F(W, W') := \left(\frac{W - W'}{H(W) - H(W')}\right)^{1-\frac{H(W')}{H(W)}}.$$

Since $W' = \delta W$ holds for an appropriate ratio δ, we have

$$\begin{aligned} F(W, \delta W) &= \left(\frac{W - \delta W}{H(W) - H(\delta W)}\right)^{1-\frac{H(\delta W)}{H(W)}} \\ &\approx \left(\frac{W - \delta W}{\ln W - \ln(\delta W)}\right)^{1-\frac{\ln(\delta W)}{\ln W}} \\ &= \left(\frac{W(1-\delta)}{-\ln \delta}\right)^{\frac{-\ln \delta}{\ln W}} \\ &\to \frac{1}{\delta} \qquad (W \to \infty). \end{aligned}$$

Therefore, when W is sufficiently large, we can use $F(W, W') \approx \frac{W}{W'}$, since $F(W, \delta W) \approx \frac{1}{\delta}$ holds for any ratio $\delta : 0 < \delta < 1$. Using this fact, we obtain an approximate formula $\tilde{PP}_1$ of $\hat{PP}_1$ as follows:

$$\begin{aligned} \tilde{PP}_1(W') &= \ln W \exp\left(\frac{\ln^2 W'}{2 \ln W}\right) \frac{W}{W'} \\ &= \sqrt{W} \ln W \exp \frac{(\ln W' - \ln W)^2}{2 \ln W}. \end{aligned}$$

The complexity of $\tilde{PP}_1$ is quasi-polynomial, i.e., $\tilde{PP}_1(W') = O(W'^{\ln W'})$, which behaves as a quadratic function on a log-log graph. Since $\tilde{PP}_1(W')$ is convex, i.e., $\frac{\partial^2}{\partial W'^2}\tilde{PP}_1(W') > 0$, and its gradient $\frac{\partial}{\partial W'}\tilde{PP}_1(W')$ is zero when $W' = W$, we infer that low-frequency words may not largely contribute to the statistics.

Considering the special case of $W' = W$, we obtain the perplexity PP_1 of the unigram model learned from the original corpus $\mathbf{w}$ as

$$PP_1 = H(W) \exp\left(\frac{B(W)}{H(W)}\right) \approx \sqrt{W} \ln W.$$

Interestingly, PP_1 is approximately expressed as a simple elementary function of vocabulary size W. This suggests that models learned from corpora with the same vocabulary size theoretically have the same perplexity.

For the test-set perplexity, we assume that both the training corpus $\mathbf{w}$ and test corpus $\mathbf{w}_\tau$ are generated from the same distribution based on Zipf's law. This assumption is natural, considering the situation of an in-domain test or cross validation test. Let $\mathbf{w}_\tau{}'$ be the longest subsequence of $\mathbf{w}_\tau$ such that for any $w \in \mathbf{w}_\tau{}'$, $w \in \mathbf{w}'$ holds. Formally, we assume $p'(w) \approx p_\tau{}'(w)$ for any $w \in \mathbf{w}'_\tau$ when $W_\tau > W'$, where $p_\tau{}'$ is the true distribution over $\mathbf{w}_\tau{}'$. Using similar arguments to those of Lemma 2 and Theorem 3 for $\mathbf{w}_\tau$, we obtain an approximation formula for the test-set perplexity, where we simply substitute W and W' in the exact formula for the training-set perplexity with W_τ and $W_\tau{}'$, respectively. For simplicity, we will only consider training-set perplexity from now on, since we can make a similar argument for the test-set perplexity in the later analysis.

3.2 Perplexity of k-gram Models

Here, we will consider the perplexity of a k-gram model learned from a reduced corpus as a standard extension of a unigram model. Our theory only assumes that the corpus is generated on the basis of Zipf's law. Thus, we can use a simple model where k-grams are calculated from a random word sequence based on Zipf's law. This model seems to be stupid, since we can easily notice that the bigram "is is" is quite frequent, and the two bigrams "is a" and "a is" have the same frequency. However, the experiments described later uncovered the fact that the model can roughly capture the behavior of real corpora.

The frequency f_k of k-gram word $w_k \in \mathbf{w}^k$ in the model is represented by the following formula:

$$f_k(w_k) = \frac{C_k}{g_k(r_k(w_k))},$$

where C_k is the maximal frequency in k-grams, r_k is the frequency ranking of w_k over k-grams, and g_k expresses the frequency decay in k-grams. For example, the decay function g_2 of bigrams is as follows:

$$\begin{aligned} (g_2(i))_i &:= (g_2(1),\ g_2(2),\ g_2(3), \cdots) \\ &= (1 \cdot 1,\ 1 \cdot 2,\ 2 \cdot 1,\ 1 \cdot 3,\ 3 \cdot 1, \cdots) \\ &= (1,\ 2,\ 2,\ 3,\ 3,\ 4,\ 4,\ 4,\ 5,\ 5,\ 6, \cdots). \end{aligned}$$

This is an inverse of the sum of Piltz's divisor functions $d_2(n) := \sum_{i_1 \cdot i_2 = n} 1$, which represents the number of divisors of an integer n (cf. (OEIS, 2001)). In general, we formally define g_k through its inverse: $g_k^{-1}(\ell) := S_k(\ell)$, where $S_k(\ell) := \sum_{n=1}^{\ell} d_k(n)$ and $d_k(n) := \sum_{i_1 \cdot i_2 \cdots i_k = n} 1$. Since $(g_k(i))_i$ is a sorted sequence of the elements of the k-th tensor power of vector $(1, \cdots, W)$, we can calculate the maximum frequency C_k as follows.

Lemma 4. *For any corpus* $\mathbf{w}$ *following Zipf's law, the maximum frequency of* k*-grams in our model is calculated by*

$$C_k = \frac{N-(k-1)D}{(H(W))^k},$$

where D *denotes the number of documents in* $\mathbf{w}$.

Proof. We use $\sum_{w_k} f_k(w_k) = C_k(\sum_w 1/r(w))^k$. □

The sum $S_k(\ell)$ of Piltz's divisor functions can be approximated by $\ell P_k(\ln \ell)$, where $P_k(x)$ is a polynomial of degree $k-1$ with respect to x, and the main term of $\ell P_k(\ln \ell)$ is given by the following residue $\mathrm{Res}_{s=1}\frac{\zeta^k(s)x^s}{s}$, where $\zeta(s)$ is the Riemann zeta function (Li, 2005). Using this fact, we obtain an approximation $\ln\left(g_k^{-1}(\ell)\right) \approx \ln \ell + O(\ln(\ln \ell)) \approx \ln \ell$, when ℓ is sufficiently large. Thus, when the corpus is sufficiently large, we can see that the behavior of f_k is roughly linear on a log-log graph, i.e., $f_k(w_k) \propto r_k(w_k)^{-1}$, since if $g_k^{-1}(\ell) \propto \ell^c$ holds, then $f_k(r) \propto (g_k(r))^{-1} \propto r^{-\frac{1}{c}}$ holds.

Unfortunately, however, most corpora in the real world are not so large that the above-mentioned relation holds. Actually, Ha et al. (Ha et al., 2002; Ha et al., 2006) experimentally found that although a k-gram corpus roughly follows a power law even when $k > 1$, its exponent is smaller than 1 (for Zipf's law). They pointed out that the exponent of bigrams is about 0.66, and that of 5-grams is about 0.59 in the Wall Street Journal corpus (WSJ87). Believing their claim that there exists a constant π_k such that $f_k(w_k) \propto r_k(w_k)^{-\pi_k}$, we estimated the exponent of k-grams in an actual situation in the form of the following lemma.

Lemma 5. *Assuming that* $f_k(w_k) \propto r_k(w_k)^{-\pi_k}$ *holds for any* k*-gram word* $w_k \in \mathbf{w}^k$ *in a corpus* $\mathbf{w}$ *following Zipf's law, the optimal exponent in our model based on the least squares criterion is calculated by*

$$\pi_k = \frac{\ln W}{(k-1)\ln(\ln W) + \ln W}.$$

Proof. We find the optimal exponent π_k by minimizing the sum of squared errors between the gradients of $g_k^{-1}(r)$ and $r^{\frac{1}{\pi_k}}$ on a log-log graph:

$$\int \left\{ \frac{\partial}{\partial y}\left(y + \ln P_k(y)\right) - \frac{\partial}{\partial y}\left(\frac{1}{\pi_k}y\right)\right\}^2 dy,$$

where $y = \ln r$. □

In the case of unigrams ($k = 1$), the formula exactly represents Zipf's law. In the case of k-grams ($k > 1$), we found that the formula approaches Zipf's law when W approaches infinity, i.e., $\lim_{W\to\infty} \pi_k = 1$.

Let us consider the perplexity of a k-gram model learned from a reduced corpus. We immediately obtain the following corollary using Lemma 5.

Corollary 6. *For any distribution* p' *on a* k*-gram model learned from a corpus* $\mathbf{w}'$ *reduced from the original corpus* $\mathbf{w}$ *following Zipf's law, assuming that* $f_k(w_k) \propto r_k(w_k)^{-\pi_k}$ *holds for any* k*-gram word* $w_k \in \mathbf{w}^k$ *and the optimal exponent* π_k *in Lemma 5, the perplexity* $\hat{PP}_k$ *of the* λ^**-restored distribution* $\hat{p}$ *of* p' *from* $\mathbf{w}'$ *to* $\mathbf{w}$ *is calculated by*

$$\hat{PP}_k(W') = H_{\pi_k}(W)\exp\left(\frac{B_{\pi_k}(W')}{H_{\pi_k}(W)}\right) \left(\frac{W-W'}{H_{\pi_k}(W)-H_{\pi_k}(W')}\right)^{1-\frac{H_{\pi_k}(W')}{H_{\pi_k}(W)}},$$

where $H_a(X) := \sum_{x=1}^{X}\frac{1}{x^a}$ *and* $B_a(X) := \sum_{x=1}^{X}\frac{a\ln x}{x^a}$.

$H_a(X)$ is the X-th partial sum of the P-series or hyper-harmonic series, which is a generalization of the harmonic series $H(X)$. $B_a(X)$ is the X-th partial sum of the Bertrand series (another special form of $B(X)$). When $0 < a < 1$, we can easily calculate $\hat{PP}_k(W')$ by using the following approximations:

$$H_a(X) \approx \frac{(X+1)^{1-a}-1}{1-a}$$
$$B_a(X) \approx \frac{a}{1-a}(X+1)^{1-a}\ln(X+1) - \frac{a}{(1-a)^2}(X+1)^{1-a} + \frac{a}{(1-a)^2}.$$

By putting the approximations of $H_a(X)$ and $B_a(X)$ into the formula of Corollary 6, we obtain an approximation $\hat{PP}_k(W') \approx O({W'}^{{W'}^{1-\pi_k}})$. This implies that $\hat{PP}_k(W')$ is approximately linear on a log-log graph, when π_k is close to 1, i.e., k is relatively small and W is sufficiently large. Note that we must use the approximation of $H(X)$, not $H_a(X)$, when $a = 1$.

The fact that the frequency of k-grams follows a power law leads us to an additional convenient

property, since the process of generating a corpus in our theory can be treated as a variant of the coupon collector's problem. In this problem, we consider how many trials are needed for collecting all coupons whose occurrence probabilities follow some stable distribution. According to a well-known result about power law distributions (Boneh and Papanicolaou, 1996), we need a corpus of size $\frac{kW^k}{1-\pi_k}\ln W$ when $\pi_k < 1$, and $W\ln^2 W$ when $\pi_k = 1$ for collecting all of the k-grams, the number of which is W^k. Using results in (Atsonios et al., 2011), we can easily obtain a lower and upper bound of the actual vocabulary size $\tilde{W}_k$ of k-grams from the corpus size N and vocabulary size W as

$$\tilde{W}_k \geq (\pi_k + 1)\left(1 - e^{-\frac{(1-\pi_k)N}{W^k-1} - \ln\frac{W^k-1}{W^k}}\right)$$

$$\tilde{W}_k \leq \frac{\pi_k}{\pi_k - 1}\left(\frac{N}{H_{\pi_k}(W^k)}\right)^{\frac{1}{\pi_k}} - \frac{NW^{1-\pi_k}}{(\pi_k - 1)H_{\pi_k}(W^k)}.$$

This means that we can determine the rough sparseness of k-grams and adjust some of the parameters such as the gram size k in learning statistical language models.

3.3 Perplexity of Topic Models

In this section, we consider the perplexity of the widely used topic model, Latent Dirichlet Allocation (LDA) (Blei et al., 2003), by using the notation given in (Griffiths and Steyvers, 2004). LDA is a probabilistic language model that generates a corpus as a mixture of hidden topics, and it allows us to infer two parameters: the document-topic distribution θ that represents the mixture rate of topics in each document, and the topic-word distribution ϕ that represents the occurrence rate of words in each topic. For a given corpus $\mathbf{w}$, the model is defined as

$$\begin{aligned} \theta_{d_i} &\sim \textit{Dirichlet}(\alpha) \\ z_i|\theta_{d_i} &\sim \textit{Multi}(\theta_{d_i}) \\ \phi_{z_i} &\sim \textit{Dirichlet}(\beta) \\ w_i|z_i, \phi_{z_i} &\sim \textit{Multi}(\phi_{z_i}), \end{aligned}$$

where d_i and z_i are respectively the document that includes the i-th word w_i and the hidden topic that is assigned to w_i. In the case of inference by Gibbs sampling presented in (Griffiths and Steyvers, 2004), we can sample a "good" topic assignment z_i for each word w_i with high probability. Using the assignments $\mathbf{z}$, we obtain the posterior distributions of two parameters as $\hat{\theta}_d(z) \propto n_z^{(d)} + \alpha$ and $\hat{\phi}_z(w) \propto n_z^{(w)} + \beta$, where $n_z^{(d)}$ and $n_z^{(w)}$ respectively represent the number of times assigning topic z in document d and the number of times topic z is assigned to word w.

Since an exact analysis is very hard, we will place rough assumptions on $\hat{\phi}$ and $\hat{\theta}$ to reduce the complexity. The assumption placed on $\hat{\phi}$ is that the word distribution $\hat{\phi}_z$ of each topic z follows Zipf's law. We think this is acceptable since we can regard each topic as a corpus that follows Zipf's law. Since $\hat{\phi}_z$ is normalized for each topic, we can assume that for any two topics, z and z', and any two words, w and w', $\hat{\phi}_z(w) \approx \hat{\phi}_{z'}(w')$ holds if $r_z(w) = r_{z'}(w')$, where $r_z(w)$ is the frequency ranking of w with respect to $n_z^{(w)}$. Note that the above assumption pertains to a posterior, and we do not discuss the fact that a Pitman-Yor process prior is better suited for a power law (Goldwater et al., 2011).

The assumption placed on $\hat{\phi}$ may not be reasonable in the case of $\hat{\theta}$, because we can easily think of a document with only one topic, and we usually use a small number T of topics for LDA, e.g., $T = 20$. Thus, we consider two extreme cases. One is where each document evenly has all topics, and the other is where each document only has one topic. Although these two cases might be unrealistic, the actual (theoretical) perplexity is expected to be between their values. We believe that analyzing such extreme cases is theoretically important, since it would be useful for bounding the computational complexity and predictive performance.

We can regard the former case as a unigram model, since the marginal predictive distribution $\sum_{z=1}^{T}\hat{\theta}_d(z)\hat{\phi}_z(w) \propto \sum_{z=1}^{T}\frac{n_z^{(w)}+\beta}{T} \propto\!\!\propto f(w)$ is independent of d; here we have used $\hat{\theta}_d(z) = 1/T$ from the assumption. In the latter case, we can obtain an exact formula for the perplexity of LDA when the topic assigned to each document follows a discrete uniform distribution, as shown in the next theorem. Note that a mixture of corpora following Zipf's law can be approximately regarded as following Zipf's law, when W is sufficiently large.

Theorem 7. *For any distribution p' on the LDA model with T topics learned from a corpus $\mathbf{w}'$ reduced from the original corpus $\mathbf{w}$ following Zipf's law, assuming that each document only has one topic which is assigned based on a discrete uniform distribution, the perplexity $\hat{PP}_{Mix}$ of the λ^*-restored distribution $\hat{p}$ of p' from $\mathbf{w}'$ to $\mathbf{w}$ is calcu-*

Table 1: Details of Reuters, 20news, Enwiki, Zipf1, and ZipfMix.

	vocab. size	corpus size	doc. size
Reuters	70,258	2,754,800	18,118
20news	192,667	4,471,151	19,997
Enwiki	409,902	16,711,226	51,231
Zipf1	69,786	2,754,800	18,118
ZipfMix	70,093	2,754,800	18,118

lated by

$$\hat{PP}_{Mix}(W') = H(W/T)\exp\left(\frac{B(W'/T)}{H(W/T)}\right)\left(\frac{W-W'}{H(W/T)-H(W'/T)}\right)^{1-\frac{H(W'/T)}{H(W/T)}}$$

Proof. We can prove this by using a similar argument to that of Theorem 3 for each topic. □

The formula of the theorem is nearly identical to the one of Theorem 3 for a $1/T$ corpus. This implies that the growth rate of the perplexity of LDA models is larger than that of unigram models, whereas the perplexity of LDA models for the original corpus is smaller than that of unigram models. In fact, a similar argument to the one in the approximate analysis in Section 3.1 leads to an approximate formula $\tilde{PP}_{Mix}$ of $\hat{PP}_{Mix}$ as

$$\tilde{PP}_{Mix}(W') = \sqrt{\frac{W}{T}}\ln\frac{W}{T}\exp\frac{(\ln W' - \ln W)^2}{2\ln(W/T)},$$

when W is sufficiently large. That is, $\tilde{PP}_{Mix}(W')$ also has a quadratic behavior in a log-log graph, i.e., $\tilde{PP}_{Mix}(W') = O(W'^{\ln W'})$.

4 Experiments

We performed experiments on three real corpora (Reuters, 20news, and Enwiki) and two synthetic corpora (Zipf1 and ZipfMix) to verify the correctness of our theory and to examine the gap between theory and practice. Reuters and 20news here denote corpora extracted from the Reuters-21578 and 20 Newsgroups data sets, respectively. Enwiki is a $1/100$ corpus of the English Wikipedia. Zipf1 is a synthetic corpus generated by Zipf's law, whose corpus is the same size as Reuters, and ZipfMix is a mixture of 20 synthetic corpora, sizes are 1/20th of Reuters. We used ZipfMix only for the experiments on topic models. Table 1 lists the details of all five corpora.

Fig. 1(a) shows the word frequency of Reuters, 20news, Enwiki, and Zipf1 versus frequency ranking on a log-log graph. In all corpora, we can regard each curve as linear with a gradient close to 1. This means that all corpora roughly follow Zipf's law. Furthermore, since the curve of Zipf1 is similar to that of Reuters, Zipf1 can be regarded as acceptable.

Fig. 1(b) plots the perplexity of unigram models learned from Reuters, 20news, Enwiki, and Zipf1 versus the size of reduced vocabulary on a log-log graph. Each value is the average over different test sets of five-fold cross validation. Theory1 is calculated using the formula in Theorem 3. The graph shows that the curve of Theory1 is nearly identical to that of Zipf1. Since the vocabulary size W_τ of each test set is small in this experiment, some errors appear when W' is large, i.e., $W_\tau < W'$. This clearly means that our theory is theoretically correct for an ideal corpus Zipf1. Comparing Zipf1 with Reuters, however, we find that their perplexities are quite different. The reason is that the gap between the frequencies of low-ranking (high-frequency) words is considerably large. For example, the frequency of the 1st-rank word of Reuters is $f(w) = 136,371$, while that of Zipf1 is $f(w) = 234,705$. Our theory seems to be suited for inferring the growth rate of perplexity rather than the perplexity value itself.

As for the approximate formula $\tilde{PP}_1$ of Theorem 3, we can surely regard the curve of Zipf1 as being roughly quadratic. The curves of real corpora also have a similar tendency, although their gradients are slightly steeper. This difference might have been caused by the above-mentioned errors. However, at least, we can ascertain the important fact that the results for the corpora reduced by 1/100 are not so different from those of the original corpora from the perspective of their perplexity measures.

Fig. 1(c) plots the frequency of k-grams ($k \in \{1,2,3\}$) in Reuters versus frequency ranking on a log-log graph. TheoryFreq (1-3) are calculated using C_k in Lemma 4 and π_k in Lemma 5. A comparison of TheoryFreq and Zipf verifies the correctness of our theory. However, comparing Zipf and Reuters, we see that C_k is poorly estimated when the gram size is large, whereas π_k is roughly correct. This may have happened because we did not put any assumptions on the word se-

Figure 1: (a) Word frequency of `Reuters`, `20news`, `Enwiki`, and `Zipf1` versus frequency ranking. (b) Perplexity of unigram models learned from `Reuters`, `20news`, `Enwiki`, and `Zipf1` versus size of reduced vocabulary. `Theory1` is calculated using the formula in Theorem 3. (c) Frequency of k-grams ($k \in \{1, 2, 3\}$) in `Reuters` and `Zipf1` versus frequency ranking. The suffix digit of each label means its gram size. `TheoryFreq` (1-3) are calculated using Lemma 4 and Lemma 5. (d) Exponent of a power law over k-grams in `Reuters` versus gram size. `TheoryGrad` is calculated using π_k in Lemma 5. (e) Perplexity of k-gram models learned from `Reuters` versus size of reduced vocabulary. `Theory2` and `Theory3` are calculated using the formula in Corollary 6. (f) Perplexity of topic models learned from `Reuters`, `20news`, `Enwiki`, `Zipf1`, and `ZipfMix` versus size of reduced vocabulary. `TheoryMix` is calculated using the formula in Theorem 7.

quences in our simple model. The frequencies of high-order k-grams tend to be lower than in reality. We might need to place a hierarchical assumption on the a power law, as in done in hierarchical Pitman-Yor processes (Wood et al., 2011).

Fig. 1(d) plots the exponent of the power law over k-grams in `Reuters` versus the gram size on a normal graph. We estimated each exponent of `Reuters` by using the least-squares method. `TheoryGrad` is calculated using π_k in Lemma 5. Surprisingly, the real exponents of `Reuters` are almost the same as the theoretical estimate π_k based on our "stupid" model that does not care about the order of words. Note that we do not use any information other than the vocabulary size W and the gram size k for estimating π_k.

Fig. 1(e) plots the perplexity of k-gram models ($k \in \{1, 2, 3\}$) learned from `Reuters` versus the size of reduced vocabulary on a log-log graph. `Theory2` and `Theory3` are calculated using the formula in Corollary 6. In the case of bigrams, the perplexities of `Theory2` are almost the same as that of `Zipf2` when the size of reduced vocabulary is large. However, in the case of trigrams, the perplexities of `Theory3` are far from those of `Zipf3`. This difference may be due to the sparseness of trigrams in `Zipf3`. To verify the correctness of our theory for higher order k-gram models, we need to make assumptions that include backoff and smoothing.

Fig. 1(f) plots the perplexity of LDA models with 20 topics learned from `Reuters`, `20news`, `Enwiki`, `Zipf1`, and `ZipfMix` versus the size of reduced vocabulary on a log-log graph. We used a collapsed Gibbs sampler with 100 iterations to infer the parameters and set the hyper parameters, $\alpha = 0.1$ and $\beta = 0.1$. In evaluating the perplexity, we estimated a posterior document-topic distribu-

Table 2: Computational time and memory size for LDA learning on the original corpus, (1/10)-reduced corpus, and (1/20)-reduced corpus of `Reuters`.

corpus	time	memory	perplexity
original	4m3.80s	71,548KB	500
(1/10)	3m55.70s	46,648KB	550
(1/20)	3m42.63s	34,024KB	611

tion $\hat{\theta}_d$ by using the first half of each test document and calculated the perplexity on the second half, as is done in (Asuncion et al., 2009). Each value is the average over different test sets of five-fold cross validation. `Theory1` and `TheoryMix` are calculated using the formulae in Theorem 3 and Theorem 7, respectively. Comparing `Zipf1` with `Theory1`, and `ZipfMix` with `TheoryMix`, we find that our theory of the extreme cases discussed in Section 3.3 is theoretically correct. `TheoryAve` is the average of `Theory1` and `TheoryMix`. Comparing `Reuters` and `TheoryAve`, we see that their curves are almost the same. If theoretical perplexity $\hat{PP}$ has a similar tendency as real perplexity PP on a log-log graph, i.e., $\ln PP(W') \approx \ln \hat{PP}(W') + c$ for some constant c, we can approximate its deterioration rate as $PP(W')/PP(W) \approx \exp(\ln \hat{PP}(W') + c)/\exp(\ln \hat{PP}(W) + c) = \hat{PP}(W')/\hat{PP}(W)$. Therefore, we can use `TheoryAve` as a heuristic function for estimating the perplexity of topic models. Since we can calculate an inverse of `TheoryAve` from the bisection or Newton-Raphson method, we can maximize the reduction rate and ensure an acceptable perplexity based on a user-specified deterioration rate. According to the fact that the three real corpora with different sizes have a similar tendency, it is expected that we can use our theory for a larger corpus.

Finally, let us examine the computational costs for LDA learning. Table 2 shows computational time and memory size for LDA learning on the original corpus, (1/10)-reduced corpus, and (1/20)-reduced corpus of `Reuters`. Comparing the memory used in the learning with the original corpus and with the (1/10)-reduced corpus of `Reuters`, we find that the learning on the (1/10)-reduced corpus used 60% of the memory used by the learning on the original corpus. While the computational time decreased a little, we believe that reducing the memory size helps to reduce computational time for a larger corpus in the sense that it can relax the constraint for in-memory computing. Although we did not examine the accuracy of real tasks in this paper, there is an interesting report that the word error rate of language models follows a power law with respect to perplexity (Klakow and Peters, 2002). Thus, we conjecture that the word error rate also has a similar tendency as perplexity with respect to the reduced vocabulary size.

5 Conclusion

We studied the relationship between perplexity and vocabulary size of reduced corpora. We derived trade-off formulae for the perplexity of k-gram models and topic models with respect to the size of reduced vocabulary and showed that each formula approximately has a simple behavior on a log-log graph under certain conditions. We verified the correctness of our theory on synthetic corpora and examined the gap between theory and practice on real corpora. We found that the estimation of the perplexity growth rate is reasonable. This means that we can maximize the reduction rate, thereby ensuring an acceptable perplexity based on a user-specified deterioration rate. Furthermore, this suggests the possibility that we can theoretically derive empirical parameters, or "rules of thumb", for different NLP problems, assuming that a corpus follows Zipf's law. We believe that our theoretical estimation has the advantages of computational efficiency and scalability especially for very large corpora, although experimental estimations such as cross-validation may be more accurate.

In the future, we want to find out the cause of the gap between theory and practice and extend our theory to bridge the gap, in the same way that we can construct equations of motion with air resistance in the example of the landing point of a ball in Section 1. For example, promising research directions include using a general law such as the Zipf-Mandelbrot law (Mandelbrot, 1965), a sophisticated model that cares the order of words such as hierarchical Pitman-Yor processes (Wood et al., 2011), and smoothing/backoff methods to handle the sparseness problem.

Abstract

We propose a two-phase framework to adapt existing relation extraction classifiers to extract relations for new target domains. We address two challenges: negative transfer when knowledge in source domains is used without considering the differences in relation distributions; and lack of adequate labeled samples for rarer relations in the new domain, due to a small labeled data set and imbalance relation distributions. Our framework leverages on both labeled and unlabeled data in the target domain. First, we determine the relevance of each source domain to the target domain for each relation type, using the consistency between the clustering given by the target domain labels and the clustering given by the predictors trained for the source domain. To overcome the lack of labeled samples for rarer relations, these clusterings operate on both the labeled and unlabeled data in the target domain. Second, we trade-off between using relevance-weighted source-domain predictors and the labeled target data. Again, to overcome the imbalance distribution, the source-domain predictors operate on the unlabeled target data. Our method outperforms numerous baselines and a weakly-supervised relation extraction method on ACE 2004 and YAGO.

1 Introduction

The World Wide Web contains information on real-world entities, such as persons, locations and organizations, which are interconnected by various semantic relations. Detecting these relations between two entities is important for many tasks on the Web, such as information retrieval (Salton and McGill, 1986) and information extraction for question answering (Etzioni et al., 2008). Recent work on relation extraction has demonstrated that supervised machine learning coupled with intelligent feature engineering can provide state-of-the-art performance (Jiang and Zhai, 2007b). However, most supervised learning algorithms require adequate labeled data for every relation type to be extracted. Due to the large number of relations among entities, it may be costly to annotate a large enough set of training data to cover each relation type adequately in every new domain of interest. Instead, it can be more cost-effective to adapt an existing relation extraction system to the new domain using a small set of labeled data. This paper considers relation adaptation, where a relation extraction system trained on many source domains is adapted to a new target domain.

There are at least three challenges when adapting a relation extraction system to a new domain. First, the same semantic relation between two entities can be expressed using different lexical or syntactic patterns. For example, the acquisition of company A by company B can be expressed with "B bought over by A", "A buys B" and "A purchases B". To extract a relation, we need to capture the different ways in which it can be expressed across different open domains on the Web.

Second, the emphasis or interest on the different relation types varies from domain to domain. For example, in the organization domain, we may be more interested in extracting relations such as *locatedIn* (between a company and a location) and *founderOf* (between a company and a person),

[*]The work is done while Nguyen was a research staff in Nanyang Technological University, Singapore.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 807–817,
Baltimore, Maryland, USA, June 23-25 2014.

whereas in the person domain we may be more interested in extracting relations such as *liveIn* (between a person and a location) and *workAt* (between a person and a company). Therefore, although the two domains may have the same set of relations, they probably have different marginal distributions on the relations. This can produce a negative transfer phenomenon (Rosenstein et al., 2005), where using knowledge from other domains degrades the performance on the target domain. Hence, when transferring knowledge from multiple domains, it is overly optimistic to believe that all source domains will contribute positively. We call a source domain *irrelevant* when it has no or negative contribution to the performance of the target domain. One example is named entities extraction adaptation, where naïve transfer of information from a mixed-case domain with capitalization information (e.g., news-wire) to a single-case domain (e.g., conversational speech transcripts) will miss most names in the single-case domain due to the absence of case information, which is typically important in the mixed-case domain.

Third, the annotated instances for the target domain are typically much fewer than those for the source domains. This is primarily due to the lack of resources such as raw target domain documents, time, and people with the expertise. Together with imbalanced relation distributions inherent in the domain, this can cause some rarer relations to constitute only a very small proportion of the labeled data set. This makes learning a relation classifier for the target domain challenging.

To tackle these challenges, we propose a two-phase Robust Domain Adaptation (RDA) framework. In the first phase, Supervised Voting is used to determine the relevance of each source domain to each region in the target domain, using both labeled and unlabeled data in the target domain. By using also unlabeled data, we alleviate the lack of labeled samples for rarer relations due to imbalanced distributions in relation types.

The second phase uses the relevances determined the first phase to produce a reference predictor by weighing the source-domain predictors for each target domain sample separately. The intention is to alleviate the effect of mismatched distributions. The final predictor in the target domain is trained on the labeled target domain data while taking reference from the reference predictions on the unlabeled target domain data. This ensures reasonable predictive performance even when all the source domains are irrelevant and augments the rarer classes with examples in the unlabeled data. We compare the proposed two-phase framework with state-of-the-art domain adaptation baselines for the relation extraction task, and we find that our method outperforms the baselines.

2 Related Work

Relation extraction is usually considered a classification problem: determine if two given entities in a sentence have a given relation. Kernel-based supervised methods such as dependency tree kernels (Culotta and Sorensen, 2004), subsequence kernels (Bunescu and Mooney, 2006) and convolution tree kernels (Qian et al., 2008) have been rather successful in learning this task. However, purely supervised relation extraction methods assume the availability of sufficient labeled data, which may be costly to obtain for new domains. We address this by augmenting a small labeled data set with other information in the domain adaptation setting.

Bootstrapping methods (Zhu et al., 2009; Agichtein and Gravano, 2000; Xu et al., 2010; Pasca et al., 2006; Riloff and Jones, 1999) to relation extraction are attractive because they require fewer training instances than supervised approaches. Bootstrapping methods are either initialized with a few instances (often designated as seeds) of the target relation (Zhu et al., 2009; Agichtein and Gravano, 2000) or a few extraction patterns (Xu et al., 2010). In subsequent iterations, new extraction patterns are discovered, and these are used to extract new instances. The quality of the extracted relations depends heavily on the seeds (Kozareva and Hovy, 2010). Different from bootstrapping, we not only use labeled target domain data as seeds, but also leverage on existing source-domain predictors to obtain a robust relation extractor for the target domain.

Open Information Extraction (Open IE) (Etzioni et al., 2008; Banko et al., 2008; Mesquita et al., 2013) is a domain-independent information extraction paradigm to extract relation tuples from collected corpus (Shinyama and Sekine, 2006) and Web (Etzioni et al., 2008; Banko et al., 2008). Open IE systems are initialized with a few domain-independent extraction patterns. To create labeled data, the texts are dependency-parsed, and the domain-independent patterns on the parses form the basis for extractions. Recently, to reduce

labeling effort for relation extraction, distant supervision (Mintz et al., 2009; Takamatsu et al., 2012; Min et al., 2013; Xu et al., 2013) has been proposed. This is an unsupervised approach that exploits textual features in large unlabeled corpora. In contrast to Open IE, we tune the relation patterns for a domain of interest, using labeled relation instances in source and target domains and unlabeled instances in the target domain.

Our work is also different from the multi-schema matching in database integration (Doan et al., 2003). Multi-schema matching finds relations between columns of schemas, which have the same semantic. In addition, current weighted schema matching methods do not address negative transfer and imbalance class distribution.

Domain adaptation methods can be classified broadly into weakly-supervised adaptation (Daume and Marcu, 2007; Blitzer et al., 2006; Jiang and Zhai, 2007a; Jiang, 2009), and unsupervised adaptation (Pan et al., 2010; Blitzer et al., 2006; Plank and Moschitti, 2013). In the weakly-supervised approach, we have plenty of labeled data for the source domain and a few labeled instances in the target domain; in the unsupervised approach, the data for the target domain are not labeled. Among these studies, Plank and Moschitti's is the closest to ours because it adapts relation extraction systems to new domains. Most other works focused on adapting from old to new relation types. Typical relation adaptation methods first identify a set of common features in source and target domains and then use those features as pivots to map source domain features to the target domain. These methods usually assume that each source domain is relevant to the task on the target domain. In addition, these methods do not handle the imbalanced distribution of relation data explicitly. In this work, we study how to learn the target prediction using only a few seed instances, while dealing with negative transfer and imbalanced relation distribution explicitly. These issues are seldom explored in relation adaptation.

3 Problem Statement

This section defines the domain adaptation problem and describes our feature extraction scheme.

3.1 Relation Extraction Domain Adaptation

Given two entities A and B in a sentence S, relation extraction is the task of selecting the relation y between A and B from a fixed set of c relation types, which includes the *not-a-relation* type. We introduce a feature extraction χ that maps the triple (A,B,S) to its feature vector x. Learning relation extraction can then be abstracted to finding a function p such that $p(\chi(A,B,S)) = p(x) = y$.

For adaptation, we have k source domains and a target domain. We shall assume that all domains have the same set of relation types. The target domain has a few labeled data $D_l = \{(x_i, y_i)\}_{i=1}^{n_l}$ and plenty of unlabeled data $D_u = \{(x_i)\}_{n_l+1}^{n_l+n_u}$, where n_l and n_u are the number of labeled and unlabeled samples respectively, x_i is the feature vector, y_i is the corresponding label (if available). Let $n = n_l + n_u$. For the sth source domain, we have an adequate labeled data set D^s. We define *domain adaptation* as the problem of learning a classifier p for relation extraction in the target domain using the data sets D_l, D_u and D^s, $s = 1,\ldots,k$.

3.2 Relational Feature Representation

We consider relation extraction as a classification problem, where each pair of entities A and B within a sentence S is a candidate relation instance. The contexts in which entities A and B co-occur provide useful features to the relations between them. We use the term context to refer a window of text in which two entities co-occur. A context might not necessarily be a complete sentence S. Retrieving contexts in which two entities co-occur has been studied in previous works investigating the relations between entities.

Given a pair of entities (A,B) in S, the first step is to express the relation between A and B with some feature representation using a feature extraction scheme χ. Lexical or syntactic patterns have been successfully used in numerous natural language processing tasks, including relation extraction. Jiang and Zhai (2007b) have shown that selected lexical and syntactic patterns can give good performance for relation extraction. Following their work[1], we also use lexical and syntactic patterns extracted from the contexts to represent the relations between entities. We extract features from a sequence representation and a parse tree representation of each relation instance. The details are as follows.

Entity Features Entity types and entity mention types are very useful for relation extraction. We

[1]The source code for extracting entity features is provided by the authors (Jiang and Zhai, 2007b).

use a subgraph in the relation instance graph (Jiang and Zhai, 2007b) that contains only the node presenting the head word of the entity A, labeled with the entity type or entity mention types, to describe a single entity attribute.

Sequence Features The sequence representation preserves the order of the tokens as they occur in the original sentence. Each node in the graph is a token augmented with its relevant attributes.

Syntactic Features The syntactic parse tree of the relation instance sentence can be augmented to represent the relation instance. Each node is augmented with relevant part-of-speech (POS) using the Python Natural Language Processing Tool Kit.

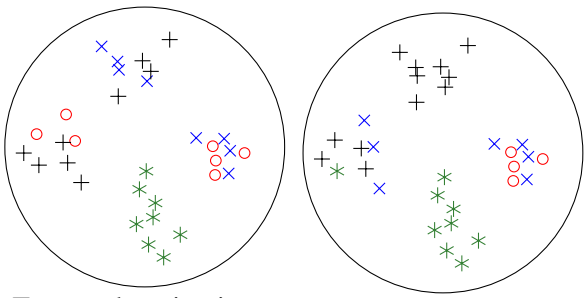
Each node in the sequence or the parse tree is augmented by an argument tag that indicates whether the node corresponds to entity A, B, both, or neither. The nodes that represent the argument are also labeled with the entity type, subtype and mention type. We trim the parse tree of a relation instance so that it contains only the most essential tree components based on constituent dependencies (Qian et al., 2008). We also use unigram features and bigram features from a relation instance graph.

4 Robust Domain Adaptation

In this section, we describe our two-phase approach, which comprises of a Supervised Voting scheme and a combined classifier learning phase.

4.1 Phase 1: Clustering Consistency via Supervised Voting

In this section, we use the concept of clustering consistency to determine the relevance of a source domain to particular regions in the target domain. Figure 1 illustrates this. There, both enclosing circles in the left and right figures denote the same input space of the target domain. There are four disjoint regions within the input space, located at the left, right, top and bottom of the space. There are four classes of labels: plus ($+$), cross ($\times$), circle ($\circ$) and asterisk ($*$). The labels in the left figure are given by a *preliminary predictor* in the target domain data, while the labels in the right figure are given by a predictor trained on the source domain data. Comparing the figures, we see the preliminary predictor and source domain predictor are consistent for the bottom and right regions,



Target domain input space with transductive learning using labeled and unlabeled target domain data.

Target domain input space with labels from the predictor trained on the source domain data set.

Figure 1: Clustering consistency is used to determine the relevance of a source domain to a region in the target domain data. The bottom and right regions are more relevant than the top and left regions. See text for explanation.

but are inconsistent for the top and left regions. This suggests that the source domain is very relevant for the bottom and right regions of the target input space, but less so for the top and left regions.

To apply this idea to relation classification, we have to (i) partition the target domain input space into regions and (ii) assign preliminary labels for all the examples. We approximate the target domain input space with all the samples from D_l and D_u. With data from both the labeled and unlabeled data sets, we apply transductive inference or semi-supervised learning (Zhou et al., 2003) to achieve both (i) and (ii). By augmenting with unlabeled data D_u, we aim to alleviate the effect of imbalanced relation distribution, which causes a lack of labeled samples for rarer classes in a small set of labeled data. Briefly, the known labels in D_l are propagated to the entire target input space by encouraging label smoothness in neighborhoods. The next three paragraphs give more details.

At present, we assume a similarity matrix W, where W_{ij} is the similarity between the ith and the jth input samples in $D_l \cup D_u$. Matrix W then determines the neighborhoods. Let Λ be a diagonal matrix where the (i,i)th entry is the sum of the ith row of W. Let us also encode the the labeled data D_l in an n-by-c matrix H, such that $H_{ij} = 1$ if sample i is labeled with relation class j in D_l, and $H_{ij} = 0$ otherwise. Our objective is the c-dimensional relation-class indicator vector F_i for the ith sample, for every sample. This is achieved

via a regularization framework (Zhou et al., 2003):

$$\min_{\{F_i\}_{i=1}^n} \left(\sum_{i,j=1}^{n} W_{ij} \left\| \frac{F_i}{\sqrt{\Lambda_{ii}}} - \frac{F_j}{\sqrt{\Lambda_{jj}}} \right\|^2 + \mu \sum_{i=1}^{n} \|F_i - H_i\|^2 \right).$$

This trades off two criteria: the first term encourages nearby samples (under distance metric W) to have the same labels, while the second encourages samples to take their labels from the labeled data. The closed-form solution is

$$F^* = (I - (1+\mu)^{-1} L)^{-1} H, \qquad (1)$$

where $L = \Lambda^{-1/2} W \Lambda^{-1/2}$; and the n-by-c matrix F^* is the concatenation of the F_is.

Using vector F_i^*, we now assign preliminary labels to the samples. For a sample i, we transform F_i^* into probabilities $p_i^1, p_i^2, \ldots, p_i^c$ using softmax. Our propagated label ℓ_i for sample i is then

$$\ell_i = \begin{cases} \textit{not-a-relation} & \text{if } (\max_j p_i^j) < \theta, \\ \arg\max_j p_i^j & \text{otherwise.} \end{cases} \qquad (2)$$

The second clause is self-evident, but the first needs further explanation. Because *not-a-relation* is a background or default relation type in the relation classification task, and because it has rather high variation when manifested in natural language, we have found it difficult to obtain a distance metric W that allows the *not-a-relation* samples to form clusters naturally using transductive inference. Therefore, we introduce the first clause to assign the *not-a-relation* label to a sample when there is no strong evidence for any of the positive relation types. The amount of evidence needed is quantified by the parameter $\theta > 1/c$. In addition, the second clause will also assign *not-a-relation* to a sample if that probability is the highest.

Next, we partition the data in $D_l \cup D_u$ into c regions, $R_1, R_2, \ldots, R_c$, corresponding to the c relation types. The intuition is to use the true label in D_l when available, or otherwise resort to using the propagated label. That is,

$$x_i \in \begin{cases} R_{y_i} & \text{if } x_i \in D_l, \\ R_{\ell_i} & \text{if } x_i \in D_u. \end{cases}$$

We now have the necessary ingredients to quantify the *clustering consistency* between a source domain and a region in the target domain. Intuitively, this is the agreement between the source-domain predictor and the preliminary predictor within the target domain. We use supervised voting in the following manner. For every source domain, say domain s, we first train a relation-type predictor p_s based on its training data D^s. Then, for every region R_j, we compute the relevance score $w_{s,j} = \sum_{x_i \in R_j} [\![p_s(x_i) = \ell_i]\!] / |R_j|$, where $[\![\cdot]\!]$ is the Iverson bracket.

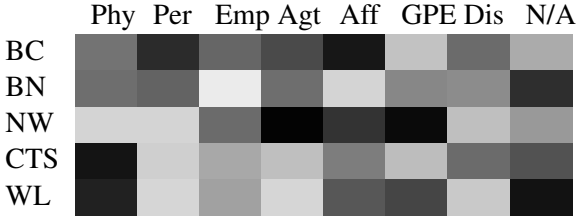


Figure 2: Heat map of the relevance scores $w_{s,j}$ between the target domain Usenet (UN) with the other domains on ACE 2004 data set. A lighter shade means a higher score, or more relevant. N/A refers to *not-a-relation*; for the other abbreviations, see the second paragraph in section 5.

Figure 2 shows the heat map of the relevance scores $w_{s,j}$ between the target domain Usenet (UN) with the other domains in the ACE 2004 corpus. We observe, for example, that the Broadcast News (BN) domain is more relevant in the Personal-Social region of the target domain than the Broadcast Conversation (BC) domain. These relevance scores will be used in the next phase of the framework to weigh the contributions of source-domain predictors to the eventual target-domain relation classifier.

4.2 Phase 2: Target Classifier Learning

The second phase uses both the weighted predictions from all sources and the target labeled data D_l to learn a relation classifier. This ensures that even when most of the source domains are irrelevant, the performance of our method is no worse than using the target-domain labeled data alone.

The previous phase has computed the relevance $w_{s,j}$ for source domain s in region R_j. We translate this to the relevance weight $u_{s,i}$ for an example x_i: if $x_i \in R_j$, then $u_{s,i} = w_{s,j}$. At our disposal from the previous phase are also k source-domain predictors p_s that have been trained on D^s. Combining and weighing the predictions from multiple sources, we obtain the *reference predic-*

tion $\hat{r}_{ji} = \sum_{s=1}^{k} u_{s,i}(2[\![p_s(x_i) = j]\!] - 1)$ for example x_i belonging to relation j, using the ± 1 encoding.

The relation classifier consists of c functions $f_1, \ldots, f_c$ using the one-versus-rest decoding for multi-class classification.[2] Inspired by the Domain Adaptive Machine (Duan et al., 2009), we combine the reference predictions and the labeled data of the target domain to learn these functions:

$$\min_{\{f_j\}_{j=1}^{c}} \sum_{j=1}^{c} \left\{ \frac{1}{n_l} \sum_{i=1}^{n_l} (f_j(x_i) - r_{ji})^2 + \gamma \|f_j\|_{\mathcal{H}}^2 + \frac{\beta}{2} \sum_{i=n_l+1}^{n} \|f_j(x_i) - \hat{r}_{ji}\|^2 \right\}, \quad (3)$$

where $r_{ji} = 2[\![y_i = j]\!] - 1$ is the ± 1 binary encoding for the i labeled sample belonging to relation j. Here, we have multiple objectives: the first term controls the training error; the second regularizes the complexity of the functions f_js in the Reproducing Kernel Hilbert Space (RKHS) $\mathcal{H}$; and the third prefers the predicted labels of the unlabeled data D_l to be close to the reference predictions. The third term provides additional pseudo-training samples for the rarer relation classes, if these are available in D_u. Parameters β and γ govern the trade-offs between these objectives.

Let $K(\cdot,\cdot)$ be the reproducing kernel for $\mathcal{H}$. By the Representer Theorem (Smola and Scholkopf, 1998), the solution for Eq. 3 is linear in $K(x_i,\cdot)$: $f_j(x) = \sum_{i=1}^{n} \alpha_{ji} K(x_i, x)$. Putting this into Eq. 3, parameter vectors α_j are (Belkin et al., 2006):

$$\alpha_j^* = (JK + \gamma(n_l + \beta n_u)I)^{-1} J R_j. \quad (4)$$

Here, R_j is an $(n_l + n_u)$-vector, where $R_{ji} = r_{ji}$ if sample i belongs to the labeled set, and $R_{ji} = \hat{r}_{ij}$ if it belongs to the unlabeled set; and J is an $(n_l + n_u)$-by-$(n_l + n_u)$ diagonal matrix where the first n_l diagonal entries are ones and the rest are βs.

5 Experiments

We evaluate our algorithm on two corpora: Automatic Content Extraction (ACE) 2004 and YAGO[3]. Table 1 provides some statistics on them.

ACE 2004 consists of six domains: Broadcast Conversations (BC), Broadcast News (BN), Conversational Telephone Speech (CTS), Newswire (NW), Usenet (UN) and Weblog (WL). There are seven positive relation types: Physical (Phy), Personal/Social (Per), Employment/Membership/Subsidiary (Emp), Agent-Artifact (Agt), PER/ORG Affiliation (Aff), GPE Affiliation (GPE) and Discourse (Dis).

Table 1: Statistics on ACE 2004 and YAGO

Properties	ACE 2004	YAGO
# relation types	7	20
# candidate relations	48,625	68,822
# gold relations	4,296	2,000
# mentions per entity pair	6	11
% mentions with +ve relations	8.8%	21%

YAGO is an open information extraction data set. The relation types of YAGO are built from Wikipedia and WordNet, while the labeled text for YAGO is from Bollegala et al. (2011). It consists of twenty relation types such as *ceo_company*, *bornIn* and *isMarriedTo*, and each of them is considered as a domain in this work. YAGO is different from ACE 2004 in two aspects: there is less overlapping of topics, entity types and relation types between domains; and it has more relation mentions with 11 mentions per pair of entities on the average.

We used Collins parser (Collins, 1999) to parse the sentences. The constituent parse trees were then transformed into dependency parse trees, using the head of each constituent (Jiang and Zhai, 2007b). The candidate relation instances were generated by considering all pairs of entities that occur in the same sentence. For the similarity matrix W in section 4.1 and the kernel $K(\cdot,\cdot)$ in section 4.2, we used the composite kernel function (Zhang et al., 2006), which is based on structured features and entity-related features.

F_1 is used to measure the performance of the algorithms. This is the harmonic mean of precision $\mathrm{TP}/(\mathrm{TP}+\mathrm{FP})$ and recall $\mathrm{TP}/(\mathrm{TP}+\mathrm{FN})$, where TP, FP and FN are the numbers of correct, missing and wrongly recognized relations.

5.1 Experimental Settings

For ACE 2004, we used each of the six domains as the target domain and the remaining domains as source domains. For YAGO, each relation type in YAGO was considered as a domain. For each domain in YAGO, we have a binary classification task: whether the instance has the relation corresponding to the domain. Five-fold cross-validation was used to evaluate the performance.

[2] For two-classes, though, only one function is needed.

[3] http://www.mpi-inf.mpg.de/yago-naga/yago/

For every target domain, we divided all data into 5 subsets, and we used each subset for testing and the other four subsets for training. In the training set, we randomly removed most of the positive instances of the target domain from the training set except for 10% of the labeled data. This gave us the *weakly-supervised* setting. This was repeated five times with different training and test sets. We report the average performance over the five runs.

In our experiments, we set $\mu = 0.8$ in Eq. 1; $\theta = 0.18$ in Eq. 2; and $\gamma = 0.1$ and $\beta = 0.3$ in Eq. 3. For each target domain, we used $k \in \{1,3,5\}$ different source domains chosen randomly from the remaining domains. Thus, the relevance of the source domains to the target domain varies from experiment to experiment.

5.2 Baselines

We compare our framework with several other methods, including state-of-the-art machine learning, relation extraction and common domain adaptation methods. These are described below.

In-domain multiclass classifier This is Support-vector-machine (Fan et al., 2008, SVM) using the one-versus-rest decoding without removing positive labeled data (Jiang and Zhai, 2007b) from the target domain. Its performance can be regarded as an upper bound on the performance of the cross-domain methods.

No-transfer classifier (NT) We only use the few labeled instances of the target relation type together with the negative relation instances to train a binary classifier.

Alternate no-transfer classifier (NT-U) We use the union of the k source-domain labeled data sets D^ss and the small set of target-domain labeled data D_l to train a binary classifier. It is then applied directly to predict on the unlabeled target-domain data D_u without any adaptation.

Laplacian SVM (L-SVM) This is a semi-supervised learning method based on label propagation (Melacci and Belkin, 2011).

Multi-task transfer (MTL) This is a learning method for weakly-supervised relation extraction (Jiang, 2009).

Adaptive domain bootstrapping (DAB) This is an instance-based domain adaptation method for relation extraction (Xu et al., 2010).

Structural correspondence learning (SCL) We use the feature-based domain adaptation approach by Blitzer et al. (2007). We apply SCL on the D^ss and D_l to train a model. The learned model then makes predictions on D_u.

Domain Adaptation Machine (DAM) We use the framework of Duan et al. (2009), which is a multiple-sources domain adaptation method.

For the kernel-based methods above, we use the same composite kernel used in our method. The source codes of L-SVM, MTL, SCL and DAM were obtained from the authors. The others were re-implemented.

5.3 Experimental Results

Tables 2, 3 and 4 present the results on ACE 2004 (corresponding to $k = 1,3,5$), and Tables 5 present those on YAGO (corresponding to $k = 5$).

From Table 3 and Table 5, we see that the proposed method has the best F_1 among all the other methods, except for the supervised upper bound (In-domain). We first notice that NT-U generally does not perform well, and sometimes it performs worse than NT. The reason is that NT-U aims to obtain a consensus among the domains, and this will give a worse label than NT when there are enough irrelevant sources to influence the classification decision wrongly. In fact, one can roughly deduce that a target domain has few relevant source domains by simply comparing columns NT with columns NT-U in the tables: a decrease in F_1 from NT to NT-U suggests that the source domains are mainly irrelevant. For example, for domain BC in ACE 2004, we find that its F_1 decreases from NT to NT-U consistently in Tables 2, 3 and 4, which suggests that BN, NW, CTS, UN and WL are generally irrelevant to it; and similarly for domain CTS. We investigate this further by examining the relevance scores $w_{s,j}$s, and we find that the decreases in F_1 from NT to NT-U happen when there are more regions in the target domain to which source-domains are irrelevant.

We find that MTL, DAB and SCL are better than NT-U when the majority of source domains are relevant. This shows that MTL, DAB and SCL are able to make more effective use of relevant sources than NT-U. Howevever, we find that their perfomances are not stable: for example, MTL for target UN in Table 2. In contrast, we find the performance of L-SVM and DAM to be more stable. The reason is their reduced vulnerability to

Table 2: The F_1 of different methods on ACE 2004 with $k = 1$ source domain. The best performance for each target domain is in bold.

Target	In-domain	NT	NT-U	L-SVM	MTL	DAB	SCL	DAM	RDA

negative transfer from irrelevant sources by relying on similarity of feature vectors between source and target domains based on labeled and unlabeled data. Further improvements can still be made, as shown by the better performance of RDA over L-SVM and DAM. This is achieved by further adjusting the relevances between source and target domains according to regions in the target-domain input space.

We analyzed histogram of the relation types to order the domains according to the imbalance of the class distributions. Using this, we observe that MTL, DAB and SCL perform relatively badly when the target-domain distribution is more imbalanced. In constrast, L-SVM, DAM and RDA are more robust.

Comparing with the baselines, RDA achieves the best performance on almost all the experiments. Using the two-phase framework, RDA can successfully transfer useful knowledge even in the pressence of irrelevant sources and imbalanced distributions. For ACE 2004, the improvement in F_1 over the best baseline can be up to 4.0% and is on average 3.6%. Similarly for YAGO, the improvement in F_1 over the best baseline can be up to 5.5% and is on average 4.3%.

Impact of Number of Source Domains Tables 2, 3, 4 and 6 also demonstrate that RDA improves monotonically as the number of source domains increases for both ACE 2004 and YAGO.

Performance Gap From Tables 2 to 4, we observe that the smallest performance gap between RDA and the in-domain settings is still high (about 12% with $k = 5$) on ACE 2004. This is because we have used a lot less labeled instances in the target domains: only 10% are used. However, the gaps reduces when the number of source domains increases. Comparing with the in-domain results in Table 5 (which is constant with k), Table 6 also shows a similar trend on YAGO. By exploiting the labeled data in ten source domains in YAGO, our RDA algorithm can reduce the gap between the cross-domain and in-domain settings to 9%.

Table 6: Average F_1 of RDA on YAGO

# source domains	F_1
$k = 1$	53.81
$k = 3$	59.43
$k = 5$	63.72
$k = 10$	65.55

6 Conclusion and Future Work

In this paper, we have proposed a robust domain adaptation (RDA) approach for the relation extraction problem where labeled data is scarce. Existing domain adaptation approaches suffer from negative transfer and under imbalanced distributions. To overcome these, we have proposed a two-phase approach to transfer only relevant information from multiple source domains, and thus derive accurate and robust predictions on the unlabeled target-domain data. Experimental results on ACE 2004 and YAGO have shown that the our domain adaptation method achieves the best performance on F_1 measure compared with the other baselines when only few labeled target instances are used. Because of the practical importance of domain adaptation for relation extraction due to lack of labeled data in new domains, we hope our study and findings will lead to further investigations into this problem.

Abstract

Most existing relation extraction models make predictions for each entity pair locally and individually, while ignoring implicit global clues available in the knowledge base, sometimes leading to conflicts among local predictions from different entity pairs. In this paper, we propose a joint inference framework that utilizes these global clues to resolve disagreements among local predictions. We exploit two kinds of clues to generate constraints which can capture the implicit type and cardinality requirements of a relation. Experimental results on three datasets, in both English and Chinese, show that our framework outperforms the state-of-the-art relation extraction models when such clues are applicable to the datasets. And, we find that the clues learnt automatically from existing knowledge bases perform comparably to those refined by human.

1 Introduction

Identifying predefined kinds of relationship between pairs of entities is crucial for many knowledge base related applications(Suchanek et al., 2013). In the literature, relation extraction (RE) is usually investigated in a classification style, where relations are simply treated as isolated class labels, while their definitions or background information are sometimes ignored. Take the relation *Capital* as an example, we can imagine that this relation will expect a country as its subject and a city as object, and in most cases, a city can be the capital of only one country. All these clues are no doubt helpful, for instance, Yao et al. (2010) explicitly modeled the expected types of a relation's arguments with the help of Freebase's type taxonomy and obtained promising results for RE.

*Yansong Feng is the corresponding author.

However, properly capturing and utilizing such typing clues are not trivial. One of the hurdles here is the lack of off-the-shelf resources and such clues often have to be coded by human experts. Many knowledge bases do not have a well-defined typing system, let alone fine-grained typing taxonomies with corresponding type recognizers, which are crucial to explicitly model the typing requirements for arguments of a relation, but rather expensive and time-consuming to collect. Similarly, the cardinality requirements of arguments, e.g., a person can have only one birthdate and a city can only be labeled as capital of one country, should be considered as a strong indicator to eliminate wrong predictions, but has to be coded manually as well.

On the other hand, most previous relation extractors process each entity pair (we will use *entity pair* and *entity tuple* exchangeably in the rest of the paper) locally and individually, i.e., the extractor makes decisions solely based on the sentences containing the current entity pair and ignores other related pairs, therefore has difficulties to capture possible disagreements among different entity pairs. However, when looking at the output of a multi-class relation predictor globally, we can easily find possible incorrect predictions such as a university locates in two different cities, two different cities have been labeled as capital for one country, a country locates in a city and so on.

In this paper, we will address how to derive and exploit two categories of these clues: the expected types and the cardinality requirements of a relation's arguments, in the scenario of relation extraction. We propose to perform joint inference upon multiple local predictions by leveraging implicit clues that are encoded with relation specific requirements and can be learnt from existing knowledge bases. Specifically, the joint inference framework operates on the output of a sentence level relation extractor as input, derives 5 types of constraints from an existing KB to implicitly capture

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 818–827,
Baltimore, Maryland, USA, June 23-25 2014.

the expected type and cardinality requirements for a relation's arguments, and jointly resolve the disagreements among candidate predictions. We formalize this procedure as a constrained optimization problem, which can be solved by many optimization frameworks. We use integer linear programming (ILP) as the solver and evaluate our framework on English and Chinese datasets. The experimental results show that our framework performs better than the state-of-the-art approaches when such clues are applicable to the datasets. We also show that the automatically learnt clues perform comparably to those refined manually.

In the rest of the paper, we first review related work in Section 2, and in Section 3, we describe our framework in detail. Experimental setup and results are discussed in Section 4. We conclude this paper in Section 5.

2 Related Work

Since traditional supervised relation extraction methods (Soderland et al., 1995; Zhao and Grishman, 2005) require manual annotations and are often domain-specific, nowadays many efforts focus on semi-supervised or unsupervised methods (Banko et al., 2007; Fader et al., 2011). Distant supervision (DS) is a semi-supervised RE framework and has attracted many attentions (Bunescu, 2007; Mintz et al., 2009; Yao et al., 2010; Surdeanu et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012). DS approaches can predict canonicalized (predefined in KBs) relations for large amount of data and do not need much human involvement. Since the automatically generated training datasets in DS often contain noises, there are also research efforts focusing on reducing the noisy labels in the training data (Takamatsu et al., 2012). To bridge the gaps between the relations extracted from open information extraction and the canonicalized relations in KBs, Yao et al. (2012) and Riedel et al. (2013) propose a universal schema which is a union of KB schemas and natural language patterns, making it possible to integrate the unlimited set of uncanonicalized relations in open settings with the relations in existing KBs.

As far as we know, few works have managed to take the relation specific requirements for arguments into account, and most existing works make predictions locally and individually. The MultiR system allows entity tuples to have more than one relations, but still predicts each entity tuple locally (Hoffmann et al., 2011). Surdeanu et al. (2012) propose a two-layer multi-instance multi-label (MIML) framework to capture the dependencies among relations. The first layer is a multi-class classifier making local predictions for single sentences, the output of which are aggregated by the second layer into the entity pair level. Their approach only captures relation dependencies, while we learn implicit relation backgrounds from knowledge bases, including argument type and cardinality requirements. Riedel et al. (2013) propose to use latent vectors to estimate the preferences between relations and entities. These can be considered as the latent type information of the relations' arguments, which is learnt from various data sources. In contrast, our approach learn implicit clues from existing KBs, and jointly optimize local predictions among different entity tuples to capture both relation argument type clues and cardinality clues. Li et al. (2011) and Li et al. (2013) use co-occurring statistics among relations or events to jointly improve information extraction performances in ACE tasks, while we mine existing KBs to collect global clues to solve local conflicts and find the optimal aggregation assignments, regarding existing knowledge facts. de Lacalle and Lapata (2013) encode general domain knowledge as FOL rules in a topic model while our instantiated constraints are directly operated in an ILP model. Zhang et al. (2013) utilize relation cardinality to create negative samples for distant supervision while we use both implicit type clues and relation cardinality expectations to discover possible inconsistencies among local predictions.

3 The Framework

Our framework takes a set of entity pairs and their supporting sentences as its input. We first train a preliminary sentence level extractor which can output confidence scores for its predictions, e.g., a maximum entropy or logistic regression model, and use this local extractor to produce local predictions. In order to implicitly capture the expected type and cardinality requirements for a relation's arguments, we derive two kinds of clues from an existing KB, which are further utilized to discover the disagreements among local candidate predictions. Our objective is to maximize the overall confidence of all the selected predictions.

3.1 Generating Candidate Relations

Since we will focus on the open domain relation extraction, we still follow the distant supervision paradigm to collect our training data guided by a KB, and train the local extractor accordingly. Specifically, we train a sentence level extractor using the maximum entropy model. Given a sentence containing an entity pair, the model will output the confidence of this sentence representing certain relationship (from a predefined relation set) between the entity pair. Formally $\mathcal{R}$ represents the relation set we are working on, $\mathcal{T}$ is the set of entity tuples that we will predict in the test set.

Keep in mind that our local extractor is trained on noisy training data, which, we admit, is not fully reliable. As we observed in a pilot experiment that there is a good chance that the predictions ranked in the second or third may still be correct, we select **top three** predictions as the candidate relations for each mention in order to introduce more potentially correct output.

On the other hand, we should discard the predictions whose confidences are too low to be true, where we set up a threshold of 0.1. For a tuple t, we obtain its candidate relation set by combining the candidate relations of all its mentions, and represent it as R^t. For a candidate relation $r \in R^t$ and a tuple t, we define M_t^r as all t's mentions whose candidate relations contain r. Now the confidence score of a relation $r \in R^t$ being assigned to tuple t can be calculated as:

$$conf(t, r) = \sum_{m \in M_t^r} \text{MEscore}(m, r) \qquad (1)$$

where MEscore(m, r) is the confidence of mention m representing relation r output by our preliminary extractor.

Traditionally, both lexical features and syntactic features are used in relation extraction. Lexical features are the word chains between the subjects and objects in the sentences, while syntactic features are the dependency paths from the subjects to the objects on the dependency graphs of the supporting sentences. However, lexical features are usually too specific to frequently appear in the test data, while the reliability of syntactic features depends heavily on the quality of dependency parsing tools. Generally, we expect more potentially correct relations to be put into the candidate relation set for further consideration. So in addition to lexical and syntactic features, we also use n-gram features to train our preliminary relation extraction model. N-gram features are considered as more ambiguous compared to traditional lexical and syntactic features, and may introduce incorrect predictions, thus improving the recall at the cost of precision.

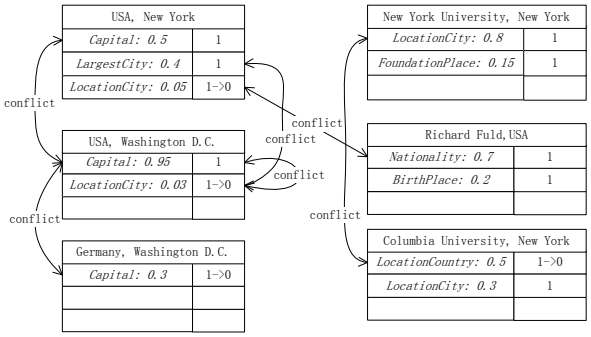

Figure 1: The different types of disagreements we will investigate in the candidate relations. The clues of detecting these inconsistencies can be learnt from a knowledge base.

3.2 Disagreements among the Candidates

The candidate relations we obtained in the previous subsection inevitably include many incorrect predictions. Ideally we should discard those wrong predictions to produce more accurate results.

As discussed earlier, we will exploit from the knowledge base two categories of clues that implicitly capture relations' backgrounds: their expected argument types and argument cardinalities, based on which we can discover two categories of disagreements among the candidate predictions, summarized as argument type inconsistencies and violations of arguments' uniqueness, which have been rarely considered before. We will discuss them in detail, and describe how to learn the clues from a KB afterwards.

Implicit Argument Types Inconsistencies: Generally, the argument types of the correct predictions should be consistent with each other. Given a relation, its arguments sometimes are required to be certain types of entities. For example, in Figure 1, the relation *LargestCity* restricts its subject to be either countries or states, and its object to be cities. If the predictions among different entity tuples require the same entity to belong to different types, we call this

an argument type inconsistency. Take <USA, New York> and <USA, Washington D.C.> as an example. In Figure 1, <USA, New York> has a candidate relation *LargestCity* which restricts *USA* to be either countries or states, while <USA, Washington D.C.> has a prediction *LocationCity* which indicates a disagreement in terms of *USA*'s type because the latter prediction expects *USA* to be an organization located in a city. This warns that at least one of the two candidate relations is incorrect.

The previous scenario shows that the subjects of two candidate relations may disagree with each other. From Figure 1, we can observe two more situations: the first one is that the objects of the two candidate relations are inconsistent with each other, for example <New York University, New York> with the prediction *LocationCity* and <Columbia University, New York> with the prediction *LocationCountry*. The second one is that the subject of one candidate relation do not agree with another prediction's object, for example <Richard Fuld, USA> with the prediction *Nationality* and <USA, New York> with the prediction *LocationCity*. Although we have not assigned explicit types to these entities, we can still exploit the inconsistencies implicitly with the help of shared entities. Note that the implicit argument typing clues here mean whether two relations can share arguments, but NOT enumate what types explicitly their arguments should have.

We formalize all the relation pairs that disagree with each other as follows. These relation pairs can be divided into three subcategories. We represent the relation pairs (r_i, r_j) that are inconsistent in terms of subjects as $\mathcal{C}^{sr}$, the relations pairs that are inconsistent in terms of objects as $\mathcal{C}^{ro}$, the relation pairs that are inconsistent in terms of one's subject and the other one's object as $\mathcal{C}^{rer}$.

It is worth mentioning that disagreements inside a tuple are also included here. For instance, an entity tuple <USA, Washington D.C.> in Figure 1 has two candidate relations, *Capital* and *LocationCity*. These two predictions are inconsistent with each other with respect to the type of *USA*. They implicitly consider *USA* as "country" and "organization", respectively.

Violations of Arguments' Uniqueness: The previous categories of disagreements are all based on the implicit type information of the relations' arguments, Now we make use of the clues of argument cardinality requirements. Given a subject, some relations should have unique objects. For example, in Figure 1, given *USA* as the subject of the relation *Capital*, we can only accept one possible object, because there is great chance that a country only have one capital. On the other hand, given *Washington D.C.* as the object of the relation *Capital*, we can only accept one subject, since usually a city can only be the capital of one country or state. If these are violating in the candidates, we could know that there may be some incorrect predictions. We represent the relations expecting unique objects as $\mathcal{C}^{ou}$, and the relations expecting unique subjects as $\mathcal{C}^{su}$.

3.3 Obtaining the Global Clues

Now, the issue is how to obtain the clues used in the previous subsection. That is, how we determine which relations expect certain types of subjects, which relations expect certain types of objects, etc. These knowledge can be definitely coded by human, or learnt from a KB.

Most existing knowledge bases represent their knowledge facts in the form of (<*subject, relation, object*>) triple, which can be seen as relational facts between entity tuples. Usually the triples in a KB are carefully defined by experts. It is rare to find inconsistencies among the triples in the knowledge base. The clues are therefore learnt from KBs, and further refined manually if needed.

Given two relations r_1 and r_2, we query the KB for all tuples bearing the relation r_1 or r_2. We use S_i and O_i to represent r_i's ($i \in \{1, 2\}$) subject set and object set, respectively. We adopt the pointwise mutual information (PMI) to estimate the dependency between the argument sets of two relations:

$$\text{PMI}(A, B) = \log \frac{p(A, B)}{p(A)p(B)} \qquad (2)$$

where $p(A, B)$ is number of the entities both in A and B, $p(A)$ and $p(B)$ are the numbers of the entities in A and B, respectively. For any pair of relations from $\mathcal{R} \times \mathcal{R}$, we calculate four scores: PMI(S_1, S_2), PMI(O_1, O_2), PMI(S_1, O_2) and PMI(S_2, O_1). To make more stable estimations, we set up a threshold for the PMI. If PMI(S_1, S_2) is lower than the threshold, we will consider that r_1 and r_2 cannot share a subject. Things are similar for the other three scores. The threshold is set to -3 in this paper.

We can also learn the uniqueness of arguments for relations. For each pre-defined relation in $\mathcal{R}$, we collect all the triples containing this relation, and count the portion of the triples which only have one object for each subject, and the portion of the triples which only have one subject for each object. The relations whose portions are higher than the threshold will be considered to have unique argument values. This threshold is set to 0.8 in this paper.

3.4 Integer Linear Program Formulation

As discussed above, given a set of entity pairs and their candidate relations output by a preliminary extractor, our goal is to find an optimal configuration for all those entities pairs jointly, solving the disagreements among those candidate predictions and maximizing the overall confidence of the selected predictions. This is an NP-hard optimization problem. Many optimization models can be used to obtain the approximate solutions.

In this paper, we propose to solve the problem by using an ILP tool, IBM ILOG Cplex[1]. Firstly, for each tuple t and one of its candidate relations r, we define a binary decision variable d_t^r indicating whether the candidate relation r is selected by the solver. Our objective is to maximize the total confidence of all the selected candidates, and the objective function can be written as:

$$\max \sum_{t\in\mathcal{T}, r\in R^t} conf(t,r) d_t^r + \sum_{\forall t, r\in R^t, m\in M_t^r} \max \text{MEscore}(m,r) d_t^r$$

where $conf(t,r)$ is the confidence of the tuple t bearing the candidate relation r. The first component is the sum of the original confidence scores of all the selected candidates, and the second one is the sum of the maximal mention-level confidence scores of all the selected candidates. The latter is designed to encourage the model to select the candidates with higher individual mention-level confidence scores.

We add the constraints with respect to the disagreements described in Section 3.2. For the sake of clarity, we describe the constraints derived from each scenario of the two categories of disagreements separately.

The subject-relation constraints avoid the disagreements between the predictions of two tuples sharing a subject. These constraints can be represented as:

$$d_{t_i}^{r^{t_i}} + d_{t_j}^{r^{t_j}} \leq 1 \quad (3)$$
$$\forall t_i, t_j : subj(t_i) = subj(t_j) \wedge (r^{t_i}, r^{t_j}) \in \mathcal{C}^{sr}$$

where t_i and t_j are two tuples in $\mathcal{T}$, $subj(t_i)$ is the subject of t_i, r^{t_i} is a candidate relation of t_i, r^{t_j} is a candidate relation of t_j.

The object-relation constraints avoid the inconsistencies between the predictions of two tuples sharing an object. Formally we add the following constraints:

$$d_{t_i}^{r^{t_i}} + d_{t_j}^{r^{t_j}} \leq 1 \quad (4)$$
$$\forall t_i, t_j : obj(t_i) = obj(t_j) \wedge (r^{t_i}, r^{t_j}) \in \mathcal{C}^{ro}$$

where $t_i \in \mathcal{T}$ and $t_j \in \mathcal{T}$ are two tuples, $obj(t_i)$ is the object of t_i.

The relation-entity-relation constraints ensure that if an entity works as subject and object in two tuples t_i and t_j respectively, their relations agree with each other. The constraints we add are:

$$d_{t_i}^{r^{t_i}} + d_{t_j}^{r^{t_j}} \leq 1 \quad (5)$$
$$\forall t_i, t_j : obj(t_i) = subj(t_j) \wedge (r^{t_i}, r^{t_j}) \in \mathcal{C}^{rer}$$

The object uniqueness constraints ensure that the relations requiring unique objects do not bear more than one object given a subject.

$$\sum_{t\in Tuple(r), subj(t)=e} d_t^r \leq 1 \quad (6)$$
$$\forall e \wedge r \in \mathcal{C}^{ou}$$

where e is an entity, $Tuple(r)$ are the tuples whose candidate relations contain r.

The subject uniqueness constraints ensure that given an object, the relations expecting unique subjects do not bear more than one subject.

$$\sum_{t\in Tuple(r), obj(t)=e} d_t^r \leq 1 \quad (7)$$
$$\forall e \wedge r \in \mathcal{C}^{su}$$

By adopting ILP, we can combine the local information including MaxEnt confidence scores and the implicit relation backgrounds that are embedded into global consistencies of the entity tuples together. After the optimization problem is solved, we will obtain a list of selected candidate relations for each tuple, which will be our final output.

4 Experiments

4.1 Datasets

We evaluate our approach on three datasets, including two English datasets and one Chinese dataset.

The first English dataset, Riedel's dataset, is the one used in (Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012), with the same split. It uses Freebase as the knowledge base and New York Time corpus as the text corpus, including about 60,000 entity tuples in the training set, and about 90,000 entity tuples in the testing set.

We generate the second English dataset, DBpedia dataset, by mapping the triples in DBpedia (Bizer et al., 2009) to the sentences in New York Time corpus. We map 51 different relations to the corpus and result in about 50,000 entity tuples, 134,000 sentences for training and 30,000 entity tuples, 53,000 sentences for testing.

For the Chinese dataset, we derive knowledge facts and construct a Chinese KB from the Infoboxes of HudongBaike, one of the largest Chinese online encyclopedias. We collect four national economic newspapers in 2009 as our corpus. 28 different relations are mapped to the corpus and this results in 60,000 entity tuples, 120,000 sentences for training and 40,000 tuples, 83,000 sentences for testing.

4.2 Baselines and Competitors

The baseline we use in this paper is Mintz++, which is described in (Surdeanu et al., 2012). It is a modification of the model proposed by Mintz et al. (2009). The model predicts for each mention separately, and allows multi-label outputs for an entity tuple by OR-ing the outputs of its mentions.

As we described in Section 3.1, originally we select the top three predicted relations as the candidates for each mention. In order to investigate whether it is necessary to use up to three candidates, we implement two variants of our approach, which select the top one and top two relations as candidates for each mention, and represented as ILP-1cand and ILP-2cand, respectively.

We also use two distant supervision approaches for the comparison. The first one is MultiR (Hoffmann et al., 2011), a novel joint model that can deal with the relation overlap issue. The second one, MIML-RE (Surdeanu et al., 2012), is one of the state-of-the-art MIML relation extraction systems. We tune the models of MultiR and MIML-RE so that they fit our datasets.

4.3 Overall Performance

First we compare our framework and its variants with the baseline and the state-of-the-art RE models. Following previous works, we use the Precision-Recall curve as the evaluation criterion in our experiment. The results are summarized in Figure 2. For the constraints, we first manually select an average of 20 relation pairs for each subcategory of the first kind of clues, and all the relations with unique argument values in $\mathcal{R}$. We also show how automatically learnt clues perform in Section 4.5.

Figure 2 shows that compared with the baseline, our framework performs consistently better in the DBpedia dataset and the Chinese dataset. Mintz++ proves to be a strong baseline on both datasets. It tends to result in a high recall, and its weakness of low precision is perfectly fixed by the ILP model. Our ILP model and its variants all outperform Mintz++ in precision in both datasets, indicating that our approach helps filter out incorrect predictions from the output of MaxEnt model. Compared with MultiR, our framework obtains better results in both datasets. Especially in the Chinese dataset, the improvement in precision reaches as high as 10-16% at the same recall points. Our framework performs better compared to MIML-RE in the English dataset. On the Chinese dataset, our framework outperforms MIML-RE except in the low-recall portion ($<$10%) of the P-R curve. All these results show that embedding the relation background information into RE can help eliminate the wrong predictions and improve the results.

However, in the Riedel's dataset, Mintz++, the MaxEnt relation extractor, does not perform well, and our framework cannot improve its performance. In order to find out the reasons, we manually investigate the dataset. The top three relations of this dataset are */location/location/contains*, */people/person/nationality* and */people/person/place_lived*. About two-thirds of the entity tuples belongs to these three relations, and the outputs of the local extractor usually bias even more to the large relations. What is worse, we cannot find any clues from the top three relations because their arguments' types are too general. Things are similar for many other

(d) The DBpedia Dataset (e) The Riedel's Dataset (f) The Chinese Dataset

Figure 2: Overall performances of our framework and its variants, the baselines and the state-of-the-art approaches on the three datasets.

relations in this dataset. Although we may find some clues any way, they are too few to make any improvement. Hence, our framework does not perform well due to the poor performance of MaxEnt extractor and the lack of clues. To solve this problem, we think of addressing the selection preferences between relations and entities proposed in (Riedel et al., 2013), which should be our future work.

We notice that in all three datasets our variant ILP-1cand is shorter than Mintz++ in recall, indicating we may incorrectly discard some predictions. Compared to ILP-2cand and original ILP, ILP-1cand leads to slightly lower precision but much lower recall, showing that selecting more candidates may help us collect more potentially correct predictions. Comparing ILP-2cand and original ILP, the latter hardly makes any improvement in precision, but is slightly longer in recall, indicating using three candidates can still collect some more potentially correct predictions, although the number may be limited.

In order to study how our framework improves the performances on the DBpedia dataset and the Chinese dataset, we further investigate the number of incorrect predictions eliminated by ILP and the number of incorrect predictions corrected by ILP. We also examine the number of correct predictions newly introduce by ILP, which were NA in Mintz++. We summarize the results in Table 1.

Table 1: Details of the improvements made by ILP in the DBpedia and Chinese datasets.

Datasets	Incorrect Predictions Eliminated	Wrong Predictioins Corrected	Correct Predictions Newly Introduced
DBpedia	268	61	1426
Chinese	1506	14	283

The results show that our framework can reduce the incorrect predictions and introduce more correct predictions at the same time. We also find an interesting results: in the DBpedia dataset, ILP is more likely to introduce correct predictions to the results, while in the Chinese dataset it tends to reduce more incorrect predictions, which may be caused by the differences between performances of Mintz++ on the two datasets, where it gets a higher recall on the Chinese dataset.

Following Surdeanu et al. (2012), we also list the peak F1 score (highest F1 score) for each model in Table 2. Different from (Surdeanu et al., 2012), we use all the entity pairs instead of the ones with more than 10 mentions. We can observe that our model obtains the best performance in the DBpedia dataset and the Chinese dataset. In the DBpedia dataset, it is 3.6% higher than Mintz++,

7.9% higher than MIML-RE and 13.9% higher than MultiR. In the Chinese dataset, Mintz++, MultiR and MIML-RE performs similarly in terms of the highest F1 score, while our model gains about 8% improvement. In the Riedel's dataset, our framework hardly obtains any improvement compared with Mintz++.

We also investigate the impacts of the constraints used in ILP, which are derived based on the two kinds of clues and can encode relation definition information into our framework. Experimental results in Table 2 shows that in the DBpedia dataset, the highest F1 score increases from 35.2% to 38.3% with the help of both kinds of clues, while in the Chinese dataset the improvement is from 44.4% to 52.8%. In the Riedel's dataset we do not see any improvements since there are almost no clues. Furthermore, using constraints derived from only one kind of clues can also improve the performance, but not as well as using both of them.

4.4 Adapting MultiR Sentence Level Extractor to Our Framework

The preliminary relation extractor of our optimization framework is not limited to the MaxEnt extractor, and can take any sentence level relation extractor with confidence scores. We also fit MultiR's mention level extractor into our framework.

As shown in Figure 3, in the DBpedia dataset and the Chinese dataset, in most parts of the curve, ILP optimized MultiR outperforms original MultiR. We think the reason is that our framework make use of global clues to discard the incorrect predictions. The results are not as high as when we use MaxEnt as the preliminary extractor. We think one reason is that MultiR does not perform well in these two datasets. Furthermore, the confidence scores which MultiR outputs are not normalized to the same scale, which brings us difficulties in setting up a confidence threshold to select the candidates. As a result, we only use the top one result as the candidate since including top two predictions without thresholding the confidences performs bad, indicating that a probabilistic sentence-level extractor is more suitable for our framework. We also notice that in the Riedel's dataset our framework does not improve the performance significantly, and we have discussed the reasons in Section 4.3.

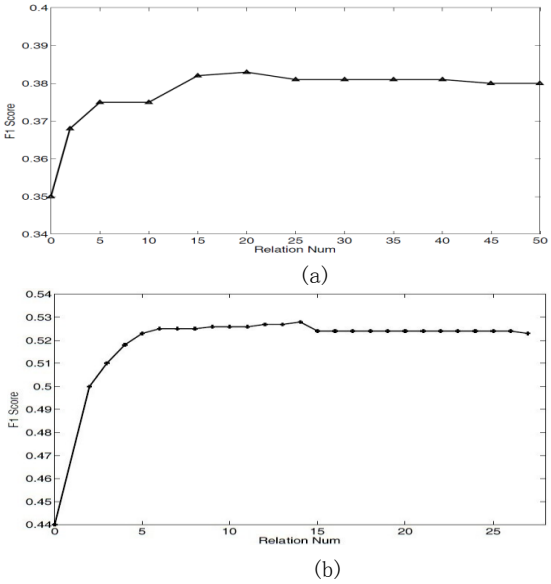

Figure 4: F1 score v.s. number of relations (used to introduce the related learnt clues into the ILP framework) on the DBpedia dataset (a) and the Chinese dataset (b).

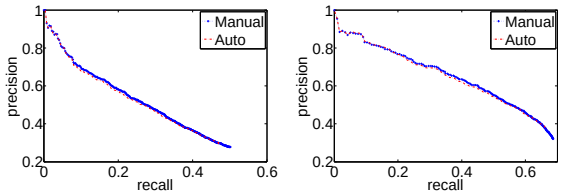

(a) The DBpedia Dataset (b) The Chinese Dataset

Figure 5: Performances of manually selected clues and automatically learnt clues on two datasets.

4.5 Examining the Automatically Learnt Clues

Now we evaluate the performance of automatically collected clues used in our model. Since there are almost no clues in the Riedel's dataset, we only investigate the other two datasets. We add clues according to their related relations' proportions in the local predictions. For example, *Country* and *birthPlace* take up about 30% in the local predictions, we thus add clues that are related to these two relations, and then move on with new clues related to other relations according to those relations' proportions in the local predictions.

As is shown in Figure 4, in both datasets, the clues related to more local predictions will solve more inconsistencies, thus are more effective. Adding the first two relations improves the model significantly, and as more relations are added, the

Figure 3: The results of original MultiR and ILP optimized MultiR on the three datasets.

performances keep increasing until approaching the still state. It is worth mentioning that when sufficient learnt clues are added into the model, the results are comparable to those based on the clues refined manually, as shown in Figure 5. This indicates that the clues can be collected automatically, and further used to examine whether predicted relations are consistent with the existing ones in the KB, which can be considered as a form of quality control.

5 Conclusions

In this paper, we make use of the global clues derived from KB to help resolve the disagreements among local relation predictions, thus reduce the incorrect predictions and improve the performance of relation extraction. Two kinds of clues, including implicit argument type information and argument cardinality information of relations are investigated. Our framework outperforms the state-of-the-art models if we can find such clues in the KB. Furthermore, our framework is scalable for other local sentence level extractors in addition to the MaxEnt model. Finally, we show that the clues can be learnt automatically from the KB, and lead to comparable performance to manually refined ones.

For future work, we will investigate other kinds of clues and attempt a joint optimization framework that could host entity disambiguation, relation extraction and entity linking together. We will also adopt selection preference between entities and relations since sometimes we may not find useful clues.

Abstract

In this paper, we present a manifold model for medical relation extraction. Our model is built upon a medical corpus containing 80M sentences (11 gigabyte text) and designed to accurately and efficiently detect the key medical relations that can facilitate clinical decision making. Our approach integrates domain specific parsing and typing systems, and can utilize labeled as well as unlabeled examples. To provide users with more flexibility, we also take label weight into consideration. Effectiveness of our model is demonstrated both theoretically with a proof to show that the solution is a closed-form solution and experimentally with positive results in experiments.

1 Introduction

There exists a vast amount of knowledge sources and ontologies in the medical domain. Such information is also growing and changing extremely quickly, making the information difficult for people to read, process and remember. The combination of recent developments in information extraction and the availability of unparalleled medical resources thus offers us the unique opportunity to develop new techniques to help healthcare professionals overcome the cognitive challenges they face in clinical decision making.

Relation extraction plays a key role in information extraction. Using question answering as an example (Wang et al., 2012): in question analysis, the semantic relations between the question focus and each term in the clue can be used to identify the weight of each term so that better search queries can be generated. In candidate answer generation, relations enable the background knowledge base to be used for potential candidate answer generation. In candidate answer scoring, relation-based matching algorithms can go beyond explicit lexical and syntactic information to detect implicit semantic relations shared across the question and passages.

To construct a medical relation extraction system, several challenges have to be addressed:

- The first challenge is how to identify a set of relations that has sufficient coverage in the medical domain. To address this issue, we study a real-world diagnosis related question set and identify a set of relations that has a good coverage of the clinical questions.

- The second challenge is how to efficiently detect relations in a large amount of medical text. The medical corpus underlying our relation extraction system contains 80M sentences (11 gigabytes pure text). To extract relations from a dataset at this scale, the relation detectors have to be fast. In this paper, we speed up relation detectors through parsing adaptation and replacing non-linear classifiers with linear classifiers.

- The third challenge is that the labeled relation examples are often insufficient due to the high labeling cost. When we build a naïve model to detect relations, the model tends to overfit for the labeled data. To address this issue, we develop a manifold model (Belkin et al., 2006) that encourages examples (including both labeled and unlabeled examples) with similar contents to be assigned with similar scores. Our model goes beyond regular regression models in that it applies constraints to those coefficients, such that the topology of the given data manifold will be respected. Computing the optimal weights in a regression model and preserving manifold topology are conflicting objectives, we

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 828–838,
Baltimore, Maryland, USA, June 23-25 2014.

present a closed-form solution to ideally balance these two goals.

The contributions of this paper on medical relation extraction are three-fold:

- The problem setup is new. There is a "fundamental" difference between our problem setup and the conventional setups, like i2b2 (Uzuner et al., 2011). In i2b2 relation extraction task, entity mentions are *manually* labeled, and each mention has 1 of 3 concepts: 'treatment', 'problem', and 'test'. To resemble real-world medical relation extraction challenges where perfect entity mentions do not exist, our new setup requires the entity mentions to be *automatically* detected. The most well-known tool to detect medical entity mentions is MetaMap (Aronson, 2001), which considers all terms as entities and automatically associates each term with a number of concepts from UMLS CUI dictionary (Lindberg et al., 1993) with more than 2.7 million distinct concepts (compared to 3 in i2b2). The huge amount of entity mentions, concepts and noisy concept assignments provide a tough situation that people have to face in real-world applications.
- From the perspective of relation extraction applications, we identify "super relations"- the key relations that can facilitate clinical decision making (Table 1). We also present approaches to collect training data for these relations with a small amount of labeling effort.
- From the perspective of relation extraction methodologies, we present a manifold model for relation extraction utilizing both labeled and unlabeled data. Our approach can also take the label weight into consideration.

The experimental results show that our relation detectors are fast and outperform the state-of-the-art approaches on medical relation extraction by a large margin. We also apply our model to build a new medical relation knowledge base as a complement to the existing knowledge bases.

2 Background

2.1 Medical Ontologies and Sources

Medical domain has a huge amount of natural language content found in textbooks, encyclopedias, guidelines, electronic medical records, and many other sources. It is also growing at an extremely high speed. Substantial understanding of the medical domain has already been included in the Unified Medical Language System (UMLS) (Lindberg et al., 1993), which includes medical concepts, relations, definitions, etc. The 2012 version of the UMLS contains information about more than 2.7 million concepts from over 160 source vocabularies. Softwares for using this knowledge also exist: MetaMap (Aronson, 2001) is able to identify concepts in text. SEMREP (Rindflesch and Fiszman, 2003) can detect some relations using hand-crafted rules.

2.2 Relation Extraction

To extract semantic relations from text, three types of approaches have been applied. Rule-based methods (Miller et al., 2000) employ a number of linguistic rules to capture relation patterns. Feature-based methods (Kambhatla, 2004; Zhao and Grishman, 2005) transform relation instances into a large amount of linguistic features like lexical, syntactic and semantic features, and capture the similarity between these feature vectors. Recent results mainly rely on kernel-based methods. Many of them focus on using tree kernels to learn parse tree structure related features (Collins and Duffy, 2001; Culotta and Sorensen, 2004; Bunescu and Mooney, 2005).

Other researchers study how different approaches can be combined to improve the extraction performance. For example, by combining tree kernels and convolution string kernels, (Zhang et al., 2006) achieved the state of the art performance on ACE data (ACE, 2004). Recently, "distant supervision" has emerged to be a popular choice for training relation extractors without using manually labeled data (Mintz et al., 2009; Jiang, 2009; Chan and Roth, 2010; Wang et al., 2011; Riedel et al., 2010; Ji et al., 2011; Hoffmann et al., 2011; Surdeanu et al., 2012; Takamatsu et al., 2012; Min et al., 2013).

Various relation extraction approaches have been adapted to the medical domain, most of which focus on designing heuristic rules targeted for diagnosis and integrating the medical ontology in the existing extraction approaches. Results of some of these approaches are reported on the i2b2 data (Uzuner et al., 2011).

3 Identifying Key Medical Relations

3.1 Super Relations in Medical Domain

The first step in building a relation extraction system for medical domain is to identify the relations that are important for clinical decision making.

Four main clinical tasks that physicians engage in are discussed in (Demner-Fushman and Lin, 2007). They are **Therapy**- select treatments to offer a patient, taking consideration of effectiveness, risk, cost and other factors (prevention is under the general category of Therapy), **Diagnosis** (including differential diagnosis based on findings and diagnostic test), **Etiology**- identify the factors that cause the disease and **Prognosis**- estimate the patient's likely course over time. These activities can be translated into "search tasks". For example, the search for therapy is usually the therapy selection given a disease.

We did an independent study regarding what clinical questions usually ask for on a set of 5,000 Doctor Dilemma (DD) questions from the American College of Physicians (ACP). This set includes questions about diseases, treatments, lab tests, and general facts[1]. Our analysis shows that about 15% of these questions ask for treatments, preventions or contraindicated drugs for a disease or another way around, 4% are about diagnosis tests, 6% are about the causes of a disease, 1% are about the locations of a disease, 25% are about the symptoms of a disease, 8% are asking for definitions, 7% are about guidelines and the remaining 34% questions either express no relations or some relations that are not very popular.

Based on the analysis in (Demner-Fushman and Lin, 2007) and our own results, we decided to focus on seven key relations in the medical domain, which are described in Table 1. We call these relations "super relations", since they cover most questions in the DD question set and align well with the analysis result in (Demner-Fushman and Lin, 2007).

3.2 Collect Training Data

This section presents how we collect training data for each relation. The overall procedure is illustrated in Figure 1.

[1]Here's an example of these questions and its answer: **Question:** The syndrome characterized by joint pain, abdominal pain, palpable purpura, and a nephritic sediment. **Answer:** Henoch-Schonlein purpura.

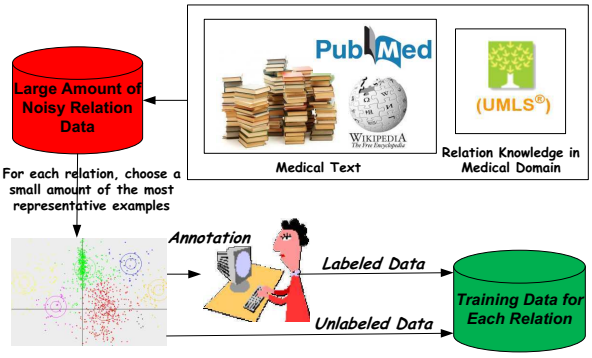

Figure 1: Collect Training Data

Our medical corpus has incorporated a set of medical books/journals[2] and MEDLINE abstracts. We also complemented these sources with Wikipedia articles. In total, the corpus contains 80M sentences (11 gigabyte pure text).

The UMLS 2012 Release contains more than 600 relations and 50M relation instances under around 15 categories. The RO category (RO stands for "has Relationship Other than synonymous, narrower, or broader") is the most interesting one, and covers relations like "may_treat", "has_finding_site", etc. Each relation has a certain number of Concept Unique Identifier (CUI) pairs that are known to bear that relation. In UMLS, some relation information is redundant. Firstly, half of these relations are simply inverse of each other (e.g. the relation "may_treat" and "may_be_treated_by"). Secondly, there is a significant amount of redundancy even among non-inverse relations (e.g. the relation "has_manifestation" and "disease_has_finding").

From UMLS relations, we manually chose a subset of them that are directly related to the super relations discussed in Section 3.1. The correspondences between them are given in Table 1. One thing to note is that super relations are more general than the UMLS relations, and one super relation might integrate multiple UMLS relations. Using the CUI pairs in the UMLS relation knowl-

[2]This is a full list of the books and journals used in our corpus: ACP-Medical Knowledge Self-Assessment Program, EBSCO-Dynamed, EBSCO-Quick Lessons, EBSCO-EBCS, EBSCO-Clinical Review, Wiley-Essential Evidence Plus: EBMG Guidelines, Wiley-Essential Evidence Topics, Wiley-Essential Evidence Plus: EBMG Summaries, Wiley-POEMs, Wiley-The Breast Journal, New England Journal of Medicine, Journal Watch, NCCN-CME, NCCN-GUS, NCCN-Compendium, NCCN-Templates, NCCN-Guidelines for Patients, NCCN-Physician Guidelines, Merck Manual of Diagnosis and Therapy, and UpToDate.

Table 1: Super relations & their arguments, UMLS sources and noise% in the annotation data

Super Relations	Argument 1	Argument 2	UMLS Sources	Noise% in Annotation Data
treats	disease	treatments	may_treat, treats	16%
prevents	disease	treatments	may_prevent	49%
contraindicates	disease	treatments	contraindicated_drug	97%
diagnoses	disease	tests	may_diagnose	63%
causes	disease	causes	cause_of, causative_agent_of	66%
location_of	disease	locations	has_finding_site disease_has_primary_anatomic_site	41%
symptom_of	disease	symptoms	disease_has_finding disease_may_have_finding has_manifestation has_definitional_manifestation	66%

edge base, we associate each super relation with a set of CUI pairs.

To collect the training data for each super relation, we need to collect sentences that express the relation. To achieve this, we parsed all 80M sentences in our medical corpus, looking for the sentences containing the terms that are associated with the CUI pairs in the knowledge base. This (distant supervision) approach resulted in a huge amount of sentences that contain the desired relations, but also brought in a lot of noise in the form of false positives. For example, we know from the knowledge base that "antibiotic drug" may treat "Lyme disease". However the sentence "This paper studies the relationship between antibiotic drug and Lyme disease" contains both terms but does not express the "treats" relation.

The most reliable way to clean the training data is to ask annotators to go through the sentences and assign the sentences with positive/negative labels. However, it will not work well when we have millions of sentences to vet. To minimize the human labeling effort, we ran a K-medoids clustering on the sentences associated with each super relation and kept the cluster centers as the most representative sentences for annotation. Depending on the number of the sentences we collected for each relation, the #clusters was chosen from 3,000 - 6,000. The similarity of two sentences is defined as the bag-of-words similarity of the dependency paths connecting arguments. Part of the resulting data was manually vetted by our annotators, and the remaining was held as unlabeled data for further experiments.

Our relation annotation task is quite straightforward, since both arguments are given and the decision is a Yes-or-No decision. The noise rate of each relation (#sentences expressing the relation / #sentences) is reported in Table 1 based on the annotation results. The noise rates differ significantly from one relation to another. For "treats" relation, only 16% of the sentences are false positives. For "contraindicates" relation, the noise rate is 97%.

To grow the size of the negative training set for each super relation, we also added a small amount of the most representative examples (also coming from K-medoids clustering) from each unrelated UMLS relation to the training set as negative examples. This resulted in more than 10,000 extra negative examples for each relation.

3.3 Parsing and Typing

The most well-known tool to detect medical entity mentions is MetaMap (Aronson, 2001), which considers all terms as entities and automatically associates each term with a number of concepts from UMLS CUI dictionary (Lindberg et al., 1993) with 2.7 million distinct concepts.

The parser used in our system is MedicalESG, an adaptation of ESG (English Slot Grammar) (McCord et al., 2012) to the medical domain with extensions of medical lexicons integrated in the UMLS 2012 Release. Compared to MetaMap, MedicalESG is based on the same medical lexicons, 10 times faster and produces very similar parsing results.

We use the semantic types defined in UMLS (Lindberg et al., 1993) to categorize argument types. The UMLS consists of a set of 133 subject categories, or semantic types, that provide a consistent categorization of more than 2M concepts represented in the UMLS Metathesaurus. Our system assigns each relation argument with one or more UMLS semantic types through a two step process. Firstly, we use MedicalESG to process the input sentence, identify segments of text that correspond to concepts in

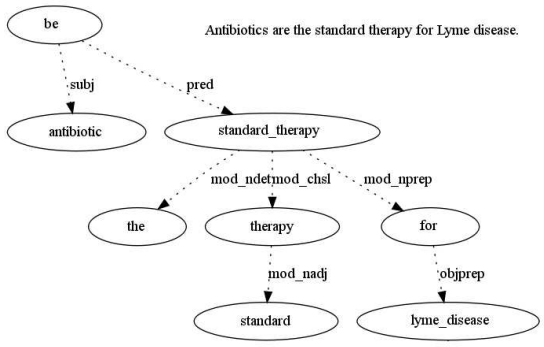

Figure 2: A Parse Tree Example

the UMLS Metathesaurus and associate each of them with one or more UMLS CUIs (Concept Unique Identifier). Then we do a CUI lookup in UMLS to find the corresponding semantic types for each CUI.

Most relation arguments are associated with multiple semantic types. For example, the term "tetracycline hydrochloride" has two types: "Organic Chemical" and "Antibiotic". Sometimes, the semantic types are noisy due to ambiguity of terms. For example, the term "Hepatitis b" is associated with both "Pharmacologic Substance" and "Disease or Syndrome" based on UMLS. The reason for this is that people use "Hepatitis b" to represent both "the disease of Hepatitis b" and "Hepatitis b vaccine", so UMLS assigns both types to it. This is a concern for relation extraction, since two types bear opposite meanings. Our current strategy is to integrate all associated types, and rely on the relation detector trained with the labeled data to decide how to weight different types based upon the context.

Here is an illustrative example. Consider the sentence: *"Antibiotics are the standard therapy for Lyme disease"*: MedicalESG first generates a dependency parse tree (Figure 2) to represent grammatical relations between the words in the sentence, and then associates the words with CUIs. For example, "Antibiotics" is associated with CUI "C0003232" and "Lyme disease" is associated with two CUIs: "C0024198" and "C0717360". CUI lookup will assign "Antibiotics" with a semantic type "Antibiotic", and "Lyme disease" with three semantic types: "Disease or Syndrome", "Pharmacologic Substance" and "Immunologic Factor". This sentence expresses a "treats" relation between "Antibiotics" and "Lyme disease".

4 Relation Extraction with Manifold Models

4.1 Motivations

Given a few labeled examples and many unlabeled examples for a relation, we want to build a relation detector leveraging both labeled and unlabeled data. Following the manifold regularization idea (Belkin et al., 2006), our strategy is to learn a function that assigns a score to each example. Scores are fit so that examples (both labeled and unlabeled) with similar content get similar scores, and scores of labeled examples are close to their labels. Integration of the unlabeled data can help solve overfitting problems when the labeled data is not sufficient.

4.2 Features

We use 8 groups of features to represent each relation example. These features are commonly used for relation extraction.

- (1) Semantic types of argument 1, such as "Antibiotic".
- (2) Semantic types of argument 2.
- (3) Syntactic features representing the dependency path between two arguments, such as "subj", "pred", "mod_nprep" and "objprep" (between arguments "antibiotic" and "lyme disease") in Figure 2.
- (4) Features modeling the incoming and outgoing links of both arguments. These features are useful to determine if a relation goes from argument 1 to argument 2 or vice versa.
- (5) Topic features modeling the words in the dependency path. In the example given in Figure 2, the dependency path contains the following words: "be", "standard therapy" and "for". These features as well as the features in (6) are achieved by projecting the words onto a 100 dimensional LSI topic space (Deerwester et al., 1990) constructed from our medical corpus.
- (6) Topic features modeling the words in the whole sentence.
- (7) Bag-of-words features modeling the dependency path. In (7) and (8), we only consider the words that have occurred in the positive training data.

Notations:

The input dataset $X = \{x_1, \cdots, x_m\}$ is represented as a feature-instance matrix.

The desired label vector $Y = \{y_1, \cdots, y_l\}$ represents the labels of $\{x_1, \cdots, x_l\}$, where $l \leq m$.

W is a weight matrix, where $W_{i,j} = e^{-\|x_i - x_j\|^2}$ models the similarity of x_i and x_j.

$\|x_i - x_j\|$ stands for the Euclidean distance between x_i and x_j in the vector space.

D is a diagonal matrix: $D_{i,i} = \sum_j W_{i,j}$.

$\mathcal{L} = D^{-0.5}(D - W)D^{-0.5}$ is called normalized graph Laplacian matrix.

Δ is a user defined $l \times l$ diagonal matrix, where Δ_i represents the weight of label y_i.

$\mathcal{A} = \begin{pmatrix} \Delta & 0 \\ 0 & 0 \end{pmatrix}$ is an $m \times m$ matrix.

$V = [y_1, \cdots y_l, 0, \cdots, 0]$ is a $1 \times m$ matrix.

μ is a weight scalar.

$()^+$ represents pseudo inverse.

Algorithm:

1. **Represent each example using features: $X = \{x_1, \cdots, x_m\}$, where x_i is the ith example.**
2. **Construct graph Laplacian matrix $\mathcal{L}$ modeling the data manifold.**
3. **Construct vector $V = [y_1, \cdots y_l, 0, \cdots, 0]$.**
4. **Compute projection function f for each relation: $f = (X(\mathcal{A} + \mu\mathcal{L})X^T)^+ X\mathcal{A}V^T$.**

Figure 3: Notations and the Algorithm to Train a Manifold Model for Relation Extraction

- (8) Bag-of-words features modeling the whole sentence.

In relation extraction, many recent approaches use non-linear kernels to get the similarity of two relation examples. To classify a relation example, a lot of dot product computations are required. This is very time consuming and becomes a bottleneck in using relation extraction to facilitate clinical decision making. To speed up the classifier during the apply time, we decided to use a linear classifier instead of non-linear classifiers.

We represent all features in a single feature space. For example, we use a vector of 133 entries (UMLS contains 133 semantic types) to represent the types of argument 1. If argument 1 is associated with two types: "Organic Chemical" and "Antibiotic", we set the two corresponding entries to 1 and all the other entries to 0. Similar approaches are used to represent the other features.

4.3 The Main Algorithm

The problem we want to solve is formalized as follows: given a relation dataset $X = \{x_1, \cdots, x_m\}$, and the desired label $Y = \{y_1, \cdots, y_l\}$ for $\{x_1, \cdots, x_l\}$, where $l \leq m$, we want to construct a mapping function f to project any example x_i to a new space, where $f^T x_i$ matches x_i's desired label y_i. In addition, we also want f to preserve the manifold topology of the dataset, such that similar examples (both labeled and unlabeled) get similar scores. Here, the label is '+1' for positive examples, and '-1' for negative examples. Notations and the main algorithm to construct f for each relation are given in Figure 3.

4.4 Justification

The solution to the problem defined in Section 4.3 is given by the mapping function f to minimize the following cost function:

$$C(f) = \sum_{i \leq l} \alpha_i (f^T x_i - y_i)^2 + \mu \sum_{i,j} W_{i,j} (f^T x_i - f^T x_j)^2.$$

The first term of $C(f)$ is based on labeled examples, and penalizes the difference between the mapping result of x_i and its desired label y_i. α_i is a user specified parameter, representing the weight of label y_i. The second term of $C(f)$ does not take label information into account. It encourages the neighborhood relationship (geometry of the manifold) within X to be preserved in the mapping. When x_i and x_j are similar, the corresponding $W_{i,j}$ is big. If f maps x_i and x_j to different positions, f will be penalized. The second term is useful to bound the mapping function f and prevents overfitting from happening. Here μ is the weight of the second term. When $\mu = 0$, the model disregards the unlabeled data, and the data manifold topology is not respected.

Compared to manifold regularization (Belkin et al., 2006), we do not include the RKHS norm term. Instead, we associate each labeled example with an extra weight for label confidence. This weight is particularly useful when the training data comes from "Crowdsourcing", where we ask

multiple workers to complete the same task to correct errors. In that scenario, weights can be assigned to labels based upon annotator agreement.

Theorem 1: $f = (X(\mathcal{A} + \mu\mathcal{L})X^T)^+ X\mathcal{A}V^T$ minimizes the cost function $C(f)$.
Proof:
Given the input X, we want to find the optimal mapping function f such that $C(f)$ is minimized:

$$f = \arg\min_f C(f).$$

It can be verified that

$$\sum_{i \leq l} \alpha_i (f^T x_i - y_i)^2 = f^T X\mathcal{A}X^T f - 2f^T X\mathcal{A}V^T + V\mathcal{A}V^T.$$

We can also verify that

$$\mu \sum_{i,j} (f^T x_i - f^T x_j)^2 W_{i,j} = \mu f^T X\mathcal{L}X^T f.$$

So $C(f)$ can be written as

$$f^T X\mathcal{A}X^T f - 2f^T X\mathcal{A}V^T + V\mathcal{A}V^T + \mu f^T X\mathcal{L}X^T f.$$

Using the Lagrange multiplier trick to differentiate $C(f)$ with respect to f, we have

$$2X\mathcal{A}X^T f + 2\mu X\mathcal{L}X^T f = 2X\mathcal{A}V^T.$$

This implies that

$$X(\mathcal{A} + \mu\mathcal{L})X^T f = X\mathcal{A}V^T.$$

So

$$f = (X(\mathcal{A} + \mu\mathcal{L})X^T)^+ X\mathcal{A}V^T,$$

where "+" represents pseudo inverse. ∎

4.5 Advantages

Our algorithm offers the following advantages:

- The algorithm exploits unlabeled data, which helps prevent "overfitting" from happening.
- The algorithm provides users with the flexibility to assign different labels with different weights. This feature is useful when the training data comes from "crowdsourcing" or "distant supervision".
- Different from many approaches in this area, our algorithm provides a closed-form solution of the result. The solution is global optimal regarding the cost function $C(f)$.
- The algorithm is computationally efficient at the apply time (as fast as linear regressions).

5 Experiments

5.1 Cross-Validation Test

We use a cross-validation test[3] with the relation data generated in Section 3.2 to compare our approaches against the state-of-the-art approaches. The task is to classify the examples into positive or negative for each relation. We applied a 5-fold cross-validation. In each round of validation, we used 20% of the data for training and 80% for testing. The F_1 scores reported here are the average of all 5 rounds. We used MedicalESG to process the input text for all approaches.

5.1.1 Data and Parameters

This dataset includes 7 relations. We do not consider the relation of "contraindicates" in this test, since it has too few positive examples. On average, each relation contains about 800 positive examples and more than 13,000 negative examples. To eliminate the examples that are trivial to classify, we removed the negative examples that do not bear the valid argument types. This removed the examples that can be easily classified by a type filter, resulting in 3,000 negatives on average per relation. For each relation, we also collected 5,000 unlabeled examples and put them into two sets: unlabeled set 1 and 2 (2,500 examples in each set).

No parameter tuning was taken and no relation specific heuristic rules were applied in all tests. In all manifold models, $\mu = 1$. In SVM implementations, the trade-off parameter between training error and margin was set to 1 for all experiments.

5.1.2 Baseline Approaches

We compare our approaches to three state-of-the-art approaches including SVM with convolution tree kernels (Collins and Duffy, 2001), linear regression and SVM with linear kernels (Schölkopf and Smola, 2002). To adapt the tree kernel to medical domain, we followed the approach in (Nguyen et al., 2009) to take the syntactic structures into consideration. We also added the argument types as features to the tree kernel. In the tree kernel implementation, we assigned the tree structure and the vector corresponding to the argument types

[3] If we take the perfect entity mentions and the associated concepts provided by i2b2 (Uzuner et al., 2011) as the input, our system can directly apply to i2b2 relation extraction data. However, the i2b2 data has a tough data use agreement. Our legal team held several rounds of negotiations with the i2b2 data owner and then decided we should not use it due to the high legal risks. We are not aware of other available medical relation extraction datasets that fit for our evaluations.

Table 2: F_1 Scores from a Five-Fold Cross Validation Experiment

	SVM Tree Kernel	SVM Linear Kernel	Linear Regression	Manifold *Unlabeled*	Manifold *Predicted Labels with Weights*	Manifold *Predicted Labels without Weights*	Manifold *Unlabeled+Predicted Labels with Weights*
treats	0.7648	0.7850	0.7267	0.8025	0.8041	0.7884	**0.8085**
prevents	0.2859	0.3887	0.3922	0.5502	0.5696	**0.6349**	0.6332
causes	0.3885	0.5024	0.5219	**0.5779**	0.5088	0.3978	0.5081
location_of	0.6113	0.6009	0.4968	0.7275	0.7363	0.6964	**0.7454**
diagnoses	0.5520	0.4934	0.3202	0.6468	0.6485	0.5720	**0.6954**
symptom_of	0.4398	0.5611	0.5984	**0.6347**	0.5314	0.4515	0.5968
average	0.5071	0.5553	0.5094	0.6566	0.6331	0.5902	**0.6646**

with equal weights. The SVM with linear kernels and the linear regression model used the same features as the manifold models.

5.1.3 Settings for the Manifold Models

We tested our manifold model for each relation under three different settings:

(1) Manifold *Unlabeled*: We combined the labeled data and unlabeled set 1 in training. We set $\alpha_i = 1$ for $i \in [1, l]$.

(2) Manifold *Predicted Labels*: We combined labeled data and unlabeled set 2 in training. $\alpha_i = 1$ for $i \in [1, l]$. Different from the previous setting, we gave a label estimation to all the examples in the unlabeled set 2 based on the noise rate (Noise%) from Table 1. The label of all unlabeled examples was set to "+1" when $100\% - 2 \cdot Noise\% > 0$, or "-1" otherwise. Two weighting strategies were applied:

- *With Weights:* We let label weight $\alpha_i = |100\% - 2 \cdot Noise\%|$ for all x_i coming from the unlabeled set 2. This setting represents an empirical rule to estimate the label and confidence of each unlabeled example based on the sampling result.
- *Without Weights:* α_i is always set to 1.

(3) Manifold *UnLabeled+Predicted Labels*: a combination of setting (1) and (2). In this setting, the data from unlabeled set 1 was used as unlabeled data and the data from unlabeled set 2 was used as labeled data (With Weights).

5.1.4 Results

The results are summarized in Table 2.

The tree kernel-based approach and linear regression achieved similar F_1 scores, while linear SVM made a 5% improvement over them. One thing to note is that the results from these approaches vary significantly. The reason for this is that the labeled training data is not sufficient. So the approaches that completely depend on the labeled data are likely to run into overfitting. Linear SVM performed better than the other two, since the large-margin constraint together with the linear model constraint can alleviate overfitting.

By integrating unlabeled data, the manifold model under setting (1) made a 15% improvement over linear regression model on F_1 score, where the improvement was significant across all relations.

Under setting (2), the *With Weights* strategy achieved a slightly worse F_1 score than the previous setting but much better result than the baseline approaches. This tells us that estimating the label of unlabeled examples based upon the sampling result is one way to utilize unlabeled data and may help improve the relation extraction results. The results also show that the label weight is important for this setting, since the *Without Weights* strategy did not perform very well.

Compared to setting (1) and (2), setting (3) made use of 2,500 more unlabeled examples, and achieved the best performance among all approaches. On one hand, this result shows that using more unlabeled data can further improve the result. On the other hand, the insignificant improvement over (1) and (2) strongly indicates that how to utilize more unlabeled data to achieve a significant improvement is non-trivial and deserves more attention. To what extensions the unlabeled data can help the learning process is an open problem. Generally speaking, when the existing data is sufficient to characterize the dataset geometry, adding more unlabeled data will not help (Singh et al., 2008).

We tested the tree kernel-based approach without integrating the medical types as well. That resulted in very poor performance: the average F_1 score was below 30%. We also applied the rules used in SEMREP (Rindflesch and Fiszman, 2003) to this dataset. Since the relations detected by

SEMREP rules cannot be perfectly aligned with super relations, we cannot directly compare the results. Overall speaking, SEMREP rules are very conservative and detect very few relations from the same text.

5.2 Knowledge Base (KB) Construction

The UMLS Metathesaurus (Lindberg et al., 1993) contains a large amount of manually extracted relation knowledge. Such knowledge is invaluable for people to collect training data to build new relation detectors. One downside of using this KB is its incompleteness. For example, it only contains the treatments for about 8,000 diseases, which are far from sufficient. Further, the medical knowledge is changing extremely quickly, making people hard to understand it, and update it in the knowledge base in a timely manner.

To address these challenges, we constructed our own relation KB as a complement to the UMLS relation KB. We directly ran our relation detectors (trained with all labeled and unlabeled examples) on our medical corpus to extract relations. Then we combined the results and put them in a new KB. The new KB covers all super relations and stores the knowledge in the format of (relation_name, argument_1, argument_2, confidence), where the confidence is computed based on the relation detector confidence score and relation popularity in the corpus. The most recent version of our relation KB contains 3.4 million such entries.

We compared this new KB against UMLS KB using an answer generation task on a set of 742 Doctor Dilemma questions. We first ran our relation detectors to detect the relation(s) in the question clue involving question focus (what the question asks for). Then we searched against both KBs using the relation name and the non-focus argument for the missing argument. The search results were then generated as potential answers. We used the same relations to do KB lookup, so the results are directly comparable. Since most questions only have one correct answer, the precision number is not very important in this experiment.

If we detect multiple relations in the question, and the same answer is generated from more than one relations, we sum up all those confidence scores to make such answers more preferable. Sometimes, we may generate too many answers from KBs. For example, if the detected relation is "location_of" and the non-focus argument is "skin", then thousands of answers can be generated. In this scenario, we sort the answers based upon the confidence scores and only consider up to p answers for each question. In our test, we considered three numbers for p: 20, 50 and 3,000.

From Table 3, we can see that the new KB outperforms the most popularly-used UMLS KB at all recall levels by a large margin. This result indicates that the new KB has a much better knowledge coverage. The UMLS KB is manually created and thus more precise. In our experiment, the UMLS KB generated fewer answers than the new KB. For example, when up to 20 answers were generated for each question, the UMLS KB generated around 4,700 answers for the whole question set, while the new KB generated about 7,600 answers.

Construction of the new KB cost 16 machines (using 4×2.8G cores per machine) 8 hours. The reported computation time is for the whole corpus with 11G pure text.

Table 3: Knowledge Base Comparison

	Recall@20	Recall@50	Recall@3000
Our KB	135/742	182/742	301/742
UMLS KB	42/742	52/742	73/742

6 Conclusions

In this paper, we identify a list of key relations that can facilitate clinical decision making. We also present a new manifold model to efficiently extract these relations from text. Our model is developed to utilize both labeled and unlabeled examples. It further provides users with the flexibility to take label weight into consideration. Effectiveness of the new model is demonstrated both theoretically and experimentally. We apply the new model to construct a relation knowledge base (KB), and use it as a complement to the existing manually created KBs.

Abstract

The essence of distantly supervised relation extraction is that it is an *incomplete* multi-label classification problem with *sparse* and *noisy* features. To tackle the sparsity and noise challenges, we propose solving the classification problem using matrix completion on factorized matrix of minimized rank. We formulate relation classification as completing the unknown labels of testing items (entity pairs) in a sparse matrix that concatenates training and testing textual features with training labels. Our algorithmic framework is based on the assumption that the rank of item-by-feature and item-by-label joint matrix is low. We apply two optimization models to recover the underlying low-rank matrix leveraging the sparsity of feature-label matrix. The matrix completion problem is then solved by the fixed point continuation (FPC) algorithm, which can find the global optimum. Experiments on two widely used datasets with different dimensions of textual features demonstrate that our low-rank matrix completion approach significantly outperforms the baseline and the state-of-the-art methods.

1 Introduction

Relation Extraction (RE) is the process of generating structured relation knowledge from unstructured natural language texts. Traditional supervised methods (Zhou et al., 2005; Bach and Badaskar, 2007) on small hand-labeled corpora, such as MUC[1] and ACE[2], can achieve high precision and recall. However, as producing hand-labeled corpora is laborius and expensive, the supervised approach can not satisfy the increasing demand of building large-scale knowledge repositories with the explosion of Web texts. To address the lacking training data issue, we consider the distant (Mintz et al., 2009) or weak (Hoffmann et al., 2011) supervision paradigm attractive, and we improve the effectiveness of the paradigm in this paper.

Entity pair	<Barack Obama, U.S.>
Relation instances from knowledge bases	1. President of (Barack Obama, U.S.) 2. Born in (Barack Obama, U.S.)
Relation mentions from free texts	1. **Barack Obama** is the 44th and current President of the **U.S.**. (President of) 2. **Barack Obama** ended **U.S.** military involvement in the Iraq War. (-) 3. **Barack Obama** was born in Honolulu, Hawaii, **U.S.**. (Born in) 4. **Barack Obama** ran for the **U.S.** Senate in 2004. (Senate of)

Figure 1: Training corpus generated by the basic alignment assumption of distantly supervised relation extraction. The relation instances are the triples related to President Barack Obama in the Freebase, and the relation mentions are some sentences describing him in the Wikipedia.

The intuition of the paradigm is that one can take advantage of several knowledge bases, such as WordNet[3], Freebase[4] and YAGO[5], to automatically label free texts, like Wikipedia[6] and New York Times corpora[7], based on some heuristic alignment assumptions. An example accounting for the basic but practical assumption is illustrated in Figure 1, in which we know that the two entities (<Barack Obama, U.S.>) are not only involved in the *relation instances*[8] coming from knowledge bases (President-of(Barack Obama, U.S.) and Born-in(Barack Obama, U.S.)),

Baltimore, Maryland, USA, June 23-25 2014.

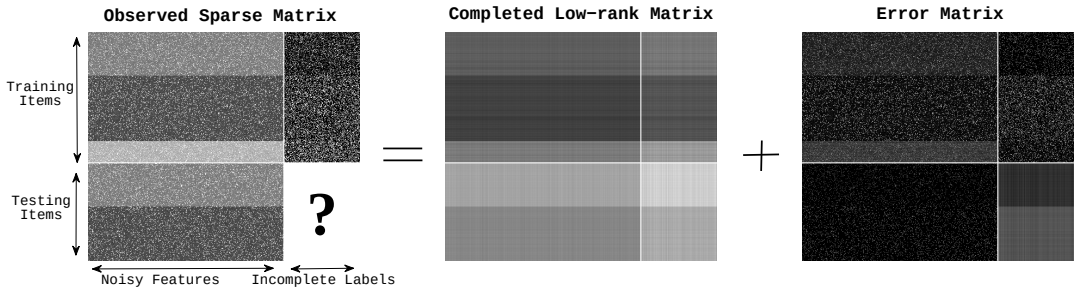

Figure 2: The procedure of noise-tolerant low-rank matrix completion. In this scenario, distantly supervised relation extraction task is transformed into completing the labels for testing items (entity pairs) in a sparse matrix that concatenates training and testing textual features with training labels. We seek to recover the underlying low-rank matrix and to complete the unknown testing labels simultaneously.

but also co-occur in several *relation mentions*[9] appearing in free texts (`Barack Obama is the 44th and current President of the U.S.` and `Barack Obama was born in Honolulu, Hawaii, U.S.`, etc.). We extract diverse textual features from all those *relation mentions* and combine them into a rich feature vector labeled by the *relation names* (`President-of` and `Born-in`) to produce a *weak* training corpus for relation classification.

This paradigm is promising to generate large-scale training corpora automatically. However, it comes up against three technical challeges:

- **Sparse features**. As we cannot tell what kinds of features are effective in advance, we have to use NLP toolkits, such as Stanford CoreNLP[10], to extract a variety of textual features, e.g., named entity tags, part-of-speech tags and lexicalized dependency paths. Unfortunately, most of them appear only once in the training corpus, and hence leading to very sparse features.

- **Noisy features**. Not all relation mentions express the corresponding relation instances. For example, the second relation mention in Figure 1 does not explicitly describe any relation instance, so features extracted from this sentence can be noisy. Such analogous cases commonly exist in feature extraction.

- **Incomplete labels**. Similar to noisy features, the generated labels can be incomplete. For example, the fourth relation mention in Figure 1 should have been labeled by the relation `Senate-of`. However, the incomplete knowledge base does not contain the corresponding relation instance (`Senate-of(Barack Obama, U.S.)`). Therefore, the distant supervision paradigm may generate incomplete labeling corpora.

In essence, distantly supervised relation extraction is an *incomplete* multi-label classification task with *sparse* and *noisy* features.

In this paper, we formulate the relation-extraction task from a novel perspective of using matrix completion with low rank criterion. To the best of our knowledge, we are the first to apply this technique on relation extraction with distant supervision. More specifically, as shown in Figure 2, we model the task with a sparse matrix whose rows present items (entity pairs) and columns contain noisy textual features and incomplete relation labels. In such a way, relation classification is transformed into a problem of completing the unknown labels for testing items in the sparse matrix that concatenates training and testing textual features with training labels, based on the assumption that the item-by-feature and item-by-label joint matrix is of low rank. The rationale of this assumption is that noisy features and incomplete labels are semantically correlated. The low-rank factorization of the sparse feature-label matrix delivers the low-dimensional representation of de-correlation for features and labels.

[9]The sentences that contain the given entity pair are called relation mentions.

[10]http://nlp.stanford.edu/downloads/corenlp.shtml

We contribute two optimization models, DRMC[11]-b and DRMC-1, aiming at exploiting the sparsity to recover the underlying low-rank matrix and to complete the unknown testing labels simultaneously. Moreover, the logistic cost function is integrated in our models to reduce the influence of noisy features and incomplete labels, due to that it is suitable for binary variables. We also modify the fixed point continuation (FPC) algorithm (Ma et al., 2011) to find the global optimum.

Experiments on two widely used datasets demonstrate that our noise-tolerant approaches outperform the baseline and the state-of-the-art methods. Furthermore, we discuss the influence of feature sparsity, and our approaches consistently achieve better performance than compared methods under different sparsity degrees.

2 Related Work

The idea of distant supervision was firstly proposed in the field of bioinformatics (Craven and Kumlien, 1999). Snow et al. (2004) used WordNet as the knowledge base to discover more hpyernym/hyponym relations between entities from news articles. However, either bioinformatic database or WordNet is maintained by a few experts, thus hardly kept up-to-date.

As we are stepping into the *big data* era, the explosion of unstructured Web texts simulates us to build more powerful models that can automatically extract relation instances from large-scale online natural language corpora without hand-labeled annotation. Mintz et al. (2009) adopted Freebase (Bollacker et al., 2008; Bollacker et al., 2007), a large-scale crowdsourcing knowledge base online which contains billions of relation instances and thousands of relation names, to *distantly supervise* Wikipedia corpus. The basic alignment assumption of this work is that if a pair of entities participate in a relation, *all sentences* that mention these entities are labeled by that relation name. Then we can extract a variety of textual features and learn a multi-class logistic regression classifier. Inspired by multi-instance learning (Maron and Lozano-Pérez, 1998), Riedel et al. (2010) relaxed the strong assumption and replaced *all sentences* with *at least one sentence*. Hoffmann et al. (2011) pointed out that many entity pairs have more than one relation. They extended the multi-instance learning framework (Riedel et al., 2010) to the multi-label circumstance. Surdeanu et al. (2012) proposed a novel approach to multi-instance multi-label learning for relation extraction, which jointly modeled all the sentences in texts and all labels in knowledge bases for a given entity pair. Other literatures (Takamatsu et al., 2012; Min et al., 2013; Zhang et al., 2013; Xu et al., 2013) addressed more specific issues, like how to construct the negative class in learning or how to adopt more information, such as name entity tags, to improve the performance.

Our work is more relevant to Riedel et al.'s (2013) which considered the task as a matrix factorization problem. Their approach is composed of several models, such as PCA (Collins et al., 2001) and collaborative filtering (Koren, 2008). However, they did not concern about the data noise brought by the basic assumption of distant supervision.

3 Model

We apply a new technique in the field of applied mathematics, i.e., low-rank matrix completion with convex optimization. The breakthrough work on this topic was made by Candès and Recht (2009) who proved that most low-rank matrices can be perfectly recovered from an incomplete set of entries. This promising theory has been successfully applied on many active research areas, such as computer vision (Cabral et al., 2011), recommender system (Rennie and Srebro, 2005) and system controlling (Fazel et al., 2001). Our models for relation extraction are based on the theoretic framework proposed by Goldberg et al. (2010), which formulated the multi-label transductive learning as a matrix completion problem. The new framework for classification enhances the robustness to data noise by penalizing different cost functions for features and labels.

3.1 Formulation

Suppose that we have built a training corpus for relation classification with n items (entity pairs), d-dimensional textual features, and t labels (relations), based on the basic alignment assumption proposed by Mintz et al. (2009). Let $X_{train} \in \mathbb{R}^{n\times d}$ and $Y_{train} \in \mathbb{R}^{n\times t}$ denote the feature matrix and the label matrix for training, respectively. The linear classifier we adopt aims to explicitly learn the weight matrix $\mathbf{W} \in \mathbb{R}^{d\times t}$ and the bias column

[11] It is the abbreviation for **D**istant supervision for **R**elation extraction with **M**atrix **C**ompletion

vector $\mathbf{b} \in \mathbb{R}^{t\times 1}$ with the constraint of minimizing the loss function l,

$$\arg\min_{\mathbf{W},\mathbf{b}} \; l(Y_{train}, \left[\begin{array}{cc} \mathbf{1} & X_{train} \end{array}\right] \left[\begin{array}{c} \mathbf{b}^T \\ \mathbf{W} \end{array}\right]), \quad (1)$$

where $\mathbf{1}$ is the all-one column vector. Then we can predict the label matrix $Y_{test} \in \mathbb{R}^{m\times t}$ of m testing items with respect to the feature matrix $X_{test} \in \mathbb{R}^{m\times d}$. Let

$$\mathbf{Z} = \left[\begin{array}{cc} X_{train} & Y_{train} \\ X_{test} & Y_{test} \end{array}\right].$$

This linear classification problem can be transformed into completing the unobservable entries in Y_{test} by means of the observable entries in X_{train}, Y_{train} and X_{test}, based on the assumption that the rank of matrix $\mathbf{Z} \in \mathbb{R}^{(n+m)\times(d+t)}$ is low. The model can be written as,

$$\begin{aligned} &\arg\min_{\mathbf{Z}\in\mathbb{R}^{(n+m)\times(d+t)}} \quad \text{rank}(\mathbf{Z}) \\ &\text{s.t. } \forall(i,j)\in\Omega_X, \;\; z_{ij} = x_{ij}, \\ &\qquad (1\le i\le n+m, \;\; 1\le j\le d), \\ &\qquad \forall(i,j)\in\Omega_Y, \;\; z_{i(j+d)} = y_{ij}, \\ &\qquad (1\le i\le n, \;\; 1\le j\le t), \end{aligned} \quad (2)$$

where we use Ω_X to represent the index set of observable feature entries in X_{train} and X_{test}, and Ω_Y to denote the index set of observable label entries in Y_{train}.

Formula (2) is usually impractical for real problems as the entries in the matrix $\mathbf{Z}$ are corrupted by noise. We thus define

$$\mathbf{Z} = \mathbf{Z}^* + \mathbf{E},$$

where $\mathbf{Z}^*$ as the underlying low-rank matrix

$$\mathbf{Z}^* = \left[\begin{array}{cc} X^* & Y^* \end{array}\right] = \left[\begin{array}{cc} X^*_{train} & Y^*_{train} \\ X^*_{test} & Y^*_{test} \end{array}\right],$$

and $\mathbf{E}$ is the error matrix

$$\mathbf{E} = \left[\begin{array}{cc} E_{X_{train}} & E_{Y_{train}} \\ E_{X_{test}} & 0 \end{array}\right].$$

The rank function in Formula (2) is a non-convex function that is difficult to be optimized. The surrogate of the function can be the convex nuclear norm $||\mathbf{Z}||_* = \sum\sigma_k(\mathbf{Z})$ (Candès and Recht, 2009), where σ_k is the k-th largest singular value of $\mathbf{Z}$. To tolerate the noise entries in the error matrix $\mathbf{E}$, we minimize the cost functions C_x and C_y for features and labels respectively, rather than using the hard constraints in Formula (2).

According to Formula (1), $\mathbf{Z}^* \in \mathbb{R}^{(n+m)\times(d+t)}$ can be represented as $[X^*, \mathbf{W}X^*]$ instead of $[X^*, Y^*]$, by explicitly modeling the bias vector $\mathbf{b}$. Therefore, this convex optimization model is called **DRMC-b**,

$$\begin{aligned} \arg\min_{\mathbf{Z},\mathbf{b}} \;\; &\mu||\mathbf{Z}||_* + \frac{1}{|\Omega_X|}\sum_{(i,j)\in\Omega_X} C_x(z_{ij}, x_{ij}) \\ &+ \frac{\lambda}{|\Omega_Y|}\sum_{(i,j)\in\Omega_Y} C_y(z_{i(j+d)} + b_j, y_{ij}), \end{aligned} \quad (3)$$

where μ and λ are the positive trade-off weights. More specifically, we minimize the nuclear norm $||\mathbf{Z}||_*$ via employing the regularization terms, i.e., the cost functions C_x and C_y for features and labels.

If we implicitly model the bias vector $\mathbf{b}$, $\mathbf{Z}^* \in \mathbb{R}^{(n+m)\times(1+d+t)}$ can be denoted by $[\mathbf{1}, X^*, \mathbf{W}'X^*]$ instead of $[X^*, Y^*]$, in which $\mathbf{W}'$ takes the role of $[\mathbf{b}^T; \mathbf{W}]$ in DRMC-b. Then we derive another optimization model called **DRMC-1**,

$$\begin{aligned} \arg\min_{\mathbf{Z}} \;\; &\mu||\mathbf{Z}||_* + \frac{1}{|\Omega_X|}\sum_{(i,j)\in\Omega_X} C_x(z_{i(j+1)}, x_{ij}) \\ &+ \frac{\lambda}{|\Omega_Y|}\sum_{(i,j)\in\Omega_Y} C_y(z_{i(j+d+1)}, y_{ij}) \\ \text{s.t.} \;\; &\mathbf{Z}(:,1) = \mathbf{1}, \end{aligned} \quad (4)$$

where $\mathbf{Z}(:,1)$ denotes the first column of $\mathbf{Z}$.

For our relation classification task, both features and labels are binary. We assume that the actual entry u belonging to the underlying matrix $\mathbf{Z}^*$ is randomly generated via a sigmoid function (Jordan, 1995): $Pr(u|v) = 1/(1+e^{-uv})$, given the observed binary entry v from the observed sparse matrix $\mathbf{Z}$. Then, we can apply the log-likelihood cost function to measure the conditional probability and derive the *logistic cost function* for C_x and C_y,

$$C(u,v) = -\log Pr(u|v) = \log(1+e^{-uv}),$$

After completing the entries in Y_{test}, we adopt the sigmoid function to calculate the conditional probability of relation r_j, given entity pair p_i pertaining to y_{ij} in Y_{test},

$$Pr(r_j|p_i) = \frac{1}{1+e^{-y_{ij}}}, \quad y_{ij}\in Y_{test}.$$

Finally, we can achieve Top-N predicted relation instances via ranking the values of $Pr(r_j|p_i)$.

4 Algorithm

The matrix rank minimization problem is NP-hard. Therefore, Candés and Recht (2009) suggested to use a convex relaxation, the nuclear norm minimization instead. Then, Ma et al. (2011) proposed the fixed point continuation (FPC) algorithm which is fast and robust. Moreover, Goldfrab and Ma (2011) proved the convergence of the FPC algorithm for solving the nuclear norm minimization problem. We thus adopt and modify the algorithm aiming to find the optima for our noise-tolerant models, i.e., Formulae (3) and (4).

4.1 Fixed point continuation for DRMC-b

Algorithm 1 describes the modified FPC algorithm for solving DRMC-b, which contains two steps for each iteration,

Gradient step: In this step, we infer the matrix gradient $g(\mathbf{Z})$ and bias vector gradient $g(\mathbf{b})$ as follows,

$$g(z_{ij}) = \begin{cases} \frac{1}{|\Omega_X|}\frac{-x_{ij}}{1+e^{x_{ij}z_{ij}}}, & (i,j) \in \Omega_X \\ \frac{\lambda}{|\Omega_Y|}\frac{-y_{i(j-d)}}{1+e^{y_{i(j-d)}(z_{ij}+b_j)}}, & (i,j-d) \in \Omega_Y \\ 0, & otherwise \end{cases}$$

and

$$g(b_j) = \frac{\lambda}{|\Omega_Y|}\sum_{i:(i,j)\in\Omega_Y}\frac{-y_{ij}}{1+e^{y_{ij}(z_{i(j+d)}+b_j)}}.$$

We use the gradient descents $\mathbf{A} = \mathbf{Z} - \tau_z g(\mathbf{Z})$ and $\mathbf{b} = \mathbf{b} - \tau_b g(\mathbf{b})$ to gradually find the global minima of the cost function terms in Formula (3), where τ_z and τ_b are step sizes.

Shrinkage step: The goal of this step is to minimize the nuclear norm $||\mathbf{Z}||_*$ in Formula (3). We perform the singular value decomposition (SVD) (Golub and Kahan, 1965) for $\mathbf{A}$ at first, and then cut down each singular value. During the iteration, any negative value in $\mathbf{\Sigma} - \tau_{\mathbf{z}}\mu$ is assigned by zero, so that the rank of reconstructed matrix $\mathbf{Z}$ will be reduced, where $\mathbf{Z} = \mathbf{U}max(\mathbf{\Sigma} - \tau_{\mathbf{z}}\mu, 0)\mathbf{V^T}$.

To accelerate the convergence, we use a continuation method to improve the speed. μ is initialized by a large value μ_1, thus resulting in the fast reduction of the rank at first. Then the convergence slows down as μ decreases while obeying $\mu_{k+1} = max(\mu_k\eta_\mu, \mu_F)$. μ_F is the final value of μ, and η_μ is the decay parameter.

For the stopping criteria in inner iterations, we define the *relative error* to measure the residual of matrix $\mathbf{Z}$ between two successive iterations,

Algorithm 1 FPC algorithm for solving DRMC-b

Input:
Initial matrix $\mathbf{Z_0}$, bias $\mathbf{b_0}$; Parameters μ, λ;
Step sizes τ_z, τ_b.

Set $\mathbf{Z} = \mathbf{Z_0}$, $\mathbf{b} = \mathbf{b_0}$.
foreach $\mu = \mu_1 > \mu_2 > ... > \mu_F$ **do**
  while relative error $> \varepsilon$ **do**
    Gradient step:
    $\mathbf{A} = \mathbf{Z} - \tau_z g(\mathbf{Z}), \mathbf{b} = \mathbf{b} - \tau_b g(\mathbf{b})$.
    Shrinkage step:
    $\mathbf{U\Sigma V^T} = \text{SVD}(\mathbf{A})$,
    $\mathbf{Z} = \mathbf{U}\ max(\mathbf{\Sigma} - \tau_{\mathbf{z}}\mu, 0)\ \mathbf{V^T}$.
  end while
end foreach

Output: Completed Matrix $\mathbf{Z}$, bias $\mathbf{b}$.

$$\frac{||\mathbf{Z}^{k+1} - \mathbf{Z}^k||_F}{max(1, ||\mathbf{Z}^k||_F)} \leq \varepsilon,$$

where ε is the convergence threshold.

4.2 Fixed point continuation for DRMC-1

Algorithm 2 is similar to Algorithm 1 except for two differences. First, there is no bias vector $\mathbf{b}$. Second, a projection step is added to enforce the first column of matrix $\mathbf{Z}$ to be $\mathbf{1}$. In addition, The matrix gradient $g(\mathbf{Z})$ for DRMC-1 is

$$g(z_{ij}) = \begin{cases} \frac{1}{|\Omega_X|}\frac{-x_{i(j-1)}}{1+e^{x_{i(j-1)}z_{ij}}}, & (i,j-1) \in \Omega_X \\ \frac{\lambda}{|\Omega_Y|}\frac{-y_{i(j-d-1)}}{1+e^{y_{i(j-d-1)}z_{ij}}}, & (i,j-d-1) \in \Omega_Y \\ 0, & otherwise \end{cases}.$$

Algorithm 2 FPC algorithm for solving DRMC-1

Input:
Initial matrix $\mathbf{Z_0}$; Parameters μ, λ;
Step sizes τ_z.

Set $\mathbf{Z} = \mathbf{Z_0}$.
foreach $\mu = \mu_1 > \mu_2 > ... > \mu_F$ **do**
  while relative error $> \varepsilon$ **do**
    Gradient step: $\mathbf{A} = \mathbf{Z} - \tau_z g(\mathbf{Z})$.
    Shrinkage step:
    $\mathbf{U\Sigma V^T} = \text{SVD}(\mathbf{A})$,
    $\mathbf{Z} = \mathbf{U}\ max(\mathbf{\Sigma} - \tau_{\mathbf{z}}\mu, 0)\ \mathbf{V^T}$.
    Projection step: $\mathbf{Z}(:,1) = \mathbf{1}$.
  end while
end foreach

Output: Completed Matrix $\mathbf{Z}$.

Dataset	# of training tuples	# of testing tuples	% with more than one label	# of features	# of relation labels
NYT'10	4,700	1,950	7.5%	244,903	51
NYT'13	8,077	3,716	0%	1,957	51

Table 1: Statistics about the two widely used datasets.

Model	NYT'10 (θ=2)	NYT'10 (θ=3)	NYT'10 (θ=4)	NYT'10 (θ=5)	NYT'13
DRMC-b	51.4 $\pm$ 8.7 (51)	45.6 $\pm$ 3.4 (46)	41.6 $\pm$ 2.5 (43)	36.2 $\pm$ 8.8(37)	84.6 $\pm$ 19.0 (85)
DRMC-1	16.0 $\pm$ 1.0 (16)	16.4 $\pm$ 1.1(17)	16 $\pm$ 1.4 (17)	16.8 $\pm$ 1.5(17)	15.8 $\pm$ 1.6 (16)

Table 2: The range of optimal ranks for DRMC-b and DRMC-1 through five-fold cross validation. The threshold θ means filtering the features that appear less than θ times. The values in brackets pertaining to DRMC-b and DRMC-1 are the exact optimal ranks that we choose for the completed matrices on testing sets.

5 Experiments

In order to conduct reliable experiments, we adjust and estimate the parameters for our approaches, DRMC-b and DRMC-1, and compare them with other four kinds of landmark methods (Mintz et al., 2009; Hoffmann et al., 2011; Surdeanu et al., 2012; Riedel et al., 2013) on two public datasets.

5.1 Dataset

The two widely used datasets that we adopt are both automatically generated by aligning Freebase to New York Times corpora. The first dataset[12], NYT'10, was developed by Riedel et al. (2010), and also used by Hoffmann et al. (2011) and Surdeanu et al. (2012). Three kinds of features, namely, lexical, syntactic and named entity tag features, were extracted from relation mentions. The second dataset[13], NYT'13, was also released by Riedel et al. (2013), in which they only regarded the lexicalized dependency path between two entities as features. Table 1 shows that the two datasets differ in some main attributes. More specifically, NYT'10 contains much higher dimensional features than NYT'13, whereas fewer training and testing items.

5.2 Parameter setting

In this part, we address the issue of setting parameters: the trade-off weights μ and λ, the step sizes τ_z and τ_b, and the decay parameter η_μ.

We set $\lambda = 1$ to make the contribution of the cost function terms for feature and label matrices equal in Formulae (3) and (4). μ is assigned by a series of values obeying $\mu_{k+1} = max(\mu_k \eta_\mu, \mu_F)$. We follow the suggestion in (Goldberg et al., 2010) that μ starts at $\sigma_1 \eta_\mu$, and σ_1 is the largest singular value of the matrix $\mathbf{Z}$. We set $\eta_\mu = 0.01$. The final value of μ, namely μ_F, is equal to 0.01. Ma et al. (2011) revealed that as long as the non-negative step sizes satisfy $\tau_z < min(\frac{4|\Omega_Y|}{\lambda}, |\Omega_X|)$ and $\tau_b < \frac{4|\Omega_Y|}{\lambda(n+m)}$, the FPC algorithm will guarantee to converge to a global optimum. Therefore, we set $\tau_z = \tau_b = 0.5$ to satisfy the above constraints on both two datasets.

5.3 Rank estimation

Even though the FPC algorithm converges in iterative fashion, the value of ε varying with different datasets is difficult to be decided. In practice, we record the rank of matrix $\mathbf{Z}$ at each round of iteration until it converges at a rather small threshold $\varepsilon = 10^{-4}$. The reason is that we suppose the optimal low-rank representation of the matrix $\mathbf{Z}$ conveys the truly effective information about underlying semantic correlation between the features and the corresponding labels.

We use the five-fold cross validation on the validation set and evaluate the performance on each fold with different ranks. At each round of iteration, we gain a recovered matrix and average the F1[14] scores from Top-5 to Top-all predicted relation instances to measure the performance. Figure 3 illustrates the curves of average F1 scores. After recording the rank associated with the highest F1 score on each fold, we compute the mean and the standard deviation to estimate the range of optimal rank for testing. Table 2 lists the range of optimal ranks for DRMC-b and DRMC-1 on NYT'10 and NYT'13.

(c) DRMC-b on NYT'13 validation set.

(d) DRMC-1 on NYT'13 validation set.

Figure 3: Five-fold cross validation for rank estimation on two datasets.

On both two datasets, we observe an identical phenomenon that the performance gradually increases as the rank of the matrix declines before reaching the optimum. However, it sharply decreases if we continue reducing the optimal rank. An intuitive explanation is that the high-rank matrix contains much noise and the model tends to be overfitting, whereas the matrix of excessively low rank is more likely to lose principal information and the model tends to be underfitting.

5.4 Method Comparison

Firstly, we conduct experiments to compare our approaches with Mintz-09 (Mintz et al., 2009), MultiR-11 (Hoffmann et al., 2011), MIML-12 and MIML-at-least-one-12 (Surdeanu et al., 2012) on NYT'10 dataset. Surdeanu et al. (2012) released the open source code[15] to reproduce the experimental results on those previous methods. Moreover, their programs can control the feature sparsity degree through a threshold θ which filters the features that appears less than θ times. They set $\theta = 5$ in the original code by default. Therefore, we follow their settings and adopt the same way to filter the features. In this way, we guarantee the fair comparison for all methods. Figure 4 (a) shows that our approaches achieve the significant improvement on performance.

We also perform the experiments to compare our approaches with the state-of-the-art NFE-13[16] (Riedel et al., 2013) and its sub-methods (N-13, F-13 and NF-13) on NYT'13 dataset. Figure 4 (b) illustrates that our approaches still outperform the state-of-the-art methods. In practical applications, we also concern about the precision on Top-N predicted relation instances. Therefore, We compare the precision of Top-100s, Top-200s and Top-500s for DRMC-1, DRMC-b and the state-of-the-

art method NFE-13 (Riedel et al., 2013). Table 3 shows that DRMC-b and DRMC-1 achieve 24.0% and 26.6% precision increments on average, respectively.

6 Discussion

We have mentioned that the basic alignment assumption of distant supervision (Mintz et al., 2009) tends to generate noisy (noisy features and incomplete labels) and sparse (sparse features) data. In this section, we discuss how our approaches tackle these natural flaws.

Due to the noisy features and incomplete labels, the underlying low-rank data matrix with truly effective information tends to be corrupted and the rank of observed data matrix can be extremely high. Figure 5 demonstrates that the ranks of data matrices are approximately 2,000 for the initial optimization of DRMC-b and DRMC-1. However, those high ranks result in poor performance. As the ranks decline before approaching the optimum, the performance gradually improves, implying that our approaches filter the noise in data and keep the principal information for classification via recovering the underlying low-rank data matrix.

Furthermore, we discuss the influence of the feature sparsity for our approaches and the state-

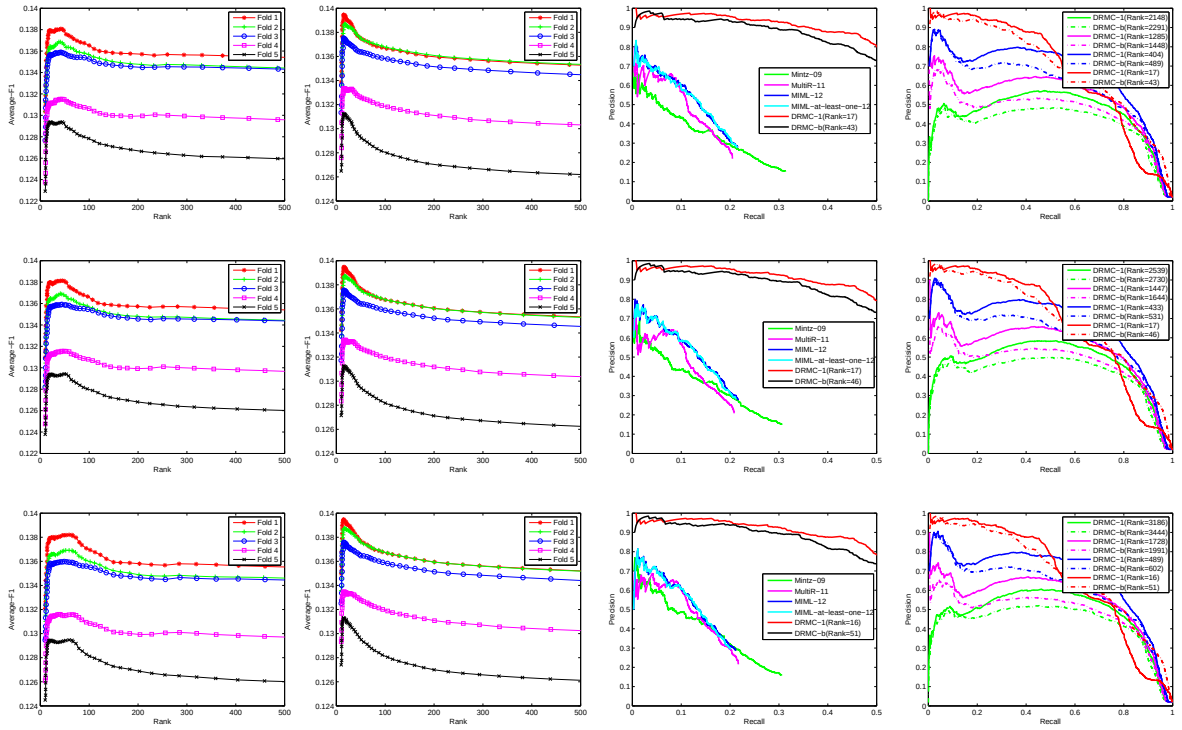

Figure 6: Feature sparsity discussion on NYT'10 testing set. Each row (from top to bottom, $\theta = 4, 3, 2$) illustrates a suite of experimental results. They are, from left to right, five-fold cross validation for rank estimation on DRMC-b and DRMC-1, method comparison and precision-recall curve with different ranks, respectively.

of-the-art methods. We relax the feature filtering threshold ($\theta = 4, 3, 2$) in Surdeanu et al.'s (2012) open source program to generate more sparse features from NYT'10 dataset. Figure 6 shows that our approaches consistently outperform the baseline and the state-of-the-art methods with diverse feature sparsity degrees. Table 2 also lists the range of optimal rank for DRMC-b and DRMC-1 with different θ. We observe that for each approach, the optimal range is relatively stable. In other words, for each approach, the amount of truly effective information about underlying semantic correlation keeps constant for the same dataset, which, to some extent, explains the reason why our approaches are robust to sparse features.

7 Conclusion and Future Work

In this paper, we contributed two noise-tolerant optimization models[17], DRMC-b and DRMC-1, for distantly supervised relation extraction task from a novel perspective. Our models are based on matrix completion with low-rank criterion. Experiments demonstrated that the low-rank representation of the feature-label matrix can exploit the underlying semantic correlated information for relation classification and is effective to overcome the difficulties incurred by sparse and noisy features and incomplete labels, so that we achieved significant improvements on performance.

Our proposed models also leave open questions for distantly supervised relation extraction task. First, they can not process new coming testing items efficiently, as we have to reconstruct the data matrix containing not only the testing items but also all the training items for relation classification, and compute in iterative fashion again. Second, the volume of the datasets we adopt are relatively small. For the future work, we plan to improve our models so that they will be capable of incremental learning on large-scale datasets (Chang, 2011).

Enhancing Grammatical Cohesion: Generating Transitional Expressions for SMT

Mei Tu **Yu Zhou** **Chengqing Zong**

Institute of Automation,
Chinese Academy of Sciences
{mtu,yzhou,cqzong}@nlpr.ia.ac.cn

Abstract

Transitional expressions provide glue that holds ideas together in a text and enhance the logical organization, which together help improve readability of a text. However, in most current statistical machine translation (SMT) systems, the outputs of compound-complex sentences still lack proper transitional expressions. As a result, the translations are often hard to read and understand. To address this issue, we propose two novel models to encourage generating such transitional expressions by introducing the source compound-complex sentence structure (CSS). Our models include a CSS-based translation model, which generates new CSS-based translation rules, and a generative transfer model, which encourages producing transitional expressions during decoding. The two models are integrated into a hierarchical phrase-based translation system to evaluate their effectiveness. The experimental results show that significant improvements are achieved on various test data meanwhile the translations are more cohesive and smooth.

1 Introduction

During the last decade, great progress has been made on statistical machine translation (SMT) models. However, these translations still suffer from poor readability, especially translations of compound-complex sentences. One of the main reasons may be that most existing models concentrate more on producing well-translated local sentence fragments, but largely ignore global cohesion between the fragments. Generally, cohesion, including lexical and grammatical cohesion, contributes much to the understandability and smoothness of a text.

Recently, researchers have begun addressing the lexical cohesion of SMT (Gong et al., 2011; Xiao et al., 2011; Wong and Kit, 2012; Xiong, 2013). These efforts focus mainly on the co-occurrence of lexical items in a similar environment. Grammatical cohesion[1] (Halliday and Hassan, 1976) in SMT has been little mentioned in previous work. Translations without grammatical cohesion is hard to read, mostly due to loss of cohesive and transitional expressions between two sentence fragments. Thus, generating transitional expressions is necessary for achieving grammatical cohesion. However, it is not easy to produce such transitional expressions in SMT. As an example, consider the Chinese-to-English translation in Figure 1.

Source Chinese sentence:

[尽管 减轻 污染 的 呼声 不断 ，]1 [公众
Although reduce pollution of calls continue , public

日渐 愤怒 ，]2 [污染 还是 变得 更 糟糕
growing angry , pollution still become more worse

了 ，]3 [越发 显出 环保 的 紧迫性 。]4
already , more show environment protection of urgent .

Target English golden translation:

***Despite** frequent calls for cutting pollution, **and** growing public anger, the problem has only got worse, **which** increasingly shows the urgency of environmental protection.*

Figure 1: An example of Chinese-to-English translation. The English translation sentence has three transitional phrases: ***Despite, and, which***.

There are 4 sub-sentences separated by commas in the Chinese sentence. We have tried to translate the Chinese sentence using many well-

[1] Grammatical cohesion can make relations among sentences more explicit. There are various grammatically cohesive devices (reference, substitution ellipsis and conjunction) that tie fragments together in a cohesive way.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 850–860,
Baltimore, Maryland, USA, June 23-25 2014.

known online translators, but find that it is very difficult to generate the target transitional expressions, especially when there is no explicit connective word in the source sentence, such as generating "***and*** " and "***which***" in Figure 1.

Fortunately, the functional relationships between two neighboring source sub-sentences provide us with a good perspective and the inspiration to generate those transitional phrases. Figure 1 shows that the first and the second Chinese sub-sentences form a ***parallel*** relation. Thus, even though there is no distinct connective word at the beginning of the second source sub-sentence, a good translator is still able to insert or generate an "***and***" as a connection word to make the target translation more cohesive.

Based on the above analysis, this paper focuses on the target grammatical cohesion in SMT to make the translation more understandable, especially for languages with great difference in linguistic structure like Chinese and English. To the best of our knowledge, our work is the first attempt to generate target transitional expressions for SMT grammatical cohesion by introducing the functional relationships of source sentences. In this work, we propose two models. One is a new translation model that is utilized to generate new translation rules combined with the information of source functional relationships. The other is a generative transfer model that encourages producing transitional phrases during decoding. Our experimental results on Chinese-to-English translation demonstrate that the translation readability is greatly improved by introducing the cohesive information.

The remainder of the paper is organized as follows. In Section 2, we describe the functional relationships of Chinese compound-complex sentences. In Section 3, we present our models and show how to integrate the models into an SMT system. Our experimental results are reported in Section 4. A survey of related work is conducted in Section 5, and we conclude our work and outline the future work in Section 6.

2 Chinese Compound-Complex Sentence Structure

To acquire the functional relationships of a Chinese compound-complex sentence, Zhou (2004) proposed a well-annotated scheme to build the Compound-complex Sentence Structure (**CSS**). The structure explicitly shows the minimal semantic spans, called elementary units (***eu***s), and also depicts the hierarchical relations among ***eu***s. There are 11 common types of functional relationships [2] annotated in the Tsinghua Chinese Treebank (Zhou, 2004).

Under the annotation scheme of the Tsinghua Chinese Treebank, the Chinese sentence of example in Figure 1 is represented as the tree shown in Figure 2. In this example, each sub-sentence is an ***eu***. $\boldsymbol{eu_1}$ and $\boldsymbol{eu_2}$ are combined with a *parallel* relationship, followed by $\boldsymbol{eu_3}$ with an *adversative* relationship. $\boldsymbol{eu_1}$, $\boldsymbol{eu_2}$, and $\boldsymbol{eu_3}$ form a large semantic span[3], connected with $\boldsymbol{eu_4}$ by a *consequence* relationship. All of the ***eu***s are organized into various functional relationships and finally form a hierarchical tree.

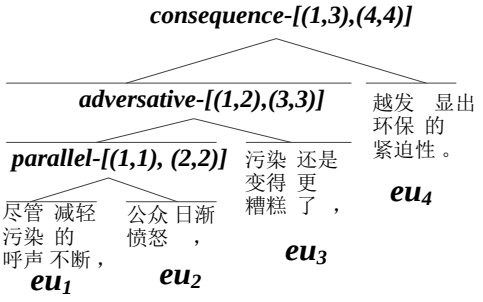

Figure 2: The compound-complex sentence structure of the Chinese sentence in Figure 1.

Formally, given a compound-complex sentence structure (CSS), each node in the CSS can be represented as a tuple $R-[(s_1,e_1),...(s_l,e_l),...,(s_L,e_L)]$. R represents the relationship, which has L children. For each child of R, a pair (s_l,e_l) records its *start* and *end* ***eu***s. For example, ***adversative-[(1,2), (3,3)]*** in Figure 2 means that two children are controlled by the relationship ***adversative***, and the left child consists of $\boldsymbol{eu_1}$ and $\boldsymbol{eu_2}$, while the right child contains only $\boldsymbol{eu_3}$.

CSS has much in common with Rhetorical Structure (Mann and Thompson, 1988) in English, which also describe the semantic relation between discourse units. But the Rhetorical Structure involves much richer relations on the document-level, and little corpus is open for Chinese.

In the following, we will describe in detail how to utilize such CSS information for modelling in SMT.

[2] They are *parallel, consequence, progressive, alternative, causal, purpose, hypothesis, condition, adversative, explanation,* and *flowing* relationships.

[3] A semantic span can include one or more ***eu***s.

3 Modelling

Our purpose is to enhance the grammatical cohesion by exploiting the source CSS information. Therefore, theoretically, the conditional probability of a target translation $\boldsymbol{e}_s$ conditioned on the source CSS-based tree $\boldsymbol{f}_t$ is given by $P(\boldsymbol{e}_s \mid \boldsymbol{f}_t)$, and the final translation $\hat{\boldsymbol{e}}_s$ is obtained with the following formula:

$$\hat{\boldsymbol{e}}_s = \arg\max_{\boldsymbol{e}_s}\{\mathrm{P}(\boldsymbol{e}_s \mid \boldsymbol{f}_t)\} \quad (1)$$

Following Och and Ney (2002), our model is framed as a log-linear model:

$$P(\boldsymbol{e}_s \mid \boldsymbol{f}_t) = \frac{\exp\sum_k \lambda_k h_k(\boldsymbol{e}_s, \boldsymbol{f}_t)}{\sum_{\boldsymbol{e}'_s} \exp\sum_k \lambda_k h_k(\boldsymbol{e}'_s, \boldsymbol{f}_t)} \quad (2)$$

where $h(\boldsymbol{e}_s, \boldsymbol{f}_t)$ is a feature with weight λ. Then, the best translation is:

$$\hat{\boldsymbol{e}}_s = \arg\max_{\boldsymbol{e}_s} \exp\sum_k \lambda_k h_k(\boldsymbol{e}_s, \boldsymbol{f}_t) \quad (3)$$

Our models make use of CSS with two strategies:

1) **CSS-based translation model**: following formula (1), we obtain the cohesion information by modifying the translation rules with their probabilities $P(\boldsymbol{e}_s \mid \boldsymbol{f}_t)$ based on word alignments between the source CSS-tree and the target string;

2) **CSS-based transfer model:** following formula (3), we introduce a transfer score to encourage the decoder to generate transitional words and phrases; the score is utilized as an additional feature $h_k(\boldsymbol{e}_s, \boldsymbol{f}_t)$ in the log-linear model.

3.1 CSS-based Translation Model

For the existing translation models, the entire training process is conducted at the lexical or syntactic level without grammatically cohesive information. As a result, it is difficult to utilize such cohesive information during decoding. Instead, we reserve the cohesive information in the training process by converting the original source sentence into tagged-flattened CSS and then perform word alignment and extract the translation rules from the bilingual flattened source CSS and the target string.

As introduced in Section 2, a CSS consists of nodes, and a node can be represented as a tuple $R-[(s_1,e_1),...(s_l,e_l),...,(s_L,e_L)]$. In this representation, the relationship R is the most important factor because different relationships directly reflect different cohesive expressions. In addition, the children's positions always play a strong role in choosing cohesive expressions because transitional expressions vary for children with different positions. For example, when translating the last child of a *parallel* relation, we always use word "*and*" as the transitional expression seen in Figure 3, but we will not use it for the first child of a *parallel* relation. Therefore, in the training process we just keep the information of relationships and children's positions when converting

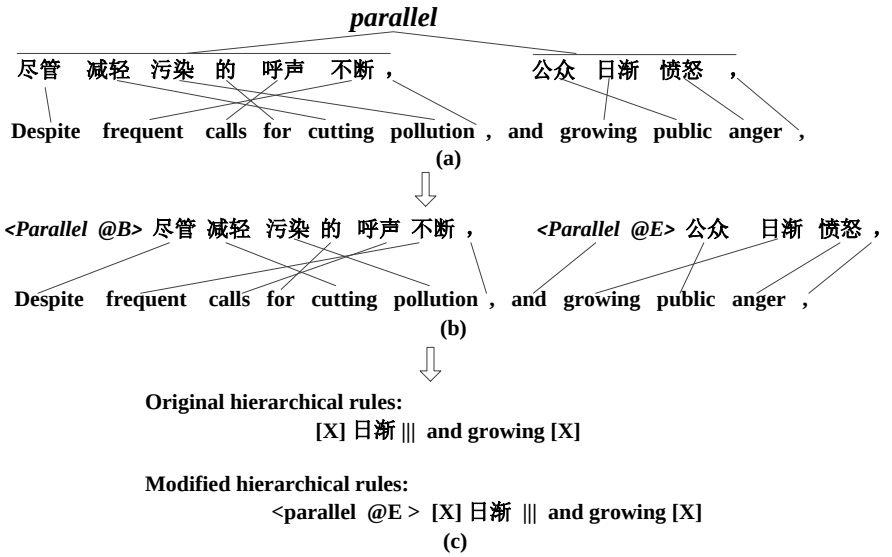

Figure 3: An example of modifying translation rules. @B means the current structure information comes from the first child, and @E means from the last child.

the source CSS to a tagged-flattened string.

Considering that the absolute position (index of the ***eu***, such as *1*, *2*, *3*) is somehow sparse in the corpus, we employ the relative position instead. *B* (*Beginning*) represents the first child of a relationship, *E* (*End*) means the last child of a relationship, and *M* (*Middle*) represents all the middle children.

Under this agreement, the original Chinese CSS-based tree will be converted to a new tagged-flattened string. Note the converting example from Figure 3(a) to Figure 3(b): node *parallel-[(1,1), (2,2)]* (see Figure 2) is converted to a flat string. Its first child is represented as <*parallel, @B*> with the semantic span, while the last child is <*parallel, @E*> with the corresponding semantic span.

We then perform word alignment on the modified bilingual sentences, and extract the new translation rules based on the new alignment, as shown in Figure 3(b) to Figure 3(c). Now the newly extracted rule "<*parallel, @E > [X] 日渐 ||| and growing [X]* " is tagged with cohesive information. Thus, if the similar relationship *parallel* occurs in the test source sentence, this type of rule is more likely to be chosen to generate the cohesive word "*and*" during decoding because it is more discriminating than the original rules (*[X] 日渐 ||| and growing [X]*). The conditional probabilities of the new translation rules are calculated following (Chiang, 2005).

3.2 CSS-based Transfer model

In general, according to formula (3), the translation quality based on the log-linear model is related tightly with the features chosen. Most translation systems adopt the features from a translation model, a language model, and sometimes a reordering model. To give a bonus to generating cohesive expressions during decoding, we have designed a special additional feature. The additional feature is represented as a probability calculated by a transfer model.

Given the source CSS information, we want our transfer model to predict the most possible cohesive expressions. For example, given two semantic spans with a *parallel* relationship and many translation candidates, our transfer model is expected to assign higher scores to those with transitional expressions such as "*and*" or "*as well as*".

Let $\boldsymbol{w} = w_0, w_1, ...w_n$ represent the transitional expressions observed in the target string. Our transfer model can be represented as a conditional probability:

$$P(\boldsymbol{w} \mid CSS) \quad (4)$$

By deriving each node of the CSS, we can obtain a factored formula:

$$P(\boldsymbol{w} \mid CSS) = \prod_{i,j} P(\boldsymbol{w}_{ij} \mid R_i, RP_j) \quad (5)$$

where $\boldsymbol{w}_{ij}$ is the transitional expression produced by the j^{th} child of the i^{th} node of the CSS. R_i is the relationship type of the i^{th} node. For the j^{th} child in the i^{th} node, RP_j is its relative position (*B, M* or *E*) introduced in Section 3.1.

The process of training this transfer model and smoothing is similar to the process of training a language model. We obtain the factored transfer probability as follows,

$$P(\boldsymbol{w}_{ij} \mid R_i, RP_j) = P(w_0 \mid R_i, RP_j) \prod_{k=1}^{n} P(w_k \mid w_0^{k-1}, R_i, RP_j) \quad (6)$$

where

$$\boldsymbol{w}_{ij} = w_0^{\,n} = w_0, ...w_n \quad (7)$$

Following (Bilmes and Kirchhoff, 2003), the conditional probabilities $P(w_k \mid w_0^{k-1}, R_i, RP_j)$ in formula (6) are estimated in the same way as a factored language model, which has the advantage of easily incorporating various linguistic information.

Considering that $\boldsymbol{w}_{ij}$ commonly appears at the beginning of the target translation of a source semantic span such as "*which …*", namely, the **left-frontier phrases,** we focus only on the left-frontier phrases when training this model. Note that if there exists a target word before a left frontier, and this word is aligned to *NULL*, we will expand the left frontier to this word. The expansion process will be repeated until there is no such word. For example, if we take the CSS and the alignment in Figure 3(a) for training, the left frontier of the second child will be expanded from "*growing*" to "*and*". In addition, taking the tri-gram left-frontier phrase for example, we can obtain a training sample such as $\boldsymbol{w}_{ij}$ = *and growing public*, *R=parallel*, *RP = E*.

By learning such probabilities for different transitional expressions conditioned on different relationships, we are able to capture the inner connection between the source CSS and the projected target cohesive phrases. Thus, during decoding, if we add the probability generated by the transfer model of $P(\boldsymbol{w} \mid CSS)$ as a feature in

formula (3), it will certainly contribute to selecting more cohesive candidates.

3.3 Elementary-Unit Cohesion Constraint

As mentioned in Section 3.2, in the transfer model, the transitional phrases are expected to occur at the left frontier of a projected span on target side. In fact, this depends on the assumption that the projected translations of any two disjoint source semantic spans are also disjoint to keep their own semantic integrity. We call this assumption the integrity assumption. This assumption is intuitive and supported by statistics. After analyzing 1,007 golden aligned Chinese-English sentence-pairs, we find that approximately 90% of the pairs comply with the assumption. However, in real automatically aligned noisy data, the ratio of complying pairs reduces to 71%[4]. Two projected translations that violate the integrity assumption may mutually overlap, which causes our confusion on where to extract the transitional phrases. In this case, extracted transitional phrases are likely to be wrong.

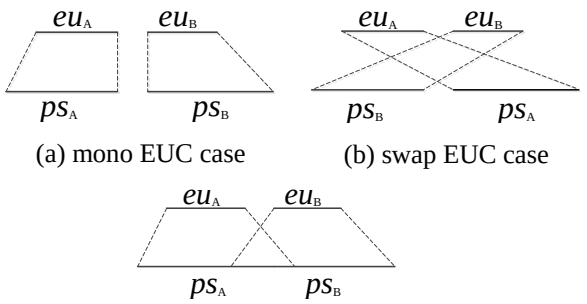
To increase the chance of extracting correct transitional phrases, the alignment results must be modified to reduce the impact of incorrect alignment. We propose a dynamic cleaning method to ensure that the most expressive transitional phrases fall in the accessible extraction range before training the transfer model.

3.3.1 EUC and non-EUC

As we have defined in Section 2, the minimal semantic span is called elementary unit (***eu***). If the source ***eu*** and its projected target span comply with the integrity assumption, we say that such an ***eu*** and its projected span have **Elementary-Unit-Cohesion (EUC).** We define EUC formally as follows.

Given two elementary units eu_A and eu_B, and their projected target spans ps_A and ps_B bound by the word alignment, the alignment complies with EUC only if there is no overlap between ps_A and ps_B. Otherwise, the alignment is called ***non-EUC***. The common ***EUC*** and ***non-EUC*** cases are illustrated in Figure 4.

EUC is the basic case for the integrity assumption. For the best cases, the elementary units comply with EUC, and thus the semantic spans combined by elementary units are certainly subject to the integrity assumption.



(a) mono EUC case (b) swap EUC case

(c) non-EUC case

Figure.4 The schematic diagram of *EUC* cases and *non-EUC* case.

3.3.2 A Dynamic Cleaning Method

An intuitive method to clean the alignment results is to drop off the noisy word-to-word links that cause non-EUC. Considering that the dropping process is a post-editing method for the original alignment obtained by a state-of-the-art aligner such as GIZA++, we do not expect over-deleting. Therefore, we tend to take a relatively conservative strategy to minimize the deleting operation.

Given a sentence-pair (***f***, ***e***), suppose that $\boldsymbol{f} = \{f_0, ..., f_i, ..., f_I\}$ is divided into M elementary units $U = \{u_0, ..., u_m, ..., u_M\}$, and ***e*** has N words, that is, $\boldsymbol{e} = \{e_0, ..., e_n, ..., e_N\}$. If A is the word alignment of (***f***, ***e***), then the goal is to construct the maximum subset $A^* \subseteq A$ under the condition that A^* is the word alignment with the constraint of EU. The search process can be described as the pseudo code in Figure 5.

In Figure 5, we scan each target word and each source ***eu*** to assign each word to a unique ***eu*** under the EUC constraint with the lowest cost. Function cost(n,m) in line 6 computes the counts of deleted links that force the n^{th} target word to align only to words in the range of the m^{th} ***eu***. For example, if the n^{th} target word is aligned to the i^{th}, $(i+1)^{th}$, and $(i+2)^{th}$ word in source side, while the i^{th} word belongs to u_{m_1} and the $(i+1)^{th}$ and $(i+2)^{th}$ words belong to u_{m_2}, then $\text{cost}(n, u_{m_1}) = 2$, and $\text{cost}(n, u_{m_2}) = 1$. In line 6, *Score*[$n$][$m$] saves a list of scores, each score computed by adding the current cost(n, m) with the history score of each list of *Score*[*n-1*].

[4] The aligning tool is GIZA++ with 5 iterations of Model 1, 5 iterations of HMM, and 10 iterations of Model 4. The GIZA++ code can be downloaded from https://code.google.com/p/giza-pp/

Before the next iteration, the bad branches are pruned, as seen in line 5. We adopt the following two ways to prune:

(1) EUC constraint: if the current link violates EUC alignment, delete it.

(2) Keep the hypothesis with a fixed maximum size to avoid too large a searching space.

```
//Pseudo code for dynamic cleaning
1: Score [N+1][M]={[0]}_{N×M}        /* initialize
                        cumulative cost score chart*/
2: Path [M]=[[]]              /*initialize tracking path*/
3: for n = 1 → N :{          /*  scan target words*/
4:   for  m = 0 → M −1:{      /*scan source U set */
5:     PrunePath();
          /* prune invalid  path and high-cost path*/
6:     Score[n][m]=GetScore(Score[n-1], cost(n, m))
     /*compute current cumulative cost score by previ-
                ous score and current cost*/
7:     SaveCurrentPath(Path[m]);
                    /*add current index to Path*/
8:  }//end m
9:}//end n
10: OptimalPath = arg max_{Path[m]} {Score[N][m]};
```

Figure 5. The pseudo code of dynamic cleaning method.

4 Experiments

4.1 Experimental Setup

To obtain the CSSs of Chinese sentences, we use the Chinese parser proposed in (Tu et al., 2013a). Their parser first segments the compound-complex sentence into a series of elementary units, and then builds structure of the hierarchical relationships among these elementary units. Their parser was reported to achieve an F-score for elementary unit segmentation of approximately 0.89. The *progressive*, *causal*, and *condition* terms of functional relationships can be recognized with precisions of 0.86, 0.8, and 0.75, respectively, while others, such as *purpose*, *parallel*, and *flowing*, achieve only 0.5, 0.59 and 0.62, respectively.

The translation experiments have been conducted in the Chinese-to-English direction. The bilingual training data for translation model and CSS-based transfer model is FBIS corpus with approximately 7.1 million Chinese words and 9.2 million English words. We obtain the word alignment with the grow-diag-final-and strategy with GIZA++. Before training the CSS-based transfer model, the alignment for transfer model is modified by our dynamic cleaning method. During the cleaning process, the maximum size of hypothesis is limited to 5. A 5-gram language model is trained with SRILM[5] on the combination of the Xinhua portion of the English Gigaword corpus combined with the English part of FBIS. For tuning and testing, we use NIST03 evaluation data as the development set. NIST04/05/06, CWMT08-Development [6] and CWMT08-Evaluation data are used for testing under the measure metric of BLEU-4 (Papineni et al. 2002) with the shortest length penalty.

Table 1 shows how the CSS is distributed in all testing sets. According to the statistics in Table 1, we see that CSS is really widely distributed in the NIST and CWMT corpora, which implies that the translation quality may benefit substantially from the CSS information, if it is well considered in SMT.

	Total	CSS	Ratio(%)
NIST04	1,788	1,307	73.1
NIST05	1,082	849	78.5
NIST06	1,000	745	74.5
CWMT08-Dev.	1,006	818	81.3
CWMT08-Eval.	1,006	818	81.3

Table 1. The numbers of sentences and the CSS ratios of all sentences. CWMT08-Dev. is short for CWMT08 Development data and CWMT08-Eval. is CWMT08 Evaluation data.

4.2 Extracted Transitional Expressions

Eleven types of Chinese functional relationships and their English left-frontier phrases (tri-gram) learned by our transfer model are given in Table 2.

The results in Table 2 show that some left-frontier phrases reflect the source functional relationship well, especially for those with better precision of relationship recognition, such as *progressive, causal* and *condition*. Conversely, lower precision of relationship recognition may weaken the learning ability of the transfer model. For example, noisy left-frontier phrases are easily generated under relationships such as *parallel* and *purpose*.

4.3 Results on SMT with Different Strategies

For this work, we use an in-house decoder to build the SMT baseline; it combines the hierarchical phrase-based translation model (Chiang, 2005; Chiang, 2007) with the BTG (Wu, 1996) reordering model (Xiong et al., 2006; Zens and Ney, 2006; He et al., 2010).

To test the effectiveness of the proposed models, we have compared the translation quality of different integration strategies. First, we adopted only the tagged-flattened rules in the hierarchical translation system. Next, we added the log probability generated by the transfer model as a feature into the baseline features. The baseline features include bi-directional phrase translation probabilities, bi-directional lexical translation probabilities, the BTG re-ordering features, and the language model feature. The tri-gram left-frontier phrase was adopted in the experiment. Then the probability generated by the transfer model with EUC constraint is added. Finally, we incorporated the tagged-flattened rules and the additional transfer model feature together.

Table 3 shows the results of these different integrated strategies. In Table 3, almost all BLEU scores are improved, no matter what strategy is used. In particular, the best performance marked in bold is as high as 1.24, 0.94, and 0.82 BLEU points, respectively, over the baseline system on NIST04, CWMT08 Development, and CWMT08 Evaluation data. The strategy of "**TFS+ Flattened Rule**" is the most stable. Meanwhile the "**Flattened Rule**" achieves better performance than "**TFS**". The merits of "**Flattened Rule**" are two-fold: 1) In training process, the new word alignment upon modified sentence pairs can align transitional expressions to flattened CSS tags; 2) In decoding process, the CSS-based rules are more discriminating than the original rules, which is more flexible than "TFS". From the table, we cannot conclude that the EUC constraint will certainly promote translation quality, but the transfer model performs better with the constraint on most testing sets.

4.4 Analysis of Different Effects of Different N-grams

As mentioned in Section 4.3, we have noted the effectiveness of tri-gram transfer model, which means $n = 2$ in formula (7). In fact, the lengths of common transitional expressions vary from one word to several words. To evaluate the effects of different n-grams for our proposed transfer model, we compared the uni-/bi-/tri-gram transfer models in SMT, and illustrate the results in Fig-

	NIST04	NIST05	NIST06	CWMT08's Dev.	CWMT08's Eval.
Baseline	33.42	31.99	33.88	26.14	23.88
+Flattened Rule	34.54**	32.32	**34.58****	26.79**	**24.70****
+TFS (without EUC)	33.93**	32.04	34.40*	26.44	24.58**
+TFS	33.84**	**32.63***	34.15	**27.08****	24.65**
+TFS+ Flattened Rule	**34.66****	32.54	34.52**	26.87**	24.49**

+ **Flattened Rule**: only use the tagged-flattened translation rules
+ **TFS:** only use the transfer model score as an additional feature (based on 3-gramtransitional phrase)
+ **TFS** + **Flattened Rule**: both are used
*: value with * means that it is significantly better than the baseline with p<0.05
**: value with ** means that it is significantly better than the baseline with p<0.01

Table 3. BLEU scores of the testing sets with different integrating strategies

ure 6. In this experiment, the CSS-based translation rules and the CSS-based transfer model are both incorporated. Considering time and computing resources, in the rest of our paper, our analysis is conducted on NIST05 and NIST06.

We choose $n = 0, 1, 2$ in this experiment for that the common English transitional expressions are primarily conjunctions, most of which are less than 4 words. Results in Figure 6 show that the uni-gram and tri-gram transitional expressions seem more fitting for our transfer model. One possible reason is that uni-gram or tri-gram conjunctions are more utilized in an English text. In a conjunction expression list proposed by (Williams, 1983) which summarizes the different kinds of conjunctions based on the work of Halliday and Hassan (1976), we obtain the statistical results on uni-/bi-/tri-gram expressions, which are about 52.1%/16.9%/23.9% respectively.

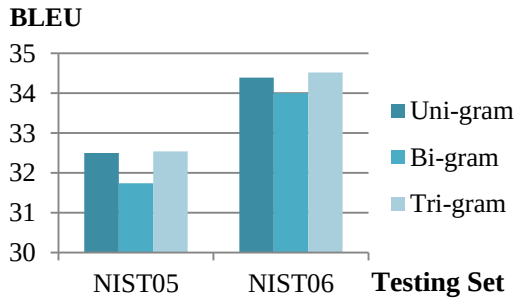

Figure 6. Different translation qualities along with different n-grams for transfer model.

4.5 Experiments on Big Training Data

To further evaluate the effectiveness of the proposed models, we also conducted an experiment on a larger set of bilingual training data from the LDC corpus[7] for translation model and transfer model. The training corpus contains 2.1M sentence pairs with approximately 27.7M Chinese words and 31.9M English words. All the other settings were the same as the SMT experiments of sub-section 4.3. The final BLEU scores on NIST05 and NIST06 are given in Table 4.

The results in Table 4 further verify the effectiveness of our proposed models. The best performance with bold marking scored as high as 0.83 and 0.64 BLEU points, respectively over the baseline system on NIST05 and NIST06 evaluation data.

	NIST05	NIST06
Baseline	35.20	35.52
+Flattened Rule	**36.03****	36.10*****
+TFS	35.56*	36.04*
+TFS +Flattened Rule	36.02**	36.16**

+ **Flattened Rule**: only use the tagged-flattened translation rules
+ **TFS:** only use the transfer model score as an additional feature (3-gram transitional phrase)
+ **TFS** + **Flattened Rule**: both are used
*: value with * means that it is significantly better than the baseline with $p<0.05$
**: value with ** means that it is significantly better than the baseline with $p<0.01$

Table 4. BLEU scores on the large-scale training data.

4.6 Translation Examples

Two SMT examples of Chinese-to-English are given in Table 5. We observe that compared to the baseline, our approach has obvious advantages on translating the implicit relations, due to generating translational expressions on target side. Moreover, with the transitional expressions, cohesion of the entire translation improves. Notably, the transitional expressions in this work like "*including*, *there are*, *the core of which*" are not linguistic conjunctions. We would like to call them "generalized" conjunctions, because they tie semantic fragments together, analogously to linguistic conjunctions.

5 Related Work

Improving cohesion for complex sentences or discourse translation has attracted much attention in recent years. Such research efforts can be roughly divided into two groups: 1) research on lexical cohesion, which mainly contributes to the selection of generated target words; 2) efforts to improve the grammatical cohesion, such as disambiguation of references and connectives.

In lexical cohesion work, (Gong et al., 2011; Xiao et al., 2011; Wong and Kit, 2012) built discourse-based models to ensure lexical cohesion or consistency. In (Xiong et al., 2013a), three different features were designed to capture the lexical cohesion for document-level machine translation. (Xiong et al., 2013b) incorporated lexical-chain-based models (Morris and Hirst, 1991) into machine translation. They generated the target lexical chains based on the source

Table 5. Examples of baseline and the improved system outputs.

chains via maximum entropy classifiers, and used the target chains to work on the word selection.

Limited work has been conducted on grammatical cohesion. (Marcu et al., 2000) designed a discourse structure transfer module, but it focused on converting the semantic structure rather than actual translation. (Tu et al., 2013b) provided a Rhetorical-Structure-Theory-based tree-to-string translation method for complex sentences with explicit relations inspired by (Marcu et al., 2000), but their models worked only for explicit functional relations, and they were concerned mainly with the translation integrity of semantic span rather than cohesion. (Meyer and Popescu-Belis, 2012) used sense-labeled discourse connectives for machine translation from English to French. They added the labels assigned to connectives as an additional input to an SMT system, but their experimental results show that the improvements under the evaluation metric of BLEU were not significant. (Nagard and Koehn, 2010) addresses the problems of reference or anaphora resolution inspired by work of Mitkov et al. (1995).

To the best of our knowledge, our work is the first attempt to exploit the source functional relationship to generate the target transitional expressions for grammatical cohesion, and we have successfully incorporated the proposed models into an SMT system with significant improvement of BLEU metrics.

6 Conclusion

In this paper, we focus on capturing cohesion information to enhance the grammatical cohesion of machine translation. By taking the source CSS into consideration, we build bridges to connect the source functional relationships in CSS to target transitional expressions; such a process is very similar to human translating.

Our contributions can be summarized as: 1) the new translation rules are more discriminative and sensitive to cohesive information by converting the source string into a CSS-based tagged-flattened string; 2) the new additional features embedded in the log-linear model can encourage the decoder to produce transitional expressions. The experimental results show that significant improvements have been achieved on various test data, meanwhile the translations are more cohesive and smooth, which together demonstrate the effectiveness of our proposed models.

In the future, we will extend our methods to other translation models, such as the syntax-based model, to study how to further improve the performance of SMT systems. Besides, more language pairs with various linguistic structures will be taken into consideration.

Abstract

We present an adaptive translation quality estimation (QE) method to predict the human-targeted translation error rate (HTER) for a document-specific machine translation model. We first introduce features derived internal to the translation decoding process as well as externally from the source sentence analysis. We show the effectiveness of such features in both classification and regression of MT quality. By dynamically training the QE model for the document-specific MT model, we are able to achieve consistency and prediction quality across multiple documents, demonstrated by the higher correlation coefficient and F-scores in finding *Good* sentences. Additionally, the proposed method is applied to IBM English-to-Japanese MT post editing field study and we observe strong correlation with human preference, with a 10% increase in human translators' productivity.

1 Introduction

Machine translation (MT) systems suffer from an inconsistent and unstable translation quality. Depending on the difficulty of the input sentences (sentence length, OOV words, complex sentence structures and the coverage of the MT system's training data), some translation outputs can be perfect, while others are ungrammatical, missing important words or even totally garbled. As a result, users do not know whether they can trust the translation output unless they spend time to analyze the MT output. This shortcoming is one of the main obstacles for the adoption of MT systems, especially in machine assisted human translation: MT post-editing, where human translators have an option to edit MT proposals or translate from scratch. It has been observed that human translators often discard MT proposals even if some are very accurate. If MT proposals are used properly, post-editing can increase translators productivity and lead to significant cost savings. Therefore, it is beneficial to provide MT confidence estimation, to help the translators to decide whether to accept MT proposals, making minor modifications on MT proposals when the quality is high or translating from scratching when the quality is low. This will save the time of reading and parsing low quality MT and improve user experience.

In this paper we propose an adaptive quality estimation that predicts sentence-level human-targeted translation error rate (HTER) (Snover et al., 2006) for a document-specific MT post-editing system. HTER is an ideal quality measurement for MT post editing since the reference is obtained from human correction of the MT output. Document-specific MT model is an MT model that is specifically built for the given input document. It is demonstrated in (Roukos et al., 2012) that document-specific MT models significantly improve the translation quality. However, this raises two issues for quality estimation. First, existing approaches to MT quality estimation rely on lexical and syntactical features defined over parallel sentence pairs, which includes source sentences, MT outputs and references, and translation models (Blatz et al., 2004; Ueffing and Ney, 2007; Specia et al., 2009a; Xiong et al., 2010; Soricut and Echihabi, 2010a; Bach et al., 2011). Therefore, when the MT quality estimation model is trained,

*This work was done when the author was with IBM Research.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 861–870,
Baltimore, Maryland, USA, June 23-25 2014.

it can not be adapted to provide accurate estimates on the outputs of document-specific MT models. Second, the MT quality estimation might be inconsistent across different document-specific MT models, thus the confidence score is unreliable and not very helpful to users.

In contrast to traditional static MT quality estimation methods, our approach not only trains the MT quality estimator dynamically for each document-specific MT model to obtain higher prediction accuracy, but also achieves consistency over different document-specific MT models. The experiments show that our MT quality estimation is highly correlated with human judgment and helps translators to increase the MT proposal adoption rate in post-editing.

We will review related work on MT quality estimation in section 2. In section 3 we will introduce the document-specific MT system built for post-editing. We describe the static quality estimation method in section 4, and propose the adaptive quality estimation method in section 5. In section 6 we demonstrate the improvement of MT quality estimation with our method, followed by discussion and conclusion in section 7.

2 Related Work

There has been a long history of study in confidence estimation of machine translation. The work of (Blatz et al., 2004) is among the best known study of sentence and word level features for translation error prediction. Along this line of research, improvements can be obtained by incorporating more features as shown in (Quirk, 2004; Sanchis et al., 2007; Raybaud et al., 2009; Specia et al., 2009b). Soricut and Echihabi (2010b) proposed various regression models to predict the expected BLEU score of a given sentence translation hypothesis. Ueffing and Hey (2007) introduced word posterior probabilities (WPP) features and applied them in the n-best list reranking. Target part-of-speech and null dependency link are exploited in a MaxEnt classifier to improve the MT quality estimation (Xiong et al., 2010).

Quality estimation focusing on MT post-editing has been an active research topic, especially after the WMT 2012 (Callison-Burch et al., 2012) and WMT2013 (Bojar et al., 2013) workshops with the "Quality Estimation" shared task. Biçici et al. (2013) proposes a number of features measuring the similarity of the source sentence to the source side of the MT training corpus, which, combined with features from translation output, achieved significantly superior performance in the MT QE evaluation. Felice and Specia (2012) investigates the impact of a large set of linguistically inspired features on quality estimation accuracy, which are not able to outperform the shallower features based on word statistics. González-Rubio et al. (2013) proposed a principled method for performing regression for quality estimation using dimensionality reduction techniques based on partial least squares regression. Given the feature redundancy in MT QE, their approach is able to improve prediction accuracy while significantly reducing the size of the feature sets.

3 Document-specific MT System

In our MT post-editing setup, we are given documents in the domain of software manuals, technical outlook or customer support materials. Each translation request comes as a document with several thousand sentences, focusing on a specific topic, such as the user manual of some software.

The input documents are automatically segmented into sentences, which are also called *segments*. Thus in the rest of the paper we will use sentences and segments interchangeably. Our parallel corpora includes tens of millions of sentence pairs covering a wide range of topics. Building a general MT system using all the parallel data not only produces a huge translation model (unless with very aggressive pruning), the performance on the given input document is suboptimal due to the unwanted dominance of out-of-domain data. Past research suggests using weighted sentences or corpora for domain adaptation (Lu et al., 2007; Matsoukas et al., 2009; Foster et al., 2010). Here we adopt the same strategy, building a document-specific translation model for each input document.

The document-specific system is built based on sub-sampling: from the parallel corpora we select sentence pairs that are the most similar to the sentences from the input document, then build the MT system with the sub-sampled sentence pairs. The *similarity* is defined as the number of n-grams that appear in both source sentences, divided by the input sentence's length, with higher weights assigned to longer n-grams. From the extracted sentence pairs, we utilize the standard pipeline in SMT system building: word align-

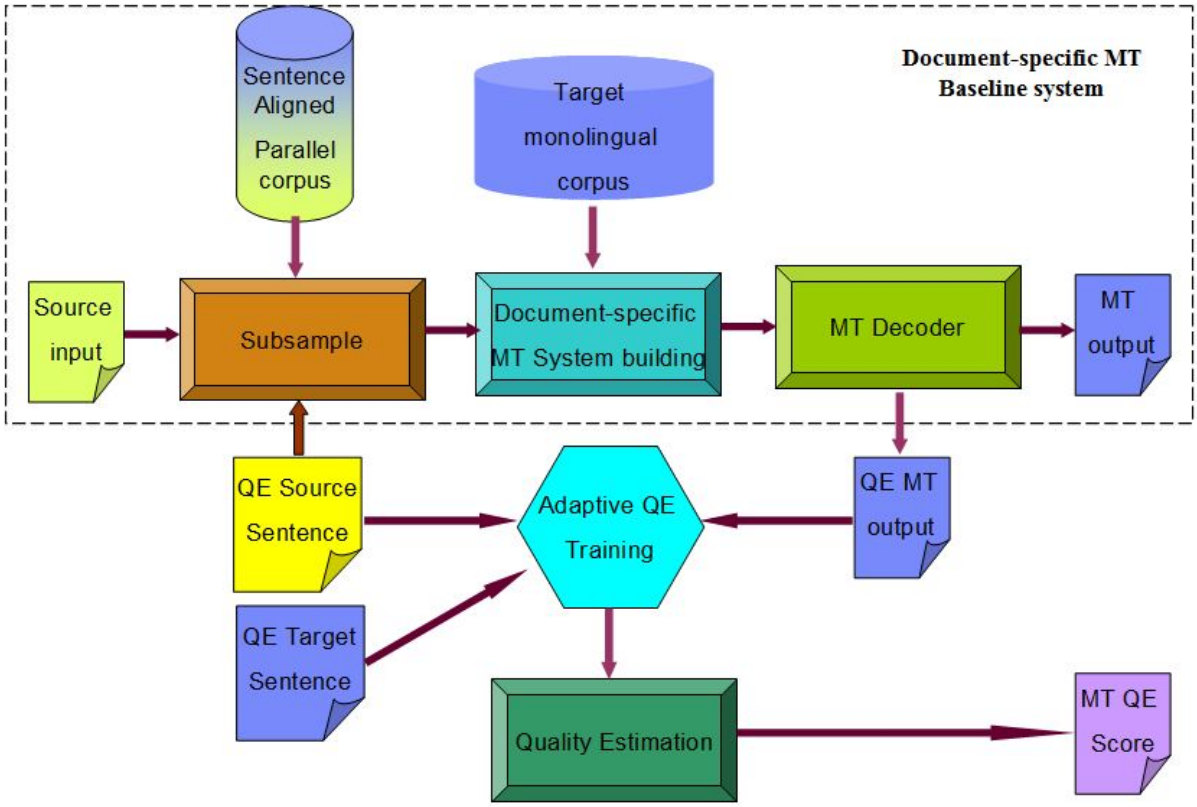

Figure 1: Adaptive QE for document-specific MT system.

ment (HMM (Vogel et al., 1996) and MaxEnt (Ittycheriah and Roukos, 2005) alignment models, phrase pair extraction, MT model training (Ittycheriah and Roukos, 2007) and LM model training. The top region within the dashed line in Figure 1 shows the overall system built pipeline.

3.1 MT Decoder

The MT decoder (Ittycheriah and Roukos, 2007) employed in our study extracts various features (source words, morphemes and POS tags, target words and POS tags, etc.) with their weights trained in a maximum entropy framework. These features are combined with other features used in a typical phrase-based translation system. Altogether the decoder incorporates 17 features with weights estimated by PRO (Hopkins and May, 2011) in the decoding process, and achieves state-of-the-art translation performance in various Arabic-English translation evaluations (NIST MT2008, GALE and BOLT projects).

4 Static MT Quality Estimation

MT quality estimation is typically formulated as a prediction problem: estimating the confidence score or translation error rate of the translated sentences or documents based on a set of features. In this work, we adopt HTER in (Snover et al., 2006) as our prediction output. HTER measures the percentage of insertions, deletions, substitutions and shifts needed to correct the MT outputs. In the rest of the paper, we use TER and HTER interchangably.

In this section we will first introduce the set of features, and then discuss MT QE problem from classification and regression point of views.

4.1 Features for MT QE

The features for quality estimation should reflect the complexity of the source sentence and the decoding process. Therefore we conduct syntactic analysis on the source sentences, extract features from the decoding process and select the following 26 features:

- 17 decoding features, including phrase translation probabilities (source-to-target and target-to-source), word translation probabilities (also in both directions), maxent probabilities[1], word count, phrase count, distor-

[1]The maxent probability is the translation probability

tion probabilities, as well as a set of language model scores.

- Sentence length, i.e., the number of words in the source sentence.
- Source sentence syntactic features, including the number of *noun phrases, verb phrases, adjective phrases, adverb phrases*, as inspired by (Green et al., 2013).
- The length of verb phrases, because verbs are typically the roots in dependency structure and they have more varieties during translation.
- The maximum length of source phrases in the final translation, since longer matching source phrase indicates better coverage of the input sentence with possibly better translations.
- The number of phrase pairs with high *fuzzy match (FM)* score. The high FM phrases are selected from sentence pairs which are closest in terms of n-gram overlap to the input sentence. These sentences are often found in previous translations of the software manual, and thus are very helpful for translating the current sentence.
- The average translation probability of the phrase translation pairs in the final translation, which provides the overall translation quality on the phrase level.

The first 17 features come from the decoding process, which are called "decoding features". The remaining 9 features not related to the decoder are called "external features". To evaluate the effectiveness of the proposed features, we train various classifiers with different feature configurations to predict whether a translation output is useful (with lower TER) as described in the following section.

4.2 MT QE as Classification

Predicting TER with various input features can be treated as a regression problem. However for the post-editing task, we argue that it could also be cast as a classification problem: MT system users (including the translators) are often interested to know whether a given translation is reasonably good or not. If useful, they can quickly look through the translation and make minor modifications. On the other hand, they will just skip reading and parsing the bad translation, and prefer to translate by themselves from scratch. Therefore we also develop algorithms that classify the translation at different levels, depending on whether the TER is less than a given threshold. In our experiments, we set TER=0.1 as the threshold.

Configuration	Training set	Test set
Baseline (All negative)	80%	77%
17 decoding features only	89%	79%
9 external features only	85%	81%
total 26 features	92%	83%

Table 1: QE classification accuracy with different feature configurations

We randomly select one input document with 2067 sentences for the experiment. We build a document-specific MT system to translate this document, then ask human translator to correct the translation output. We compute TER for each sentence using the human correction as the reference. The TER of the whole document is 0.31, which means about 30% errors should be corrected. In the classification task, our goal is to predict whether a sentence is a *Good* translation (with TER $\leq$ 0.1), and label them for human correction. We adopt a decision tree-based classifier, experimenting with different feature configurations. We select the top 1867 sentences for training and the bottom 200 sentences for test. In the test set, there are 46 sentences with TER $\leq$ 0.1. Table 1 shows the classification accuracy.

First we can see that as the overall TER is around 0.3, predicting all the sentences being *negative* already has a strong baseline: 77%. However this is not helpful for the human translators, because that means they have to translate every sentence from scratch, and consequently there is no productivity gain from MT post-editing. If we only use the 17 decoding features, it improves the classification accuracy by 9% on the training set, but only 2% on the test set. This is probably due to the overfitting when training the decision tree classifier. While using the 7 external features, the gain on training set is less but the gain on the test set

derived from a Maximum Entropy translation model (Ittycheriah and Roukos, 2005).

is greater (4% improvement), because the translation output is generated based on the log-linear combination of these decoding features, which are biased towards the final translations. The external features capture the syntactic structure of the source sentence, as well as the coverage of the training data with regard to the input sentence, which are good indicators of the translation quality. Combining both the decoding features and the external features, we observed the best accuracy on both the training and test set. We will use the combined 26 features in the following work.

4.3 MT QE as Regression

For the QE regression task, we predict the TER for each sentence translation using the above 26 features. We experiment with several classifiers: linear regression model, decision tree based regression model and SVM model. With the same training and test data set up, we predict the TER for each sentence in the test set, and compute the correlation coefficient (r) and root mean square error (RMSE). Our experiments show that the decision tree-based regression model obtains the highest correlation coefficients (0.53) and lowest RMSE (0.23) in both the training and test sets. We will use this model for the adaptive MT QE in the following work.

5 Adaptive MT Quality Estimation

The above QE regression model is trained on a portion of the sentences from the input document, and evaluated on the remaining sentences from the same document. One would like to know whether the trained model can achieve consistent TER prediction accuracy on other documents. When we use the cross-document models for prediction, the correlation is significantly worse (the details are discussed in section 6.1). Therefore it is necessary to build a QE regression model that's robust to different document-specific translation models. To deal with this problem, we propose this adaptive MT QE method described below.

Our proposed method is as follows: we select a fixed set of sentence pairs (S_q, R_q) to train the QE model. The source side of the QE training data S_q is combined with the input document S_d for MT system training data subsampling. Once the document-specific MT system is trained, we use it to translate both the input document and the source QE training data, obtaining the translation T_d and

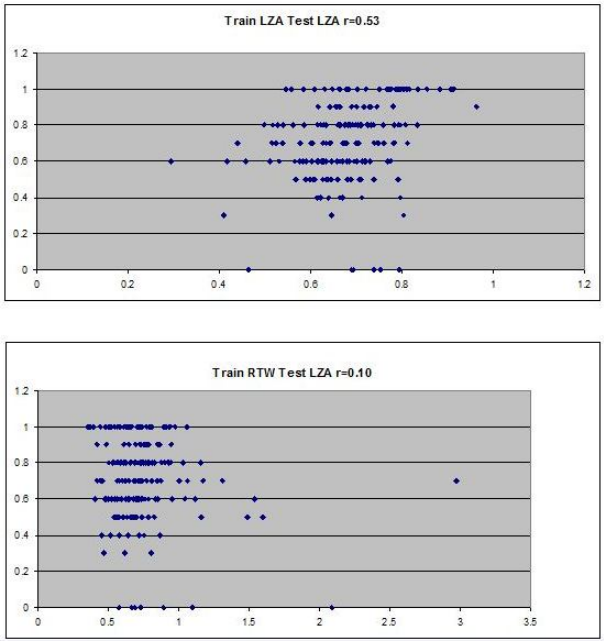

Figure 2: Correlation coefficient r between predicted TER (x-axis) and true TER (y-axis) for QE models trained from the same document (top figure) or different document (bottom figure).

T_q . We compute the TER of T_q using R_q as the reference, and train a QE regression model with the 26 features proposed in section 4.1. Then we use this *document-specific* QE model to predict the TER of the document translation T_d. As the QE model is adaptively re-trained for each document-specific MT system, its prediction is more accurate and consistent. Figure 1 shows the flow of our MT system with the adaptive QE training integrated as part of the built.

6 Experiments

In this section, we first discuss experiments that compare adaptive QE method and static QE method on a few documents, and then present results we obtained after deploying the adaptive QE method in an English-to-Japanese MT Post-Editing project. As mentioned before, the main motivation for us to develop MT QE classification scheme is that translators often discard good MT proposals and translate the segments from scratch. We would like to provide translators with some guidance on reasonably good MT proposals–the sentences with low TERs–to help them increase the leverage on MT proposals to achieve improved productivity.

6.1 Evaluation on Test Set

Our experiment and evaluation is conducted over three documents, each with about 2000 segments. We first build document-specific MT model for each document, then ask human translators to correct the MT outputs and obtain the reference translation. In a typical MT QE scenario, the QE model is pre-trained and applied to various MT outputs, even though the QE training data and MT outputs are generated from different translation models. To evaluate whether such model mismatch matters, we compare the cross-model QE with the same-model QE, where the QE training data and the MT outputs are generated from the same MT model.

We select one document LZA with 2067 sentences. We use the first 1867 sentences to train the static QE model and the remaining 200 sentences are used as test set for TER prediction. We compute the correlation coefficient (r) between each predicted TER and true TER, as shown in Figure 2. We find that the TER predictions are reasonably correct when the training and test sentences are from the same MT model (the top figure), with correlation coefficients around 0.5. For the cross-model QE, we train a static QE model with 1867 sentences from another document RTW, and use it to predict the TER of the same 200 sentences from document LZA (the bottom figure). We observe significant degradation of correlation coefficient, dropping from 0.5 to 0.1. This degradation and unstable nature is the prime motivation to develop a more robust MT quality estimation model.

We select 1700 sentences from multiple previously translated documents as the QE training data, which are independent of the test documents. We train the static QE model with this training set, including the source sentences, references and MT outputs (from multiple translation models). To train the adaptive QE model for each test document, we build a translation model whose subsampling data includes source sentences from both the test document and the QE training data. We translate the QE source sentences with this newly built MT model, and the translation output is used to train the QE model specific to each test document. We compare these two QE models on three documents, LZA, RTW and WC7, measuring r and RMSE for each QE model. The result is shown in Table 2. We find that the adaptive QE model demonstrates higher r and lower RMSE than the static QE model for all the test documents.

Besides the general correlation with human judgment, we particularly focus on those reasonably good translations, i.e., the sentences with low TERs which can help improve the translator's productivity most. Here we report the precision, recall and F-score of finding such "*Good*" sentences (with TER ≤ 0.1) on the three documents in Table 3. Again, the adaptive QE model produces higher recall, mostly higher precision, and significantly improved F-score. The overall F-score of the adaptive QE model is 0.28[2]. Compared with the static QE model's 0.17 F-score, this is relatively 64% improvement.

In the adaptive QE model, the source side QE training data is included in the subsampling process to build the document-specific MT model. It would be interesting to know whether this process will negatively affect the MT quality. We evaluate the TER of MT outputs with and without the adaptive QE training on the same three documents. As seen in Table 4, we do not notice translation quality degradation. Instead, we observe slightly improvement on two document, with TERs reduction by 0.1-0.4 pt. As our MT model training data include proprietary data, the MT performance is significantly better than publicly available MT software.

6.2 Impact on Human Translators

We apply the proposed adaptive QE model to large scale English-to-Japanese MT Post-Editing project on 36 documents with 562K words. Each English sentence can be categorized into 3 classes:

- Exact Match (**EM**): the source sentence is completely covered in the bilingual training corpora thus the corresponding target sentence is returned as the translation;
- Fuzzy Match (**FM**): the source sentence is similar to some sentence in the training data (similarity measured by string editing distance), the corresponding fuzzy match target sentence (FM proposal) as well as the MT translation output (MT proposal) are returned for human translators to select and correct;
- No Proposal (**NP**): there is no close match source sentences in the training data (the FM

[2]The adaptive QE model obtains much higher F-score (80%) on the rest of the sentences (with TER > 0.1).

Document	LZA		RTW		WC7	
Num. of Sents	2067		2003		2405	
	$r \uparrow$	RMSE $\downarrow$	$r \uparrow$	RMSE $\downarrow$	$r \uparrow$	RMSE $\downarrow$
Static QE	0.10	0.38	0.40	0.32	0.13	0.36
Adaptive QE	**0.58**	0.23	**0.61**	0.22	**0.47**	0.20

Table 2: QE regression with static and adaptive models

Document	LZA	RTW	WC7
Num. of Sents	2067	2003	2405
	P/R/F-score	P/R/F-score	P/R/F-score
Static QE	0.73/0.08/0.14	0.69/ 0.11/ 0.19	0.74/ 0.10/ 0.18
Adaptive QE	0.69/0.14/**0.24**	0.84/ 0.16/ **0.26**	0.80/ 0.23/ **0.35**

Table 3: Performance on predicting *Good* sentences with static and adaptive models

similarity score of 70% is used as the threshold), therefore only the MT output is returned.

EM sentences are excluded from the study because in general they do not require editing. We focus on the FM and NP sentences[3]. In Table 5 we present the precision, recall and F-score of the "Good" sentences in the FM and NP categories, similar to those shown in Table 3. We consistently observe higher performance on the FM sentences, in terms of precision, recall and F-score. This is expected because these sentences are well covered in the training data. The overall F-score is in line with the test set results shown in Table 3.

We are also interested to know whether the proposed adaptive QE method is helpful to human translators in the MT post-editing task. Based on the TERs predicted by the adaptive QE model, we assign each MT proposal with a confidence label: High ($0 \leq$ TER ≤ 0.2), Medium ($0.2 <$ TER ≤ 0.3), or Low (TER > 0.3). We present the MT proposals with confidence labels to human translators, then measure the percentage of sentences whose MT proposals are used. From Table 6 and 7, we can see that sentences with High and Medium confidence labels are more frequently used by the translators than those with Low labels, for both the FM and NP categories. The MT usage for the FM category is less than that for the NP category because translators can choose FM proposals instead of the MT proposals for correction.

We also measure the translator's productivity gain for MT proposals with different confidence labels. The productivity of a translator is defined as the number of source words translated per unit time. The post editing tool, IBM TranslationManager, records the time that a translator spends on a segment and computes the number of characters that a translator types on the segment so that we can compute how many words the translator has finished in a given time.

[3]The word count distribution of EM, FM and NP is 21%, 38% and 41%, respectively.

Document	LZA	RTW	WC7
TER-Baseline	30.81	30.74	29.96
TER-with Adaptive QE	30.69	30.78	29.56

Table 4: MT Quality with and without Adaptive QE measured by TER

We choose the overall productivity of NP0 as the base unit 1, where there is no proposal presents and the translator has to translate the segments from scratch. Measured with this unit, for example, the overall productivity of FM0 being 1.14 implies a relative gain of 14% over that of NP0, which demonstrates the effectiveness of FM proposals.

Table 6 and 7 also show the productivity gain on sentences with High, Medium and Low labels from FM and NP categories. Again, the productivity gain is consistent with the confidence labels from the adaptive QE model's prediction. The overall productivity gain with confidence-labeled MT proposals is about 10% (comparing FM1 vs. FM0 and NP1 vs. NP0). These results clearly demonstrate the effectiveness of the adaptive QE model in aiding the translators to make use of MT proposals and improve productivity.

Category	Class	FM usage	**MT usage**	**Productivity**
FM1	High	33%	**34%**	**1.35**
	Medium	47%	**18%**	**1.21**
	Low	60%	**8%**	**1.20**
	Overall	45%	**21%**	**1.26**
FM0	High	53%	-	1.12
	Medium	64%	-	1.14
	Low	67%	-	1.16
	Overall	59%	-	1.14

Table 6: MT proposal usage and productivity gain in FM category.
In FM1, both Fuzzy Match and MT proposals present. In control class FM0, only Fuzzy Match proposals present, and therefore, MT usage is not available for FM0. Strong correlation is observed between predicted "High" , "Medium" and "Low" sentences with MT usage and post editing productivity.

Category	Class	**MT usage**	**Productivity**
NP1	High	**50%**	**1.25**
	Medium	**42%**	**1.08**
	Low	**27%**	**1.00**
	Overall	**38%**	**1.09**
NP0	High	-	1.08
	Medium	-	1.00
	Low	-	0.96
	Overall	-	1.00

Table 7: MT proposal usage and productivity gain in NP category.
In NP1, MT is the only proposal available, while in control NP0, there presents no proposal at all and the translator has to translate from scratch. Strong correlation is observed between predicted "High" , "Medium" and "Low" sentences with MT usage and post editing productivity

Type	Precision	Recall	F-score
FM	0.71	0.23	0.35
NP	0.67	0.18	0.29
Overall	**0.69**	**0.21**	**0.32**

Table 5: Performance on predicting *Good* sentences (TER ≤ 0.1) by adaptive QE model

7 Discussion and Conclusion

In this paper we proposed a method to adaptively train a quality estimation model for document-specific MT post editing. With the 26 proposed features derived from decoding process and source sentence syntactic analysis, the proposed QE model achieved better TER prediction, higher correlation with human correction of MT output and higher F-score in finding good translations. The proposed adaptive QE model is deployed to a large scale English-to-Japanese MT post editing project, showing strong correlation with human preference and leading to about 10% gain in human translator productivity.

The training data for QE model can be selected independent of the input document. With such fixed QE training data, it is possible to measure the consistency of the trained QE models, and to allow the sanity check of the document-specific MT models. However, adding such data in the subsampling process extracts more bilingual data for building the MT models, which slightly increase the model building time but increased the translation quality. Another option is to select the sentence pairs from the MT system subsampled training data, which is more similar to the input document thus the trained QE model could be a better match to the input document. However, the QE model training data is no longer constant. The model consistency is no longer guaranteed, and the QE training data must be removed from the MT system training data to avoid data contamination.

Translation Assistance by Translation of L1 Fragments in an L2 Context

Radboud University Nijmegen
proycon@anaproy.nl

Abstract

In this paper we present new research in translation assistance. We describe a system capable of translating native language (L1) fragments to foreign language (L2) fragments in an L2 context. Practical applications of this research can be framed in the context of second language learning. The type of translation assistance system under investigation here encourages language learners to write in their target language while allowing them to fall back to their native language in case the correct word or expression is not known. These code switches are subsequently translated to L2 given the L2 context. We study the feasibility of exploiting cross-lingual context to obtain high-quality translation suggestions that improve over statistical language modelling and word-sense disambiguation baselines. A classification-based approach is presented that is indeed found to improve significantly over these baselines by making use of a contextual window spanning a small number of neighbouring words.

1 Introduction

Whereas machine translation generally concerns the translation of whole sentences or texts from one language to the other, this study focusses on the translation of native language (henceforth L1) words and phrases, i.e. smaller fragments, in a foreign language (L2) context. Despite the major efforts and improvements, automatic translation does not yet rival human-level quality. Vexing issues are morphology, word-order change and long-distance dependencies. Although there is a morpho-syntactic component in this research, our scope is more constrained; its focus is on the faithful preservation of meaning from L1 to L2, akin to the role of the translation model in Statistical Machine Translation (SMT).

The cross-lingual context in our research question may at first seem artificial, but its design explicitly aims at applications related to computer-aided language learning (Laghos and Panayiotis, 2005; Levy, 1997) and computer-aided translation (Barrachina et al., 2009). Currently, language learners need to refer to a bilingual dictionary when in doubt about a translation of a word or phrase. Yet, this problem arises in a context, not in isolation; the learner may have already translated successfully a part of the text into L2 leading up to the problematic word or phrase. Dictionaries are not the best source to look up context; they may contain example usages, but remain biased towards single words or short expressions.

The proposed application allows code switching and produces context-sensitive suggestions as writing progresses. In this research we test the feasibility of the foundation of this idea.The following examples serve to illustrate the idea and demonstrate what output the proposed translation assistance system would ideally produce. The parts in bold correspond to respectively the inserted fragment and the system translation.

- Input (L1=English,L2=Spanish): *"Hoy vamos a **the swimming pool**."*
  Desired output: *"Hoy vamos a **la piscina**."*
- Input (L1-English, L2=German): *"Das wetter ist wirklich **abominable**."*
  Desired output: *"Das wetter ist wirklich **ekelhaft**."*
- Input (L1=French,L2=English): *"I **rentre à la maison** because I am tired."*
  Desired output: *"I **return home** because I am tired."*
- Input (L1=Dutch, L2=English): *"Workers are facing a massive **aanval op** their employ-*

Baltimore, Maryland, USA, June 23-25 2014.

ment and social rights."
Desired output: *"Workers are facing a massive **attack on** their employment and social rights."*

The main research question in this research is how to disambiguate an L1 word or phrase to its L2 translation based on an L2 context, and whether such cross-lingual contextual approaches provide added value compared to baseline models that are not context informed or compared to standard language models.

2 Data preparation

Preparing the data to build training and test data for our intended translation assistance system is not trivial, as the type of interactive translation assistant we aim to develop does not exist yet. We need to generate training and test data that realistically emulates the task. We start with a parallel corpus that is tokenised for both L1 and L2. No further linguistic processing such as part-of-speech tagging or lemmatisation takes place in our experiments; adding this remains open for future research.

The parallel corpus is randomly sampled into two large and equally-sized parts. One is the basis for the training set, and the other is the basis for the test set. The reason for such a large test split shall become apparent soon.

From each of the splits (S), a phrase-translation table is constructed automatically in an unsupervised fashion. This is done using the scripts provided by the Statistical Machine Translation system Moses (Koehn et al., 2007). It invokes GIZA++ (Och and Ney, 2000) to establish statistical word alignments based on the IBM Models and subsequently extracts phrases using the `grow-diag-final` algorithm (Och and Ney, 2003). The result, independent for each set, will be a phrase-translation table (T) that maps phrases in L1 to L2. For each phrase-pair (f_s, f_t) this phrase-translation table holds the computed translation probabilities $P(f_s|f_t)$ and $P(f_t|f_s)$.

Given these phrase-translation tables, we can now extract both training data and test data using the algorithm in Figure 1. In our discourse, the source language (s) corresponds to L1, the fallback language used for by the end-user for inserting fragments, whilst the target language (t) is L2.

Step 4 is effectively a filter: two thresholds can be configured to discard weak alignments,

1. using phrase-translation table T and parallel corpus split S
2. **for** each aligned sentence pair $(sentence_s \in S_s, sentence_t \in S_t)$ in the parallel corpus split (S_s,S_t):
3. **for** each fragment $(f_s \in sentence_s, f_t \in sentence_t)$ where $(f_s, f_t) \in T$:
4. **if** $P(f_s|f_t) \cdot P(f_t|f_s) \geq \lambda_1$ **and** $P(f_s|f_t) \cdot P(f_t|f_s) \geq \lambda_2 \cdot P(f_s|f_{strongest\_t}) \cdot P(f_{strongest\_t}|f_s)$:
5. Output a pair $(sentence'_t, sentence_t)$ where $sentence'_t$ is a copy of t but with fragment f_t substituted by f_s, i.e. the introduction of an L1 word or phrase in an L2 sentence.

Figure 1: Algorithm for extracting training and test data on the basis of a phrase-translation table (T) and subset/split from a parallel corpus (S). The indentation indicates the nesting.

i.e. those with low probabilities, from the phrase-translation table so that only strong couplings make it into the generated set. The parameter λ_1 adds a constraint based on the product of the two conditional probabilities ($P(f_t|f_s) \cdot P(f_s|f_t)$), and sets a threshold that has to be surpassed. A second parameter λ_2 further limits the considered phrase pairs (f_s, f_t) to have the product of their conditional probabilities not not deviate more than a fraction λ_2 from the joint probability for the strongest possible pairing for f_s, the source fragment. $f_{strongest\_t}$ in Figure 1 corresponds to the best scoring translation for a given source fragment f_s. This metric thus effectively prunes weaker alternative translations in the phrase-translation table from being considered if there is a much stronger candidate. Nevertheless, it has to be noted that even with λ_1 and λ_2, the test set will include a certain amount of errors. This is due to the nature of the unsupervised method with which the phrase-translation table is constructed. For our purposes however, the test set suffices to test our hypothesis.

In our experiments, we choose fixed values for these parameters, by manual inspection and judgement of the output. The λ_1 parameter was set to 0.01 and λ_2 to 0.8. Whilst other thresholds may possibly produce cleaner sets, this is hard to evaluate as finding optimal values causes a prohibitive increase in complexity of the search space, and again this is not necessary to test our hypothesis.

The output of the algorithm in Figure 1 is a modified set of sentence pairs $(sentence'_t, sentence_t)$, in which the same sentence pair may be used multiple times with different L1 substitutions for different fragments. The final test set is created by randomly sampling the desired number of test instances.

Note that the training set and test set are constructed on their own respective and independently generated phrase-translation tables. This ensures complete independence of training and test data. Generating test data using the same phrase-translation table as the training data would introduce a bias. The fact that a phrase-translation table needs to be constructed for the test data is also the reason that the parallel corpus split from which the test data is derived has to be large enough, ensuring better quality.

We concede that our current way of testing is a mere approximation of the real-world scenario. An ideal test corpus would consist of L2 sentences with L1 fallback as crafted by L2 language learners with an L1 background. However, such corpora do not exist as yet. Nevertheless, we hope to show that our automated way of test set generation is sufficient to test the feasibility of our core hypothesis that L1 fragments can be translated to L2 using L2 context information.

3 System

We develop a classifier-based system composed of so-called "classifier experts". Numerous classifiers are trained and each is an expert in translating a single word or phrase. In other words, for each word type or phrase type that occurs as a fragment in the training set, and which does not map to just a single translation, a classifier is trained. The classifier maps the L1 word or phrase in its L2 context to its L2 translation. Words or phrases that always map to a single translation are stored in a simple mapping table, as a classifier would have no added value in such cases. The classifiers use the IB1 algorithm (Aha et al., 1991) as implemented in TiMBL (Daelemans et al., 2009).[1] IB1 implements k-nearest neighbour classification. The choice for this algorithm is motivated by the fact that it handles multiple classes with ease, but first and foremost because it has been successfully employed for word sense disambiguation in other studies (Hoste et al., 2002; Decadt et al., 2004), in particular in cross-lingual word sense disambiguation, a task closely resembling our current task (van Gompel and van den Bosch, 2013). It has also been used in machine translation studies in which local source context is used to classify source phrases into target phrases, rather than looking them up in a phrase table (Stroppa et al., 2007; Haque et al., 2011). The idea of local phrase selection with a discriminative machine learning classifier using additional local (source-language) context was introduced in parallel to Stroppa *et al.* (2007) by Carpuat and Wu (2007) and Giménez and Márquez (2007); cf. Haque *et al.* (2011) for an overview of more recent methods.

The feature vector for the classifiers represents a local context of neighbouring words, and optionally also global context keywords in a binary-valued bag-of-words configuration. The local context consists of an X number of L2 words to the left of the L1 fragment, and Y words to the right.

When presented with test data, in which the L1 fragment is explicitly marked, we first check whether there is ambiguity for this L1 fragment and if a direct translation is available in our simple mapping table. If so, we are done quickly and need not rely on context information. If not, we check for the presence of a classifier expert for the offered L1 fragment; only then we can proceed by extracting the desired number of L2 local context words to the immediate left and right of this fragment and adding those to the feature vector. The classifier will return a probability distribution of the most likely translations given the context and we can replace the L1 fragment with the highest scoring L2 translation and present it back to the user.

In addition to local context features, we also experimented with global context features. These are a set of L2 contextual keywords for each L1 word/phrase and its L2 translation occurring in the same sentence, not necessarily in the immediate neighbourhood of the L1 word/phrase. The keywords are selected to be indicative for a specific

[1] `http://ilk.uvt.nl/timbl`

translation. We used the method of extraction by Ng and Lee (1996) and encoded all keywords in a binary bag of words model. The experiments however showed that inclusion of such keywords did not make any noticeable impact on any of the results, so we restrict ourselves to mentioning this negative result.

Our full system, including the scripts for data preparation, training, and evaluation, is implemented in Python and freely available as open-source from `http://github.com/proycon/colibrita/` . Version tag `v0.2.1` is representative for the version used in this research.

3.1 Language Model

We also implement a statistical language model as an optional component of our classifier-based system and also as a baseline to compare our system to. The language model is a trigram-based backoff language model with Kneser-Ney smoothing, computed using SRILM (Stolcke, 2002) and trained on the same training data as the translation model. No additional external data was brought in, to keep the comparison fair.

For any given hypothesis H, results from the L1 to L2 classifier are combined with results from the L2 language model. We do so by normalising the class probability from the classifier ($score_T(H)$), which is our translation model, and the language model ($score_{lm}(H)$), in such a way that the highest classifier score for the alternatives under consideration is always 1.0, and the highest language model score of the sentence is always 1.0. Take $score_T(H)$ and $score_{lm}(H)$ to be log probabilities, the search for the best (most probable) translation hypothesis $\hat{H}$ can then be expressed as:

$$\hat{H} = \arg\max_H (score_T(H) + score_{lm}(H)) \quad (1)$$

If desired, the search can be parametrised with variables λ_3 and λ_4, representing the weights we want to attach to the classifier-based translation model and the language model, respectively. In the current study we simply left both weights set to one, thereby assigning equal importance to translation model and language model.

4 Evaluation

Several automated metrics exist for the evaluation of L2 system output against the L2 reference output in the test set. We first measure absolute accuracy by simply counting all output fragments that exactly match the reference fragments, as a fraction of the total amount of fragments. This measure may be too strict, so we add a more flexible *word accuracy* measure which takes into account partial matches at the word level. If output o is a subset of reference r then a score of $\frac{|o|}{|r|}$ is assigned for that sentence pair. If instead, r is a subset of o, then a score of $\frac{|r|}{|o|}$ will be assigned. A perfect match will result in a score of 1 whereas a complete lack of overlap will be scored 0. The word accuracy for the entire set is then computed by taking the sum of the word accuracies per sentence pair, divided by the total number of sentence pairs.

We also compute a recall metric that measures the number of fragments that the system provided a translation for as a fraction of the total number of fragments in the input, regardless of whether the fragment is translated correctly or not. The system may skip fragments for which it can find no solution at all.

In addition to these, the system's output can be compared against the L2 reference translation(s) using established Machine Translation evaluation metrics. We report on BLEU, NIST, METEOR, and word error rate metrics WER and PER. These scores should generally be much better than the typical MT system performances as only local changes are made to otherwise "perfect" L2 sentences.

5 Baselines

A context-insensitive yet informed baseline was constructed to assess the impact of L2 context information in translating L1 fragments. The baseline selects the most probable L1 fragment per L2 fragment according to the phrase-translation table. This baseline, henceforth referred to as the 'most likely fragment' baseline (MLF) is analogous to the 'most frequent sense'-baseline common in evaluating WSD systems.

A second baseline was constructed by weighing the probabilities from the translation table directly with the L2 language model described earlier. It adds a LM component to the MLF baseline. This LM baseline allows the comparison of classification through L1 fragments in an L2 context, with a more traditional L2 context modelling (i.e. target language modelling) which is also cus-

tomary in MT decoders. Computing this baseline is done in the same fashion as previously illustrated in Equation 1, where $score_T$ then represents the normalised $p(t|s)$ score from the phrase-translation table rather than the class probability from the classifier.

6 Experiments & Results

The data for our experiments were drawn from the Europarl parallel corpus (Koehn, 2005) from which we extracted two sets of $200,000$ sentence pairs each for several language pairs. These were used to form the training and test sets. The final test sets are a randomly sampled $5,000$ sentence pairs from the $200,000$-sentence test split for each language pair.

All input data for the experiments in this section are publicly available[2].

Let us first zoom in to convey a sense of scale on a specific language pair. The actual Europarl training set we generate for English (L1) to Spanish (L2), i.e. English fallback in a Spanish context, consists of $5,608,015$ sentence pairs. This number is much larger than the $200,000$ we mentioned before because single sentence pairs may be reused multiple times with different marked fragments. From this training set of sentence pairs over $100,000$ classifier experts are derived. The eleven largest classifiers are shown in Table 1, along with the number of training instances per classifier. The full table would reveal a Zipfian distribution.

Fragment	Training instances	Translations
the	256,772	la, el, los, las
of	139,273	de, del
and	128,074	y, de, e
to	66,565	a, para, que, de
a	54,306	un, una
is	40,511	es, está, se
for	34,054	para, de, por
this	29,691	este, esta, esto
European	26,543	Europea, Europeo Europeas, Europeos
on	23,147	sobre, en
of the	22,361	de la, de los

Table 1: The top eleven classifier experts for English to Spanish. The eleventh entry is included as an example of a common phrasal fragment

Among the classifier experts are only words and phrases that are ambiguous and may thus map to multiple translations. This implies that such words and phrases must have occurred at least twice in the corpus, though this threshold is made configurable and could have been set higher to limit the number of classifiers. The remaining $246,380$ unambiguous mappings are stored in a separate mapping table.

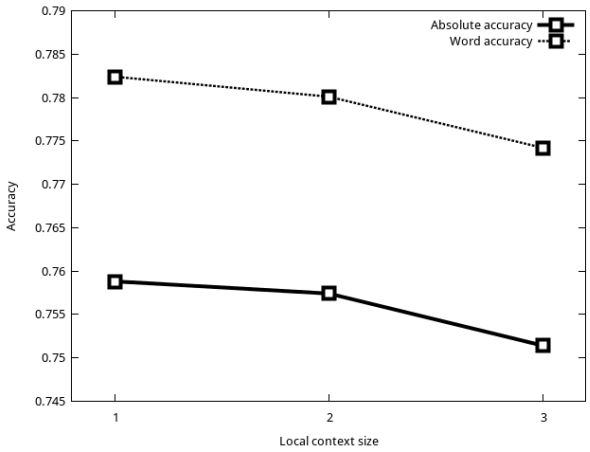

Figure 2: Accuracy for different local context sizes, Europarl English to Spanish

For the classifier-based system, we tested various different feature vector configurations. The first experiment, of which the results are shown in Figure 2, sets a fixed and symmetric local context size across all classifiers, and tests three context widths. Here we observe that a context width of one yields the best results. The BLEU scores, not included in the figure but shown in Table 2, show a similar trend. This trend holds for all the MT metrics.

Table 2 shows the results for English to Spanish in more detail and adds a comparison with the two baseline systems. The various `lXrY` configurations use the same feature vector setup for all classifier experts. Here X indicates the left context size and Y the right context size. The `auto` configuration does not uniformly apply the same feature vector setup to all classifier experts but instead seeks to find the optimal setup per classifier expert. This shall be further discussed in Section 6.1.

As expected, the LM baseline substantially outperforms the context-insensitive MLF baseline. Second, our classifier approach attains a substantially higher accuracy than the LM baseline. Third, we observe that adding the language model to our classifier leads to another significant gain

Configuration	Accuracy	Word Accuracy	BLEU	METEOR	NIST	WER	PER

Table 2: Europarl results for English to Spanish (i.e English fallback in Spanish context). Recall = 0.9422

(configuration `l1r1+LM` in the results in Table 2). It appears that the classifier approach and the L2 language model are able to complement each other.

Statistical significance on the BLEU scores was tested using pairwise bootstrap sampling (Koehn, 2004). All significance tests were performed with $5,000$ iterations. We compared the outcomes of several key configurations. We first tested `l1r1` against both baselines; both differences are significant at $p < 0.01$ for both. The same significance level was found when comparing `l1r1+LM` against `l1r1`, `auto+LM` against `auto`, as well as the LM baseline against the MLF baseline. Automatic feature selection `auto` was found to perform statistically better than `l1r1`, but only at $p < 0.05$. Conclusions with regard to context width may have to be tempered somewhat, as the performance of the `l1r1` configuration was found to not be significantly better than that of the `l2r2` configuration. However, `l1r1` performs significantly better than `l3r3` at $p < 0.01$, and `l2r2` performs significantly better than `l3r3` at $p < 0.01$.

In Table 3 we present some illustrative examples from the English→Spanish Europarl data. We show the difference between the most-likely-fragment baseline and our system.

Likewise, Table 4 exemplifies small fragments from the `l1r1` configuration compared to the same configuration enriched with a language model. We observe in this data that the language model often has the added power to choose a correct translation that is not the first prediction of the classifier, but one of the weaker alternatives that nevertheless fits better. Though the classifier generally works best in the `l1r1` configuration, i.e. with context size one, the trigram-based language model allows further left-context information to be incorporated that influences the weights of the classifier output, successfully forcing the system to select alternatives. This combination of a classifier with context size one and trigram-based language model proves to be most effective and reaches the best results so far. We have not conducted experiments with language models of other orders.

6.1 Context optimisation

It has been argued that classifier experts in a word sense disambiguation ensemble should be individually optimised (Decadt et al., 2004; van Gompel and van den Bosch, 2013). The latter study on cross-lingual WSD finds a positive impact when conducting feature selection per classifier. This intuitively makes sense; a context of one may seem to be better than any other when uniformly applied to all classifier experts, but it may well be that certain classifiers benefit from different feature selections. We therefore proceed with this line of investigation as well.

Automatic configuration selection was done by performing leave-one-out testing (for small number of instances) or 10-fold-cross validation (for larger number of instances, $n \geq 20$) on the training data per classifier expert. Various configurations were tested. Per classifier expert, the best scoring configuration was selected, referred to as the `auto` configuration in Table 2. The `auto` configuration improves results over the uniformly

Table 3: Some illustrative examples of MLF-baseline output versus system output, in which system output matches the correct human reference output. The actual fragments concerned are highlighted in bold. The first example shows our system correcting for number agreement, the second a correction in selecting the right preposition, and the third shows that the English word *last* can be translated in different ways, only one of which is correct in this context. The last example shows a phrasal translation, in which the determiner was duplicated in the baseline

applied feature selection. However, if we enable the language model as we do in the `auto+LM` configuration we do not notice an improvement over `l1r1+LM`, surprisingly. We suspect the lack of impact here can be explained by the trigram-based Language Model having less added value when the (left) context size of the classifier is two or three; they are now less complementary.

Table 5 lists what context sizes have been chosen in the automatic feature selection. A context size of one prevails in the vast majority of cases, which is not surprising considering the good results we have already seen with this configuration.

In this study we did not yet conduct optimisation of the classifier parameters. We used the IB1 algorithm with $k = 1$ and the default values of the TiMBL implementation. In earlier work van Gompel and van den Bosch (2013), we reported a decrease in performance due to overfitting when this is done, so we do not expect it to make a positive impact. The second reason for omitting this is more practical in nature; to do this in combination with feature selection would add substantial search complexity, making experiments far more time consuming, even prohibitively so.

Table 4: Some examples of l1r1 versus the same configuration enriched with a language model.

sults. We experimented with several asymmetric configurations and found that taking two words to the left and one to the right yields even better results than symmetric configurations for this data set. This result is in line with the positive effect of adding the LM to the `l1r1`.

In order to draw accurate conclusions, experiments on a single data set and language pair are not sufficient. We therefore conducted a number of experiments with other language pairs, and present the abridged results in Table 6.

There are some noticeable discrepancies for some experiments in Table 6 when compared to our earlier results in Table 2. We see that the language model baseline for English→French shows the same substantial improvement over the baseline as our English→Spanish results. The same holds for the Chinese→English experiment. However, for English→Dutch and English→Chinese we find that the LM baseline actually performs slightly worse than baseline. Nevertheless, in all these cases, the positive effect of including a Language Model to our classifier-based system again shows. Also, we note that in all cases our system performs better than the two baselines.

Another discrepancy is found in the BLEU scores of the English→Chinese experiments, where we measure an unexpected drop in BLEU score under baseline. However, all other scores do show the expected improvement. The error rate metrics show improvement as well. We therefore attach low importance to this deviation in BLEU here.

In all of the aforementioned experiments, the system produced a single solution for each of the fragments, the one it deemed best, or no solution at all if it could not find any. Alternative evaluation metrics could allow the system to output multiple alternatives. Omission of a solution by definition causes a decrease in recall. In all of our experiments recall is high (well above 90%), mostly because train and test data lie in the same domain and have been generated in the same fashion, lower recall is expected with more real-world data.

7 Discussion and conclusion

In this study we have shown the feasibility of a classifier-based translation assistance system in which L1 fragments are translated in an L2 context, in which the classifier experts are built individually per word or phrase. We have shown that such a translation assistance system scores both above a context-insensitive baseline, as well as an L2 language model baseline.

Furthermore, we found that combining this cross-language context-sensitive technique with an L2 language model boosts results further.

The presence of a one-word right-hand side context proves crucial for good results, which has implications for practical translation assistance application that translate as soon as the user finishes an L1 fragment. Revisiting the translation when right context becomes available would be advisable.

We tested various configurations and conclude that small context sizes work better than larger ones. Automated configuration selection had positive results, yet the system with context size one and an L2 language model component often produces the best results. In static configurations, the failure of a wider context window to be more suc-

Here we used of just over $70,000$ sentences for training. Recall for each of the four datasets is 0.9498 (en-nl), 0.9494 (en-fr), 0.9386 (en-zh), and 0.9366 (zh-en)

cesful may be attributed to the increased sparsity that comes from such an expansion.

The idea of a comprehensive translation assistance system may extend beyond the translation of L1 fragments in an L2 context. There are more NLP components that might play a role if such a system were to find practical application. Word completion or predictive editing (in combination with error correction) would for instance seem an indispensable part of such a system, and can be implemented alongside the technique proposed in this study. A point of more practically-oriented future research is to see how feasible such combinations are and what techniques can be used.

An application of our idea outside the area of translation assistance is post-correction of the output of some MT systems that, as a last-resort heuristic, copy source words or phrases into their output, producing precisely the kind of input our system is trained on. Our classification-based approach may be able to resolve some of these cases operating as an add-on to a regular MT system – or as a independent post-correction system.

Our system allows L1 fragments to be of arbitrary length. If a fragment was not seen during training stage, and is therefore not covered by a classifier expert, then the system will be unable to translate it. Nevertheless, if a longer L1 fragment can be decomposed into subfragments that are known, then some recombination of the translations of said sub-fragments may be a good translation for the whole. We are currently exploring this line of investigation, in which the gap with MT narrows further.

Finally, an important line of future research is the creation of a more representative test set. Lacking an interactive system that actually does what we emulate, we hypothesise that good approximations would be to use gap exercises, or cloze tests, that test specific aspects difficulties in language learning. Similarly, we may use L2 learner corpora with annotations of code-switching points or errors. Here we then assume that places where L2 errors occur may be indicative of places where L2 learners are in some trouble, and might want to fall back to generating L1. By then manually translating gaps or such problematic fragments into L1 we hope to establish a more realistic test set.

Abstract

We propose a novel learning approach for statistical machine translation (SMT) that allows to extract supervision signals for structured learning from an extrinsic response to a translation input. We show how to generate responses by grounding SMT in the task of executing a semantic parse of a translated query against a database. Experiments on the GEOQUERY database show an improvement of about 6 points in F1-score for response-based learning over learning from references only on returning the correct answer from a semantic parse of a translated query. In general, our approach alleviates the dependency on human reference translations and solves the reachability problem in structured learning for SMT.

1 Introduction

In this paper, we propose a novel approach for learning and evaluation in statistical machine translation (SMT) that borrows ideas from response-based learning for grounded semantic parsing. In this framework, the meaning of a sentence is defined in the context of an extrinsic task. Successful communication of meaning is measured by a successful interaction in this task, and feedback from this interaction is used for learning.

We suggest that in a similar way the preservation of meaning in machine translation should be defined in the context of an interaction in an extrinsic task. For example, in the context of a game, a description of a game rule is translated successfully if correct game moves can be performed based only on the translation. In the context of a question-answering scenario, a question is translated successfully if the correct answer is returned based only on the translation of the query.

We propose a framework of response-based learning that allows to extract supervision signals for structured learning from the response of an extrinsic task to a translation input. Here, learning proceeds by "trying out" translation hypotheses, receiving a response from interacting in the task, and converting this response into a supervision signal for updating model parameters. In case of positive feedback, the predicted translation can be treated as reference translation for a structured learning update. In case of negative feedback, a structural update can be performed against translations that have been approved previously by positive task feedback. This framework has several advantages:

- The supervision signal in response-based learning has a different quality than supervision by human-generated reference translations. While a human reference translation is generated independently of the SMT task, conversion of predicted translations into references is always done with respect to a specific task. In this sense we speak of grounding meaning transfer in an extrinsic task.

- Response-based learning can repeatedly try out system predictions by interacting in the extrinsic task. Instead of and in addition to learning from human reference translations, response-based learning allows to convert multiple system translations into references. This alleviates the supervision problem in cases where parallel data are scarce.

- Task-specific response acts upon system translations. This avoids the problem of unreachability of independently generated reference translations by the SMT system.

The proposed approach of response-based learning opens the doors for various extrinsic tasks

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 881–891,
Baltimore, Maryland, USA, June 23-25 2014.

in which SMT systems can be trained and evaluated. In this paper, we present a proof-of-concept experiment that uses feedback from a simulated world environment. Building on prior work in grounded semantic parsing, we generate translations of queries, and receive feedback by executing semantic parses of translated queries against the database. Successful response is defined as receiving the same answer from the semantic parses for the translation and the original query. Our experimental results show an improvement of about 6 points in F1-score for response-based learning over standard structured learning from reference translations. We show in an error analysis that this improvement can be attributed to using structural and lexical variants of reference translations as positive examples in response-based learning. Furthermore, translations produced by response-based learning are found to be grammatical. This is due to the possibility to boost similarity to human reference translations by the additional use of a cost function in our approach.

2 Related Work

The key idea of *grounded language learning* is to study natural language in the context of a non-linguistic environment, in which meaning is grounded in perception and/or action. This presents an analogy to human learning, where a learner tests her understanding in an actionable setting. Such a setting can be a simulated world environment in which the linguistic representation can be directly executed by a computer system. For example, in semantic parsing, the learning goal is to produce and successfully execute a meaning representation. Executable system actions include access to databases such as the GEOQUERY database on U.S. geography (Wong and Mooney (2006), *inter alia*), the ATIS travel planning database (Zettlemoyer and Collins (2009), *inter alia*), robotic control in simulated navigation tasks (Chen and Mooney (2011), *inter alia*), databases of simulated card games (Goldwasser and Roth (2013), *inter alia*), or the user-generated contents of FREEBASE (Cai and Yates (2013), *inter alia*). Since there are many possible correct parses, matching against a single gold standard falls short of grounding in a non-linguistic environment. Rather, the semantic context for interpretation, as well as the success criterion in evaluation is defined by successful execution of an action in the extrinsic environment, e.g., by receiving the correct answer from the database or by successful navigation to the destination. Recent attempts to learn semantic parsing from question-answer pairs without recurring to annotated logical forms have been presented by Kwiatowski et al. (2013), Berant et al. (2013), or Goldwasser and Roth (2013). The algorithms presented in these works are variants of structured prediction that take executability of semantic parses into account. Our work builds upon these ideas, however, to our knowledge the presented work is the first to embed translations into grounded scenarios in order to use feedback from interactions in these scenarios for structured learning in SMT.

A recent important research direction in SMT has focused on employing automated translation as an aid to human translators. *Computer assisted translation* (CAT) subsumes several modes of interaction, ranging from binary feedback on the quality of the system prediction (Saluja et al., 2012), to human post-editing operations on a system prediction resulting in a reference translation (Cesa-Bianchi et al., 2008), to human acceptance or overriding of sentence completion predictions (Langlais et al., 2000; Barrachina et al., 2008; Koehn and Haddow, 2009). In all interaction scenarios, it is important that the system learns dynamically from its errors in order to offer the user the experience of a system that adapts to the provided feedback. Since retraining the SMT model after each interaction is too costly, *online adaptation* after each interaction has become the learning protocol of choice for CAT. Online learning has been applied in generative SMT, e.g., using incremental versions of the EM algorithm (Ortiz-Martínez et al., 2010; Hardt and Elming, 2010), or in discriminative SMT, e.g., using perceptron-type algorithms (Cesa-Bianchi et al., 2008; Martínez-Gómez et al., 2012; Wäschle et al., 2013; Denkowski et al., 2014). In a similar way to deploying human feedback, extrinsic loss functions have been used to provide learning signals for SMT. For example, Nikoulina et al. (2012) propose a setup where an SMT system feeds into cross-language information retrieval, and receives feedback from the performance of translated queries with respect to cross-language retrieval performance. This feedback is used to train a reranker on an n-best list of translations order with respect to retrieval performance. In con-

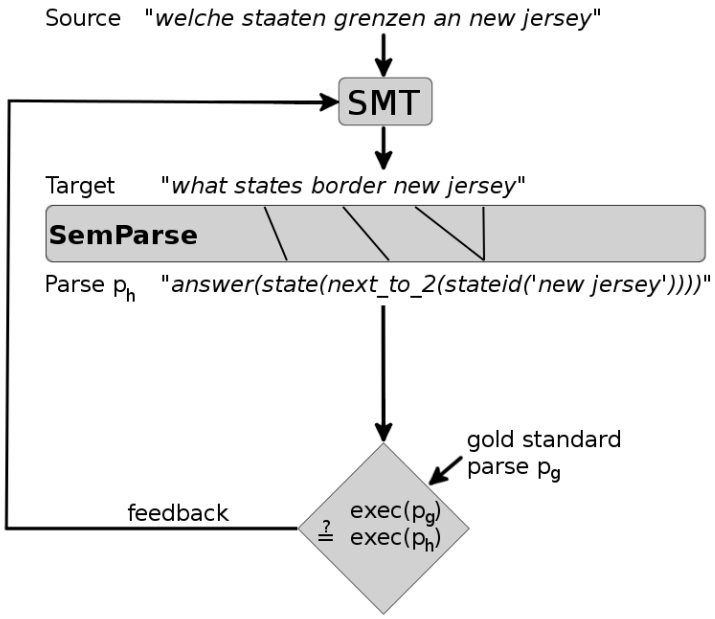

Figure 1: Response-based learning cycle for grounding SMT in virtual trivia gameplay.

trast to our work, all mentioned approaches to interactive or adaptive learning in SMT rely on human post-edits or human reference translations. Our work differs from these approaches in that exactly this dependency is alleviated by learning from responses in an extrinsic task.

Interactive scenarios have been used for evaluation purposes of translation systems for nearly 50 years, especially using *human reading comprehension* testing (Pfafflin, 1965; Fuji, 1999; Jones et al., 2005), and more recently, using face-to-face conversation mediated via machine translation (Sakamoto et al., 2013). However, despite offering direct and reliable prediction of translation quality, the cost and lack of reusability has confined task-based evaluations involving humans to *testing* scenarios, but prevented a use for interactive *training* of SMT systems as in our work.

Lastly, our work is related to *cross-lingual natural language processing* such as cross-lingual question answering or cross-lingual information retrieval as conducted at recent evaluation campaigns of the CLEF initiative.[1] While these approaches focus on improvements of the respective natural language processing task, our goal is to improve SMT by gathering feedback from the task.

3 Grounding SMT in Semantic Parsing

In this paper, we present a proof-of-concept of our ideas of embedding SMT into simulated world environments as used in semantic parsing. We use the well-known GEOQUERY database on U.S. geography for this purpose. Embedding SMT in a semantic parsing scenario means to define translation quality by the ability of a semantic parser to construct a meaning representation from the translated query, which returns the correct answer when executed against the database. If viewed as simulated gameplay, a valid game move in this scenario returns the correct answer to a translated query.

The diagram in Figure 1 gives a sketch of response-based learning from semantic parsing in the geographical domain. Given a manual German translation of the English query as source sentence, the SMT system produces an English target translation. This sentence is fed into a semantic parser that produces an executable parse representation p_h. Feedback is generated by executing the parse against the database of geographical facts. Positive feedback means that the correct answer is received, i.e., $\text{exec}(p_g) \stackrel{?}{=} \text{exec}(p_h)$ indicates that the same answer is received from the gold standard parse p_g and the parse for the hypothesis translation p_h; negative feedback results in case a different or no answer is received.

The key advantage of response-based learning

is the possibility to receive positive feedback even from predictions that differ from gold standard reference translations, but yet receive the correct answer when parsed and matched against the database. Such structural and lexical variation broadens the learning capabilities in contrast to learning from fixed labeled data. For example, assume the following English query in the geographical domain, and assume positive feedback from executing the corresponding semantic parse against the geographical database:

```
Name prominent elevations in the
USA
```

The manual translation of the English original reads

```
Nenne prominente Erhebungen in
den USA
```

An automatic translation[2] of the German string produces the result

```
Give prominent surveys in the US
```

This translation will trigger negative task-based feedback: A comparison with the original allows the error to be traced back to the ambiguity of the German word `Erhebung`. Choosing a general domain translation instead of a translation appropriate for the geographical domain hinders the construction of a semantic parse that returns the correct answer from the database. An alternative translation might look as follows:

```
Give prominent heights in the US
```

Despite a large difference to the original English string, key terms such as `elevations` and `heights`, or `USA` and `US`, can be mapped into the same predicate in the semantic parse, thus allowing to receive positive feedback from parse execution against the geographical database.

4 Response-based Online Learning

Recent approaches to machine learning for SMT formalize the task of discriminating good from bad translations as a structured prediction problem. Assume a joint feature representation $\phi(x, y)$ of input sentences x and output translations $y \in Y(x)$, and a linear scoring function $s(x, y; w)$ for predicting a translation $\hat{y}$ (where $\langle \cdot, \cdot \rangle$ denotes the standard vector dot product) s.t.

$$\hat{y} = \underset{y \in Y(x)}{\arg\max}\ \mathrm{s}(x, y; w) = \underset{y \in Y(x)}{\arg\max} \langle w, \phi(x, y) \rangle .$$

[2] `http://translate.google.com`

The structured perceptron algorithm (Collins, 2002) learns an optimal weight vector w by updating w on input $x^{(i)}$ by the following rule, in case the predicted translation $\hat{y}$ is different from and scored higher than the reference translation $y^{(i)}$:

$$w = w + \phi(x^{(i)}, y^{(i)}) - \phi(x^{(i)}, \hat{y}).$$

This stochastic structural update aims to demote weights of features corresponding to incorrect decisions, and to promote weights of features for correct decisions.

An application of structured prediction to SMT involves more than a straightforward replacement of labeled output structures by reference translations. Firstly, update rules that require to compute a feature representation for the reference translation are suboptimal in SMT, because often human-generated reference translations cannot be generated by the SMT system. Such "unreachable" gold-standard translations need to be replaced by "surrogate" gold-standard translations that are close to the human-generated translations and still lie within the reach of the SMT system. Computation of distance to the reference translation usually involves cost functions based on sentence-level BLEU (Nakov et al. (2012), *inter alia*) and incorporates the current model score, leading to various ramp loss objectives described in Gimpel and Smith (2012).

An alternative approach to alleviate the dependency on labeled training data is response-based learning. Clarke et al. (2010) or Goldwasser and Roth (2013) describe a response-driven learning framework for the area of semantic parsing: Here a meaning representation is "tried out" by iteratively generating system outputs, receiving feedback from world interaction, and updating the model parameters. Applied to SMT, this means that we predict translations and use positive response from acting in the world to create "surrogate" gold-standard translations. This decreases the dependency on a few (mostly only one) reference translations and guides the learner to promote translations that perform well with respect to the extrinsic task.

In the following, we will present a framework that combines standard structured learning from given reference translations with response-based learning from task-approved references. We need to ensure that gold-standard translations lead to positive task-based feedback, that means they can

be parsed and executed successfully against the database. In addition, we can use translation-specific cost functions based on sentence-level BLEU in order to boost similarity of translations to human reference translations.

We denote feedback by a binary execution function $\mathrm{e}(y) \in \{1, 0\}$ that tests whether executing the semantic parse for the prediction against the database receives the same answer as the parse for the gold standard reference. Our cost function $\mathrm{c}(y^{(i)}, y) = (1 - \mathrm{BLEU}(y^{(i)}, y))$ is based on a version of sentence-level BLEU Nakov et al. (2012). Define y^+ as a surrogate gold-standard translation that receives positive feedback, has a high model score, and a low cost of predicting y instead of $y^{(i)}$:

$$y^+ = \underset{y \in Y(x^{(i)}):\mathrm{e}(y)=1}{\arg\max} \Big(\mathrm{s}(x^{(i)}, y; w) - \mathrm{c}(y^{(i)}, y) \Big) .$$

The opposite of y^+ is the translation y^- that leads to negative feedback, has a high model score, and a high cost. It is defined as follows:

$$y^- = \underset{y \in Y(x^{(i)}):\mathrm{e}(y)=0}{\arg\max} \Big(\mathrm{s}(x^{(i)}, y; w) + \mathrm{c}(y^{(i)}, y) \Big) .$$

Update rules can be derived by minimization of the following ramp loss objective:

$$\min_w \Bigg(- \max_{y \in Y(x^{(i)}):\mathrm{e}(y)=1} \Big(\mathrm{s}(x^{(i)}, y; w) - \mathrm{c}(y^{(i)}, y) \Big) + \max_{y \in Y(x^{(i)}):\mathrm{e}(y)=0} \Big(\mathrm{s}(x^{(i)}, y; w) + \mathrm{c}(y^{(i)}, y) \Big) \Bigg) .$$

Minimization of this objective using stochastic (sub)gradient descent (McAllester and Keshet, 2011) yields the following update rule:

$$w = w + \phi(x^{(i)}, y^+) - \phi(x^{(i)}, y^-).$$

The intuition behind this update rule is to discriminate the translation y^+ that leads to positive feedback and best approximates (or is identical to) the reference within the means of the model from a translation y^- which is favored by the model but does not execute and has high cost. This is done by putting all the weight on the former.

Algorithm 1 presents pseudo-code for our response-driven learning scenario. Upon predicting translation $\hat{y}$, in case of positive feedback from the task, we treat the prediction as surrogate reference by setting $y^+ \leftarrow \hat{y}$, and by adding it to the set of reference translations for future use. Then we need to compute y^-, and update by the difference in feature representations of y^+ and y^-, at a learning rate η. If the feedback is negative, we want to move the weights away from the prediction, thus we treat it as y^-. To perform an update, we need to compute y^+. If either y^+ or y^- cannot be computed, the example is skipped.

Algorithm 1 Response-based Online Learning

```
repeat
    for i = 1, ..., n do
        Receive input string x^(i)
        Predict translation ŷ
        Receive task feedback e(ŷ) ∈ {1, 0}
        if e(ŷ) = 1 then
            y^+ ← ŷ
            Store ŷ as reference y^(i) for x^(i)
            Compute y^-
        else
            y^- ← ŷ
            Receive reference y^(i)
            Compute y^+
        end if
        w ← w + η(φ(x^(i), y^+) − φ(x^(i), y^-))
    end for
until Convergence
```

The sketched algorithm allows several variations. In the form depicted above, it allows to use human reference translations in addition to task-approved surrogate references. The cost function can be implemented by different versions of sentence-wise BLEU, or it can be omitted completely so that learning relies on task-based feedback alone, similar to algorithms recently suggested for semantic parsing (Goldwasser and Roth, 2013; Kwiatowski et al., 2013; Berant et al., 2013). Lastly, regularization can be introduced by using update rules corresponding to primal form optimization variants of support vector machines (Collobert and Bengio, 2004; Chapelle, 2007; Shalev-Shwartz et al., 2007).

5 Experiments

5.1 Experimental Setup

In our experiments, we use the GEOQUERY database on U.S. geography as provided by Jones

method	precision	recall	F1	BLEU
1 CDEC	63.67	58.21	60.82	46.53
2 EXEC	70.36	63.57	66.79[1]	48.00[1]
3 RAMPION	75.58	69.64	72.49[12]	**56.64**[12]
4 REBOL	**81.15**	**75.36**	**78.15**[123]	55.66[12]

Table 1: Experimental results using extended parser for returning answers from GEOQUERY (precision, recall, F1) and n-gram match to original English query (BLEU) on 280 re-translated test examples. Best results for each column are highlighted in **bold face**. Superscripts [1234] denote a significant improvement over the respective method.

method	precision	recall	F1	BLEU
1 CDEC	65.59	57.86	61.48	46.53
2 EXEC	66.54	61.79	64.07	46.00
3 RAMPION	67.68	63.57	65.56	**55.67**[12]
4 REBOL	**70.68**	**67.14**	**68.86**[12]	**55.67**[12]

Table 2: Experimental results using the original parser for returning answers from GEOQUERY (precision, recall, F1) and n-gram match to original English query (BLEU) on 280 re-translated test examples.

et al. (2012).[3] The dataset includes 880 English questions and their logical forms. The English strings were manually translated into German by the authors of Jones et al. (2012)), and corrected for typos by the authors of this paper. We follow the provided split into 600 training examples and 280 test examples.

For response-based learning, we retrained the semantic parser of Andreas et al. (2013)[4] on the full 880 GEOQUERY examples in order to reach full parse coverage. This parser is itself based on SMT, trained on parallel data consisting of English queries and linearized logical forms, and on a language model trained on linearized logical forms. We used the hierarchical phrase-based variant of the parser. Note that we do not use GEOQUERY test data in SMT training. Parser training includes GEOQUERY test data in order to be less dependent on parse and execution failures in the evaluation: If a translation system, response-based or reference-based, translates the German input into the gold standard English query it should be rewarded by positive task feedback. To double-check whether including the 280 test examples in parser training gives an unfair advantage to response-based learning, we also present experimental results using the original parser of Andreas et al. (2013) that is trained only on the 600 GEOQUERY training examples.

The bilingual SMT system used in our experiments is the state-of-the-art SCFG decoder CDEC (Dyer et al., 2010)[5]. We built grammars using its implementation of the suffix array extraction method described in Lopez (2007). For language modeling, we built a modified Kneser-Ney smoothed 5-gram language model using the English side of the training data. We trained the SMT system on the English-German parallel web data provided in the COMMON CRAWL[6] (Smith et al., 2013) dataset.

5.2 Compared Systems

Method 1 is the baseline system, consisting of the CDEC SMT system trained on the COMMON CRAWL data as described above. This system does not use any GEOQUERY data for training. Methods 2-4 use the 600 training examples from GEOQUERY for discriminative training only.

Variants of the response-based learning algorithm described above are implemented as a standalone tool that operates on CDEC n-best lists of 10,000 translations of the GEOQUERY training data. All variants use sparse features of CDEC as described in Simianer et al. (2012) that extract rule

Table 3: Predicted translations by response-based learning (REBOL) leading to positive feedback versus gold standard references.

shapes, rule identifiers, and bigrams in rule source and target directly from grammar rules. Method 4, named REBOL, implements REsponse-Based Online Learning by instantiating y^+ and y^- to the form described in Section 4: In addition to the model score s, it uses a cost function c based on sentence-level BLEU (Nakov et al., 2012) and tests translation hypotheses for task-based feedback using a binary execution function e. This algorithm can convert predicted translations into references by task-feedback, and additionally use the given original English queries as references. Method 2, named EXEC, relies on task-execution by function e and searches for executable or non-executable translations with highest score s to distinguish positive from negative training examples. It does not use a cost function and thus cannot make use of the original English queries.

We compare response-based learning with a standard structured prediction setup that omits the use of the execution function e in the definition of y^+ and y^-. This algorithm can be seen as a stochastic (sub)gradient descent variant of RAMPION (Gimpel and Smith, 2012). It does not make use of the semantic parser, but defines positive and negative examples based on score s and cost c with respect to human reference translations.

We report BLEU (Papineni et al., 2001) of translation system output measured against the original English queries. Furthermore, we report precision, recall, and F1-score for executing semantic parses built from translation system outputs against the GEOQUERY database. Precision is defined as the percentage of correctly answered examples out of those for which a parse could be produced; recall is defined as the percentage of total examples answered correctly; F1-score is the harmonic mean of both. Statistical significance is measured using Approximate Randomization (Noreen, 1989) where result differences with a p-value smaller than 0.05 are considered statistically significant.

Methods 2-4 perform structured learning for SMT on the 600 GEOQUERY training examples and re-translate the 280 unseen GEOQUERY test data, following the data split of Jones et al. (2012). Training for RAMPION, REBOL and EXEC was repeated for 10 epochs. The learning rate η is set to a constant that is adjusted by cross-validation on the 600 training examples.

5.3 Empirical Results

We present an experimental comparison of the four different systems according to BLEU and

reference	RAMPION	REBOL
how many colorado rivers are there	how many rivers with the name colorado gives it	how many rivers named colorado are there
what are the populations of states which border texas	how big are the populations of the states , which in texas borders	how big are the populations of the states which on texas border
what is the biggest capital city in the us	what is the largest city in the usa	what is the largest capital in the usa
what state borders new york	what states limits of new york	what states border new york
which states border the state with the smallest area	what states boundaries of the state with the smallest surface area	what states border the state with the smallest surface area

Table 4: Predicted translations by response-based learning (REBOL) leading to positive feedback versus translations by supervised structured learning (RAMPION) leading to negative feedback.

F1, using an extended semantic parser (trained on 880 GEOQUERY examples) and the original parser (trained on 600 GEOQUERY training examples). The extended parser reaches and F1-score of 99.64% on the 280 GEOQUERY test examples; the original parser yields an F1-score of 82.76%.

Table 1 reports results for the extended semantic parser. A system ranking according to F1-score shows about 6 points difference between the respective methods, ranking REBOL over RAMPION, EXEC and CDEC. The exploitation of task-feedback allows both EXEC and REBOL to improve task-performance over the baseline. REBOL's combination of task feedback with a cost function achieves the best results since positively executable hypotheses and reference translations can both be exploited to guide the learning process. Since all English reference queries lead to positively executable parses in the setup that uses the extended semantic parser, RAMPION implicitly also has access to task feedback. This allows RAMPION to improve F1 over the baseline. All result differences are statistically significant.

In terms of BLEU score measured against the original English GEOQUERY queries, the best nominal result is obtained by RAMPION which uses them as reference translations. REBOL performs worse since BLEU performance is optimized only implicitly in cases where original English queries function as positive examples. However, the result differences between these two systems do not score as statistically significant. Despite not optimizing for BLEU performance against references, the fact that positively executable translations include the references allows even EXEC to improve BLEU over CDEC which does not use GEOQUERY data at all in training. This result difference is statistically significant.

Table 2 compares the same systems using the original parser trained on 600 training examples. The system ranking according to F1-score shows the same ordering that is obtained when using an extended semantic parser. However, the respective methods are separated only by 3 or less points in F1 score such that only the result difference of REBOL over the baseline CDEC and over EXEC is statistically significant. We conjecture that this is due to a higher number of empty parses on the test set which makes this comparison unstable.

In terms of BLEU measured against the original queries, the result differences between REBOL and RAMPION are not statistically significant, and neither are the result differences between EXEC and CDEC. The result differences between systems of the former group and the systems of latter group are statistically significant.

5.4 Error Analysis

For a better understanding of the differences between the results produced by supervised and response-based learning, we conducted an er-

Table 5: Predicted translations where supervised structured learning (RAMPION) leads to positive feedback versus translations by response-based learning (REBOL) leading to negative feedback.

ror analysis on the test examples. Table 3 shows examples where the translation predicted by response-based learning (REBOL) differs from the gold standard reference translation, but yet leads to positive feedback via a parse that returns the correct answer from the database. The examples show structural and lexical variation that leads to differences on the string level at equivalent positive feedback from the extrinsic task. This can explain the success of response-based learning: Lexical and structural variants of reference translations can be used to boost model parameters towards translations with positive feedback, while the same translations might be considered as negative examples in standard structured learning.

Table 4 shows examples where translations from REBOL and RAMPION differ from the gold standard reference, and predictions by REBOL lead to positive feedback, while predictions by RAMPION lead to negative feedback. Table 5 shows examples where translations from RAMPION outperform translations from REBOL in terms of task feedback. We see that predictions from both systems are in general grammatical. This can be attributed to the use of sentence-level BLEU as cost function in RAMPION and REBOL. Translation errors of RAMPION can be traced back to mistranslations of key terms (`city` versus `capital`, `limits` or `boundaries` versus `border`). Translation errors of REBOL more frequently show missing translations of terms.

6 Conclusion

We presented a proposal for a new learning and evaluation framework for SMT. The central idea is to ground meaning transfer in successful interaction in an extrinsic task, and use task-based feedback for structured learning. We presented a proof-of-concept experiment that defines the extrinsic task as executing semantic parses of translated queries against the GEOQUERY database. Our experiments show an improvement of about 6 points in F1-score for response-based learning over structured learning from reference translations. Our error analysis shows that response-based learning generates grammatical translations which is due to the additional use of a cost function that boosts similarity of translations to human reference translations.

In future work, we would like to extend our work on embedding SMT in virtual gameplay to larger and more diverse datasets, and involve human feedback in the response-based learning loop.

Abstract

Abstractive text summarization of news requires a way of representing events, such as a collection of pattern clusters in which every cluster represents an event (e.g., *marriage*) and every pattern in the cluster is a way of expressing the event (e.g., *X married Y, X and Y tied the knot*). We compare three ways of extracting event patterns: heuristics-based, compression-based and memory-based. While the former has been used previously in multi-document abstraction, the latter two have never been used for this task. Compared with the first two techniques, the memory-based method allows for generating significantly more grammatical and informative sentences, at the cost of searching a vast space of hundreds of millions of parse trees of known grammatical utterances. To this end, we introduce a data structure and a search method that make it possible to efficiently extrapolate from every sentence the parse sub-trees that match against any of the stored utterances.

1 Introduction

Text summarization beyond extraction requires a semantic representation that abstracts away from words and phrases and from which a summary can be generated (Mani, 2001; Spärck-Jones, 2007). Following and extending recent work in semantic parsing, information extraction (IE), paraphrase generation and summarization (Titov and Klementiev, 2011; Alfonseca et al., 2013; Zhang and Weld, 2013; Mehdad et al., 2013), the representation we consider in this paper is a large collection of clusters of event patterns. An abstractive summarization system relying on such a representation proceeds by (1) detecting the most relevant event cluster for a given sentence or sentence collection, and (2) using the most representative pattern from the cluster to generate a concise summary sentence. Figure 1 illustrates the summarization architecture we are assuming in this paper. Given input text(s) with resolved and typed entity mentions, event mentions and the most relevant event cluster are detected (first arrow). Then, a summary sentence is generated from the event and entity representations (second arrow).

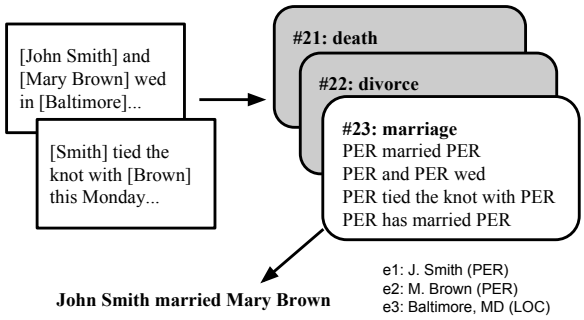

Figure 1: An example of abstracting from input sentences to an event representation and generation from that representation.

However, the utility of such a representation for summarization depends on the quality of pattern clusters. In particular, event patterns must correspond to grammatically correct sentences. Introducing an incomplete or incomprehensible pattern (e.g., *PER said PER*) may negatively affect both event detection and sentence generation. Related work on paraphrase detection and relation extraction is mostly *heuristics-based* and has relied on hand-crafted rules to collect such patterns (see Sec. 2). A standard approach is to focus on binary relations between entities and extract

*Work done during an internship at Google Zurich.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 892–901,
Baltimore, Maryland, USA, June 23-25 2014.

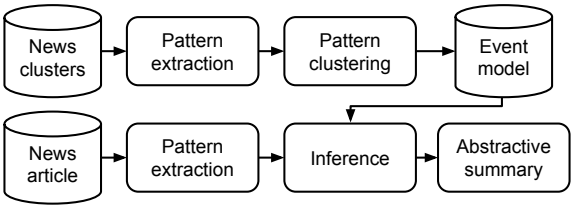

Figure 2: A generic pipeline for event-driven abstractive headline generation.

the dependency path between the two entities as an event representation. An obvious limitation of this approach is there is no guarantee that the extracted pattern corresponds to a grammatically correct sentence, e.g., that an essential prepositional phrase is retained like in *file for a divorce*.

In this paper we explore two novel, data-driven methods for event pattern extraction. The first, *compression-based* method uses a robust sentence compressor with an aggressive compression rate to get to the core of the sentence (Sec. 3). The second, *memory-based* method relies on a vast collection of human-written headlines and sentences to find a substructure which is known to be grammatically correct (Sec. 4). While the latter method comes closer to ensuring perfect grammaticality, it introduces a problem of efficiently searching the vast space of known well-formed patterns. Since standard iterative approaches comparing every pattern with every sentence are prohibitive here, we present a search strategy which scales well to huge collections (hundreds of millions) of sentences.

In order to evaluate the three methods, we consider an abstractive summarization task where the goal is to get the gist of single sentences by recognizing the underlying event and generating a short summary sentence. To the best of our knowledge, this is the first time that this task has been proposed; it can be considered as *abstractive sentence compression*, in contrast to most existing sentence compression systems which are based on selecting words from the original sentence or rewriting with simpler paraphrase tables. An extensive evaluation with human raters demonstrates the utility of the new pattern extraction techniques. Our analysis highlights advantages and disadvantages of the three methods.

To better isolate the qualities of the three extraction methodologies, all three methods use the same training data and share components of the very same summarization architecture, as shown in Figure 2: an event model is constructed by clustering the patterns extracted according to the selected extraction method. Then, the same extraction method is used to collect patterns from sentences in never-seen-before news articles. Finally, the patterns are used to query the event model and generate an abstractive summary. The three different pattern extractors are detailed in the next three sections.

Algorithm 1 HEURISTICEXTRACTOR(T, E): heuristically extract relational patterns for the dependency parse T and the set of entities E.

2 Heuristics-based pattern extraction

In order to be able to work in an Open-IE manner, applicable to different domains, most existing pattern extraction systems are based on linguistically motivated heuristics. Zhang and Weld (2013) is based on REVERB (Fader et al., 2011), which uses a regular expression on part-of-speech tags to produce the extractions. An alternative system,

OLLIE (Schmitz et al., 2012), uses syntactic dependency templates to guide the pattern extraction process.

The heuristics used in this paper are inspired by Alfonseca et al. (2013), who built well formed relational patterns by extending minimum spanning trees (MST) which connect entity mentions in a dependency parse. Algorithm 1 details our reimplementation of their method and the specific set of rules that we rely on to enforce pattern grammaticality. We use the standard Stanford-style set of dependency labels (de Marneffe et al., 2006). The input to the algorithm are a parse tree T and a set of target entities E. We first generate combinations of 1-3 elements of E (line 10), then for each combination C we identify all the nodes in T that mention any of the entities in C. We continue by constructing the MST of these nodes, and finally apply our heuristics to the nodes in the MST. The procedure APPLYHEURISTICS (:16) recursively grows a nodeset N' by including children and parents of noun and verb nodes in N' based on dependency labels. For example, we include all children of verbs in N' whose label is listed in V_c (:3), e.g., active or passive subjects, direct or indirect objects, particles and auxiliary verbs. Similarly, we include the parent of a noun in N' if the dependency relation between the node and its parent is listed in N_p.

3 Pattern extraction by sentence compression

Sentence compression is a summarization technique that shortens input sentences preserving the most important content (Grefenstette, 1998; McDonald, 2006; Clarke and Lapata, 2008, inter alia). While first attempts at integrating a compression module into an extractive summarization system were not particularly successful (Daumé III and Marcu, 2004, inter alia), recent work has been very promising (Berg-Kirkpatrick et al., 2011; Wang et al., 2013). It has shown that dropping constituents of secondary importance from selected sentences – e.g., temporal modifiers or relative clauses – results in readable and more informative summaries. Unlike this related work, our goal here is to compress sentences to obtain an event pattern – the minimal grammatical structure expressing an event. To our knowledge, this application of sentence compressors is novel. As in Section 2, we only consider sentences mentioning entities and require the compression (pattern) to retain at least one such mention.

Sentence compression methods are abundant but very few can be configured to produce output satisfying certain constraints. For example, most compression algorithms do not accept compression rate as an argument. In our case, sentence compressors which formulate the compression task as an optimization problem and solve it with integer linear programming (ILP) tools under a number of constraints are particularly attractive (Clarke and Lapata, 2008; Filippova and Altun, 2013). They can be extended relatively easily with both the length constraint and the constraint on retaining certain words. The method of Clarke and Lapata (2008) uses a trigram language model (LM) to score compressions. Since we are interested in very short outputs, a LM trained on standard, uncompressed text would not be suitable. Instead, we chose to modify the method of Filippova and Altun (2013) because it relies on dependency parse trees and does not use any LM scoring.

Like other syntax-based compressors, the system of Filippova and Altun (2013) prunes dependency structures to obtain compression trees and hence sentences. The objective function to maximize in an ILP problem (Eq. 1) is formulated over weighted edges in a transformed dependency tree and is subject to a number of constraints. Edge weight is defined as a linear function over a feature set: $w(e) = \mathbf{w} \cdot \mathbf{f}(e)$.

$$F(X) = \sum_{e \in E} x_e \times w(e) \quad (1)$$

In our reimplementation we followed the algorithm as described by Filippova and Altun (2013). The compression tree is obtained in two steps. First, the input tree is transformed with deterministic rules, most of which aim at collapsing indispensable modifiers with their heads (determiners, auxiliary verbs, negation, multi-word expressions, etc.). Then a sub-tree maximizing the objective function is found under a number of constraints.

Apart from the structural constrains from the original system which ensure that the output is a valid tree, the constraints we add state that:

1. tree size in edges must be in [3, 6],
2. entity mentions must be retained,
3. subject of the clause must be retained,
4. the sub-tree must be covered by a single clause – exactly one finite verb must used.

Since we consider compressions with different lengths as candidates, from this set we select the one with the maximum averaged edge weight as the final compression. Figure 3 illustrates the use of the compressor for obtaining event patterns. Dashed edges are dropped as a result of constrained compression so that the output is *John Smith married Mary Brown* and the event pattern is *PER married PER*. Note that the root of a subclause is allowed to be the top-level node in the extracted compression.

Compared with patterns obtaines with heuristics, compression patterns should retain prepositional verb arguments whose removal would render the pattern ungrammatical. As an example consider *[C. Zeta-Jones] and [M. Douglas] filed for divorce*. The heuristics-based pattern is *PER and PER filed* which is incomplete. Unlike it, the compression-based method keeps the essential prepositional phrase *for divorce* in the pattern because the average edge weight is greater for the tree with the prepositional phrase.

4 Memory-based pattern extraction

Neither heuristics-based, nor compression-based methods provide a guarantee that the extracted pattern is grammatically correct. In this section we introduce an extraction technique which makes it considerably more likely because it only extracts patterns which have been observed as full sentences in a human-written text (Sec. 4.1). However, this memory-based method also poses a problem not encountered by the two previous methods: how to search over the vast space of observed headlines and sentences to extract a pattern from a given sentence? Our trie-based solution, which we present in the remainder of this section, makes it possible to compare a dependency graph against millions of observed grammatical utterances in a fraction of a second.

4.1 A *tree-trie* to store them all...

Our objective is to construct a compact representation of hundreds of millions of observed sentences that can fit in the memory of a standard workstation. This data structure should make it possible to efficiently identify the sub-trees of a sentence that match any complete utterance previously observed. To this end, we build a trie of dependency trees (which we call a *tree-trie*) by scanning all the dependency parses in the news training data, and index each tree in the tree-trie according to Algorithm 2. For better clarity, the process is also described graphically in Figure 4. First, each dependency tree (a) is *linearized*, resulting in a data structure that consists of two aligned sequences (b). The first sequence (*tokens*) encodes word/parent-relation pairs, while the second sequence (*structure*) encodes the offsets of parent nodes in the linearized tree. As an example, the first word "The" is a determiner ("det") for the second node (offset 1) in the sequence, which is "cat". In turn, "cat" is the subject ("nsubj") of the node in position 2, i.e., "sleeps". As described in Algorithm 2, we recursively store the token sequence in the trie, each word/relation pair being stored in a node. When the token sequence is completely consumed, we store in the current trie node the structure of the linearized tree. Combining structural information with the sequential information encoded by each path in the trie makes it possible to rebuild a complete dependency graph. Figure 4(c) shows an example trie encoding 4 different sentences. We highlighted in bold the path corresponding to the linearized form (b) of the example parse tree (a).

Algorithm 2 STORE(T, I): store the dependency tree T in the tree-trie I.

```
1:  /* Entry point */
2:  L ← T.LINEARIZE()
3:  STORERECURSION(I.ROOT(), L, 0)
4:  return M
5:  /* Procedures */
6:  procedure STORERECURSION(n, L, o)
7:    if o == L.LENGTH() then
8:      n.ADDTREESTRUCTURE(L.STRUCTURE())
9:      return
10:   if not n.HASCHILD(L.TOKEN(o)) then
11:     n.ADDCHILD(L.TOKEN(o))
12:   n' ← n.GETCHILD(L.TOKEN(o))
13:   STORERECURSION(n', L, o + 1)
```

The figure shows that the tree contains two kinds of nodes: end-of-sentence (EOS) nodes (red) and non-terminal nodes (in blue). EOS nodes do not necessarily coincide with trie leaves, as it is possible to observe complete sentences embedded in longer ones. EOS nodes differ from non-terminal nodes in that they store one or more structural sequences corresponding to different syntactic representations of observed sentences with the same tokens.

Space-complexity and generalization. Storing all the observed sentences in a single trie requires huge amounts of memory. To make it possible to

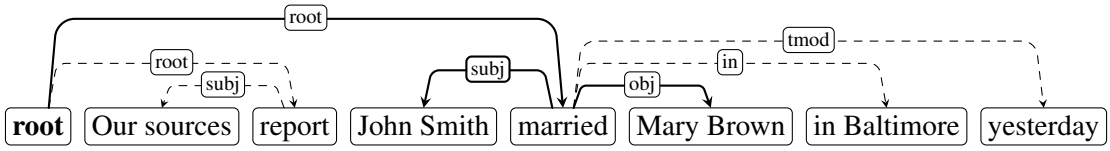

Figure 3: Transformed dependency tree with a sub-tree expressing an event pattern.

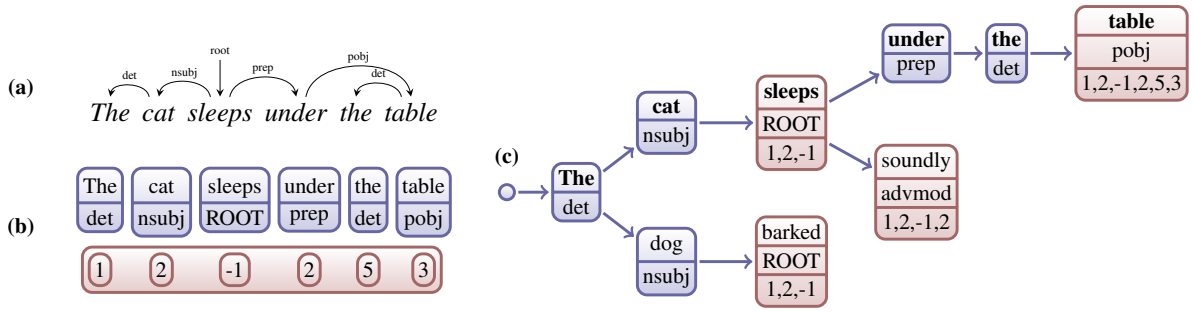

Figure 4: A dependency tree (a), its linearized form (b) and the resulting path in a trie (c), in bold.

store a complete tree-trie in memory, we adopt the following strategy. We replace the surface form of entity nodes with the coarse entity type (e.g., PER, LOC, ORG) of the entity. Similarly, we replace proper nouns with the placeholder "[P]", thus significantly reducing lexical sparsity. Then, we encode each distinct word/relation pair as a 32-bit unsigned integer. Assuming a maximum tree size of 255 nodes, we represent structure sequences as vectors of type unsigned char (8 bit per element). Finally, we store trie-node children as sorted vectors instead of hash maps to reduce memory footprint. As a result, we are able to load a trie encoding 400M input dependency parses, 170M distinct nodes and 48M distinct sentence structures in under 10GB of RAM.

4.2 . . . and in the vastness match them

At lookup time, we want to use the tree-trie to identify all sub-graphs of an input dependency tree T that match at least a complete observed sentence. To do so, we need to identify all paths in the trie that match any sub-sequence s of the linearized sequence of T nodes. Whenever we encounter an EOS node e, we verify if any of the structures stored at e matches the sub-tree generated by s. If so, then we have a positive match. As a sentence might embed many shorter utterances, each input T will generally yield multiple matches. For example, querying the tree-trie in Figure 4(c) with the input tree shown in (a) would yield two results, as both *The cat sleeps* and *The cat sleeps under the table* are complete utterances stored in the trie.

Algorithm 3 LOOKUP(T, I): Lookup for matches of subset of tree T in the trie index I.

```
1:  /* Entry point */
2:  L ← T.LINEARIZE()
3:  M ← ∅
4:  LOOKUPRECURSIVE(T, L, 0, I.ROOT(), ∅, M)
5:  return M
6:  /* Procedures */
7:  procedure LOOKUPRECURSIVE(T, L, o, n, P, M)
8:    for all i ∈ [o, L.LENGTH()) do
9:      if n.HASCHILD(L.TOKEN(i)) then
10:       n' ← n.GETCHILD(L.TOKEN(i))
11:       P' ← P ∪ {i}
12:       for all S ∈ n'.TREESTRUCTURES() do
13:         if L.ISCOMPATIBLE(S, P') then
14:           M ← M ∪ {T.GETNODES(P')}
15:       LOOKUPRECURSIVE(L, i, o + 1, n', P', M)
```

Algorithm 3 describes the lookup process in more detail. The first step consists in the linearization of the input tree T. Then, we recursively traverse the trie calling LOOKUPRECURSIVE. The inputs of this procedure are: the input tree T, its linearization L and an offset o (starting at 0), the trie node currently being traversed n (starting with the root), the set of offsets in L that constitute a partial match P (initially empty) and the set of complete matches found M. We recursively traverse all the nodes in the trie that yield a partial match with any sub-sequence of the linearized tokens of T. At each step, we scan all the tokens in L in the range $[o, L.\text{LENGTH}())$ looking for tokens matching any of the children of n. If a matching node is found, a new partial match P' is constructed by extending P with the matching token

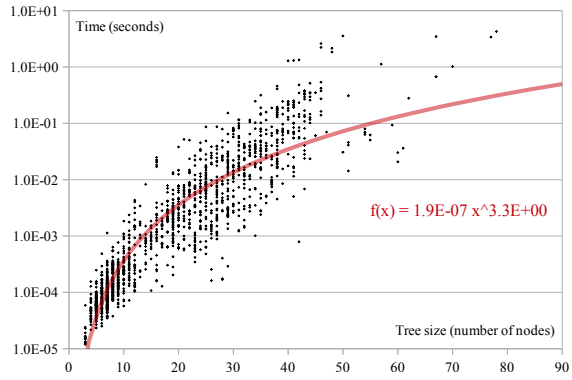

Figure 5: Time complexity of lookup operations for inputs of different sizes.

offset i (line 11), and the recursion continues from the matching trie node n' and offset i (line 15). Every time a partial match is found, we verify if the partial match is compatible with any of the tree structures stored in the matching node. If that is the case, we identify the corresponding set of matching nodes in T and add it to the result M (lines 12-14). A pattern is generated from each complete match returned by LOOKUP after applying a simple heuristic: for each verb node v in the match, we enforce that negations and auxiliaries in T depending from x are also included in the pattern.

Time complexity of lookups. Let k be the maximum fan-out of trie nodes, d be the depth of the trie and n be the size of an input tree (number of nodes). If trie node children are hashed (which has a negative effect on space complexity), then worst case complexity of LOOKUP() is $O(nk)^{d-1}$. If they are stored as sorted lists, as in our memory-efficient implementation, theoretical complexity becomes $O(nk\log(k))^{d-1}$. It should be noted that worst case complexity can only be observed under extremely unlikely circumstances, i.e., that at every step of the recursion all the nodes in the tail of the linearized tree match a child of the current node. Also, in the actual trie used in our experiments the average branching factor k is very small. We observed that a trie storing 400M sentences (170M nodes) has an average branching factor of 1.02. While the root of the trie has unsurprisingly many children (210K, all the observed first sentence words), already at depth 2 the average fan-out is 13.7, and at level 3 it is 4.9.

For an empirical analysis of lookup complexity, Figure 5 plots, in black, wall-clock lookup time as a function of tree size n for a random sample of 1,600 inputs. As shown by the polynomial regression curve (red), observed lookup complexity is approximately cubic with a very small constant factor. In general, we can see that for sentences of common length (20-50 words) a lookup operation can be completed in well under one second.

5 Evaluation

5.1 Experimental settings

All the models for the experiments that we present have been trained using the same corpus of news crawled from the web between 2008 and 2013. The news have been processed with a tokenizer, a sentence splitter (Gillick and Favre, 2009), a part-of-speech tagger and dependency parser (Nivre, 2006), a co-reference resolution module (Haghighi and Klein, 2009) and an entity linker based on Wikipedia and Freebase (Milne and Witten, 2008). We use Freebase types as fine-grained named entity types, so we are also able to label e.g. instances of *sports teams* as such instead of the coarser label ORG.

Next, the news have been grouped based on temporal closeness (Zhang and Weld, 2013) and cosine similarity (using tf·idf weights). For each of the three pattern extraction methods we used the same summarization pipeline (as shown above in Figure 2):

1. Run pattern extraction on the news.
2. For every news collection $Coll$ and entity set E, generate a set containing all the extracted patterns from news in $Coll$ mentioning all the entities in E. These are patterns that are likely to be paraphrasing each other.
3. Run a clustering algorithm to group together patterns that typically co-occur in the sets generated in the previous step. There are many choices for clustering algorithms (Alfonseca et al., 2013; Zhang and Weld, 2013). Following Alfonseca et al. (2013) we use in this work a Noisy-OR Bayesian Network because it has already been applied for abstractive summarization (albeit multi-document), it provides an easily interpretable probabilistic clustering, and training can be easily parallelized to be able to handle large training sets. The hidden events in the Bayesian network represent pattern clusters. When training is done, for each extraction pattern p_j

Original sentence	*Abstractive summary (method)*
Two-time defending overall World Cup champion Marcel Hirscher won the challenging giant slalom on the Gran Risa course with two solid runs Sunday and attributed his victory to a fixed screw in his equipment setup.	Marcel Hirscher has won the giant slalom. (**C**)
Zodiac Aerospace posted a 7.9 percent rise in first-quarter revenue, below market expectations, but reaffirmed its full-year financial targets.	Zodiac Aerospace has reported a rise in profits. (**C**)
Australian free-agent closer Grant Balfour has agreed to terms with the Baltimore Orioles on a two-year deal, the Baltimore Sun reported on Tuesday citing multiple industry sources.	Balfour will join the Baltimore Orioles. (**H**)

Method	*Extractions*	*Abstractions*
HEURISTIC	24,630	956
COMPRESSION	15,687	657
MEMORY-BASED	11,459	967

Table 2: Patterns extracted in each method, before Noisy-OR inference.

and pattern cluster c_i, the network provides $p(p_j|c_i)$ —the probability that c_i will generate p_j— and $p(c_i|p_j)$ —the probability that, given a pattern p_j, c_i was the hidden event that generated it.

At generation time we proceed in the following way:

1. Given the title or first sentence of a news article, run the same pattern extraction method that was used in training and, if possible, obtain a pattern p involving some entities.

2. Find the model clusters that contain this pattern, $C_p = \{c_i \text{ such that } p(c_i|p) > 0\}$.

3. Return a ranked list of model patterns $output = \{(p_j, score(p_j))\}$, scored as follows:

$$score(p_j) = \prod_{c_i \in C_p} p(p_j|c_i)p(c_i|p)$$

where p was the input pattern.

4. Replace the entity placeholders in the top-scored patterns p_j with the entities that were actually mentioned in the input news article.

In all cases the parameters of the network were predefined as 20,000 nodes in the hidden layer (model clusters) and 40 Expectation Maximization (EM) training iterations. Training was distributed across 20 machines with 10 GB of memory each.

For testing we used 37,584 news crawled during December 2013, which had not been used for training the models. Table 3 shows one pattern cluster example from each of the three trained models. The table shows only the surface form of the pattern for simplicity.

Pattern cluster (MEMORY-BASED)
organization$_1$ gets *organization*$_0$ nod for drug

organization$_0$ is to acquire *organization*$_1$
organization$_0$ has agreed to buy *organization*$_1$
organization$_0$ announces acquisition of *organizations*$_1$
organization$_0$ may bid for *organization*$_1$
organization$_1$ sold to *organization*$_0$
organization$_1$ acquired by *organization*$_0$
Pattern cluster (COMPRESSION)
the *sports team*$_1$ have acquired *person*$_0$ from the *sports team*$_2$
the *sports team*$_1$ acquired *person*$_0$ from the *sports team*$_2$
the *sports team*$_2$ have traded *person*$_0$ to the *sports team*$_1$
sports team$_1$ acquired the rights to *person*$_0$ from *sports team*$_2$
sports team$_2$ acquired from *sports team*$_1$ in exchange for *person*$_0$
sports team$_2$ have acquired from the *sports team*$_1$ in exchange for *person*$_0$

Table 3: Examples of pattern clusters. In each cluster c_i, patterns are sorted by $p(p_j|c_i)$.

5.2 Results

Table 2 shows the number of extracted patterns from the test set, and the number of abstractive event descriptions produced.

As expected, the number of extracted patterns using the memory-based model is smaller than with the two other models, which are based on generic rules and are less restricted in what they can generate. As mentioned, the memory-based model can only extract previously-seen structures. Compared to this model, with heuristics we can obtain patterns for more than twice more news articles. At the same time, looking at the number of summary sentences generated they are comparable, meaning that a larger proportion of the memory-based patterns actually appeared in the pattern clusters and could be used to produce summaries. This is also consistent with the fact that using heuristics the space of extracted patterns is basically unbounded and many new patterns can be generated that were previously unseen –and these cannot generate abstractions. A positive outcome is that restricting the syntactic structure of the extracted patterns to what has been observed in past news does not negatively affect end-to-end coverage when generating the abstractive summaries.

Table 1 shows some of the abstractive summaries generated with the different methods. For manually evaluating their quality, a random sample of 100 original sentences was selected for each method. The top ranked summary for each original sentence was sent to human raters for evaluation, and received three different ratings. None of the raters had any involvement in the development of the work or the writing of the paper, and a constraint was added that no rater could rate more than 50 abstractions. Raters were presented with the original sentence and the compressed abstraction, and were asked to rate it along two dimensions, in both cases using a 5-point Likert scale:

- **Readability**: whether the abstracted compression is grammatically correct.
- **Informativeness**: whether the abstracted compression conveys the most important information from the original sentence.

Inter-judge agreement was measured using the Intra-Class Correlation (ICC) (Shrout and Fleiss, 1979; Cicchetti, 1994). The ICC for readability was 0.37 (95% confidence interval [0.32, 0.41]), and for informativeness it was 0.64 (95% confidence interval [0,60, 0.67]), representing fair and substantial reliability.

Method	*Readability*	*Informativeness*
HEURISTIC	3.95	3.07
COMPRESSION	3.98	2.35
MEMORY-BASED	**4.20**	**3.70**

Table 4: Results for the three methods when rating the top-ranked abstraction.

Table 4 shows the results when rating the top ranked abstraction using either of the three different models for pattern extraction. The abstractions produced with the memory-based method are more readable than those produced with the other two methods (statistically significant with 95% confidence).

Regarding informativeness, the differences between the methods are bigger, because the first two methods have a proportionally larger number of items with a high readability but a low informativeness score. For each method, we have manually reviewed the 25 items where the difference between readability and informativeness was the largest, to understand in which cases grammatical, yet irrelevant compressions are produced. The results are shown in Table 5. *Be+adjective* includes examples where the pattern is of the form *Entity is Adjective*, which the compression-based systems extracts often represents an incomplete extraction. *Wrong inference* contains the cases where patterns that are related but not equivalent are clustered, e.g. *Person arrived in Country* and *Person arrived in Country for talks*. *Info. missing* represents cases where very relevant information has been dropped and the summary sentence is not complete. *Possibility* contains cases where the original sentence described a possibility and the compression states it as a fact, or vice versa. *Disambiguation* are entity disambiguations errors, and *Opposite* contains cases of patterns clustered together that are opposite along some dimension, e.g. *Person quits TV_Program* and *Person to return to TV_Program*.

The method with the largest drop between the readability and informativeness scores is COMPRESSION. As can be seen, many of these mistakes are due to relevant information being missing in the summary sentence. This is also the largest source of errors for the HEURISTIC system. For the MEMORY-BASED system, the drop in read-

Method	*Be+adjective*	*Wrong inference*	*Info. missing*	*Possibility*	*Disambiguation*	*Opposite*
HEURISTIC	0	7	14	3	1	0
COMPRESSION	3	10	10	0	0	2
MEMORY-BASED	0	17	4	2	0	2

Table 5: Sources of errors for the top 25 items with high readability and low informativeness.

Original sentence	*Pattern extracted (method)*	*Abstraction*
David Moyes is happy to use tough love on Adnan Januzaj to ensure the Manchester United youngster fulfils his massive potential.	David Moyes is happy. (**C**)	Fortune will start to favour David Moyes.
The Democratic People's Republic of Korea will "achieve nothing by making threats or provocation," the United States said Friday.	The United States said Friday. (**C, H**)	United States officials said Friday.
EU targets Real and Barca over illegal state aid.	EU targets Real Madrid. (**H**)	EU is going after Real Madrid.
EU warns Israel over settlement construction	EU warns Israel. (**M**)	EU says Israel needs reforms.

Table 6: Examples of compression (**C**), heuristic (**H**) and memory-based (**M**) patterns that led to abstractions with high readability but a low informativeness score. Both incomplete summary sentences and wrong inferences can be observed.

ability score is much smaller, so there were less of these examples. And most of these examples belong to the class of wrong inferences (patterns that are related but not equivalent, so we should not abstract one of them from the other, but they were clustered together in the model). Our conclusion is that the examples with missing information are not such a big problem with the MEMORY-BASED system, as using the trie is an additional safeguard that the generated titles are complete statements, but the method is not preventing the wrong inference errors so this class of errors become the dominant class by a large margin.

Some examples with high readability but low informativeness are shown in Table 6.

6 Conclusions

Most Open-IE systems are based on linguistically-motivated heuristics for learning patterns that express relations between entities or events. However, it is common for these patterns to be incomplete or ungrammatical, and therefore they are not suitable for abstractive summary generation of the relation or event mentioned in the text.

In this paper, we describe a memory-based approach in which we use a corpus of past news to learn valid syntactic sentence structures. We discuss the theoretical time complexity of looking up extraction patterns in a large corpus of syntactic structures stored as a trie and demonstrate empirically that this method is effective in practice. Finally, the evaluation shows that summary sentences produced by this method outperform heuristics and compression-based ones both in terms of readability and informativeness. The problem of generating incomplete summary sentences, which was the main source of informativeness errors for the alternative methods, becomes a minor problem with the memory-based approach. Yet, there are some cases in which also the memory based approach extracts correct but misleading utterances, e.g., a pattern like *PER passed away* from the sentence *PER passed the ball away*. To solve this class of problems, a possible research direction would be the inclusion of more complex linguistic features in the tree-trie, such as verb subcategorization frames.

As another direction for future work, more effort is needed in making sure that no incorrect inferences are made with this model. These happen when a more specific pattern is clustered together with a less specific pattern, or when two non-equivalent patterns often co-occur in news as two events are somewhat correlated in real life, but it is generally incorrect to infer one from the other. Improvements in the pattern-clustering model, outside the scope of this paper, will be required.

Abstract

Multi-document summarization (MDS) systems have been designed for short, unstructured summaries of 10-15 documents, and are inadequate for larger document collections. We propose a new approach to scaling up summarization called *hierarchical summarization*, and present the first implemented system, SUMMA.

SUMMA produces a hierarchy of relatively short summaries, in which the top level provides a general overview and users can navigate the hierarchy to drill down for more details on topics of interest. SUMMA optimizes for coherence as well as coverage of salient information. In an Amazon Mechanical Turk evaluation, users preferred SUMMA ten times as often as flat MDS and three times as often as timelines.

1 Introduction

The explosion in the number of documents on the Web necessitates automated approaches that organize and summarize large document collections on a complex topic. Existing methods for multi-document summarization (MDS) are designed to produce short summaries of 10-15 documents.[1] MDS systems do not scale to data sets ten times larger and proportionately longer summaries: they either cannot run on large input or produce a disorganized summary that is difficult to understand.

We present a novel MDS paradigm, *hierarchical summarization*, which operates on large document collections, creating summaries that organize the information coherently. It mimics how someone with a general interest in a complex topic would learn about it from an expert – first, the expert would provide an overview, and then more specific information about various aspects. Hierarchical summarization has the following novel characteristics:

- The summary is hierarchically organized along one or more organizational principles such as time, location, entities, or events.
- Each non-leaf summary is associated with a set of child summaries where each gives details of an element (e.g. sentence) in the parent summary.
- A user can navigate within the hierarchical summary by clicking on an element of a parent summary to view the associated child summary.

For example, given the topic, "1998 embassy bombings," the first summary (Figure 1) might

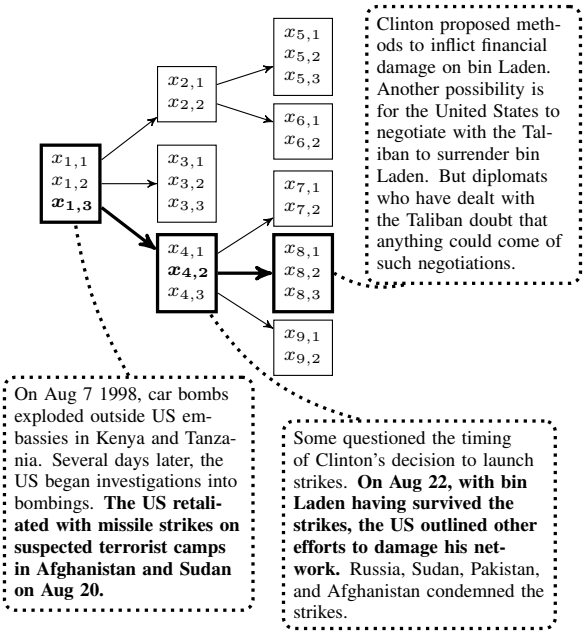

Figure 1: A hierarchical summary of the 1998 embassy bombings. Each rectangle represents a summary and each $x_{i,j}$ is a sentence within a summary. The root summary provides an overview of the events of August 1998. When the third sentence is selected, a more detailed summary of the missile strikes is displayed. Selecting the second sentence of that summary produces a more detailed summary of the US' options.

[1] In the DUC evaluations, summaries have a budget of 665 bytes and cover 10 documents.

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 902–912,
Baltimore, Maryland, USA, June 23-25 2014.

mention that the US retaliated by striking Afghanistan and Sudan. The user can click on this information to learn more about these attacks. In this way, the system can present large amounts of information without overwhelming the user, and the user can tailor the output to their interests.

In this paper, we describe SUMMA, the first hierarchical summarization system for multi-document summarization.[2] It operates on a corpus of related news articles. SUMMA hierarchically clusters the sentences by time, and then summarizes the clusters using an objective function that optimizes salience and coherence.

We conducted an Amazon Mechanical Turk (AMT) evaluation where AMT workers compared the output of SUMMA to that of timelines and flat summaries. SUMMA output was judged superior more than three times as often as timelines, and users learned more in twice as many cases. Users overwhelmingly preferred hierarchical summaries to flat summaries (92%) and learned just as much.

Our main contributions are as follows:

- We introduce and formalize the novel task of hierarchical summarization.
- We present SUMMA, the first hierarchical summarization system, which operates on news corpora and summarizes over an order of magnitude more documents than traditional MDS systems, producing summaries an order of magnitude larger.
- We present a user study which demonstrates the value of hierarchical summarization over timelines and flat multi-document summaries in learning about a complex topic.

In the next section, we formalize hierarchical summarization. We then describe our methodology to implement the SUMMA hierarchical summarization system: hierarchical clustering in Section 3 and creating summaries based on that clustering in Section 4. We discuss our experiments in Section 5, related work in Section 6, and conclusions in Section 7.

2 Hierarchical Summarization

We propose a new task for large-scale summarization called *hierarchical summarization*. Input to a hierarchical summarization system is a set of related documents D and a budget b for each summary within the hierarchy (in bytes, words, or sentences). The output is the hierarchical summary H, which we define formally as follows.

[2] http://knowitall.cs.washington.edu/summa/

Definition A *hierarchical summary* H of a document collection D is a set of summaries X organized into a hierarchy. The top of the hierarchy is a summary X_1 representing all of D, and each summary X_i consists of summary units $x_{i,j}$ (*e.g.* the jth sentence of summary i) that point to a child summary, except at the leaf nodes of the hierarchy.

A child summary adds more detail to the information in its parent summary unit. The child summary may include sub-events or background and reactions to the event or topic in the parent.

We define several metrics in Section 4 for a well-constructed hierarchical summary. Each summary should maximize coverage of *salient* information; it should minimize *redundancy*; and it should have *intra-cluster coherence* as well as *parent-to-child coherence*.

Hierarchical summarization has two important strengths in the context of large-scale summarization. First, the information presented at the start is small and grows only as the user directs it, so as not to overwhelm the user. Second, each user directs his or her own experience, so a user interested in one aspect need only explore that section of the data without having to view or understand the entire summary. The parent-to-child links provide a means for a user to navigate, drilling down for more details on topics of interest.

There are several possible organizing principles for the hierarchy – by date, by entities, by locations, or by events. Some organizing principles will fit the data in a document collection better than others. A system may select different organization for different portions of the hierarchy, for example, organizing first by location or prominent entity and then by date for the next level.

3 Hierarchical Clustering

Having defined the task, we now describe the methodology behind our implementation, SUMMA. In future work we intend to design a system that dynamically selects the best organizing principle for each level of the hierarchy. In this first implementation, we have opted for temporal organization, since this is generally the most appropriate for news events.

The problem of hierarchical summarization as described in Section 2 has all of the requirements of MDS, and additional complexities of inducing a hierarchical structure, processing an order of magnitude bigger input, generating a much larger output, and enforcing coherence between parent and

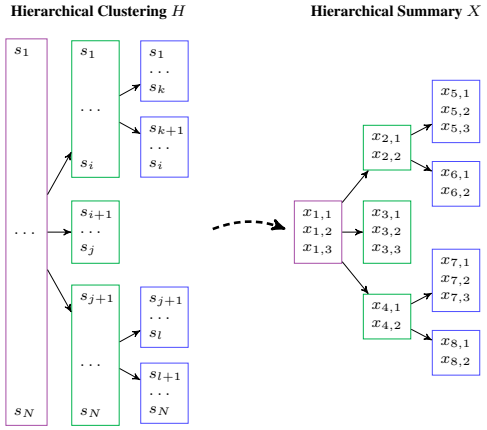

Figure 2: Examples of input and output to hierarchical summarization. The input sentences are $s \in S$, the number of input sentences is N, and the summary sentences are $x \in X$.

child summaries.

We simplify the problem by decomposing it into two steps: hierarchical clustering and summarizing over the clustering (see Figure 2 for an example). A hierarchical clustering is a tree in which if a cluster g_p is the parent of cluster g_c, then each sentence in g_c is also in g_p. This organizes the information into manageable, semantically-related sections and induces a hierarchical structure over the input.

The hierarchical clustering serves as input to the second step – summarizing given the hierarchy. The hierarchical summary follows the hierarchical structure of the clustering. Each node in the hierarchy has an associated flat summary, which summarizes the sentences in that cluster. Moreover, the number of sentences in a flat summary is exactly equal to the number of child clusters of the node, since the user will click a sentence to get to the child summary. See Figure 2 for an illustration of this correspondence.

Because we are interested in *temporal* hierarchical summarization, we hierarchically cluster all the sentences in the input documents by time. Unfortunately, neither agglomerative nor divisive clustering is suitable, since both assume a binary split at each node (Berkhin, 2006). The number of clusters at each split should be what is most natural for the input data. We design a recursive clustering algorithm that automatically chooses the appropriate number of clusters at each split.

Before clustering, we timestamp all sentences. We use SUTime (Chang and Manning, 2012) to normalize temporal references, and we parse the sentences with the Stanford parser (Klein and Manning, 2003) and use a set of simple heuristics to determine if the timestamps in the sentence refer to the root verb. If no timestamp is given, we use the article date.

3.1 Temporal Clustering

After acquiring the timestamps, we must hierarchically cluster the sentences into sets that make sense to summarize together. Since we wish to partition along the temporal dimension, our problem reduces to identifying the best dates at which to split a cluster into subclusters. We identify these dates by looking for bursts of activity.

News tends to be *bursty* – many articles on a topic appear at once and then taper out (Kleinberg, 2002). For example, Figure 3 shows the number of articles per day related to the 1998 embassy bombings published in the New York Times (identified using a key word search). There were two main events – on the 7th, the embassies were bombed and on the 20th, the US retaliated through missile strikes. The figure shows a correspondence between these events and news spikes.

Ideal splits for this example would occur just before each spike in coverage. However, when there is little differentiation in news coverage, we prefer clusters evenly spaced across time. We thus choose clusters $C = \{c_1, \ldots, c_k\}$ as follows:

$$\underset{C}{\text{maximize}} \quad B(C) + \alpha E(C) \tag{1}$$

where C is a clustering, $B(C)$ is the burstiness of the set of clusters, $E(C)$ is the evenness of the clusters, and α is the tradeoff parameter.

$$B(C) = \sum_{c \in C} burst(c) \tag{2}$$

$burst(c)$ is the difference in the number of sentences published the day before the first date in c and the average number of sentences published on the first and second date of c:

$$burst(c) = \frac{pub(d_i) + pub(d_{i+1})}{2} - pub(d_{i-1}) \tag{3}$$

where d is a date indexed over time, such that d_j is a day before d_{j+1}, and d_i is the first date in c. $pub(d_i)$ is the number of sentences published on d_i. The evenness of the split is measured by:

$$E(C) = \min_{c \in C} size(c) \tag{4}$$

where $size(c)$ is the number of dates in cluster c.

We perform hierarchical clustering top-down, at each point solving for Equation 1. α was set using a grid-search over a development set.

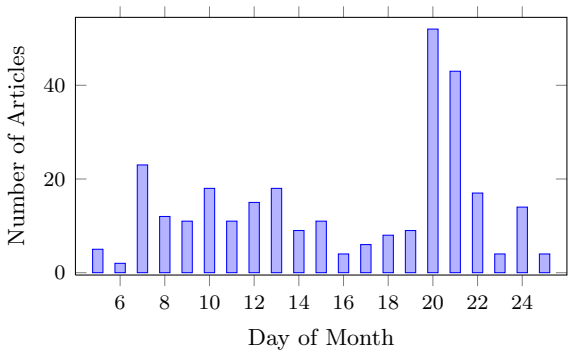

Figure 3: News coverage by date for the embassy bombings in Tanzania and Kenya. There are spikes in the number of articles published at the two major events.

3.2 Choosing the number of clusters

We cannot know *a priori* the number of clusters for a given topic. However, when the number of clusters is too large for the given summary budget, the sentences will have to be too short, and when the number of clusters is too small, we will not use enough of the budget. We set the maximum number of clusters k_{max} and minimum number of clusters k_{min} to be a function of the budget b and the average sentence length in the cluster s_{avg}, such that $k_{max} \cdot s_{avg} \leq b$ and $k_{min} \cdot s_{avg} \geq b/2$.

Given a maximum and minimum number of clusters, we must determine the appropriate number of clusters. At each level, we cluster the sentences by the method described above and choose the number of clusters k according to the gap statistic (Tibshirani et al., 2000). Specifically, for each level, the algorithm will cluster repeatedly with k varying from the minimum to the maximum. The algorithm will return the k that maximizes the gap statistic:

$$Gap_n(k) = E_n^*\{\log(W_k)\} - log(W_k) \qquad (5)$$

where W_k is the score for the clusters computed with Equation 1, and E_n^* is the expectation under a sample of size n from a reference distribution.

Ideally, the maximum depth of the clustering would be a function of the number of sentences in each cluster, but in our implementation, we set the maximum depth to three, which works well for the size of the datasets we use (300 articles).

4 Summarizing within the Hierarchy

After the sentences are clustered, we have a structure for the hierarchical summary that dictates the number of summaries and the number of sentences in each summary. We also have the set of sentences from which each summary is drawn.

Intuitively, each cluster summary in the hierarchical summary should convey the most **salient** information in that cluster. Furthermore, the hierarchical summary should not include **redundant** sentences. A hierarchical summary that is only salient and nonredundant may still not be suitable if the sentences within a cluster summary are disconnected or if the parent sentence for a summary does not relate to the child summary. Thus, a hierarchical summary must also have **intra-cluster coherence** and **parent-to-child coherence**.

4.1 Salience

Salience is the value of each sentence to the topic from which the documents are drawn. We measure salience of a summary ($Sal(X)$) as the sum of the saliences of individual sentences ($\sum_i Sal(x_i)$). Following previous research in MDS, we computed individual saliences using a linear regression classifier trained on ROUGE scores over the DUC'03 dataset (Lin, 2004; Christensen et al., 2013). This method finds those sentences more salient that mention nouns or verbs that occur frequently in the cluster.

In preliminary experiments, we noticed that many sentences that were *reaction* sentences were given a higher salience than *action* sentences. For example, the reaction sentence, "President Clinton vowed to track down the perpetrators behind the bombs that exploded outside the embassies in Tanzania and Kenya on Friday," would have a higher score than the *action* sentence, "Bombs exploded outside the embassies in Tanzania and Kenya on Friday." This problem occurs because the first sentence has a higher ROUGE score (it covers more important words than the second sentence). To adjust for this problem, we use only words identified in the main clause (heuristically identified via the parse tree) to compute our salience scores.

4.2 Redundancy

We identify redundant sentences using a linear regression classifier trained on a manually labeled subset of the DUC'03 sentences. The features include shared noun counts, sentence length, TF*IDF cosine similarity, timestamp difference, and features drawn from information extraction such as number of shared tuples in Open IE (Mausam et al., 2012).

4.3 Summary Coherence

We require two types of coherence: coherence between the parent and child summaries and coherence within each summary X_i.

We rely on the approximate discourse graph (ADG) that was proposed in (Christensen et al., 2013) as the basis for measuring coherence. Each node in the ADG is a sentence from the dataset. An edge from sentence s_i to s_j with positive weight indicates that s_j may follow s_i in a coherent summary, *e.g.* continued mention of an event or entity, or coreference link between s_i and s_j. A negative edge indicates an unfulfilled discourse cue or co-reference mention.

Parent-to-Child Coherence: Users navigate the hierarchical summary from parent sentence to child summary, so if the parent sentence bears no relation to the child summary, the user will be understandably confused. The parent sentence must have positive evidence of coherence with the sentences in its child summary.

We estimate parent to child coherence as the coherence between a parent sentence and each sentence in its child summary as:

$$PCoh(X) = \sum_{c \in C} \sum_{i=1..|X_c|} w_{G+}(x_c^p, x_{c,i})) \quad (6)$$

where x_c^p is the parent sentence for cluster c and $w_{G+}(x_c^p, x_{c,i})$ is the sum of the positive edge weights from x_c^p to $x_{c,i}$ in the ADG G.

Intra-cluster Coherence: In traditional MDS, the documents are usually quite focused, allowing for highly focused summaries. In hierarchical summarization, however, a cluster summary may span hundreds of documents and a wide range of information. For this reason, we may consider a summary acceptable even if it has limited positive evidence of coherence in the ADG, as long as there is no negative evidence in the form of negative edges. For example, the following is a reasonable summary for events spanning two weeks:

s_1 *Bombs exploded at two US embassies.*

s_2 *US missiles struck in Afghanistan and Sudan.*

Our measure of intra-cluster coherence minimizes the number of *missing references*. These are coreference mentions or discourse cues where none of the sentences read before (either in an ancestor summary or in the current summary) contain an antecedent:

$$CCoh(X) = -\sum_{c \in C} \sum_{i=1..|X_c|} \#missingRef(x_{c,i}) \quad (7)$$

4.4 Objective Function

Having estimated salience, redundancy, and two forms of coherence, we can now put this information together into a single objective function that measures the quality of a candidate hierarchical summary.

Intuitively, the objective function should balance salience and coherence. Furthermore, the summary should not contain redundant information and each cluster summary should honor the given budget, i.e., maximum summary length b. We treat redundancy and budget as hard constraints and coherence and salience as soft constraints. Lastly, we require that sentences are drawn from the cluster that they represent and that the number of sentences in the summary corresponding to each non-leaf cluster c is equivalent to the number of child clusters of c. We optimize:

$$\begin{aligned} \textbf{maximize:} \quad & F(x) \triangleq Sal(X) + \beta PCoh(X) + \gamma CCoh(X) \\ s.t. \quad & \forall c \in C : \textstyle\sum_{i=1..|X_c|} len(x_{c,i}) < b \\ & \forall x_i, x_j \in X : \text{redundant}(x_i, x_j) = 0 \\ & \forall c \in C, \forall x_c \in X_c : x_c \in c \\ & \forall c \in C : |X_c| = \#children(c) \end{aligned}$$

The tradeoff parameters β and γ were set based on a development set.

4.5 Algorithm

Optimizing this objective function is NP-hard, so we approximate a solution by using beam search over the space of partial hierarchical summaries. Notice the contribution from a sentence depends on individual salience, coherence ($CCoh$) based on sentences visible on the user path down the hierarchy to this sentence, and coherence ($PCoh$) based on its parent sentence and its child summary. Since most of the sentence contributions depend on the path from the root to the sentence, we build our partial summary by incrementally adding a sentence top-down in the hierarchy and from first sentence to last within a cluster summary.

To account for $PCoh$, we estimate the contribution of the sentence by jointly identifying its best child summary. However, we do not fix the child summary at this time – we simply use it to estimate $PCoh$ when using that sentence. Since computing the best child summary is also intractable we approximate a solution by a local search algorithm over the child cluster.

Overall, our algorithm is a two level nested search algorithm – beam search in the outer loop to

search through the space of partial summaries and local search (hill climbing with random restarts) in the inner loop to pick the best sentence to add to the existing partial summary. We use a beam of size ten in our implementation.

5 Experiments

Our experiments are designed to evaluate how effective hierarchical summarization is in summarizing a large, complex topic and how well this helps users learn about the topic. Our evaluation addresses the following questions:

- Do users prefer hierarchical summaries for topic exploration? (Section 5.1)
- Are hierarchical summaries more effective than other methods for learning about complex events? (Section 5.2)
- How informative are the hierarchical summaries compared to the other methods? (Section 5.3)
- How coherent is the hierarchical structure in the summaries? (Section 5.4)

We compared SUMMA against two baseline systems which represent the main NLP methods for large-scale summarization: an algorithm for creating timelines over sentences (Chieu and Lee, 2004),[3] and a state-of-the-art flat MDS system (Lin and Bilmes, 2011).[4] Each system was given the same budget (over 10 times the traditional MDS budget, which is 665 bytes).

We evaluated the questions on ten news topics, representing a range of tasks: (1) Pope John Paul II's death and the 2005 Papal Conclave, (2) Bush v. Gore, (3) the Tulip Revolution, (4) Daniel Pearl's kidnapping, (5) the Lockerbie bombing handover of suspects, (6) the Kargil War, (7) NATO's bombing of Yugoslavia in 1999, (8) Pinochet's arrest in London, (9) the 2005 London bombings, and (10) the crash and investigation of SwissAir Flight 111. We chose topics containing a set of related events that unfolded over several months and were prominent enough to be reported in at least 300 articles.

We drew our articles from the Gigaword corpus, which contains articles from the New York Times and other major newspapers. For each topic, we used the 300 documents that best matched a key word search. We selected topics which were between five and fifteen years old so that evaluators would have relatively less pre-existing knowledge about the topic.

5.1 User Preference

In our first experiment, we simply wished to evaluate which system users most prefer. We hired Amazon Mechanical Turk (AMT) workers and assigned two topics to each worker. We paired up workers such that one worker would see output from SUMMA for the first topic and a competing system for the second and the other worker would see the reverse. For quality control, we asked workers to complete a qualification task first, in which they were required to write a short summary of a news article. We also manually removed spam from our results. Previous work has used AMT workers for summary evaluations and has shown high correlations with expert ratings (Christensen et al., 2013). Five workers were hired to view each topic-system pair.

We asked the workers to choose which format they preferred and to explain why. The results are as follows:

SUMMA	**76%**	TIMELINE	24%
SUMMA	**92%**	FLAT-MDS	8%

Users preferred the hierarchical summaries three times more often than timelines and over ten times more often than flat summaries. When we examined the reasons given by the users, we found that the people who preferred the hierarchical summaries liked that they gave a big picture overview and were then allowed to drill down deeper. Some also explained that it was easier to remember information when presented with the overview first. Typical responses included, "Could gather and absorb the information at my own pace," and, "Easier to follow and understand." When users preferred the timelines, they usually remarked that it was more familiar, i.e. "I liked the familiarity of the format. I am used to these timelines and they feel comfortable." Users complained that the flat summaries were disjointed, confusing, and very frustrating to read.

5.2 Knowledge Acquisition

Evaluating how much a user learned is inherently difficult, more so when the goal is to allow the user the freedom to explore information based on individual interest. For this reason, instead of asking a set of predefined questions, we assess the knowl-

[3] Unfortunately, we were unable to obtain more recent timeline systems from authors of the systems.

[4] (Christensen et al., 2013) is a state-of-the-art coherent MDS system, but does not scale to 300 documents.

edge gain by following the methodology of (Shahaf et al., 2012) – asking users to write a paragraph summarizing the information learned.

Using the same setup as in the previous experiment, for each topic, five AMT workers spent three minutes reading through a timeline or summary and were then asked to write a description of what they had learned. Workers were not allowed to see the timeline or summary while writing. We collected five descriptions for each topic-system combination. We then asked other AMT workers to read and compare the descriptions written by the first set of workers. Each evaluator was presented with a corresponding Wikipedia article and descriptions from a pair of users (timeline vs. SUMMA or flat MDS vs. SUMMA). The descriptions were randomly ordered to remove bias. The workers were asked which user appeared to have learned more and why. For each pair of descriptions, four workers evaluated the pair. Standard checks such as approval rating, location filtering, etc. were used for removing spam. The results of this experiment are as follows:

Prefer		Indiff.	Prefer	
SUMMA	**58%**	17%	TIMELINE	25%
SUMMA	**40%**	22%	FLAT-MDS	38%

Descriptions written by workers using SUMMA were preferred over twice as often as those from timelines. We looked more closely at those cases where the participants either preferred the timelines or were indifferent and found that this preference was most common when the topic was not dominated by a few major events, but was instead a series of similarly important events. For example, in the kidnapping and beheading of Daniel Pearl there were two or three obviously major events, whereas in the Kargil War there were many smaller important events. In latter cases, the hierarchical summaries provided little advantage over the timelines because it was more difficult to arrange the sentences hierarchically.

Since SUMMA was judged to be so much superior to flat MDS systems in Section 5.1, it is surprising that users descriptions from flat MDS were preferred nearly as often as those from SUMMA. While the flat summaries were disjointed, they were good at including salient information, with the most salient tending to be near the start of the summary. Thus, descriptions from both SUMMA and flat MDS generally covered the most salient information.

5.3 Informativeness

In this experiment, we assess the salience of the information captured by the different systems, and the ability of SUMMA to organize the information so that more important information is placed at higher levels.

ROUGE Evaluation: We first automatically assessed informativeness by calculating the ROUGE-1 scores of the output of each of the systems. For the gold standard comparison summary, we use the Wikipedia articles for the topics.[5] Note that there is no good translation of ROUGE for hierarchical summarization. Thus, we simply use the traditional ROUGE metric, which will not capture any of the hierarchical format. This score will essentially serve as a rough measure of coverage of the entire summary to the Wikipedia article. The scores for each of the systems are as follows:

	P	R	F1
SUMMA	0.25	**0.67**	0.31
TIMELINE	0.28	0.65	0.33
FLAT-MDS	**0.30**	0.64	**0.34**

None of the differences are significant. From this evaluation, one can gather that the systems have similar coverage of the Wikipedia articles.

Manual Evaluation: While ROUGE serves as a rough measure of coverage, we were interested in gathering more fine-grained information on the informativeness of each system. We performed an additional manual evaluation that assesses the recall of important events for each system.

We first identified which events were most important in a news story. Because reading 300 articles per topic is impractical, we asked AMT workers to read a Wikipedia article on the same topic and then identify the three most important events and the five most important secondary events. We aggregated responses from ten workers per topic and chose the three most common primary and five most common secondary events.

One of the authors then manually identified the presence of these events in the hierarchical summaries, the timelines and the flat MDS summaries. Below we show event recall (the percentage of the events that were mentioned).

[5] We excluded one topic (the handover of the Lockerbie bombing suspects) because the corresponding Wikipedia article had insufficient information.

Events	SUMMA	TIMELINE	FLAT-MDS
Prim.	**96%**	74%	93%
Sec.	**76%**	53%	64%

The difference in recall between SUMMA and TIMELINE was significant in both cases, and the difference between SUMMA and FLAT-MDS was not. In general, the flat summaries were quite redundant, which contributed to the slightly lower event recall. The timelines, on the other hand, were both incoherent and at the same time reported less important facts.

We also evaluated at what level in the hierarchy the events were identified for the hierarchical summaries. The event recall shows the percentage of events mentioned at that level or above in the hierarchical summary:

Events	Level 1	Level 2	Level 3
Prim.	63%	81%	96%
Sec.	27%	51%	76%

81% of the primary events are present in the first or second level, and 76% of the secondary events are mentioned by the third level. While recognizing primary events is relatively simple because they are repeated frequently, identification of important secondary events often requires external knowledge.

5.4 Parent-to-Child Coherence

We next tested the hierarchical coherence. One of the authors graded how much each non-leaf sentence in a summary was coherent with its child summary on a scale of one to five, with one being incoherent and five being perfectly coherent. We used the coherence scale from DUC'04.[6]

	Level 1	Level 2
Coherence	3.8	3.4

We found that for the top level of the summary, the parent sentence generally represented the most important event in the cluster and the child summary usually expressed details or reactions of the event. The lower coherence scores were often the result of too few lexical connections or lack of a theme or story. While the facts of the sentences made sense together, the summaries sometimes did not read as if they were written by a human, but as a series of disparate sentences.

For the second level, the problems were more basic. The parent sentence occasionally expressed a less important fact that the child summary did not then expand on or, more commonly, the child summary was not focused enough. This result stems from two problems in our algorithm. First, summarizing sentences are rare, making good choices for parent sentences difficult to find. The second problem relates to the difficulty in identifying whether two sentences are on the same topic. For example, suppose the parent sentence is, "A Swissair plane Wednesday night crashed off Nova Scotia, Canada." A very good child sentence is, "The airline confirmed that all passengers died." However, based on their surface features, the sentence, "A plane made an unscheduled landing after a Swissair plane crashed off the coast of Canada," appears to be a better choice.

Even though there is scope for improvement, we find these coherence scores encouraging for a first algorithm for the task.

6 Related Work

Traditional approaches to large-scale summarization have included flat summaries and timelines. There are two primary shortcomings to these approaches: first, they require the user to sort through large amounts of potentially overwhelming information, and second, the output is static – users with different interests will see the same information. Below we describe related work on traditional MDS, structured summaries, timelines, discovering threads of documents and the uses of hierarchies in generating summaries.

6.1 Traditional MDS

Traditionally, MDS systems have focused on three to six sentence summaries covering 10-15 documents. Most extractive summarization research aims to maximize coverage while reducing redundancy (e.g. (Carbonell and Goldstein, 1998; Saggion and Gaizauskas, 2004; Radev et al., 2004)). Lin and Bilmes (2011) proposed a state-of-the-art system that uses submodularity in sentence selection to accomplish these goals. Christensen et al. (2013) presented an algorithm for coherent MDS, but it does not scale to larger output.

Structured Summaries: Some research has explored generating structured summaries. These approaches attempt to identify major aspects of a topic, but do not compile content to describe those aspects. Rather, they rely on pre-existing, labeled paragraphs (for example, a paragraph titled, "Symptoms of Meningitis"). Aspects are identified either by a training corpus of articles in the

[6] http://duc.nist.gov/duc2004/quality.questions.txt

same domain (Sauper and Barzilay, 2009), by an entity-aspect LDA model (Li et al., 2010), or by Wikipedia templates of related topics (Yao et al., 2011). These methods assume a common structure for all topics in a category, and do not allow for more than two levels in the structure.

Timeline Generation: Recent papers in timeline generation have emphasized the relationship with summarization. Yan et al. (2011b) balanced coherence and diversity to create timelines, Yan et al. (2011a) used inter-date and intra-date sentence dependencies, and Chieu and Lee (2004) used sentence similarity. Others have emphasized identifying important dates, primarily by bursts of news (Swan and Allen, 2000; Akcora et al., 2010; Hu et al., 2011; Kessler et al., 2012). While timelines can be useful for understanding events, they do not generalize to other domains. Additionally, long timelines can be overwhelming, short timelines have low information content, and there is no method for personalized exploration.

Document Threads: A related track of research investigates discovering threads of documents. While we aim to summarize collections of information, this track seeks to identify relationships between documents. This research operates on the document level, while ours operates on the sentence level. Shahaf and Guestrin (2010) formalized the characteristics of a good chain of articles and proposed an algorithm to connect two specified articles. Gillenwater et al. (2012) proposed a probabilistic technique for extracting a diverse set of threads from a given collection. Shahaf et al. (2012) extended work on coherent threads to finding coherent maps of documents, where a map is set of intersecting threads representing how the threads interact and relate.

Summarization and Hierarchies: A few papers have examined the relationship between summarization and hierarchies. Some focused on creating a hierarchical summary of a single document (Buyukkokten et al., 2001; Otterbacher et al., 2006), relying on the structure inherent in single documents. Others investigated creating hierarchies of words or phrases to organize documents (Lawrie et al., 2001; Lawrie, 2003; Takahashi et al., 2007; Haghighi and Vanderwende, 2009).

Other research identifies the hierarchical structure of the documents and generates a summary that prioritizes more general information according to the structure (Ouyang et al., 2009; Celikyilmaz and Hakkani-Tur, 2010), or gains coverage by drawing sentences from different parts of the hierarchy (Yang and Wang, 2003; Wang et al., 2006).

7 Conclusions

We have introduced a new paradigm for large-scale summarization called hierarchical summarization, which allows a user to navigate a hierarchy of relatively short summaries. We present SUMMA, an implemented hierarchical news summarization system,[7] and demonstrate its effectiveness in a user study that compares SUMMA with a timeline system and a flat MDS system. When compared to timelines, users learned more with SUMMA in twice as many cases, and SUMMA was preferred more than three times as often. When compared to flat summaries, users overwhelming preferred SUMMA and learned just as much.

This first implementation performs temporal clustering – in future work, we will investigate dynamically selecting an organizing principle that is best suited to the data at each level of the hierarchy: by entity, by location, by event, or by date. We also intend to scale the system to even larger document collections, and explore joint clustering and summarization. Lastly, we plan to research hierarchical summarization in other domains.

Abstract

Update summarization is a form of multi-document summarization where a document set must be summarized in the context of other documents assumed to be known. Efficient update summarization must focus on identifying new information and avoiding repetition of known information. In *Query-focused summarization*, the task is to produce a summary as an answer to a given query. We introduce a new task, *Query-Chain Summarization*, which combines aspects of the two previous tasks: starting from a given document set, increasingly specific queries are considered, and a new summary is produced at each step. This process models *exploratory search*: a user explores a new topic by submitting a sequence of queries, inspecting a summary of the result set and phrasing a new query at each step. We present a novel dataset comprising 22 query-chains sessions of length up to 3 with 3 matching human summaries each in the consumer-health domain. Our analysis demonstrates that summaries produced in the context of such exploratory process are different from informative summaries. We present an algorithm for Query-Chain Summarization based on a new LDA topic model variant. Evaluation indicates the algorithm improves on strong baselines.

1 Introduction

In the past 10 years, the general objective of text summarization has been refined into more specific tasks. Such summarization tasks include: (i) Generic Multi Document Summarization: aims at summarizing a cluster of topically related documents, such as the top results of a search engine query; (ii) in Update Summarization, a set of documents is summarized while assuming the user has already read a summary of earlier documents on the same topic; (iii) in Query-Focused Summarization, the summary of a documents set is produced to convey an informative answer in the context of a specific query. The importance of these specialized tasks is that they help us distinguish criteria that lead to the selection of content in a summary: centrality, novelty, relevance, and techniques to avoid redundancy.

We present in this paper a variant summarization task which combines the two aspects of update and query-focused summarization. The task is related to *exploratory search* (Marchionini, 2006). In contrast to classical information seeking, in exploratory search, the user is uncertain about the information available, and aims at learning and understanding a new topic (White and Roth, 2009). In typical exploratory search behavior, a user posts a series of queries, and based on information gathered at each step, decides how to further explore a set of documents. The metaphor of *berrypicking* introduced in (Bates, 1989) captures this interactive process. At each step, the user may *zoom in* to a more specific information need, *zoom out* to a more general query, or *pan sideways*, in order to investigate a new aspect of the topic.

We define *Query-Chain Focused Summarization* as follows: for each query in an exploratory search session, we aim to extract a summary that answers the information need of the user, in a manner similar to *Query-Focused Summarization*, while not repeating information already provided in previous steps, in a manner similar to *Update Summarization*. In contrast to query-focused summarization, the context of a sum-

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 913–922,
Baltimore, Maryland, USA, June 23-25 2014.

mary is not a single query, but the set of queries that led to the current step, their result sets and the corresponding summaries.

We have constructed a novel dataset of Query-Sets with matching manual summarizations in the consumer health domain (Cline and Haynes, 2001). Queries are extracted from PubMed search logs (Dogan et al., 2009). We have analyzed this manual dataset and confirm that summaries written in the context of berry-picking are markedly different from those written for similar queries on the same document set, but without the query-chain context.

We have adapted well-known multi-document algorithms to the task, and present baseline algorithms based on LexRank (Erkan and Radev, 2004), KLSum and TopicSum (Haghighi and Vanderwende, 2009). We introduce a new algorithm to address the task of Query-Chain Focused Summarization, based on a new LDA topic model variant, and present an evaluation which demonstrates it improves on these baselines.

The paper is structured as follows. Section 2 formulates the task of Query-Chain Focused Summarization. Section 3 reviews related work. In Section 4, we describe the data collection process and the resulting dataset. We then present our algorithm, as well as the baseline algorithms used for evaluation. We conclude with evaluation and discussion.

2 Query- Chain Summarization

In this work, we focus on the *zoom in* aspect of the exploratory search process described above. We formulate the Query-Chain Focused Summarization (QCFS) task as follows:

Given an ordered chain of queries Q and a set of documents D, for each query $q_i \in Q$ a summary S_i is generated from D answering q_i under the assumption that the user has already read the summaries S_{i-1} for queries $q_0 \ldots q_{i-1}$.

A typical example of query chain in the consumer health domain we investigate includes the following 3 successive queries: (*Causes of asthma, Asthma and Allergy*, Asthma *and Mold Allergy*). We consider a single set of documents relevant to the domain of Asthma as the reference set *D*. The QCFS task consists of generating one summary of *D* as an answer to each query, so that the successive answers do not repeat information already provided in a previous answer.

3 Previous Work

We first review the closely related tasks of Update Summarization and Query-Focused Summarization. We also review key summarization algorithms that we have selected as baseline and adapted to the QCFS task.

Update Summarization focuses on identifying new information relative to a previous body of information, modeled as a set of documents. It has been introduced in shared tasks in DUC 2007 and TAC 2008. This task consists of producing a multi-document summary for a document set on a specific topic, and then a multi-document summary for a different set of articles on the same topic published at later dates. This task helps us understand how update summaries identified and focused on new information while reducing redundancy compared to the original summaries.

The TAC 2008 dataset includes 48 sets of 20 documents, each cluster split in two subsets of 10 documents (called A and B). Subset B documents were more recent. Original summaries were generated for the A subsets and update summaries were then produced for the B subsets. Human summaries and candidate systems are evaluated using the Pyramid method (Nenkova and Passonneau, 2004). For automatic evaluation, ROUGE (Lin, 2004) variants have been proposed (Conroy et al., 2011). In contrast to this setup, QCFS distinguishes the subsets of documents considered at each step of the process by facets of the underlying topic, and not by chronology. In addition, the document subsets are not identified as part of the task in QCFS (as opposed to the explicit split in A and B subsets in Update Summarization).

Most systems working on Update Summarization have focused on removing redundancy. DualSum (Delort and Alfonseca, 2012) is notable in attempting to directly model novelty using a specialized topic-model to distinguish words expressing background information and those introducing new information in each document.

In Query-Focused Summarization (QFS), the task consists of identifying information in a document set that is most relevant to a given query.

This differs from generic summarization, where one attempts to identify central information. QFS helps us distinguish models of relevance and centrality. Unfortunately, detailed analysis of the datasets produced for QFS indicates that these two notions are not strongly distinguished in practice: (Gupta et al., 2007) observed that in QFS datasets, up to 57% of the words in the document sets were closely related to the query (through simple query expansion). They note that as a consequence, a generic summarizer forms a strong baseline for such biased QFS tasks.

We address this limitation of existing QFS datasets in our definition of QCFS: we identify a chain of at least 3 related queries which focus on different facets of the same central topic and require the generation of distinct summaries for each query, with little repetition across the steps.

A specific evaluation aspect of QFS measures responsiveness (how well the summary answers the specific query). QFS must rely on Information Retrieval techniques to overcome the scarceness of the query to establish relevance. As evidenced since (Daume and Marcu, 2006), Bayesian techniques have proven effective at this task: we construct a latent topic model on the basis of the document set and the query. This topic model effectively serves as a query expansion mechanism, which helps assess the relevance of individual sentences to the original query.

In recent years, three major techniques have emerged to perform multi-document summarization: graph-based methods such as LexRank (Erkan and Radev, 2004) for multi document summarization and Biased-LexRank (Otterbacher et al., 2008) for query focused summarization, language model methods such as KLSum (Haghighi and Vanderwende, 2009) and variants of KLSum based on topic models such as BayesSum (Daume and Marcu, 2006) and TopicSum (Haghighi and Vanderwende, 2009).

LexRank is a stochastic graph-based method for computing the relative importance of textual units in a natural text. The LexRank algorithm builds a weighted graph $G = (V, E)$ where each vertex in V is a linguistic unit (in our case sentences) and each weighted edge in E is a measure of similarity between the nodes. In our implementation, we model similarity by computing the cosine distance between the $TF \times IDF$ vectors representing each node. After the graph is generated, the PageRank algorithm *(*Page et al., 1999) is used to determine the most central linguistic units in the graph. To generate a summary we use the n most central lexical units, until the length of the target summary is reached. This method has no explicit control to avoid redundancy among the selected sentences, and the original algorithm does not address update or query-focused variants. Biased-LexRank (Otterbacher et al., 2008) makes LexRank sensitive to the query by introducing a prior belief about the ranking of the nodes in the graph, which reflects the similarity of sentences to the query. PageRank spreads the query similarity of a vertex to its close neighbors, so that we rank higher sentences that are similar to other sentences which are similar to the query. As a result, Biased-LexRank overcomes the lexical sparseness of the query and obtained state of the art results on the DUC 2005 dataset.

KLSum adopts a language model approach to compute relevance: the documents in the input set are modeled as a distribution over words (the original algorithm uses a unigram distribution over the bag of words in documents *D*). KLSum is a sentence extraction algorithm: it searches for a subset of the sentences in D with a unigram distribution as similar as possible to that of the overall collection D, but with a limited length. The algorithm uses Kullback-Lieber (KL) divergence $KL(P||Q) = \sum_w \log(\frac{P(w)}{Q(w)})P(w)$ to compute the similarity of the distributions. It searches for $S^* = \text{argmin}_{|S|<L} KL(P_D||P_S)$. This search is performed in a greedy manner, adding sentences one by one to S until the length L is reached, and choosing the best sentence as measured by KL-divergence at each step. The original method has no update or query focusing capability, but as a general modeling framework it is easy to adapt to a wide range of specific tasks.

TopicSum uses an LDA-like topic model (Blei *et al*. 2003) to classify words from a number of document sets (each set discussing a different topic) as either general non-content words, topic specific words and document specific word (this category refers to words that are specific to the writer and not shared across the document set). After the words are classified, the algorithm uses a KLSum variant to find the summary that best matches the unigram distribution of topic specific words. This method improves the results of

KLSum but it also has no update summary or query answering capabilities.

4 Dataset Collection

We now describe how we have constructed a dataset to evaluate QCFS algorithms, which we are publishing freely. We selected to build our dataset in the Consumer Health domain, a popular domain in the web (Cline and Haynes 2001) providing medical information at various levels of complexity, ranging from layman and up to expert information, because consumer health illustrates the need for exploratory search.

The PubMed repository, while primarily serving the academic community, is also used by laymen to ask health related questions. The PubMed query logs (Dogan et al., 2009) provide user queries with timestamps and anonymized user identification. They are publically available and include over 600K queries per day. In this dataset, Dogan and Murray found that query reformulation (typical of exploratory search) is quite frequent: "*In our dataset, 47% of all queries are followed by a new subsequent query. These users did not select any abstract or full text views from the result set. We make an operational assumption that these users' intent was to modify their search by reformulating their query.*" We used these logs to extract laymen queries relating to four topics: Asthma, Lung Cancer, Obesity and Alzheimer's disease. We extracted a single day query log. From these, we extracted sessions which contained the terms "*Asthma*", "*Lung Cancer*", "*Obesity*" or "*Alzheimer*". Sessions containing search tags (such as "[Author]") were removed to reduce the number of academic searches. The sessions were then manually examined and used to create zoom-in query chains of length 3 at most. The queries appear below:

Asthma:

Asthma causes→ asthma allergy→ asthma mold allergy;

Asthma treatment→asthma medication→corticosteroids;

Exercise induced asthma→ exercise for asthmatic;

Atopic dermatitis→ atopic dermatitis medications→ atopic dermatitis side effects;

Atopic dermatitis→ atopic dermatitis children→ atopic dermatitis treatment;

Atopic dermatitis → atopic dermatitis exercise activity → atopic dermatitis treatment;

Cancer:

Lung cancer→ lung cancer causes→ lung cancer symptoms;

Lung cancer diagnosis→ lung cancer treatment→lung cancer treatment side effects;

Stage of lung cancer→ lung cancer staging tests→ lung cancer TNM staging system;

Types of lung cancer→non-small cell lung cancer treatment→non-small cell lung cancer surgery;

Lung cancer in women→ risk factors for lung cancer in women→ treatment of lung cancer in women;

Lung cancer chemotherapy→ goals of lung cancer chemotherapy→ palliative care for lung cancer;

Obesity:

Salt obesity→retaining fluid;

Obesity screening→body mass index→BMI Validity;

Childhood obesity→childhood obesity low income→children diet and exercise;

Causes of childhood obesity→obesity and nutrition→school lunch;

Obesity and lifestyle change→obesity metabolism→superfoods antioxidant;

Obesity and diabetes→emergence of type 2 diabetes→type 2 diabetes and obesity in children;

Alzheimer's disease:

Alzheimer memory→helping retrieve memory alzheimer →alzheimer memory impairment nursing;

Cognitive impairment→Vascular Dementia→Vascular Dementia difference alzheimer;

Alzheimer's symptoms→alzheimer diagnosis→alzheimer medications;

Semantic dementia→first symptoms dementia→first symptoms alzheimer;

Figure 1: Queries Used to Construct Dataset

We asked medical experts to construct four document collections from well-known and reliable consumer health websites relating to the four subjects (Wikipedia, WebMD, and the NHS), so that they would provide general information relevant to the queries.

We then asked medical students to manually produce summaries of these four document collections for each query-chain. The medical students were instructed construct a text of up to 250 words that provides a good answer to each query in the chain. For each query in a chain the summarizers should assume that the person reading the summaries is familiar with the previous

summaries in the chain so they should avoid redundancy.

Three distinct human summaries were produced for each chain. For each chain, one summary was produced for each of the three queries, where the person producing the summary was not shown the next steps in the chain when answering the first query.

To simulate the exploratory search of the user we provided the annotators with a Solr[1] query interface for each document collection. The interface allowed querying the document set, reading the documents and choosing sentences which answer the query. After choosing the sentences, annotators can copy and edit the resulting summary in order to create an answer of up to 250 words. After processing the first two query chain summaries, the annotators held a post-hoc discussion about the different summaries in order to adjust their conception of the task.

The statistics on the collected dataset appear in the Tables below:

Document sets	# Docs	# Sentences	#Tokens / Unique
Asthma	125	1,924	19,662 / 2,284
Lung-Cancer	135	1,450	17,842 / 2,228
Obesity	289	1,615	21,561 / 2,907
Alzheimer's Disease	191	1,163	14,813 / 2,508

Queries	# Sessions	# Sentences	#Tokens / Unique
Asthma	5	15	36 / 14
Lung-Cancer	6	18	71 / 25
Obesity	6	17	45 / 29
Alzheimer's Disease	4	12	33 / 16

Manual Summaries	# Docs	# Sentences	#Tokens / Unique
Asthma	45	543	6,349 / 1,011
Lung-Cancer	54	669	8,287 / 1,130
Obesity	51	538	7,079 / 1,270
Alzheimer's Disease	36	385	5,031 / 966

Table 1: Collected Dataset Size Statistics

A key aspect of the dataset is that the same documents are summarized for each step of the chains, and we expect the summaries for each step to be different (that is, each answer is indeed responsive to the specific query it addresses). In addition, each answer is produced in the context of the previous steps, and only provides updated information with respect to previous answers. To ensure that the dataset indeed reflects these two aspects (responsiveness and freshness), we empirically verified that summaries created for advanced queries are different from the summaries created for the same queries by summarizers who did not see the previous summaries in the chain. We asked from additional annotators to create manual summaries of advanced queries from the query chain without ever seeing the queries from the beginning of the chain. For example, given the chain (*asthma causes* → *asthma allergy* → *asthma mold allergy*), we asked summarizers to produce an answer for the second query (*asthma allergy*) without seeing the first step, on the same input documents.

We used ROUGE to perform this validation: ROUGE compares a summary with a set of reference summaries and source documents. We first computed the mean ROUGE score of the second query summaries. The mean ROUGE score is the mean score of each manual summary *vs.* all other summaries about the same query. We got ($r1 = 0.52, r2 = 0.22, rs4 = 0.13$). The mean ROUGE scores of the same second query summaries by people who did not see the previous query were markedly lower: ($r1 = 0.40, r2 = 0.22, rs4 = 0.01$). We only verified the asthma dataset in this manner. The results, except for the R2 test, had statistically significant difference with 95% confidence interval. All the data, code and an annotated example can be found in our site[2].

We show below slightly shortened manual summaries created in answer to the following query chain: "*obesity screening -> body mass index -> BMI Validity*". We manually annotated the summaries to highlight how the exploration process develops and indicate some of the information retrieval challenges faced when addressing the task: underlined terms are directly relevant to the current query; ***bold italic terms*** have likely triggered the curiosity of the reader and led to asking the next query. In this example, a user asks about obesity screening, and reformulates his query using the technical term of BMI, which is prevalent in the produced answer.

Q1: obesity screening

Body mass index (BMI) is a measure used to determine

[1] http://lucene.apache.org/solr/

[2] http://www.cs.bgu.ac.il/~nlpproj/QCFS/dataset.html

childhood overweight and obesity. A child's weight status is determined using an age- and sex-specific percentile for ***BMI*** rather than the ***BMI*** categories used for adults because children's body composition varies as they age and varies between boys and girls. For children and adolescents (aged 2-19 years): Overweight is defined as a ***BMI*** at or above the 85th percentile and lower than the 95th percentile for children of the same age and sex. Obesity is defined as a ***BMI*** at or above the 95th percentile for children of the same age and sex. ***BMI*** is not a perfect measure, but rather a helpful indicator. It doesn't consider things like being muscular or having a larger than average body frame and because growth patterns vary greatly among children. As a result, doctors also factor a child's growth and development into consideration when screening for overweight and obesity. Obesity screening of adults using ***BMI*** may be less accurate for adults, due to the coarseness of the measurement: Heavily muscled athletes may have a high ***BMI***, as many women who enter menopause, who tend to gain weight due to increased water retention.

Q2: body mass index

The ***body mass index (BMI)***, or Quetelet ***index***, is a measure for human body shape based on an individual's mass and height. Devised in the mid-1800s by Adolphe Quetelet during the course of developing "social physics", it is defined as an individual's body mass divided by the square of their height, the units being kg/m^2. ***BMI*** was explicitly cited as being ***appropriate*** for population studies, and ***inappropriate*** for individual diagnosis. ***BMI*** provides a simple measure of a person's thickness, allowing health professionals to discuss over-weight and underweight problems more objectively with their patients. However, ***BMI*** has become ***controversial*** because many people, including physicians, have come to rely on its apparent ***authority*** for medical diagnosis. However, it was originally meant to be used as a simple means of classifying sedentary individuals, or rather, populations, with an average body composition. For these individuals, the current value settings are as follows: (...). Nick Korevaar (a mathematics lecturer from the University of Utah) suggests that instead of squaring the body height or cubing the body height, it would be more ***appropriate*** to use an exponent of between 2.3 and 2.7 (as originally noted by Quetelet).

Q3: BMI Validity

BMI has become controversial because many people, including physicians, have come to rely on its apparent numerical authority for medical diagnosis, but that was never the BMI's purpose; it is meant to be used as a simple means of classifying sedentary populations with an average body composition. In an article published in the July edition of 1972 of the Journal of Chronic Diseases, Ancel Keys explicitly cited BMI as being appropriate for population studies, but inappropriate for individual diagnosis. These ranges of BMI values are valid only as statistical categories While BMI is a simple, inexpensive method of screening for weight categories, it is not a good diagnostic tool: It does not take into account age, gender, or muscle mass. (...).

Figure 2: Query Chain Summary Annotated Example

5 Algorithms

In this section, we first explain how we adapted the previously mentioned methods to the QCFS task, thus producing 3 strong baselines. We then describe our new algorithm for QCFS.

5.1 Focused KLSum

We adapted KLSum to QCFS by introducing a simple document selection step in the algorithm. The method is: given a query step q, we first select a focused subset of documents from $D, D(q)$. We then apply the usual KLSum algorithm over $D(q)$. This approach does not make any effort to reduce redundancy from step to step in the query chain. In our implementation, we compute $D(q)$ by selecting the top-10 documents in D ranked by $TF \times IDF$ scores to the query, as implemented in SolR.

5.2 KL-Chain-Update

KL-Chain-Update is a slightly more sophisticated variation of KLSum that answers a query chain (instead a single query). When constructing a summary, we update the unigram distribution of the constructed summary so that it includes a smoothed distribution of the previous summaries in order to eliminate redundancy between the successive steps in the chain. For example, when we summarize the documents that were retrieved as a result to the first query, we calculate the unigram distribution in the same manner as we did in Focused KLSum; but for the second query, we calculate the unigram distribution as if all the sentences we selected for the previous summary were selected for the current query too, with a damping factor. In this variant, the Unigram Distribution estimate of word X is computed as:

$$\frac{\left(\text{Count}(W, CurrentSum) + \frac{\text{Count}(W, PreviousSum)}{SmoothingFactor}\right)}{\text{Length}(CurrentSum) + \frac{\text{Length}(\text{PreviousSum} \cap CurrentSum)}{SmoothingFactor}}$$

5.3 ChainSum

ChainSum is our adaptation of TopicSum to the QCFS task. We developed a novel Topic Model to identify words that are associated to the current query and not shared with the previous queries. We achieved this with the following model. For each query in a chain, we consider the documents D_c which are "good answers" to the query; and D_P which are the documents used to answer the previous steps of the chain. We assume in this model that these document subsets are observable (in our implementation, we select these subsets by ranking the documents for the query based on *TFxIDF* similarity).

1. G is the *general words* topic, it is intended to capture stop words and non-topic specific vocabulary. Its distribution φ_G is drawn for all the documents from $Dirichlet(V, \lambda_G)$.

2. S_i is the *document specific* topic; it represents words which are local for a specific document. ϕ_{S_i} is drawn for each document from $Dirichlet(V, \lambda_{S_i})$.

3. N is the *new content* topic, which should capture words that are characteristic for D_c. ϕ_N is drawn for all the documents in D_c from $Dirichlet(V, \lambda_N)$.

4. O captures *old content* from D_P, ϕ_O is drawn for all the documents in D_P from $Dirichlet(V, \lambda_O)$.

5. R captures *redundant information* between D_c and D_p, ϕ_R is drawn for all the documents in $D_p \cup D_c$ from $Dirichlet(V, \lambda_R)$.

6. For documents from D_c we draw from the distribution ψ_{t_1} over topics (G, N, R, S_i) from a Dirichlet prior with pseudo-counts (10.0,15.0,15.0,1.0)[3] . For each word in the document, we draw a topic Z from ψ_t, and a word W from the topic indicated by Z.

7. For documents from D_p, we draw from the distribution ψ_{t_2} over topics (G, O, R, S_i) from a Dirichlet prior with pseudo-counts (10.0,15.0,15.0,1.0) . The words are drawn in the same manner as in t_1.

8. For documents in $D \setminus (D_c \cup D_p)$ we draw from the distribution ψ_{t_3} over topics (G, S_i) from a Dirichlet prior with pseudo-counts (10.0,1.0) . The words are also drawn in the same manner as in t_1.

The plate diagram of this generative model is shown in Fig.3.

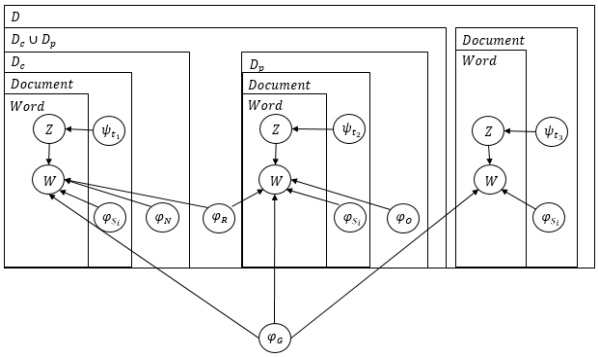

Figure 3 Plate Model for Our Topic Model

We implemented inference over this topic model using Gibbs Sampling (we distribute the code of the sampler together with our dataset). After the topic model is applied to the current query, we apply KLSum only on words that are assigned to the new content topic. Fig.4 summarizes the algorithm data flow.

When running this topic model on our dataset, we observe: D_c mean size was 978 words and 375 unique words. D_P mean size was 1374 words and 436 unique words. D_c and D_P mean on average 159 words. These figures show there is high lexical overlap between the summaries answering query qi and qi+1 and highlight the need to distinguish new and previously exposed content.

In the ChainSum model, the topic R aims at modeling redundant information between the previous summaries and the new summary. We intend in the future to exploit this information to construct a contrastive model of content selection. In the current version, R does not play an active role in content selection. We, therefore, tested a variant of ChainSum that did not include φ_R and obtained results extremely similar to the full model, which we report below.

[3] All pseudo-counts were selected empirically

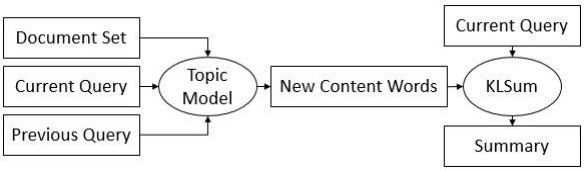

Figure 4 ChainSum Architecture

5.4 Adapted LexRank

In LexRank, the algorithm creates a graph where nodes represent the sentences from the text and weighted edges represent the cosine-distance of each sentence's *TFxIDF* vectors. After creating the graph, PageRank is run to rank sentences. We adapted LexRank to QCFS in two main ways: we extend the sentence representation scheme to capture semantic information and refine the model of sentences similarity so that it captures query answering instead of centrality. We tagged each sentence with Wikipedia terms using the Illinois Wikifier (Ratinov et al., 2011) and with UMLS (Bodenreider, 2004) terms using HealthTermFinder (Lipsky-Gorman and Elhadad, 2011). UMLS is a rich medical ontology, which is appropriate to the consumer health domain.

We changed the edges scoring formula to use the sum of Lexical Semantic Similarity (LSS) functions (Li et al., 2007) on lexical terms, Wikipedia terms and UMLS terms:

$$Score(U,V) = LSS_{lexical}(U,V) + a * LSS_{wiki}(U,V) + b * LSS_{UMLS}(U,V)$$

Where:

$$LSS(S_1,S_2) = \frac{\sum_i (MAX_j(\frac{Sim(W_i^1, W_j^2)}{Sim(W_i^1, W_i^1)}) IDF(W_i^1))}{\sum_i IDF(W_i^1)}$$

Instead of using the cosine distance, in order to incorporate advanced word/term similarity functions. For lexical terms, we used the identity function, for Wikipedia term we used Wikiminer (Milne, 2007), and for UMLS we used Ted Pedersen UMLS similarity function (McInnes et al., 2009). Finally, instead of PageRank, we used SimRank (Haveliwala, 2002) to identify the nodes most similar to the query node and not only the central sentences in the graph.

6 Evaluation

6.1 Evaluation Dataset

We worked on the dataset we created for QCFS and added semantic tags: 10% of the tokens had Wikipedia annotations and 33% had a UMLS annotation.

6.2 Results

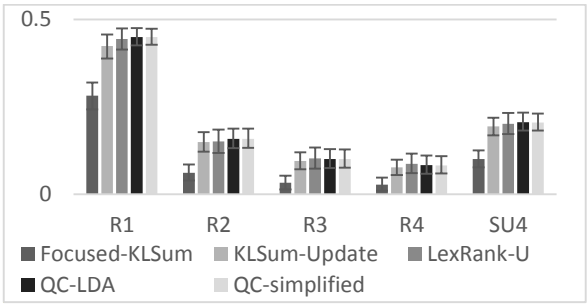

Figure 5: ROUGE Recall Scores (with stemming and stop-words)

For Focused KLSum we received ROUGE scores of (r1 = 0.281, r2 = 0.061, su4 = 0.100), KL-Chain-Update (r1 = 0.424, r2 = 0.149, su4 = 0.193), ChainSum (r1 = 0.44988, r2 = 0.1587, su4 = 0.20594), ChainSum with t Simplified Topic model (r1 = 0.44992, r2 = 0.15814, su4 = 0.20507) and for Modified-LexRank (r1 = 0.444, r2 = 0.151, su4 = 0.201). All of the modified versions of our algorithm performed better than Focused KLSum with more than 95% confidence.

7 Conclusions

We presented a new summarization task tailored for the needs of exploratory search system. This task combines elements of question answering by sentence extraction with those of update summarization.

The main contribution of this paper is the definition of a new summarization task that corresponds to exploratory search behavior and the contribution of a novel dataset containing human summaries. This dataset is annotated with Wikipedia and UMLS terms for over 30% of the tokens. We controlled that the summaries cover only part of the input document sets (and are, therefore, properly focused) and sensitive to the position of the queries in the chain.

Four methods were evaluated for the task. The baseline methods based on KL-Sum show a sig-

nificant improvement when penalizing redundancy with the previous summarization.

This paper concentrated on "zoom in" query chains, other user actions such as "zoom out" or "switch topic" were left to future work. This paper concentrated on "zoom in" query chains, other user actions such as "zoom out" or "switch topic" were left to future work. The task remains extremely challenging, and we hope the dataset availability will allow further research to refine our understanding of topic-sensitive summarization and redundancy control.

In future work, we will attempt to derive a task-specific evaluation metric that exploits the structure of the chains to better assess relevance, redundancy and contrast.

Abstract

We study the use of temporal information in the form of timelines to enhance multi-document summarization. We employ a fully automated temporal processing system to generate a timeline for each input document. We derive three features from these timelines, and show that their use in supervised summarization lead to a significant 4.1% improvement in ROUGE performance over a state-of-the-art baseline. In addition, we propose TIMEMMR, a modification to Maximal Marginal Relevance that promotes temporal diversity by way of computing time span similarity, and show its utility in summarizing certain document sets. We also propose a filtering metric to discard noisy timelines generated by our automatic processes, to purify the timeline input for summarization. By selectively using timelines guided by filtering, overall summarization performance is increased by a significant 5.9%.

1 Introduction

There has been a good amount of research invested into improving the temporal interpretation of text. Besides the increasing availability of annotation standards (e.g., TIMEML (Pustejovsky et al., 2003a)) and corpora (e.g., TIDES (Ferro et al., 2000), TimeBank (Pustejovsky et al., 2003b)), the community has also organized three successful evaluation workshops — TempEval-1 (Verhagen et al., 2009), -2 (Verhagen et al., 2010), and -3 (Uzzaman et al., 2013). As the state-of-the-art improves, these workshops have moved away from the piecemeal evaluation of individual temporal processing tasks and towards the evaluation of complete end-to-end systems in TempEval-3. We believe our understanding of the temporal information found in text is sufficiently robust, and that there is an opportunity to now leverage this information in downstream applications. In this paper, we present our work in incorporating the use of such temporal information into multi-document summarization.

The goal of multi-document summarization is to generate a summary which includes the main points from an input collection of documents with minimal repetition of similar points. We hope to improve the quality of the summaries that are generated by considering temporal information found in the input text. To motivate how temporal information can be useful in summarization, let us refer to Figure 1. The three sentences describe a recent cyclone and a previous one which happened in 1991. Recognizing that sentence (3) is about a storm that had happened in the past is important when writing a summary about the recent storm, as it is not relevant and can likely be excluded.

It is reasonable to expect that a collection of documents about the recent storm will contain more references to it, compared with the earlier one that happened in 1991. Visualized on a timeline, this will translate to more events (bolded in Figure 1) around the time when the recent storm occurred. There should be fewer events mentioned in the collection for the earlier 1991 time period. Figure 2 illustrates a possible timeline laid out with the events found in Figure 1. The events from the more recent storm are found together at the same time. There are fewer events which talk about the previous storm. Thus, temporal information does assist in identifying which sentences are more relevant to the final summary.

Our work is significant as it addresses an important gap in the exploitation of temporal information. While there has been prior work making use of temporal information for multi-document

summarization, they 1) have been largely confined to helping to chronologically order content within summaries (Barzilay et al., 1999), or 2) focus only on the use of recency as an indicator of saliency (Goldstein et al., 2000; Wan, 2007). In this work we construct timelines (as a representation of temporal information) automatically and incorporate them into a state-of-the-art multi-document summarization system. This is achieved with 1) three novel features derived from timelines to help measure the saliency of sentences, as well as 2) TIMEMMR, a modification to the traditional Maximal Marginal Relevance (MMR) (Carbonell and Goldstein, 1998). TimeMMR promotes diversity by additionally considering temporal information instead of just lexical similarities. Through these, we demonstrate that temporal information is useful for multi-document summarization. Compared to a competitive baseline, significant improvements of up to 4.1% are obtained.

Automatic temporal processing systems are not perfect yet, and this may have an impact on their use for downstream applications. This work additionally proposes the use of the lengths of timelines as a metric to gauge the usefulness of timelines. Together with the earlier described contributions, this metric further improves summarization, yielding an overall 5.9% performance increase.

2 Related Work

Barzilay et al. (1999) were one of the first to use time for multi-document summarization. They recognized the importance of generating a summary which presents the time perspective of the summarized documents correctly. They estimated the chronological ordering of events with a small set of heuristics, and also made use of lexical patterns to perform basic time normalization on terms like "today" relative to the document creation time. The induced ordering is used to present the selected summary content, following the chronological order in the original documents.

In another line of work, Goldstein et al. (2000) made use of the temporal ordering of documents to be summarized. In computing the relevance of a passage for inclusion into the final summary, they considered the recency of the passage's source document. Passages from more recent documents are deemed to be more important. Wan (2007) and Demartini et al. (2010) made similar assumptions in their work on TIMEDTEXTRANK and entity summarization, respectively.

Instead of just considering the notion of recency, Liu et al. (2009) proposed an interesting approach using a temporal graph. Events within a document set correspond to vertices in their proposed graph, while edges are determined by the temporal ordering of events. From the resulting weakly-connected graph, the largest forests are assumed to contain key topics within the document set and used to influence a scoring mechanism which prefers sentences touching on these topics.

Wu (2008) also made use of the relative ordering of events. He assigned complete timestamps to events extracted from text. After laying out these events onto a timeline by making use of these timestamps, the number of events that happen within the same day is used to influence sentence scoring. The motivation behind this approach is that days which have a large number of events should be more important and more worthy of reporting than others.

These prior works target either 1) sentence re-ordering, or 2) the use of recency as an indicator of saliency. In sentence re-ordering, final summaries are re-arranged so that the extracted sentences that form the summary are in a chronological order. We argue that this may not be appropriate for all summaries. Depending on the style of writing or journalistic guidelines, a summary can arguably be written in a number of ways. The use of recency

as an indicator of saliency is useful, yet disregards other accessible temporal information. If a summary of a whole sequence of events is desired, recency becomes less useful.

The work of Wu (2008) is closely related to one of the features proposed in this paper. He had also made use of temporal information to weight sentences to generate summaries. However his approach is guided by the number of events happening within the same time span, and relies on event co-referencing. In this work, we have simplified this idea by dropping the need for event co-referencing (removing a source of propagated error), and augmented it with two additional features derived from timelines. By doing so, we are able to make better use of the available temporal information, taking into account all known events and the time in which they occur.

A useful note here is that this work is arguably different from the Temporal Summarization (TmpSum) track at the Text Retrieval Conference (Aslam et al., 2013). Given a large stream of data in real-time, the purpose of the TmpSum track is to look out for a query event, and retrieve specific details about the event over a period of time. Systems are also expected to identify the source sentences from which these details are retrieved. This is not the same as our approach here, which makes use of temporal information encoded in timelines to generate prose summaries.

3 Methodology

To incorporate temporal information into multi-document summarization, we adopt the workflow in Figure 3, which has two key processes: 1) temporal processing, and 2) summarization.

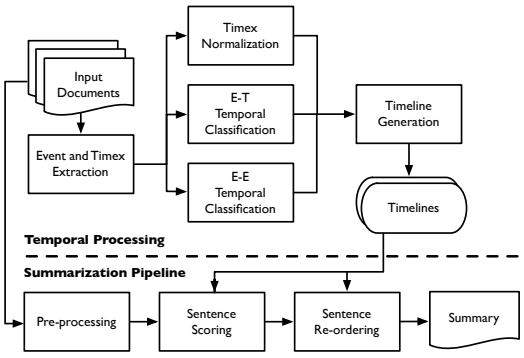

Figure 3: Incorporating temporal information into the SWING summarization pipeline.

Temporal Processing generates timelines from text, one for each input document. Timelines are well-understood constructs which have often been used to represent temporal information (Denis and Muller, 2011; Do et al., 2012). They indicate the temporal relationships between two basic temporal units: 1) events, and 2) time expressions (or timexes for short). In this work, we adopt the definitions proposed in the standardized TIMEML annotation (Pustejovsky et al., 2003a). An event refers to an eventuality, a situation that occurs or an action; while a timex is a reference to a particular date or time (e.g. "*2013 December 31*").

Following the "divide-and-conquer" approach described in Verhagen et al. (2010), results from the three temporal processing steps: 1) timex normalization, 2) event-timex temporal relationship classification, and 3) event-event temporal relationship classification, are merged to obtain timelines (top half of Figure 3). We tap on existing systems for each of these steps (Ng and Kan, 2012; Strötgen and Gertz, 2013; Ng et al., 2013).

Summarization. We make use of a state-of-the-art summarization system, SWING (Ng et al., 2012) (bottom half of Figure 3). SWING is a supervised, extractive summarization system which ranks sentences based on scores computed using a set of features in the *Sentence Scoring* phase. The Maximal Marginal Relevance (MMR) algorithm is then used in the *Sentence Re-ordering* phase to re-order and select sentences to form the final summary. The timelines built in the earlier temporal processing can be incorporated into this pipeline by deriving a set of features used to score sentences in *Sentence Scoring*, and as input to the MMR algorithm when computing similarity in *Sentence Re-ordering*.

3.1 Timelines from Temporal Processing

A typical timeline used in this work has been shown earlier in Figure 2. The arrowed, horizontal axis is the timeline itself. The timeline can be viewed as a continuum of time, with points on the timeline referring to specific moments of time. Small solid blocks on the timeline itself are references to absolute timestamps along the timeline (e.g., "*2013-Feb-13 11:32 +0000*" in the figure).

The black square boxes above the timeline denote events. Events can either occur at a specific instance of time (e.g., an explosion), or over a period of time (e.g. a football match). Generalizing, we refer to the time period an event takes place in as its *time span* (vertical dotted lines). As a simpli-

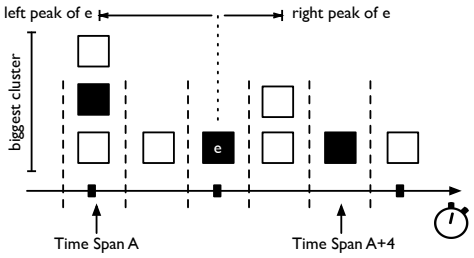

Figure 4: A simplified timeline illustrating how the various timeline features can be derived.

fying assumption, events are laid out on the timeline based on the starting time of their time span. Note that in our work, time spans may not correspond to specific instances of time, but instead help in inferring an ordering of events. Events which appear to the left of others take place earlier, while events within the same time span happen together over the same time period.

3.2 Sentence Scoring with Timelines

We derive three features from the constructed timelines, which are then used for downstream *Sentence Scoring*. Figure 4 shows a simplified timeline, along with annotations that are referenced in this section to help explain how these timeline features are derived.

1. Time Span Importance (TSI). We hypothesize that when more events happen within a particular time span, that time span is potentially more relevant for summarization. Sentences that mention events found in such a time span should be assigned higher scores. Referring to Figure 1, whose timeline is shown in Figure 2, we see that the time span with the most number of events is when the latest cyclone made landfall. Assigning higher scores for sentences which contain events in this time span will help us to select more relevant sentences if we want a summary about the cyclone.

Let TS_L be the time span with the largest number of events in a timeline. The importance of a time span TS_i is computed by normalizing the number of events in TS_i against the number of events in TS_L. The TSI of a sentence s is then the sum of the time span importance associated to all the words in s:

$$TSI(s) = \frac{\sum_{w \in s} \frac{|TS_w|}{|TS_L|}}{|s|} \quad (1)$$

where TS_w denotes the time span which a word w is associated with, and $|TS_w|$ is the number of events within the time span.

2. Contextual Time Span Importance (CTSI). The importance of a time span may not depend solely on the number of events that happen within it. If it is near time spans which are "important" (i.e., one that has a large number of events), it should also be of relative importance. A more concrete illustration of this can also be seen in Figure 1. Sentence (2) explains that a lot of people have been evacuated prior to the cyclone making landfall. It is imaginable that this can be useful information to be included in a summary, even though from looking at the corresponding timeline in Figure 2, the "*evacuated*" event falls in a time span with a low importance score (i.e., the time span only has one event). CTSI seeks to promote sentences such as this.

We derive the CTSI of a sentence by first computing the contextual importance of words in the sentence. We define the contextual importance of a word found in time span TS_i as a weighted sum of the time span importance of the two nearest peaks TS_{lp} and TS_{rp} found to the left and right of TS_i, respectively. In Figure 4, taking reference from event e (shaded in black), the left peak to the time span which e is in happens to be time span A, while the right peak is time span $A + 4$. The contribution of each peak to the weighted sum is decayed by its distance from TS_i. Formally, the contextual time span importance of a word w can be expressed as:

$$\zeta(w) = \alpha \left(\frac{I_{lp}}{|TS_w - TS_{lp}|} \right) \times (1 - \alpha) \left(\frac{I_{rp}}{|TS_{rp} - TS_w|} \right) \quad (2)$$

where TS_w is the time span associated with w. I_{lp} and I_{rp} are the time span importance of the peaks to the left and right of TS_w respectively, while $|TS_w - TS_{lp}|$ and $|TS_{rp} - TS_w|$ are the number of time spans between the left and right peaks of TS_w respectively. α balances the importance of the left and right peaks, intuitively set to 0.5. The CTSI of a sentence is computed as:

$$CTSI(s) = \frac{\sum_{e \in \mathbb{E}_s} \zeta(e)}{|\mathbb{E}_s|} \quad (3)$$

where $\mathbb{E}_s$ denotes the set of events words in s.

3. Sentence Temporal Coverage Density (TCD). We first define the *temporal coverage* of a sentence. This corresponds to the number of time spans that the events in a sentence talk about. Suppose a sentence contains events which are associated with time spans TS_a, TS_b, TS_c. The time spans are ordered in the sequence they appear on

the timeline. Then the temporal coverage of a sentence is defined as the number of time spans between the earliest time span TS_a and the latest time span TS_c. Referring to Figure 4, suppose a sentence contains the three events which have been shaded black. The temporal coverage in this case includes all the time spans from time span A to time span $A + 4$, inclusive.

The constraint on the number of sentences that can be included in a summary requires us to select compact sentences which contain as many relevant facts as possible. Traditional lexical measures may attempt to achieve this by computing the ratio of keyphrases to the number of words in a sentence (Gong and Liu, 2001). Stated equivalently, when two sentences are of the same length, if one contains more keyphrases, it should contain more useful facts. TCD parallels this idea with the use of temporal information, i.e. if two sentences are of the same temporal coverage, then the one with more events should carry more useful facts.

Formally, if a sentence s contains events $\mathbb{E}_s = \{e_1, \ldots, e_n\}$, where each event is associated with a time span TS_i, then TCD is computed using:

$$TCD(s) = \frac{|\mathbb{E}_s|}{|TS_n - TS_1|} \quad (4)$$

where $|\mathbb{E}_s|$ is the number of events found in s, and $|TS_n - TS_1|$ is the temporal coverage of s.

3.3 Enhancing MMR with TimeMMR

In the sentence re-ordering stage of the SWING pipeline, the iterative MMR algorithm is used to adjust the score of a candidate sentence, s. In each iteration, s is penalized if it is lexically similar to other sentences that have already been selected to form the eventual summary $S = \{s_1, s_2, \ldots\}$. The motivating idea is to reduce repeated information by preferring sentences which bring in new facts.

Incorporating temporal information can potentially improve this. In Figure 5, the sentences describe many events which took place within the same time span. They describe the destruction caused by a hurricane with trees uprooted and buildings blown away. A summary about the hurricane need not contain all of these sentences as they are all describing the same thing. However it is not trivial for the lexically-motivated MMR algorithm to detect that events like "*passed*", "*uprooted*" or "*damaged*" are in fact repetitive.

Thus, we propose further penalizing the score of s if it contains events that happen in similar time spans as those contained in sentences within S. We refer to this as TIMEMMR. Modifying the MMR equation from Ng et al. (2012):

$$TimeMMR(s) = Score(s) - \gamma R2(s, S) - (1 - \gamma)\mathcal{T}(s, S) \quad (5)$$

where $Score(s)$ is the score of s, S is the set of sentences already selected to be in the summary from previous iterations, and $R2$ is the predicted ROUGE-2 score of s with respect to the already selected sentences (S). γ is a weighting parameter which is empirically set to 0.9 after tuning over a development dataset. $\mathcal{T}$ is the proportion of events in s which happen in the same time span as another event in any other sentence in S. Two events are said to be in the same time span if one happens within the time period the other happens in. For example, an event that takes place in "*2014 June*" is said to take place within the year "*2014*".

While TIMEMMR is proposed here as an improvement over MMR, the premise is that incorporating temporal information can be helpful to minimize redundancy in summaries. In future work, one could apply it to other state-of-the-art lexical-based approaches including that of Hendrickx et al. (2009) and Celikyilmaz and Hakkani-Tur (2010). We also believe the same idea can be transplanted even to non-lexical motivated techniques such as the corpus-based similarity measure proposed by Xie and Liu (2008). We chose to use MMR here as a proof-of-concept to demonstrate the viability of such a technique, and to easily integrate our work into SWING.

3.4 Gauging Usefulness of Timelines

Temporal processing is imperfect. Together with the simplifying assumptions that were made in timeline construction, our generated timelines have errors which propagate into the summarization process. With this in mind, we selectively employ timelines to generate summaries only when we are confident of their accuracy. This can be done by computing a metric which can be used to decide whether or not timelines should be used for a particular input document collection. We refer to this as *reliability filtering*.

We postulate that the length of a timeline can serve as a simple reliability filtering metric. The intuition for this is that for longer timelines (which contain more events), possible errors are spread over the entire timeline, and do not overpower any useful signal that can be obtained from the timeline features outlined earlier. Errors are however

(1) An official in Barisal, 120 kilometres south of Dhaka, spoke of severe **destruction** as the 500 kilometre-wide mass of cloud **passed** overhead.
(2) "Many trees have been **uprooted** and houses and schools **blown** away," Mostofa Kamal, a district relief and rehabilitation officer, told AFP by telephone.
(3) "Mud huts have been **damaged** and the roofs of several houses **blown** off," said the state's relief minister, Mortaza Hossain.

Figure 5: Extract from a news article which describes several events (bolded) happening at the same time.

very easily propagated into summary generation for shorter timelines, leading to less useful results.

We incorporate this into our process as follows: given an input document collection (which consists of 10 documents), the average size of all the timelines for each of these 10 documents is computed. Only when this value is larger than a threshold value are the timelines used.

4 Experiments and Results

The proposed timeline features and TIMEMMR were implemented on top of SWING, and evaluated on the test documents from TAC-2011 (Owczarzak and Dang, 2011). SWING makes use of three generic features and two features targeted specifically at guided summarization. Since the focus of this paper is on multi-document summarization, we employ only the three generic features, i.e., 1) sentence position, 2) sentence length, and 3) interpolated n-gram document frequency in our experiments below. Summarization evaluation is done using ROUGE-2 (R-2) (Lin and Hovy, 2003), as it has previously been shown to correlate well with human assessment (Lin, 2004) and is often used to evaluate automatic text summarization.

The results obtained are shown in Table 1. In the table, each row refers to a specific summarization system configuration. We also show the results of two reference systems, CLASSY (Conroy et al., 2011) and POLYCOM (Zhang et al., 2011), as benchmarks. CLASSY and POLYCOM are top performing systems at TAC-2011 (ranked 2nd and 3rd by R-2 in TAC 2011, respectively; the full version of SWING was ranked 1st with a R-2 score of 0.1380). From these results, we can see that SWING is a very competitive baseline.

Rows 9 to 16 additionally incorporate our timeline reliability filtering. We assume that the various input document sets to be summarized are available at the time of processing. Hence in these experiments, the threshold for filtering is set to be the average of all the timeline sizes over the whole input dataset. In a production environment where this assumption may not hold, this threshold could be set by empirical tuning over a development set.

	Configuration	R-2	Sig

14	SWING+TSI+CTSI+TMMR	0.1397	**
15	SWING+TSI+TCD+TMMR	0.1376	*
16	SWING+CTSI+TCD+TMMR	0.1390	**

Table 1: R-2 scores after incorporating temporal information into SWING. '**' and '*' denotes significant differences with respect to Row R (paired one-tailed Student's t-test; $p < 0.05$ and $p < 0.1$ respectively), and TMMR denotes TIMEMMR.

Row 1 shows the usefulness of the proposed timeline-based features. A statistically significant improvement of 4.1% is obtained with the use of all three features over SWING. When we use reliability filtering (Row 9), this improvement increases to 5.9%.

The ablation test results in Rows 2 to 4 show a drop in R-2 each time a feature is left out. With the exception of Row 4, removing a feature lessens the improvement in R-2 to be insignificant from SWING's. The same drop occurs even when reliability filtering is used (Rows 9 to 12). These indicate that all the proposed features are important and need to be used together to be effective.

Rows 5 to 8 and Rows 13 to 16 show the effect of TIMEMMR. While the results do not uniformly show that TIMEMMR is effective, it can be helpful, such as when comparing Rows 2 and 6, or Rows 10 and 14, where R-2 improves marginally.

Looking at Rows 1 to 8, and Rows 9 to 16, we see the importance of reliability filtering. It is able

to guide the use of timelines such that significant improvements in R-2 over SWING are obtained.

To help visualize what the differences in these ROUGE scores mean, Figure 7 shows two summaries[1] generated for document set D1117C of the TAC-2011 dataset. The left one is produced by the configuration in Row 9, and the right one is produced by SWING without the use of any temporal information.

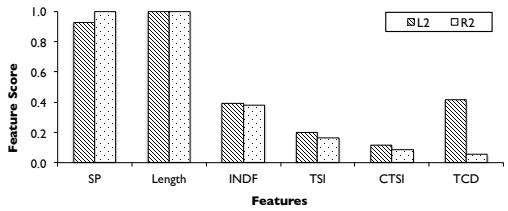

Figure 6: Breakdown of raw feature scores for sentences ($\mathbb{L}2$) and ($\mathbb{R}2$) from Figure 7.

The higher R-2 score obtained by the summary on the left (0.0873) compared to the one on the right (0.0723) suggests that temporal information can help to identify salient sentences more accurately. A closer look at sentences ($\mathbb{L}2$) and ($\mathbb{R}2$) and their R-2 scores (0.0424 and 0.0249, respectively) is instructive. Figure 6 shows the raw feature scores of both sentences. Both sentences score similarly for the SWING features of sentence position (SP), sentence length (Length), and interpolated n-gram document frequency (INDF); however, the scores for all three timeline features higher for ($\mathbb{L}2$) than ($\mathbb{R}2$). This helps our time sensitive system prefer ($\mathbb{L}2$).

5 Discussion

We now examine the proposed 1) timeline features, 2) TIMEMMR algorithm, and 3) reliability filtering metric in greater detail to gain insight into their efficacy. For the analysis on timeline features, we only present an analysis for TSI and CTSI due to space constraints.

Time Span Importance. Figure 8 shows the last sentences from a pair of summaries generated with and without the use of TSI (all other sentences were the same). The original articles describe an accident where casualties were suffered when a crane toppled onto a building. It is easy to see why ($\mathbb{L}1$) scores higher for R-2 — it describes the cause of the accident just as it occurred. ($\mathbb{R}1$) however talks about events which happened before the accident itself (e.g., how much of the tower had already been erected). In this case time span importance is able to correctly guide summary generation by favoring time spans containing events related to the actual toppling.

Contextual Time Span Importance. CTSI recognizes that events which happen around the time of a big cluster of other events can be important too. The benefits of this feature can be clearly seen in Figure 9. The summary on the left achieved a R-2 score of 0.1215 while the one on the right achieved 0.0861. ($\mathbb{L}2$) and ($\mathbb{L}3$) were both boosted by the use of the contextual importance feature.

Figure 10 shows an extract of the timeline generated for the source document from which ($\mathbb{L}3$) is extracted. The two events inside ($\mathbb{L}3$) fall in time spans A and B marked in the figure. Their proximity to the peak P between them gives the sentence a higher score for CTSI. This boost results in the sentence being selected for inclusion in the final summary. It turns out that this sentence was lifted exactly in one of the model summaries for this document set, resulting in a very good R-2 score when contextual importance is used.

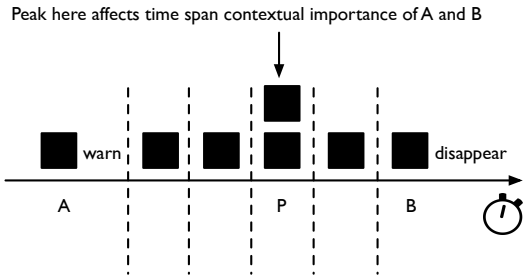

Figure 10: Extract of timeline generated for document APW_ENG_20070615.0356 from the TAC-2011 dataset.

Is TIMEMMR Useful? The experimental results do not conclusively affirm the usefulness of TIMEMMR. However we believe it is because the ROUGE measures that are used for evaluation are not suited for this purpose. Recall that TIMEMMR seeks to eliminate redundancy based on time span similarities and not lexical likeness. ROUGE, however, measures the latter.

An interesting case in point is given in Figure 11. The summary on the left is generated using TIMEMMR and achieved a lower ROUGE score. The one on the right is generated without TIMEMMR and scores higher, suggesting that TIMEMMR is not helpful. The key difference in

[1]The produced summaries are truncated to fit within a 100-word limit imposed by the TAC-2011 guidelines.

the two summaries is (ℝ3). (𝕃3) is the equivalent of (ℝ4), while (𝕃4) is the full version of the truncated (ℝ5). TIMEMMR penalizes (ℝ3). (ℝ3) reports that the shoe-throwing incident happened as the U.S. President Bush appeared together with the Iraqi Prime Minister Nouri al-Maliki. However their joint appearance is already reported in (ℝ1) (and similarly (𝕃1)). (ℝ3) repeats what had been presented earlier. Since (ℝ1) and (ℝ3) talk about the same time span, TIMEMMR down-weights (ℝ3). We argue that this is better even though the ROUGE scores indicate otherwise. In future work it will be worthwhile to consider the use of metrics like Pyramid (Passonneau et al., 2005) which are less bound to superficial lexicons.

Reliability Filtering. Table 2 shows the effect of varying the filtering threshold on R-2 for the best performing configuration from Table 1 (i.e., SWING+TSI+CTSI+TCD). The result obtained in Row 9 using a threshold of 42.68 is also re-produced for reference. **T**=0 means that timelines are used for all input document sets, whereas **T**=100 means that no timelines are used, as the length of the longest timeline is less than 100.

As the threshold increases from 0 to 40–50, summarization performance improves while the number of document sets where temporal information is used is reduced. This suggests that filtering is successful in identifying timelines that are not sufficiently accurate to be useful for summarization. R-2 performance peaks around a threshold of 40. This affirms our use of the average length of timelines as the threshold value in our earlier experiments. Beyond 60, the R-2 scores are still higher than that obtained by SWING, but no longer significantly different. At these higher thresholds, temporal information is still able to help get an improvement in R-2. However as this affects only very few out of the 44 document sets, statistical variances mean that these R-2 scores are no longer

significant from that produced by SWING.

6 Conclusion

We have shown in this work how temporal information in the form of timelines can be incorporated into multi-document summarization. We achieve this through two means, using: 1) three novel features derived from timelines to measure the saliency of sentences, and 2) TIMEMMR which considers time span similarity to enhance the traditional MMR's lexical diversity measure.

To overcome errors propagated from the underlying temporal processing systems, we proposed a reliability filtering metric which can be used to help decide when temporal information should be used for summarization. The use of this metric leads to an overall 5.9% gain in R-2 over the competitive SWING baseline.

In future work, we are keen to study our proposed timeline-related features more intrinsically in the context of human-generated summaries. This can help us better understand their value in improving content selection. As noted earlier, it will be also be useful to repeat our experiments with less lexicon-influenced measures like the Pyramid method (Passonneau et al., 2005). Manual assessment of the generated summaries can also be done to give a better picture of the quality of the summaries generated with the use of timelines. Finally, given the importance of reliability filtering, a natural question is if there are other metrics that can be used to get better results.

A chance-corrected measure of inter-annotator agreement for syntax

Arne Skjærholt

arnskj@ifi.uio.no

Abstract

Following the works of Carletta (1996) and Artstein and Poesio (2008), there is an increasing consensus within the field that in order to properly gauge the reliability of an annotation effort, chance-corrected measures of inter-annotator agreement should be used. With this in mind, it is striking that virtually all evaluations of syntactic annotation efforts use uncorrected parser evaluation metrics such as bracket F_1 (for phrase structure) and accuracy scores (for dependencies).

In this work we present a chance-corrected metric based on Krippendorff's α, adapted to the structure of syntactic annotations and applicable both to phrase structure and dependency annotation without any modifications. To evaluate our metric we first present a number of synthetic experiments to better control the sources of noise and gauge the metric's responses, before finally contrasting the behaviour of our chance-corrected metric with that of uncorrected parser evaluation metrics on real corpora.[1]

1 Introduction

It is a truth universally acknowledged that an annotation task in good standing be in possession of a measure of inter-annotator agreement (IAA). However, no such measure is in widespread use for the task of syntactic annotation. This is due to a mismatch between the formulation of the agreement measures, which assumes that the annotations have no or relatively little internal structure, and syntactic annotation where structure is the entire point of the annotation. For this reason efforts to gauge the quality of syntactic annotation are hampered by the need to fall back to simple accuracy measures. As shown in Artstein and Poesio (2008), such measures are biased in favour of annotation schemes with fewer categories and do not account for skewed distributions between classes, which can give high observed agreement, even if the annotations are inconsistent.

In this article we propose a family of chance-corrected measures of agreement, applicable to both dependency- and constituency-based syntactic annotation, based on Krippendorff's α and tree edit distance. First we give an overview of traditional agreement measures and why they are insufficient for syntax, before presenting our proposed metrics. Next, we present a number of synthetic experiments performed in order to find the best distance function for this kind of annotation; finally we contrast our new metric and simple accuracy scores as applied to real-world corpora before concluding and presenting some potential avenues for future work.

1.1 Previous work

The definitive reference for agreement measures in computational linguistics is Artstein and Poesio (2008), who argue forcefully in favour of the use of chance-corrected measures of agreement over simple accuracy measures. However, most evaluations of syntactic treebanks use simple accuracy measures such as bracket F_1 scores for constituent trees (NEGRA, Brants, 2000; TIGER, Brants and Hansen, 2002; Cat3LB, Civit et al., 2003; The Arabic Treebank, Maamouri et al., 2008) or labelled or unlabelled attachment scores for dependency syntax (PDT, Hajič, 2004; PCEDT Mikulová and Štěpánek, 2010; Norwegian Dependency Treebank, Skjærholt, 2013). The only work we know of using chance-corrected metrics

[1] The code used to produce the data in this paper, and some of the datasets used, are available to download at https://github.com/arnsholt/syn-agreement/

Proceedings of the 52nd Annual Meeting of the Association for Computational Linguistics, pages 934–944,
Baltimore, Maryland, USA, June 23-25 2014.

is Ragheb and Dickinson (2013), who use MASI (Passonneau, 2006) to measure agreement on dependency relations and head selection in multi-headed dependency syntax, and Bhat and Sharma (2012), who compute Cohen's κ (Cohen, 1960) on dependency relations in single-headed dependency syntax. A limitation of the first approach is that token ID becomes the relevant category for the purposes of agreement, while the second approach only computes agreements on relations, not on structure.

In grammar-driven treebanking (or parsebanking), the problems encountered are slightly different. In HPSG and LFG treebanking annotators do not annotate structure directly. Instead, the grammar parses the input sentences, and the annotator selects the correct parse (or rejects all the candidates) based on discriminants[2] of the parse forest. In this context, de Castro (2011) developed a variant of κ that measures agreement over discriminant selection. This is different from our approach in that agreement is computed on annotator decisions rather than on the treebanked analyses, and is only applicable to grammar-based approaches such as HPSG and LFG treebanking.

The idea of using edit distance as the basis for an inter-annotator agreement metric has previously been explored by Fournier (2013). However that work used a boundary edit distance as the basis of a metric for the task of text segmentation.

1.2 Notation

In this paper, we mostly follow the notation and terminology of Artstein and Poesio (2008), with some additions. The key components in an agreement study are the *items* annotated, the *coders* who make judgements on individual items, and the *annotations* created for the items. We denote these as follows:

- The set of items $I = \{i_1, i_2, \dots\}$
- The set of coders $C = \{c_1, c_2, \dots\}$
- The set of annotations X is a set of sets $X = \{X_i | i \in I\}$ where each set $X_i = \{x_{ic} | c \in C\}$ contains the annotations for each item. If not all coders annotate all items, the different X_i will be of different sizes.

[2] A discriminant is an attribute of the analyses produced by the grammar where some of the analyses differ, e.g. is the word *jump* a noun or a verb, or does a PP attach to a VP or the VP's object NP.

In the case of nominal categorisation we will also use the set K of possible categories.

2 The metric

The most common metrics used in computational linguistics are the metrics κ (Cohen, 1960, introduced to computational linguistics by Carletta, 1996) and π (Scott, 1955). These metrics express agreement on a nominal coding task as the ratio $\kappa, \pi = {A_o - A_e}/{1 - A_e}$ where A_o is the observed agreement and A_e the expected agreement according to some model of "random" annotation. Both metrics have essentially the same model of expected agreement:

$$A_e = \sum_{k \in K} P(k|c_1)P(k|c_2) \quad (1)$$

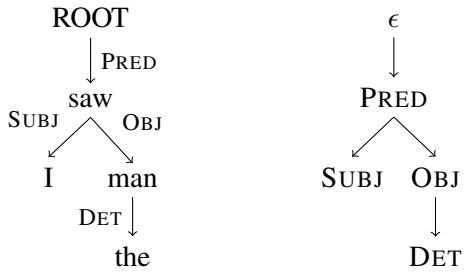
differing only in how they estimate the probabilities: κ assigns separate probability distributions to each coder based on their observed behaviour, while π uses the same distribution for both coders based on their aggregate behaviour.

Now, if we want to perform this same kind of evaluation on syntactic annotation it is not possible to use κ or π directly. In the case of dependency-based syntax we could conceivably use a variant of these metrics by considering the ID of a token's head as a categorical variable (the approach taken in Ragheb and Dickinson, 2013), but we argue that this is not satisfactory. This use of the metrics would consider agreement on categories such as "tokens whose head is token number 24", which is obviously not a linguistically informative category. Thus we have to reject this way of assessing the reliability of dependency syntax annotation. Also, this approach is not directly generalisable to constituency-based syntax.

For dependency syntax we could generalise these metrics similarly to how κ is generalised to κ_w to handle partial credit for overlapping annotations. Let the function $\text{LAS}(t_1, t_2)$ be the number of tokens with the same head and label in the two trees t_1 and t_2, $T(i)$ the set of trees possible for an item $i \in I$, and tokens the number of tokens in the corpus. Then we can compute an expected agreement as follows:

$$A_e = \frac{1}{\text{tokens}} \sum_{i \in I} \sum_{t_1, t_2 \in T(i)^2} \text{LAS}_e(t_1, t_2) \quad (2)$$

$$\text{LAS}_e(t_1, t_2) = P(t_1|c_1)P(t_2|c_2)\text{LAS}(t_1, t_2)$$



(a) The original dependency tree

(b) The tree used in comparisons

Figure 1: Transformation of dependency trees before comparison

We see three problems with this approach. First of all the number of possible trees for a sentence grows exponentially with sentence length, which means that explicitly iterating over all possible such pairs is computationally intractable, nor have we been able to easily derive an algorithm for this particular problem from standard algorithms.

Second, the question of which model to use for $P(t|c)$ is not straightforward. It is possible to use generative parsing models such as PCFGs or the generative dependency models of Eisner (1996), but agreement metrics require a model of *random* annotation, and as such using models designed for parsing runs the risk of over-estimating A_e, resulting in artificially low agreement scores.

Finally, it may be hard to establish a consensus in the field of which particular metric to use. As shown by the existence of three different metrics (κ, π and S (Bennett et al., 1954)) for the relatively simple task of nominal coding, the choice of model for $P(t|c)$ will not be obvious, and thus differing choices of generative model as well as different choices for parameters such as smoothing will result in subtly different agreement metrics. The results of these different metrics will not be directly comparable, which will make the results of groups using different metrics unnecessarily hard to compare.

Instead, we propose to use an agreement measure based on Krippendorff's α (Krippendorff, 1970; Krippendorff, 2004) and tree edit distance. In this approach we compare tree structures directly, which is extremely parsimonious in terms of assumptions, and furthermore sidesteps the problem of probabilistically modelling annotators' behaviour entirely. Krippendorff's α is not as commonly used as κ and π, but it has the advantage of being expressed in terms of an arbitrary *distance function* δ.

A full derivation of α is beyond the scope of this article, and we will simply state the formula used to compute the agreement. Krippendorff's α is normally expressed in terms of the ratio of observed and expected disagreements: $\alpha = 1 - {}^{D_o}/_{D_e}$, where D_o is the mean squared distance between annotations of the same item and D_e the mean squared distance between all pairs of annotations:

$$D_o = \sum_{i \in I} \frac{1}{|X_i| - 1} \sum_{c \in C} \sum_{c' \in C} \delta(x_{ic}, x_{ic'})^2$$

$$D_e = \frac{1}{\sum_{i \in I} |X_i| - 1} \sum_{i \in I} \sum_{c \in C} \sum_{i' \in I} \sum_{c' \in C} \delta(x_{ic}, x_{i'c'})^2$$

Note that in the expression for D_e, we are computing the difference between annotations for *different* items; thus, our distance function for syntactic trees needs to be able to compute the difference between arbitrary trees for completely unrelated sentences. The function δ can be any function as long as it is a metric; that is, it must be (1) non-negative, (2) symmetric, (3) zero only for identical inputs, and (4) it must obey the triangle inequality:

1. $\forall x, y : \delta(x, y) \geq 0$
2. $\forall x, y : \delta(x, y) = \delta(x, y)$
3. $\forall x, y : \delta(x, y) = 0 \Leftrightarrow x = y$
4. $\forall x, y, z : \delta(x, y) + \delta(y, z) \geq \delta(x, z)$

This immediately excludes metrics like PARSEVAL (Black et al., 1991) and Leaf-Ancestor (Sampson and Babarczy, 2003), since they assume that the trees being compared are parses of the same sentence. Instead, we base our work on tree edit distance. The tree edit distance (TED) problem is defined analogously to the more familiar problem of string edit distance: what is the minimum number of edit operations required to transform one tree into the other? See Bille (2005) for a thorough introduction to the tree edit distance problem and other related problems. For this work, we used the algorithm of Zhang and Shasha (1989). Tree edit distance has previously been used in the TEDEVAL software (Tsarfaty et al., 2011; Tsarfaty et al., 2012) for parser evaluation agnostic to both annotation scheme and theoretical framework, but this by itself is still an

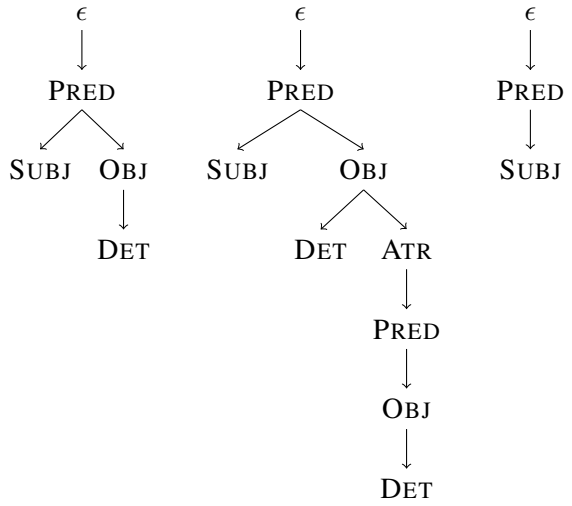


Figure 2: Three trees with distance zero using δ_{diff}

uncorrected accuracy measure and thus unsuitable for our purposes.[3]

When comparing syntactic trees, we only want to compare dependency relations or non-terminal categories. Therefore we remove the leaf nodes in the case of phrase structure trees, and in the case of dependency trees we compare trees whose edges are unlabelled and nodes are labelled with the dependency relation between that word and its head; the root node receives the label ϵ. An example of this latter transformation is shown in Figure 1.

We propose three different distance functions for the agreement computation: the unmodified tree edit distance function, denoted δ_{plain}, a second function $\delta_{diff}(x, y) = \mathrm{TED}(x, y) - \mathrm{abs}(|x| - |y|)$, the edit distance minus the difference in length between the two sentences, and finally $\delta_{norm}(x, y) = {}^{\mathrm{TED}(x,y)}/_{|x|+|y|}$, the edit distance normalised to the range $[0, 1]$.[4]

The plain TED is the simplest in terms of parsimony assumptions, however it may overestimate the difference between sentences, we intuitively find to be syntactically similar. For example the only difference between the two leftmost trees in Figure 2 is a modifier, but δ_{plain} gives them distance 4 and δ_{diff} 0. On the other hand, δ_{diff} might underestimate some distances as well; for example the leftmost and rightmost trees also have distance zero using δ_{diff}, despite our syntactic intuition that the difference between a transitive and an intransitive should be taken account of.

The third distance function, δ_{norm}, takes into account a slightly different concern; namely that when comparing a long sentence and a short sentence, the distance has to be quite large simply to account for the difference in number of nodes, unlike comparing two short or two long sentences. Normalising to the range $[0, 1]$ puts all pairs on an equal footing.

However, we cannot *a priori* say which of the three functions is the optimal choice of distance functions. The different functions have different properties, and different advantages and drawbacks, and the nature of their strengths and weaknesses differ. We will therefore perform a number of synthetic experiments to investigate their properties in a controlled environment, before applying them to real-world data.

3 Synthetic experiments

In the previous section, we proposed three different agreement metrics α_{plain}, α_{diff} and α_{norm}, each involving different trade-offs. Deciding which of these metrics is the best one for our purposes of judging the consistency of syntactic annotation poses a bit of a conundrum. We could at this point apply our metrics to various real corpora and compare the results, but since the consistency of the corpora is unknown, it's impossible to say whether the best metric is the one resulting in the highest scores, the lowest scores or somewhere in the middle. To properly settle this question, we first performed a number of synthetic experiments to gauge how the different metrics respond to disagreement.

The general approach we take is based on that used by Mathet et al. (2012), adapted to dependency trees. An already annotated corpus, in our case 100 randomly selected sentences from the Norwegian Dependency Treebank (Solberg et al., 2014), are taken as correct and then permuted to produce "annotations" of different quality. For dependency trees, the input corpus is permuted as follows:

1. Each token has a probability $p_{relabel}$ of being assigned a different label uniformly at random from the set of labels used in the corpus.

[3] While it is quite different from other parser evaluation schemes, TEDEVAL does not correct for chance agreement and is thus an uncorrected metric. It could of course form the basis for a corrected metric, given a suitable measure of expected agreement.

[4] We can easily show that $|x| + |y|$ is an upper bound on the TED, corresponding to deleting all nodes in the source tree and inserting all the nodes in the target.

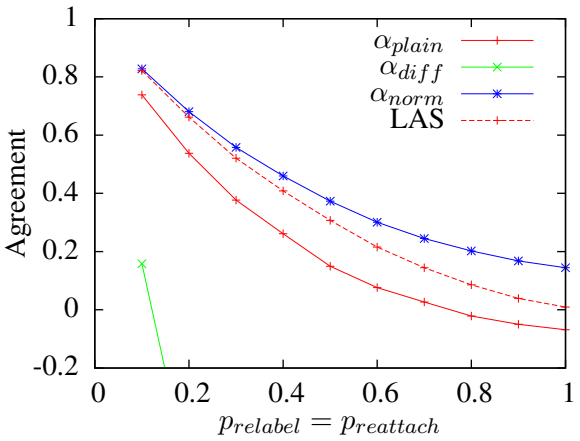

Figure 3: Mean agreement over ten runs

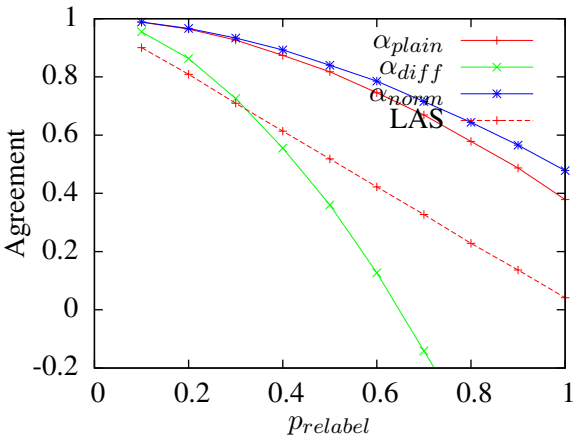

Figure 4: Mean agreement over ten runs, $p_{reattach} = 0$

2. Each token has a probability $p_{reattach}$ of being assigned a new head uniformly at random from the set of tokens not dominated by the token.

The second permutation process is dependent on the order the tokens are processed, and we consider the tokens in the post-order[5] as dictated by the original tree. This way tokens close to the root have a fair chance of having candidate heads if they are selected. A pre-order traversal would result in tokens close to the root having few options, and in particular if the root has a single child, that node has no possible new heads unless one of its children has been assigned the root as its new head first. For example in the trees in figure 2, assigning any other head than the root to the PRED nodes directly dominated by the root will result in invalid (cyclic and unconnected) dependency trees. Traversing the tokens in the linear order dictated by the sentence has similar issues for tokens close to the root and close to the start of the sentence.

For our first set of experiments, we set $p_{relabel} = p_{reattach}$ and evaluated the different agreement metrics for 10 evenly spaced p-values between 0.1 and 1.0. Initial exploration of the data showed that the mean follows the median very closely regardless of metric and perturbation level, and therefore we only report the mean scores across runs in this paper. The results of these experiments are shown in Figure 3, with the labelled attachment score[6] (LAS) for comparison.

The α_{diff} metric is clearly extremely sensitive to noise, with $p = 0.1$ yielding mean $\alpha_{diff} = 15.8\%$, while α_{norm} is more lenient than both LAS and α_{plain}, with mean $\alpha_{norm} = 14.5\%$ at $p = 1$, quite high compared to LAS $= 0.9\%$, $\alpha_{plain} = -6.8\%$ and $\alpha_{diff} = -246\%$. To further study the sensitivity of the metrics to the two kinds of noise, we performed an additional set of experiments, setting one $p = 0$ while varying the other over the same range as in the previous experiment, the results of which are shown in Figures 4 and 5.

The LAS curves are mostly unremarkable, with one exception: Mean LAS at $p_{reattach} = 1$ of Figure 5 is 23.9%, clearly much higher than we would expect if the trees were completely random. In comparison, mean LAS when only labels are perturbed is 4.1%, and since the sample space of trees of size n is clearly much larger than that of relabellings, a uniform random selection of tree would yield a LAS much closer to 0. This shows that our tree shuffling algorithm has a non-uniform distribution over the sample space.

While the behaviour of our alphas and LAS are relatively similar in Figure 3, Figures 4 and 5 show that they do in fact have important differences. Whereas LAS responds linearly to perturbation of both labels and structure, with its parabolic behaviour in Figure 3 being simply the product of these two linear responses, the α metrics respond differently to structural noise and label noise, with label disagreements being penalised less harshly

[5] That is, the child nodes of a node are all processed before the node itself. Nodes on the same level are traversed from left to right.

[6] The *de facto* standard parser evaluation metric in dependency parsing: the percentage of tokens that receive the correct head *and* dependency relation.

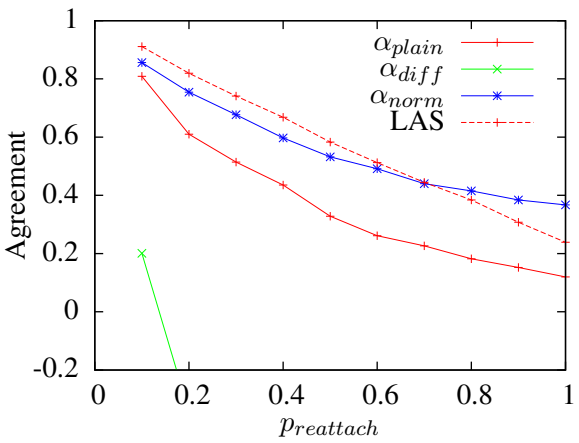

Figure 5: Mean agreement over ten runs, $p_{relabel} = 0$

than structural disagreements.

The reason for the strictness of the α_{diff} metric and the laxity of α_{norm} is the effects the modified distance functions have on the distribution of distances. The δ_{diff} function causes an extreme shift of the distances towards 0; more than 30% of the sentence pairs have distance 0, 1, or 2, which causes D_e^{diff} to be extremely low and thus gives disproportionally large weight to non-zero distances in D_o^{diff}. On the other hand δ_{norm} causes a rightward shift of the distances, which results in a high D_e^{norm} and thus individual disagreements having less weight.

4 Real-world corpora

Synthetic experiments do not always fully reflect real-world behaviour, however. Therefore we will also evaluate our metrics on real-world inter-annotator agreement data sets. In our evaluation, we will contrast labelled accuracy, the standard parser evaluation metric, and our three α metrics. In particular, we are interested in the correlation (or lack thereof) between LAS and the alphas, and whether the results of our synthetic experiments correspond well with the results on real-world IAA sets. Finally, we also evaluate the metric on both dependency and phrase structure data.

4.1 The corpora

We obtained[7] data from four different corpora. Three of the data sets are dependency treebanks (NDT, CDT, PCEDT) and one phrase structure treebank (SSD), and of the dependency treebanks the PCEDT contains semantic dependencies, while the other two have traditional syntactic dependencies. The number of annotators and sizes of the different data sets are summarised in Table 1.

Corpus	Sentences	Tokens
NDT 1[a]	130	1674
NDT 2[a]	110	1594
NDT 3[a]	150	1997
CDT (da)[a]	162	2394
CDT (en)[a]	264	5528
CDT (es)[b]	55	924
CDT (it)[c]	136	3057
PCEDT[d]	3531	61737
SSD[e]	96	1581

[b] 4 annotators, avg. 2.8 annotators/text (min. 2, max. 4)
[c] 3 annotators, avg. 2.7 annotators/text
[d] 11 annotators, avg. 2.5 annotators/text (min. 2, max. 6)
[e] 3 annotators, avg. 2.9 annotators/sent.

Table 1: Sizes of the different IAA corpora

NDT The Norwegian Dependency Treebank (Solberg et al., 2014) is a dependency treebank constructed at the National Library of Norway. The data studied in this work has previously been used by Skjærholt (2013) to study agreement, but using simple accuracy measures (UAS, LAS) rather than chance-corrected measures. The IAA data set is divided into three parts, corresponding to different parsers used to preprocess the data before annotation; what we term NDT 1 through 3 correspond to what Skjærholt (2013) labels Danish, Swedish and Norwegian, respectively.

CDT The Copenhagen Dependency Treebanks (Buch-Kromann et al., 2009; Buch-Kromann and Korzen, 2010) is a collection of parallel dependency treebanks, containing data from the Danish PAROLE corpus (Keson, 1998b; Keson, 1998a) in the original Danish and translated into English, Italian and Spanish.

PCEDT The Prague Czech-English Dependency Treebank 2.0 Hajič et al. (2012) is a parallel corpus of English and Czech, consisting of English data from the Wall Street Journal Section of the Penn Treebank (Marcus et al., 1993) and

[7] We contacted a number of treebank projects, among them the Penn Treebank and the Prague Dependency Treebank, but not all of them had data available.

Czech translations of the English data. The syntactic annotations are layered and consist of an analytical layer similar to the annotations in most other dependency treebanks, and a more semantic tectogrammatical layer.

Our data set consists of a common set of analytical annotations shared by all the annotators, and the tectogrammatical analyses built on top of this common foundation. A distinguishing feature of the tectogrammatical analyses, vis a vis the other treebanks we are using, is that semantically empty words only take part in the analytical annotation layer and nodes are inserted at the tectogrammatical layer to represent covert elements of the sentence not present in the surface syntax of the analytical layer. Thus, inserting and deleting nodes is a central part of the task of tectogrammatical annotation, unlike the more surface-oriented annotation of our other treebanks, where the tokenisation is fixed before the text is annotated.

SSD The Star-Sem Data is a portion of the dataset released for the *SEM 2012 shared task (Morante and Blanco, 2012), parsed using the LinGO English Resource Grammar (ERG, Flickinger, 2000) and the resulting parse forest disambiguated based on discriminants. The ERG is an HPSG-based grammar, and as such its analyses are attribute-value matrices (AVMs); an AVM is not a tree but a directed acyclic graph however, and for this reason we compute agreement not on the AVM but the so-called *derivation tree*. This tree describes the types of the lexical items in the sentence and the bottom-up ordering of rule applications used to produce the final analysis and can be handled by our procedure like any phrase-structure tree.

4.2 Agreement results

To evaluate our corpora, we compute the three α variants described in the previous two sections, and compare these with labelled accuracy scores.

When there are more than two annotators, we generalise the metric to be the average pairwise LAS for each sentence, weighted by the length of the sentence. Let $\mathrm{LAS}(t_1, t_2)$ be the fraction of tokens with identical head and label in the trees t_1 and t_2; the pairwise labelled accuracy $\mathrm{LAS}_p(X)$ of a set of annotations X as described in section 1.2 is:

$$\mathrm{LAS}_p(X) = \frac{1}{\sum_i |x_{i1}|} \sum \frac{|x_{i1}|\Lambda(X_i)}{|X_i|(|X_i|-1)/2} \quad (3)$$

$$\Lambda(X_i) = \sum_{c=1}^{|C|} \sum_{c'=c+1}^{|C|} \mathrm{LAS}(x_{ic}, x_{ic'})$$

This is equivalent to the traditional metric in the case where there are only two annotators.

As our uncorrected metric for comparing two phrase structure trees we do not use the traditional bracket F_1 as it does not generalise well to more than two annotators, but rather Jaccard similarity. The Jaccard similarity of two sets A and B is the ratio of the size of their intersection to the size of their union: $J(A, B) = |A \cap B| / |A \cup B|$, and we use the Jaccard similarity of the sets of labelled bracketings of two trees as our uncorrected measure. To compute the similarity for a complete set of annotations we use the mean pairwise Jaccard similarity weighted by sentence length; that is, the same procedure as in 3, but using Jaccard similarity rather than LAS.

Since LAS assumes that both of the sentences compared have identical sets of tokens, we had to exclude a number of sentences from the LAS computation in the cases of the English and Italian CDT corpora, and especially the PCEDT. The large number of sentences excluded in the PCEDT is due to the fact that in the tectogrammatical analysis of the PCEDT, inserting and deleting nodes is an important part of the annotation task.

Looking at the results in Table 2, we observe

Corpus	α_{plain}	α_{diff}	α_{norm}	LAS
NDT 1	98.4	93.0	98.8	94.0
NDT 2	98.9	95.0	99.1	94.4
NDT 3	97.9	91.2	98.7	95.3
CDT (da)	95.7	84.7	96.2	90.4
CDT (en)	92.4	70.7	95.0	88.4
CDT (es)	86.6	48.8	85.8	78.9[a]
CDT (it)	84.5	55.7	89.2	81.3[b]
PCEDT	95.9	89.9	96.5	68.0[c]
SSD	99.1	98.6	99.3	87.9[d]

[a] 2 sentences ignored
[b] 15 sentences ignored
[c] 1178 sentences ignored

Table 2: Agreement scores on real-world corpora

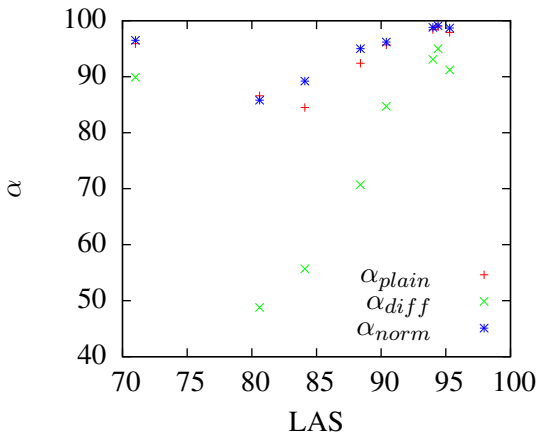

Figure 6: Correlation of LAS with α

two things. Most obvious, is the extremely large gap between the LAS and α metrics for the PCEDT data. However, there is a more subtle point; the orderings of the corpora by the different metrics are not the same. LAS order the corpora NDT 3, 2, 1, CDT da, en, it, es, PCEDT, whereas α_{diff} and α_{norm} gives the order NDT 2, 1, 3, PCEDT, CDT da, en, it, es, and α_{plain} gives the same order as the other alphas but with CDT es and it changing places. Furthermore, as the scatterplot in Figure 6 shows, there is a clear correlation between the α metrics and LAS, if we disregard the PCEDT results.

The reason the PCEDT gets such low LAS is essentially the same as the reason many sentences had to be excluded from the computation in the first place; since inserting and deleting nodes is an integral part of the tectogrammatical annotation task, the assumption implicit in the LAS computation that sentences with the same number of nodes have the same nodes in the same order is obviously false, resulting in a very low LAS.

The corpus that scores the highest for all three metrics is the SSD corpus; the reason for this is uncertain, as our corpora differ along many dimensions, but the fact that the annotation was done by professional linguists who are very familiar with the grammar used to parse the data is likely a contributing factor. The difference between the α metrics and the Jaccard similarity is larger than the difference between α and LAS for our dependency corpora, however the two similarity metrics are not comparable, and it is well known that for phrase structures single disagreements such as a PP-attachment disagreement can result in multiple disagreeing bracketings.

5 Conclusion

The most important conclusion we draw from this work is the most appropriate agreement metric for syntactic annotation. First of all, we disqualify the LAS metric, primarily due to the methodological inadequacies of using an uncorrected measure. While our experiments did not reveal any serious shortcomings (unlike those of Mathet et al., 2012 who in the case of categorisation showed that for large p the uncorrected measure can be *increasing*), the methodological problems of uncorrected metrics makes us wary of LAS as an agreement metric. Next, of the three α metrics, α_{plain} is clearly the best; α_{diff} is extremely sensitive to even moderate amounts of disagreement, while α_{norm} is overly lenient.

Looking solely at Figure 3, one might be led to believe that LAS and α_{plain} are interchangeable, but this is not the case. As shown by Figures 4 and 5, the paraboloid shape of the LAS curve in Figure 3 is simply the combination of the metric's linear responses to both label and structural perturbations. The behaviour of α on the other hand is more complex, with structural noise being penalised harder than perturbations of the labels. Thus, the similarity of LAS and α_{plain} is not at all assured when the amounts of structural and labelling disagreements differ. Additionally, we consider this imbalanced weighting of structural and labelling disagreements a benefit, as structure is the larger part of syntactic annotation compared to the labelling of the dependencies/bracketings. Finally our experiments show that α is a single metric that is applicable to both dependencies and phrase structure trees.

Furthermore, α metrics are far more flexible than simple accuracy metrics. The use of a distance function to define the metric means that more fine-grained distinctions can be made; for example, if the set of labels on the structures is highly structured, partial credit can be given for differing annotations that overlap. For example, if different types of adverbials (temporal, negation, etc.) receive different relations, as is the case in the Swedish Talbanken05 (Nivre et al., 2006) corpus, confusion of different adverbial types can be given less weight than confusion between subject and object. The α-based metrics are also far easier to apply to a more complex annotation task such

as the tectogrammatical annotation of the PCEDT. In this task inserting and deleting nodes is an integral part of the annotation, and if two annotators insert or delete different nodes the all-or-nothing requirement of identical yield of the LAS metric makes it impossible as an evaluation metric in this setting.

5.1 Future work

In future work, we would like to investigate the use of other distance functions, in particular the use of approximate tree edit distance functions such as the pq-gram algorithm (Augsten et al., 2005). For large data sets such as the PCEDT set used in this work, computing α with tree edit distance as the distance measure can take a very long time.[8] This is due to the fact that α requires $O(n^2)$ comparisons to be made, each of which is $O(n^2)$ using our current approach. The problem of directed graph edit distance is NP-hard, which means that to apply our method to HPSG analyses directly approximate algorithms are a requirement.

Another avenue for future work is improved synthetic experiments. As we saw, our implementation of tree perturbations was biased towards trees similar in shape to the source tree, and an improved permutation algorithm may reveal interesting edge-case behaviour in the metrics. A method for perturbing phrase structure trees would also be interesting, as this would allow us to repeat the synthetic experiments performed here using phrase structure corpora to compare the behaviour of the metrics on the two types of corpus.

Finally, annotator modelling techniques like that presented in Passonneau and Carpenter (2013) has obvious advantages over agreement coefficients such as α. These techniques are interpreted more easily than agreement coefficients, and they allow us to assess the quality of individual annotators, a crucial property in crowd-sourcing settings and something that's impossible using agreement coefficients.

Acknowledgements

I would like to thank Jan Štěpánek at Charles University for data from the PCEDT and help with the conversion process, the CDT project for publishing their agreement data, Per Erik Solberg at the Norwegian National Library for data from the NDT, and Emily Bender at the University of Washington for the SSD data.

[8]The Python implementation used in this work, using NumPy and the PyPy compiler, took seven and a half hours compute a single α for the PCEDT data set on an Intel Core i7 2.9 GHz computer. The program is single-threaded.
